The setting and focus of this study is a large electronic manufacturing facility in the south of Ireland, which prepares and distributes technology goods to both national and global customers. In the dispatching unit of the facility, operators are provided with work stations and conveyors to prepare the products for dispatch and shipment through pack out procedures. The aim of this study was to carry out an observational, empirical study on the existing human errors in the dispatching department of the facility in a subsequent phase the study also lead to the identification of suitable approaches to reduce and/or eliminate such errors.

Two primary workstations were the focus of the assessment of the project, namely the conveyor line and another packaging workstation called the POD cell. To examine these workstations, an overview of the existing error rate at the conveyor line was required to be used as a benchmark against other workstations in the facility and to identify any possible improvements. As a means of comparison, the error rates for nine control workstations from within the manufacturing facility were acquired to facilitate data analysis and interpretation.

Error rates for both the control and non-control workstations were calculated in the same manner. Records were filtered from 1st December 2016 to 31st March 2017 for all workstations to retrieve the information for the calculations. This four months timeframe was deemed adequate due to the large number of products passing through the workstations. We considered only errors classified as stemming from a human related cause.

The human error rates were calculated using the following formula:

Number of Human Errors/the opportunity for error (2)

where the number of human errors were the errors recorded or captured due to a human cause

While the opportunities for error were the total output at the workstation i.e. number of processed units

For the pod and the conveyor, to attain the number of human errors, data relating to MWDs (missing, wrong or damaged) goods was collected within the four month period from 01/12/16 to 31/03/17. The MWDs originate from customer complaints or returned goods following disparities from the sales orders or damaged goods. MWDs can be slow information to capture, due to the possible time lapse between the shipment of an order, the start of use of the product by the customer and the identification of an error. MWDs may be reported some months after a product was shipped, however due to the nature of the timeframe selected, it was deemed appropriate that by the completion of the project, the number of MWDs recorded for that time frame would be sufficient. The opportunity for error was derived from the total output at the workstations within the four months period from the beginning of December 2016 to the end of March 2017.

For the control workstations, the numbers of human errors were retrieved from an online software platform within the four months period outlined above. The platform is used to record both the total output at the workstations and the number of errors recorded. The platform records errors with varying root causes through a classification system, many of which are not of a human nature. Twenty-seven classifications were deemed suitable for inclusion for the human errors recorded.

In the control workstations, when an error has occurred, the operator or technician is forced to input an error report at the time of the error occurring detailing the source of the error i.e. human, equipment, technical. The process cannot continue until an error report has been submitted. Due to this, the error reports recorded in the system can be regarded as representative of the total number of errors occurring during the timeframe. When an error is recorded, users are prompted to categorise the error under a variety of descriptions. The categories can include aspects of technology or equipment failure, and not all were relevant for inclusion in the error rate calculation.

3.2 *The observation and questionnaire protocol used for the wider case study*

Members of staff who work closely with the workstations involved in the project and the control workstations were invited to complete questionnaires to assess their opinions relating to:

- The importance of skills at different workstations
- Skills rating of individual operators
- Job satisfaction/motivation
- Mental workload requirements
- Physical workload requirements
- Perceived task complexity

Two questionnaires were prepared with one for supervisors, group leaders and process engineers, and a second questionnaire for operators and

technicians. Questionnaires were broken up in this fashion in order to capture observable variables from the supervisors/management and the individual subjective opinions of the operators. There was a difference in the type and volume of questions in the questionnaires, as the supervisor/group leader questionnaires asked two different things:

- Asked supervisors role participants to rate the skills of operators under their supervision
- Asked all participants to rate the skills requirement to complete work at the workstations

The questionnaires were completed by the employees of all eleven workstations and their supervisors leading to a total of 149 employees completing the questionnaire (100% response rate).

Participants were asked to rate their answers on a 10-point Likert Scale, with one meaning low and ten meaning high. Questionnaires were used to measure the mental and physical workload, worker skills, job satisfaction (motivation) and the perceived task complexity for operators, supervisors, group leaders and process engineers. As different duties and tasks require certain skills (e.g. manual skills, memory), practical training and underpinning knowledge, the questionnaire was designed to capture information relating to the following areas:

Mental Workload Requirements

- Need to cope with pace
- Variance of product
- Recognition requirements
- Load due to quality of coordination
- Requirement for training/experience
- Requirements for human machine interface (HMI)

Physical Workload Requirements

- Ergonomic score (REBA Assessment)
- Dexterity requirements/manual skills
- Adherence to procedure
- Reliance on automation

Job Satisfaction/Motivation

- Motivation e.g. satisfaction, meaningfulness

Worker Skills

- Memory
- Decision-making
- Recognition
- Coordination/communication—teamwork
- Coping with pace
- Experience
- Dexterity/manual skills
- Physical resilience
- Adherence to procedure

Perceived Task Complexity

- How mentally demanding are the tasks
- How physically demanding are the tasks
- How complex is this task

The error rate for all eleven workstations has been calculated and is outlined in Table 1

Data collection involved a rich integration of data from many sources, acquired observationally or through documented information. There were four primary sources of data:

1. The questionnaires outlined above. The data collected would facilitate the assessment of the relationship between the task complexity (mental workload requirements, physical workload requirements) and the worker capability (cognitive skills, physical skills).
2. Focus groups were conducted to understand the process and procedures at the workstations and aspects of the workstations that would benefit from redesign.
3. Key Performance Indicators (KPI's) were gathered for information relating to:

Table 1. Error rate dataset collected for each workstation.

Workstation No	No of human errors	Opportunity for errors i.e. total output	No of operators	Error per 1000pc
1 Pod	0	747	19	0.01
2 Conveyor	14	8,913	19	1.5
3 Control A	3	12,055	19	0.2
4 Control B	1	1,359	19	0.7
5 Control C	44	221	2	203.6
6 Control D	93	221	2	425
7 Control E	28	3,971	5	7
8 Control F	81	3,971	7	20.3

10 Control H	107	5,402	0.019	19.8
11 Control I	133	5,402	0.0246	24.6

- The actual time at the workstation (productivity KPI)
- The number of quality issues due to human error (quality KPI)

4. Error rates for the workstations were formulated to provide insight into the rate of human error and its resulting quality effects on the workstation end products.

Videos/Pictures

In order to capture and assess information regarding the routine activities and work patterns of staff in the facility, video recordings and photographs were taken as an observational method of data collection. The videos were used to:

– Measure the amount of time the entire task took to complete
– Measure the amount of time an aspect of the task took to complete e.g. closing with sellotape
– Compare the procedure completed to the actual projected procedure for the completion of actions
– Task analysis using Video TimerPro software to break down the tasks required of the operator to complete
– The photographs and video recordings were used to:
– Provide a basis for the Ergonomic Risk Assessment method used
– Compare comparable tasks completed at alternate work stations

For the first part of the regression model, an assessment of task complexity was conducted. The data gathered was evaluated on the basis of Task Complexity with a linear regression model. In order to complete this evaluation, a task complexity index was applied, namely:

Task Complexity index = a (Memory req.) + b (recognition req) + c (coordination req.) + d (cope with pace req) + e (Experience req) + f (Resilience req.) + g (adherence to procedure req.)

The Correlation matrix obtained for the element used for the regression to evaluate task complexity obtained in the statistical software R are shown in Figure 1.

Figure 2 reports the preliminary results of the linear regression model used to predict task complexity in R.

The model indicates that the parameters used to estimate task complexity in the linear regression are quite significant. They predict task complexity with a Standard error of 0.2991 on 36 degrees of freedom. The adjusted R squared obtained is 0.93996 and the F statistics on 36 Degrees of freedom is 96.52, with a p value of 2.2 e-16. Therefore

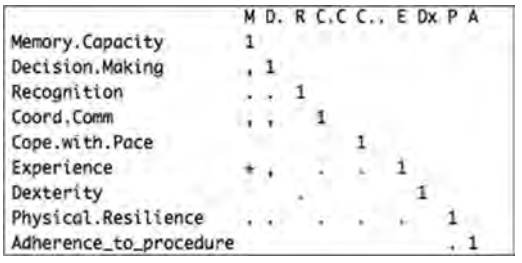

Figure 1. Correlation matrix evaluated for the element used for the regression to evaluate task complexity.

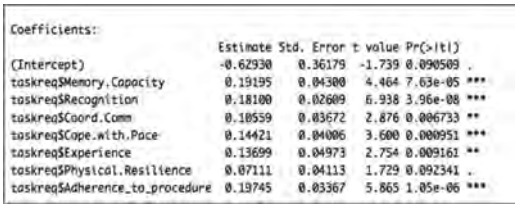

Figure 2. Results obtained from R to evaluate the relevance for the coefficient used to estimate task complexity.

the linear regression model to estimate task complexity seems to deliver significant results.

For the second part of the model, an estimation of the error occurrence of each workstation considering task complexity and operator capability was conducted. The use of the Rasch model with the dataset gathered was not possible as for the Rasch model the output needed to be a binary success or failure for each individual task. This was a type of data which was not able to be collected. Due to this, a generalised linear regression with a Poisson model, which was still based on the assumption that Human Performance can be represented as directly dependent from two macrofactors of task complexity and human capability, was used (see formula 3).

$$\lambda_i = e^{\beta_0+\beta_1 x_1-\beta_2 x_2+\varepsilon_i} = e^{\eta_i} \rightarrow log\lambda_i = \eta_i \quad (3)$$

where λ_i is the amount of error recorded, x_1 is task complexity and x_2 is operator skill level/capacity. The results obtained in R suggest that both elements are significant in predicting error occurrence, as shown in Figure 3.

The likelihood ratio test results confirmed the meaningfulness of the significance for the parameter chosen for estimating the error rate with this model, as shown in Figure 4.

However the limited data set and that the estimates of skill rating were gathered done using a subjective rating. Therefore the model could be

4 CONCLUSIONS AND WAY FORWARD

Following this study a focus group and some observations study were performed suggesting that a reorganisation of work practices between the original conveyor line and the new pod cell design served to improve overall human performance in the facility. This has been demonstrated through the reduction in the number of human errors reported for the workstations during the four month timeframe of the project.

The data formed the basis of an empirically based, cross-verified model of human performance that can be used to provide objective feedback to users increasing their awareness of risks related to their own human characteristics and impact the design of safety critical systems and current approaches for vocational training. For the manufacturing facility involved in the project, further developments may include engaging operators in all elements of a process, induction testing to match operator's capabilities to task most suited to them and orientation of workstations to facilitate operators considering human error and ergonomics principles.

Human error in the manufacturing facility prior to an intervention or examination of human performance contributed to the occurrence of a large number of errors resulting in financial costs and productivity losses for the organisation. The reorientation of work practices at work stations, considering the role of human error and ergonomic principles, has allowed for a reduction in

the incidence of human related errors across the workstations examined.

The results may be limited by the four month time frame for which human errors were considered. However results shown that task complexity can be significantly predicted starting from the variables observed in the case study.

The TERM model used (the Poisson generalised linear regression) also suggests that both task complexity and operator's skill are valid predictors of error occurrence in a workstation. It is maybe also possible that while task complexity increases a corresponding linear increase in worker skills and capability is not able to sufficiently compensate for the increased complexity.

Bayesian aggregation of expert judgment data for quantification of human failure probabilities for radiotherapy

L. Podofillini, D. Pandya, F. Emert, A.J. Lomax & V.N. Dang
Paul Scherrer Institute, Villigen, Switzerland

G. Sansavini

ABSTRACT: The paper deals with the quantification of probabilities for human failures in the radiotherapy domain. The probabilities are used as input for the development of a Human Reliability Analysis (HRA) method specific for radiotherapy. Quantification is based on expert judgment, in view of the lack of relevant data. A Bayesian aggregation model is used to aggregate the judgments collected during elicitation sessions with domain experts. A qualitative scale is first used; then the judgments are interpreted as information on the order of magnitude of the error likelihood and aggregated under the Bayesian scheme. Besides for the specific domain of interest, this work is relevant for novel HRA applications outside typical domains, for which the need to incorporate expert judgment in traceable and defendable ways is key.

1 INTRODUCTION

Human failures are important contributors to near misses, incidents, and accidents in radiotherapy (WHO 2008), as in many other domains. Efforts are undertaken to systematically address the potential for failures and continuously improve the patient treatment process, e.g. Huq et al. (2016). In this context, the Risk and Human Reliability research group at the Paul Scherrer Institute (Switzerland), in collaboration with the institute's Center for Proton Therapy, is developing a method to support Human Reliability Analysis (HRA), specific for external beam radiotherapy. Previous work by the authors identified the personnel tasks critical to patient safety and possibly influencing factors (Pandya et al. 2017). Current work is addressing the quantification of the corresponding human failure probabilities.

In particular, the present paper focusses on the quantification of the failure probabilities for representative tasks, given a set of Performance Influencing Factors (PIFs). Given the shortage of directly usable experience data, the quantification resorts to expert judgment. The paper presents the application of a Bayesian aggregation model (Podofillini and Dang, 2013) to the judgments collected during elicitation sessions with domain experts. To avoid direct elicitation of probability values, the experts are asked to provide their judgments on a qualitative scale. The judgments are then interpreted as information on the order of magnitude of the error likelihood and aggregated under the Bayesian scheme. The paper presents the results of the aggregation. The application shows the ability of the aggregation approach to formally represent the variability of the experts' estimates.

Besides for the radiotherapy domain, the work presented in this paper is relevant for the various efforts recently done to extend HRA methods for application beyond their most typical applications, i.e. nuclear power plant operation. Lack of relevant data is a major issue for these novel applications (Bye et al. 2017, NASA 2012, Gibson 2012, Mkrtchyan et al. 2015, NUREG 2016) and methods to elicit expert judgment in a formal and defendable way are needed along with specific data collection initiatives.

The paper is organized as follows. The next Section provides the background on the HRA method under development, for which probability values are sought for in this paper. Section 3 presents the design of the elicitation sessions and the concepts underlying the Bayesian approach for processing and aggregation of the judgments. Section 4 presents the application to two Decision Trees part of the framework of the HRA method under development. Concluding remarks close the paper.

2 BACKGROUND INFORMATION

The framework for the HRA method consists of eighteen decision trees, one for each failure mode

corresponding to a different Generic Task Type (GTT, Table 1). The concept behind the GTTs is taken from the Human Error Assessment and Reduction Technique (HEART, Williams 2017), and is intended to define a set of task types, each with similar characteristics as it relates to the factors influencing performance and to the corresponding failure probabilities. The definition of the GTTs and of the influencing factors is based on GTTs- Performance influencing Factors (PIFs) structures developed in (Pandya et al. 2017): these structures link each GTT to the set of PIFs that influence the failure probability. These structures have been developed via a systematic and traceable process which, for each GTT, progressively identifies the involved cognitive functions, their failure modes and causes, failure mechanisms and PIFs.

The DT framework is well suited to represent the cause-based influences on failures identified by the GTT-PIF structures: the DTs identify the causes possibly leading to the GTT failure; in a similar way as done in other HRA methods (e.g. NUREG 2016, Moieni et al. 1994), each decision tree addresses a failure mode, with branching points representing the effects of PIFs. Two examples of DTs are presented in Figure 1. The decision trees develop from eight branching points, e.g. "Problematic interface", "Information content unclear", "Low vigilance due to expectations". As shown in Figure 1, each DT includes a subset of the eight branching points, three or four in most cases. The same branching point heading may appear across different DTs, e.g. "Problematic interface" in Figure 1; however, the influence of the branch on the failure probability may not necessarily be the same. This aspect will be returned to in the result Section 4. Each branch point is specified in terms of negative conditions: if any of the negative conditions is verified, then the lower branch applies. Example negative conditions are given in Table 2. The presentation of the development of the DTs from the GTT-PIF framework and of the negative conditions for each branching point is outside the scope of the present paper and will be presented in a separate publication (Pandya et al., working paper).

Table 1. Set of Generic Task Types (GTTs) and corresponding failure modes identified in Pandya et al. (2017). DTs are developed for each failure mode of the GTTs.

#	GTT	Failure mode
1	Identification of patient or patient related items	Patient information incorrectly matched
		Identification check not performed (decision based)
		Failure to execute desired action
2	Quality Check	Deviation from requirement not recognized
		Inappropriate understanding of underlying principles
		Check not performed (decision based)
		Execute desired action incorrectly
		Failure to execute desired action
		Coordination failure
3	Complex interaction with software or tool	Misinterpretation of data
		Execute desired action incorrectly
		Mismatch or inconsistency not recognized
4	Simple interaction with software or tool	Execute desired action incorrectly
		Failure to execute desired action
5	Iterative determination of optimum parameters	Misinterpretation of information
		Inappropriate decision on strategy selection
6	Verbal communication	Communication failure
		Not communicated (decision based)

To assess the failure probability of a specific radiotherapy task, an analyst would have to select the applicable DTs based on the relevant type of task and failure mode. Then, for each branching point, the analyst would have to select the appropriate branch based on the negative conditions proposed for each branch, in a similar way as done with other HRA methods involving DTs, e.g. NUREG (2016), Moieni et al. (1994).

The present paper focuses on the quantification of the DTs, i.e. on the assessment of the failure probabilities in correspondence of each path defined by the combination of the branching points.

3 EXPERT JUDGMENT ELICITATION AND AGGREGATION APPROACH

3.1 *Expert judgment elicitation*

As mentioned in the Introduction, due to the lack of relevant data, quantification is made via expert judgment. In particular, the expert elicitation sessions were designed with two aims. First, to support the identification of the negative conditions underlying each branch point. Second, to assess the impact of each branching point on the failure probability. Only the effects of single branch points were addressed (i.e. determining failure probabilities 1, 2, and 4 in Figure 1, top part). The combination effects will be addressed in future work.

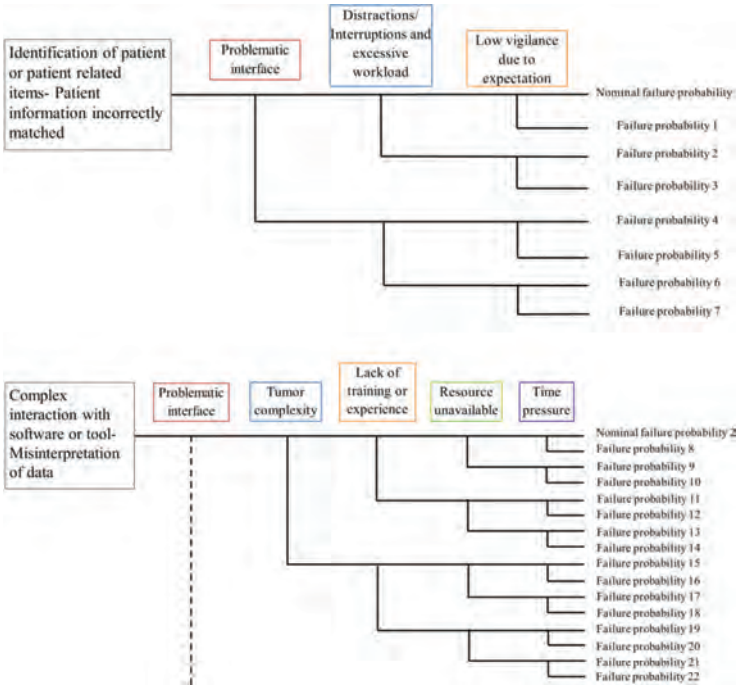

Figure 1. Two examples of decision tree; above: GTT "Identification of patient and patient related items", Failure mode "Patient information incorrectly matched"; below: GTT "GTT: Complex interaction with software or tool", Failure mode "Misinterpretation of data". The focus of the present paper is on quantification of the failure probabilities at each tree branch (only single branch effects elicited).

Table 2. Examples of negative conditions for two branching points in two different DTs.

DT	Branch point	Negative conditions
GTT: Identification of patient or patient related items; Failure mode: patient information incorrectly matched	Problematic interface	The written values look alike *(e.g. 111, 117)* The value on the label or file not easily readable There is no ID number on the patient item
GTT: Complex interaction with software or tool; Failure mode: Misinterpretation of data	Lack of adequate training or experience	Lack of familiarity with the tumor case Lack of training or experience on treating special tumor locations (e.g. close to multiple artefacts) Lack of experience or training to distinguish healthy and tumor tissues

Six failure scenarios were developed for the elicitation, Table 3 gives two examples. The idea is to elicit the impact of the branching point on these failure scenarios, which would then be representative of the overall GTT. The selection aimed at addressing the largest set of GTT failure modes, as well as prioritizing failure scenarios with the most critical consequences on patient safety. As shown for the examples in Table 3, each failure scenario is associated to a different GTT. Indeed as again shown in Table 3 and by the negative conditions in Table 2, the elicitation of the branching point impact was conducted on specific tasks and situations. This has been made to help experts to contextualize their judgments to the real tasks they perform and link their assessments to the daily experience. Alternatively, judgments may have been elicited directly for the GTTs and branching point categories. The former approach was chosen to avoid that experts would need to deal with abstract categories such as GTTs and the branch point labels. The focus of this paper is on the part of the elicitation session aimed at eliciting the impact of each branching point on the failure probability. The details of the overall elicitation design and its results will be presented in a different paper (Pandya et al., working paper).

Indeed, the elicitation addressed directly only part of the DTs required for quantification, i.e. six out of the eighteen from Table 1. However, some branching points may be thought of having very similar impact across different DTs; therefore the results from the elicitation for one DT may be used for others. It was assessed that the selected tasks may allow to quantify about two thirds of the whole set of branching points (recall only single branch point effects are considered here). Indeed future work may address the quantification of the remaining DTs and develop an approach to address multiple branch points as well.

Twelve experts were interviewed: medical physicists, medical doctors, dosimetrists and radiation technologists. Each expert dealt with tasks part of his/her daily job. Three tasks were elicited at most per expert. Each expert took part in the exercise alone. For each of the assigned tasks and each of the negative conditions corresponding to the branching points, the experts were asked to assess the impact of the negative condition on the failure probability when performing the task. The impact is elicited on a qualitative scale (Table 4), to avoid the known shortcomings of directly eliciting probability values, see e.g. Meyer and Booker (2001), Tversky and Kahneman (1974).

3.2 *Aggregation of expert assessments*

The approach to process the expert assessments has been as follows. The qualitative scale in Table 4 is first anchored to quantitative values, as shown in Table 5. The basis for the anchoring is the scale

Table 3. Example of failure situations used to elicit the impact of the branch points on the failure probability.

Failure situations	Failure mode	Generic task type
Failure to identify correct ID from control document on the bite-block, couch or file etc. such that incorrect item is picked up	Patient information incorrectly matched	Identification of patient or patient related items
Draw suboptimal (incorrect or incomplete) contours around volumes of interest for every slice due to misunderstanding of the data	Misinterpretation of data	Complex interaction with software or tool

Table 4. Qualitative scale used to elicit impact of negative conditions on the personnel tasks.

Impact	Descriptor	Meaning
Low impact	Failure is not expected to happen, although I see how it could happen.	Given the negative condition, the desired task is still so easy that it is inconceivable that any personnel would fail if they were to experience this condition.
Moderate impact	Failures happen occasionally/ sometimes with such conditions	Given the negative condition, the desired task becomes moderately difficult that it is possible so that personnel would occasionally/ sometimes fail if they were to experience this condition.
High impact	Failures happen often with such conditions	Given the negative condition, the desired task becomes highly difficult that is expected so that personnel would often fail if they were to experience this condition.
Extreme impact	Failure is almost unavoidable	Failure is almost unavoidable. Almost all personnel would not be able to perform the desired task.

Table 5. Anchoring of the qualitative impact scale to probability values (adapted from NUREG 2007).

Impact	Order of magnitude of failure probability
Low	1e-3
Moderate	1e-2
High	1e-1
Extreme	1

presented as part of the ATHEANA human reliability analysis method (NUREG 2007). Note the values on the scale are to be interpreted as reference orders of magnitude for the failure probability value. The value representative for low impact (1e-3) is confirmed in the studies by Wahi et al. (2008) and Salinas et al. (2013), from which it can be inferred that nominal error rates in patient identification and data entry in healthcare lie around 1e-3 and 3e-3. These are interpreted as lower bounds for error probabilities for the sector. Low impact of the branching point is not expected to change the order of magnitude of the probability so that the reference lower bound value still remains in the same order of magnitude.

The scale allows converting each assessment by the experts into a statement on the order of magnitude where the probability value would lie. It is interpreted as evidence of the relevant order of magnitude, and used to update the belief on that quantity in a Bayesian framework.

The process for aggregation of the judgments comprises two steps. First, for each negative condition, the judgments by the experts are aggregated: a distribution of the applicable probability for each condition is obtained. Then, these distributions are themselves aggregated into the final distribution of the corresponding branch. The aggregation approach is based on the Bayesian model presented in Podofillini & Dang (2013). The model represents the human error probability as an inherently variable quantity, resulting from the inherent variability of people performance as well as of the specific manifestations of the type of tasks and of the influencing factors. More specifically, the combination of GTTs and branch point conditions envelop specific tasks and specific performance conditions that are assumed to be characterized by inherently different failure probability values. The elicitation carried out in this work addressed specific manifestations of the combination (see Table 3 and Table 2): the Bayesian model is intended to consider the expert assessments on these manifestations (a specific task affected by specific negative performance conditions) and determine the original variability distribution of interest. Mathematically, the failure probability is assumed to be lognormally distributed, with unknown median to be determined based on the expert input. The error factor (square root of 95th and 5th percentile) is assumed to be known, equal to 3. The latter assumption of known error factor is not a requirement of the approach, but largely simplifies the calculations and decreases the amount of data required to be elicited. It is indeed a typically used and accepted value in HRA. The prior distribution of the median is assumed uniform for the four orders of magnitude in Table 5 (all impact levels are equally likely).

For the first part of the aggregation process, the expert assessments are used to update the degree of belief on the correct order of magnitude for the median of the probability distribution. The model requires as well assumptions on the confidence that the experts would be able to provide the correct value of the probability. The confidence is expressed in terms of a conditional probability that, given the real order of magnitude of the probability is one of the four in Table 5, the experts would assess the correct one or be off by one or more orders of magnitude. This conditional probability can be defined to model biases and dependence across experts, indeed provided that adequate information on the distribution is available (these are not modeled in the present work). In this work, it is assumed that experts have about 80% probability to provide the correct order of magnitude, 10% of being one order of magnitude off, 5% of being two or more orders of magnitude off. The exact values of these probabilities depend on the position of the interval with respect to the lower and upper bounds to have them normalized to a probability distribution. These values have been assumed by the authors of the paper; they appear to represent reasonable assumptions on the ability of the experts to provide correct estimates in this context. It is anyway important to mention that as more than a few experts are available (say five or more), the specific assumptions on the confidence to each expert do not play a significant role anymore in the final probability distribution. The output of this step is a distribution of the degree of belief on which of the levels in Table 5 represents the real value of the median of the probability distribution, for each negative condition possibly affecting each branch point.

The second part of the aggregation entails combining the degrees of belief obtained for each negative condition underlying each branch points. As the negative conditions are assumed equally likely, the final distribution is simply obtained as the average distribution across the negative conditions. In particular, for each of the levels in Table 5, the final degree of belief is the average degree of belief across the corresponding negative conditions. Applications of the approach will be presented in the next section.

4 AGGREGATION OF EXPERT ASSESSMENT: RESULTS AND DISCUSSION

This paper presents the result obtained for two DTs:

- GTT "Identification of patient and patient related items", failure mode "Patient information incorrectly matched";
- GTT "GTT: Complex interaction with software or tool", failure mode "Misinterpretation of data".

These are the two DTs shown in Figure 1. The results obtained from the whole elicitation are planned to be presented in Pandya et al. (Working paper).

The first part of this Section presents an overview of the aggregated results for the two DTs. The aim is to discuss how the quantitative results relate to the justification provided by the experts on their assessments. In other words, the goal is to check if the different values of error probability reflect in corresponding differences in the assessments by the experts. The second part of the Section provides details on how the expert assessments are aggregated.

Figure 2 shows the aggregated results from the expert assessments. The largest impact on failure probability corresponds to the branch point "Lack of training or experience" branching point affecting GTT "Complex interaction with software/tool". This is a complex task, related to defining an optimal therapy plan and requiring knowledge and expertise. As shown by the expert assessments, the influence of inadequacies in this respect can have high impact on the failure probability. Indeed, the resulting median probability is around 0.01, corresponding to the "high" impact level on the adopted scale. Branching point "Time pressure" was also assessed among the most influencing ones: it was felt that the need to complete the task with urgency would highly impact the quality of the therapy plan. On the other hand, two branching points were assessed to have generally low impact. In particular, interface issues (branching point "Problematic interface") were not felt to affect much the performance when identifying patients: identification of patients is made with diverse means; besides checking the patient ID, identification is checked verbally (calling patient name) and by the patient picture. Additionally the interface to deal with is extremely simple so that there is little possibility for confusion. Also, the complexity, in shape, size and location of the tumor was not felt to increase much the probability of errors in the development of the therapy plan. Typically, complex tumor cases are discussed in larger groups and the treatment details are thoroughly defined.

It is interesting to see in Figure 2 how the same type of branching point may affect GTTs differently. For example, the assessed probability for "Problematic interface" affecting GTT "Complex interaction with software/tool" is more than one order of magnitude larger than when affecting GTT "Identification of patient or patient-related tools". Again, this is the result of the expert opinions on the importance of the respective influences. The reasoning underlying the low impact according to the experts of the branch point on the latter GTT has already been discussed. On the other hand, the former GTT involves complex interactions with multiple software interfaces, dialog boxes, figures, etc: the impact of interface issues for this task was considered to have important effects on the failure probability.

The length of the error bars reflects differences in the expert assessments both for each negative condition and across the different conditions. The larger the bar, the larger the differences. This aspect will be returned to later in this Section.

Figures 3 and 4 show how the expert assessments are progressively processed to obtain the final probability distributions presented in Figure 2. The left side of the figures gives the assessments of the experts provided on the scale for each of the negative conditions. The middle shows the distribution results aggregated across the experts for each negative condition. The right side gives the final distribution, aggregating across the conditions. Specifically, Figure 3 addresses the effect of branching point "Problematic interface" on GTT

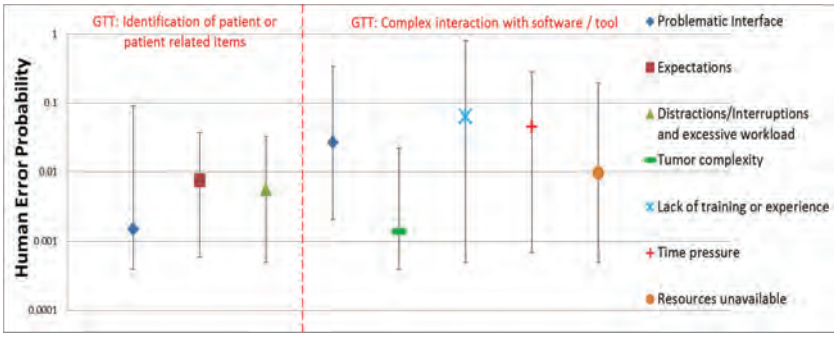

Figure 2. Aggregated results for the two considered GTTs; Symbols identify the median failure probability affected by each branch point (acting one at a time, presented on the right of the figure), error bars the 5th and the 95th percentiles.

"Identification of patient or patient-related items". It is interesting to see in the Figure how different assessments from the experts result in different distributions. For the first negative conditions, three experts provided the assessments of "low" (thus corresponding to an error probability of about 0.001) and two of "moderate". Correspondingly, the aggregated distribution in the middle of Figure 3 presents larger degree of belief for the latter level on the scale compared to the former. Degrees of belief for the other levels are in practice negligible. For the second condition, there is strong agreement for low impact: the peak in the degree of belief for the latter value is accordingly higher than in the previous case. A very different situation is present for the last condition, where the three experts provided three different assessments. The effect to spread the degree of belief for the latter condition is evident.

Another interesting case is presented in Figure 4, related to the effect of "Lack of adequate training or experience" for the GTT "Complex interaction with software/tool". There is general consistency across the expert on the effect of each condition, as reflected in the distributions in the middle part of the figure. The large span in the expert assessments, from "low" to "extreme", results then in the large spread in the final aggregated distribution on the right.

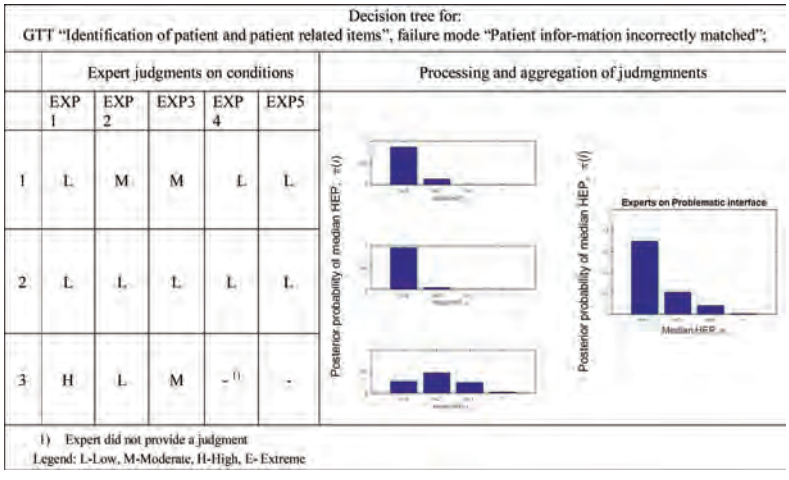

Figure 3. Processing and aggregation of judgments (GTT "Identification of patient and patient related items", failure mode "Patient information incorrectly matched"): Left: judgements from experts, Middle: expert-aggregated posterior distribution of median HEP for each condition, Right: posterior probability distribution of median HEP for the branch point.

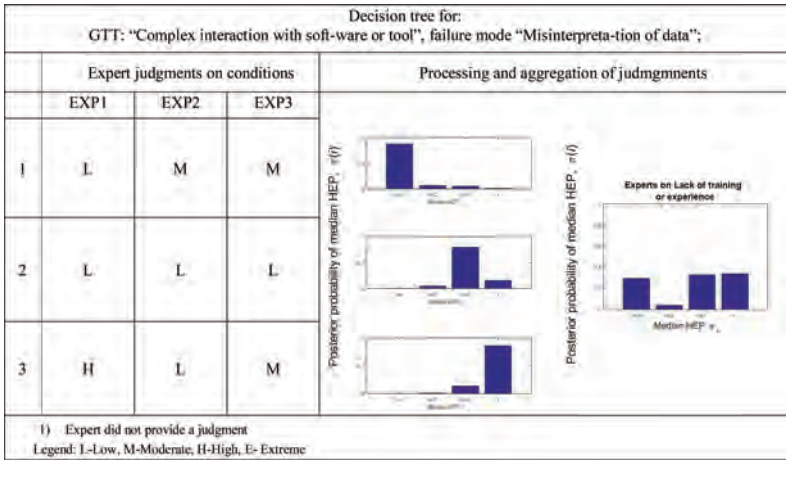

Figure 4. Processing and aggregation of judgments (GTT: "Complex interaction with software or tool", failure mode "Misinterpretation of data") Left: judgements from experts, Middle: expert-aggregated posterior distribution of median HEP for each condition, Right: posterior probability distribution of median HEP for the branch point.

5 CONCLUSIONS

The paper has presented the work performed to quantify the human failure probabilities to be used as input to a novel HRA method. Elicitation sessions were designed, with the following two main features. First, information on probabilities is asked to experts on a qualitative scale, with the goal of getting evidence on the order of magnitude for the probability. Second, specific situations are presented to the expert, i.e. specific failure scenarios influences by specific negative conditions. The latter feature was incorporated to avoid that the expert deal with abstract categories such as tasks types and influencing factors.

The expert statements are processed and aggregated to determine degrees of belief on the correct values of the failure probability. The latte is assumed as an inherently variable quantity so that the main parameter of its distribution is the subject of the elicitation. The Bayesian model used to aggregate the assessments was found to represent well the differences in the experts statements, providing a credible approach to process the expert input.

As a next step of the work, comparison of the obtained values with values from existing HRA methods is envisioned. Indeed, although HRA methods are sector-specific, some of the underlying data can be thought of being general, e.g. data regarding dealing with indicators, simple execution tasks. This comparison may provide some validation to the elicitation process.

With broader perspective, future work will apply the developed HRA method to hypothetical accident scenarios at the institute's Center for Proton Therapy.

An optimal maintenance policy based on partial information

R. Ahmadi

ABSTRACT: This paper proposes an integrated model for maintenance scheduling of parallel systems whose failures are detected by inspections. A common characteristic of such systems is that the system failures are detected only by inspections and the failure of a component may not cause its system to fail. As such, the failure may not be immediately detected and the random (disruption) time at which the number of failed components reaches a certain predefined number d may therefore be unknown. For such systems, scheduling maintenance policy is a difficult task, which is tackled in this paper. The main issue considered here is to get an estimate of the disruption time on the basis of inspection point process observations in the framework of filtering theorem. The paper develops a unified cost structure to jointly optimise inspection frequency and replacement time for the system when the lifetime distribution of a component follows the Weibull distribution. Numerical results are provided to show the application of the proposed model. In addition, a sensitivity analysis is performed to examine the effect of maintenance parameters on the model.

1 INTRODUCTION

This paper proposes an approach to the joint determination of optimal inspection and replacement policies for m-component parallel systems subject to non-self announcing failures. The interest in such systems is natural as they provide a redundant approach to improving system reliability and availability. Nuclear reactor safety systems, emergency core cooling systems, fire detectors, and protective devise are good examples of parallel systems used in the real world. A common feature of such systems is that the failure of a component may not cause its system to fail and the system failures are detected only by inspections. As such, the failure may not be immediately detected and can be regarded as a hidden failure. Consequently, the number of failed components may be unknown at a given time. This raises a thought-provoking question: how can the failure time of d^{th} $(d = 1,2,\cdots,m-1)$ components (called disruption time) and the reliability and the maintenance cost be respectively estimated and analyzed to handle such a lack of data scenario while providing effective decision making? This paper attempts to answer those questions. The approach depends on the identification of the disruption time based on the inspection point process observations. The estimated disruption time contributes to scheduling a maintenance policy for an m-component parallel system. More generally, given partial information, the approach explored here can deal with two basic problems: how to inspect and when to stop operating the system and carrying out a replacement in order to detect the system failure and minimize some maintenance cost.

Although some maintenance models consider joint inspection and maintenance policies for systems whose state are detected only by inspections (He, Maillart, & Prokopyev 2015, Tambe, Mohite, & Kulkarni 2013, Tsaia, Sheu, & Zhangc 2017), there is only a few research handling such a lack of data while providing effective decision making. For instance, using the filtering theorem argument, Ahmadi & Wu (2017) propose a novel technique to estimate the disruption time, aiming at revealing the true state of the system. The technique also helps to deliver a warning, or an alert on approaching a disruption. This alert is the signal that an inspection or a preventive maintenance has to be performed. As such, the proposed technique augments the detection of failure. Further advantages of their model enhancing its applicability include modeling inspection through the modulated Poisson process and introducing a state-dependent cost structure. Both modeling approaches make the model superior to those (Berrade & Scarf 2012, He, Maillart, & Prokopyev 2015, Liu, Wang, Peng, &

Zhao 2015, Bjarnason & Teghipour 2016, Babishin & Teghipour 2016, Tsaia, Sheu, & Zhangc 2017) in which the inspection frequency and/or cost parameters do not respond to the variation of the system state. The structure also allows aperiodic inspections that is often more useful and realistic than the periodic policy, since it is more adaptive to deteriorating systems and typically leads to policies with lower costs.

The approach in this paper differs through the use of a general degradation model motivated by the extension of the model in the earlier paper by Ahmadi & Wu (2017). Furthermore, it encompasses and examines some characteristics which have not been addressed or studied in isolation.

2 ASSUMPTION AND MODEL DEVELOPMENT

2.1 *Model assumptions*

The following assumptions are made. (a) The paralell system consists of m components. (b) The failure of the system can only be detected by inspections ("hidden or non-self announcing failures"). (c) The inspection intensity process is assumed to follow a modulated Poisson process. (d) The only available information is given by the inspection point process observations (observation filtration). (e) The system is replaced at periodic times $\{t_r, 2t_r, \cdots\}$ (f) Inspections do not impact on the failure characteristics of the system.

2.2 *Model development*

2.2.1 *Modelling degradation*

Here we describe a stochastic model of degradation. For this discussion, we assume that all random variables are defined on a complete probability space $(\Omega, \mathcal{F}, \mathbb{P})$. Consider a multicomponent parallel system consisting of m components whose lifetimes are independent and identically distributed random variables. The system is subject to random failure which can only be detected through inspection. The system state is characterized by a two unobservable states: a normal state and a degraded state. The transition time from the steady state to the degraded state called "disruption time" is defined as the first time the total number of failed components reach a predetermined threshold d:

$$\tau_d = \inf\{t : Y(t) = d\}; d = 1,2,\cdots,m-1 \tag{1}$$

where τ_d is the disruption time and $Y(t)$ is a stochastic process counting the total number of failed components up to time t. Denote

$$X_d(t) = \begin{cases} 0, & \text{if} \quad \tau_d > t, \\ 1, & \text{if} \quad \tau_d \le t. \end{cases} \tag{2}$$

From equations (1) and (2), one can see that the disruption time at which the system state, $X_d(t)$, jumps from 0 to 1 depends on the threshold's value d: a smaller value of d may result in earlier disruption.

2.2.2 *Modelling inspections*

The inspection modeling approach to detect the system failure is similar to that of Ahmadi & Newby (2011) and Ahmadi & Wu (2017) assuming that inter-inspection times conform to a modulated Poisson process. Specifically, let $N(t)$ be a modulated Poisson process such that $N(t)$ with the associated time points of inspections, $T_1 < T_2 < \cdots$, depicts the total number of arrivals up to time t. In other words, according to Aven and Jensen (Aven & Jensen 1998), $N(t)$ admits a smooth semimartingale (SSM) with the $\mathcal{F}$-intensity λ_t and the $\mathcal{F}$-martingale M_t:

$$N(t) = \int_0^t \lambda_s ds + M_t$$

where $t \in \mathbb{R}^+, M \in \mathcal{M}$ and $\mathcal{M}$ denotes the class of martingales adapted to the filtration $\mathcal{F}_t$. As noted, the inspection intensity process λ_t is modulated by the stochastic process $X_d(t)$ such that

$$\lambda_t = \lambda_{X_d(t)} = \lambda_0 + (\lambda_1 - \lambda_0) X_d(s), \quad \forall t \ge 0, \tag{3}$$

where λ_i satisfying

$$\lambda_0 < \lambda_1 < \infty, \tag{4}$$

denotes the rate of arrivals when the state of $X_d(t)$ is i (i = 0,1). Here, $X_d(t)$ influences and modulates the arrival rate of the Poisson process. The reader is referred to Özekici (Ozekici 1996) for more details about the modulated Poisson process. Equations (1)–(3) indicate that changes in the threshold's value d induce changes in both the disruption time and the inspection intensity: as d decreases, the state process $X_d(t)$ jumps sooner from the normal state to the degraded state which implies an increase in the number of inspections. It is evident that this modeling technique, in an elegant way, not only allows the inspection intensity responds to the variation of the system state, but also ensures (see equation (4)) the system upon approaching disruption is inspected more frequently which properly results in more certain detection of failure. Since the model including $N(t)$ is driven by the unobservable state process $X_d(t)$,

the first main problem investigated here is to get an estimate of the unobservable state $X_d(t)$ given the inspection point process observations up to time t, $\mathcal{F}_t^N = \sigma\{N(s): 0 \le s \le t\}$, that is

$$\phi_d(t) = \mathbf{E}\left[X_d(t) \middle| \mathcal{F}_t^N \right] = \mathbf{P}\left[\tau_d \le t \middle| \mathcal{F}_t^N \right]. \qquad (5)$$

The measure (5) not only contributes to detecting the disruption time τ_d at which the state process $X_d(t)$ jumps from the normal state to the degraded state (or, the estimate of components lifetime), but also allows the estimation of the intensity process $\lambda_{X_d(t)}$ by projection on the observed history. That is,

$$\hat{\lambda}_t = \mathbb{E}\left[\lambda_{X_d(t)} \middle| \mathcal{F}_t^N \right] = \mathbb{E}\left[\lambda_0 + (\lambda_1 - \lambda_0) X_d(t) \middle| \mathcal{F}_t^N \right].$$

The function $\hat{\lambda}_t$ reflecting the reaction of the maintenance crew is called inspection alert function. Indeed, given that the probability of the disruption detection at time t is $\phi_d(t)$, the inspection intensity that is at the discretion of the maintenance crew should be $\hat{\lambda}_t = \lambda_0 + (\lambda_1 - \lambda_0)\phi_d(t)$. The situation may be regarded as a case of condition-based maintenance in a sense that the function (5) provides some information (alert) regarding the state of the disruption. Through the inspection alert function $\hat{\lambda}_t$, the crew will use the information to perform inspections in order to detect system failures. Intuitively, this alert is the signal that an inspection has to be performed.

2.3 *Modelling disruption*

This section aims to provide a solution to the disruption alert function $\phi_d(t)$ by setting in the filtering theorem framework (Bremaud 1981). The solution technique used here is similar to that of models proposed by Ahmadi & Newby (2011).

2.3.1 *Complete information-based disruption model*

We have to detect the random time τ_d at which the inspection intensity $\lambda_{X_d(t)}$ increases: $\lambda_0 \mapsto \lambda_1$. For this, let $F(t) = \int_0^t f(u)du$ be the cumulative distribution of components lifetime. Using the semi-martingale argument (Aven & Jensen 1998), one can note that the increasing right-continuous state process $X_d(t) = I(\tau_d \le t)$ with the associated maintenance parameter d admits the following semi-martingale representation:

$$X_d(t) = \int_0^t \tilde{q}_{01}(s)\big(1 - X_d(s)\big)ds + m_t,$$

where m_t is an $\mathcal{F}_t$ -martingale and

$$\tilde{q}_{01}(t) = \begin{cases} \dfrac{f_d(t)}{1 - F_d(t)}, & \text{if } F_d(t) < 1; \\ 0, & \text{otherwise,} \end{cases}$$

denotes the transition rate of the state process $X_d(t)$ from normal state (0) to the degraded state (1) with the disruption distribution function

$$F_d(t) = \mathbf{P}(\tau_d \le t) = \sum_{k=d}^{m} \binom{m}{k} [F(t)]^k [1 - F(t)]^{m-k}.$$

Using the fact that the density function of the disruption time is

$$f_d(t) = \frac{m!}{(d-1)!(m-d)!} [F(t)]^{m-1} [1 - F(t)]^{m-d} f(t),$$

the transition rate of the state process $X_d(t)$ can be formulated as

$$\tilde{q}_{01}(t) = \frac{\binom{m}{d-1, m-d} q_{01}(t)}{\sum_{k=0}^{d-1} \binom{m}{k} [\exp(Q_{01}(t)) - 1]^{k-d+1}} \qquad (6)$$

where $q_{01}(t) = \frac{f(t)}{\bar{F}(t)}$ denotes the failure rate of the system and

$$Q_{01}(t) = \int_0^t q_{01}(s)ds.$$

2.3.2 *Partial information-based disruption model*

Since the disruption time at which the process $X_d(t)$ jumps from 0 to 1 is not directly observed, in the filtering theorem framework (Bremaud 1981), we get an estimate of the state process $X_d(t) = I(\tau_d \le t)$ based on the observed history F_t^N. More precisely, the problem is that of computing $\phi_d(t)$ given in (5) and getting an $\mathcal{F}^N$-adapted estimate of the inspection intensity process

$$\lambda_t = \lambda_{X_d(t)} = \lambda_0 + (\lambda_1 - \lambda_0) X_d(t), \qquad (7)$$

that is to say, before the disruption time τ_d, $\lambda_t = \lambda_0$, and after τ_d, $\lambda_t = \lambda_1$.

By projection on the observed history $\mathcal{F}_t^N$ one can show that

$$\phi_d(t) = \int_0^t [\tilde{q}_{01}(s) + (\lambda_1 - \lambda_0)\phi_d(s)]\big(1 - \phi_d(s)\big)ds + \sum_{n \ge 1} \frac{(\lambda_1 - \lambda_0)\phi_d(T_n^-)\big(1 - \phi_d(T_n^-)\big)}{\lambda_0 + (\lambda_1 - \lambda_0)\phi_d(T_n^-)} I(T_n \le t),$$

or, equivalently, between the jumps $\left(t \in [T_n, T_{n+1})\right)$,

$$\bar{\phi}_d(t,n) = \bar{\phi}_d(t)\, I(T_n \le t < T_{n+1}) = \bar{\phi}_d(T_n) - \int_{T_n}^{t} (\tilde{q}_{01}(s) + \bar{\lambda}\phi_d(s,n))\big(1 - \phi_d(s,n)\big)\, ds; \quad (8)$$

at the jumps,

$$\phi_d(T_n) = \frac{\lambda_1 \phi_d(T_n^-)}{\lambda_0 + \bar{\lambda}\phi_d(T_n^-)}, \quad (9)$$

where $\phi_d(T_n^-)$ denote the left limit of $\phi_d(\cdot)$ at time T_n, $\bar{\phi}(\cdot) = 1 - \phi(\cdot)$ and $\bar{\lambda} = \lambda_1 - \lambda_0$. From (8) one can see that for $t \in [T_n, T_{n+1})$

i. the sojourn time distribution in normal state is a decreasing function of the transition rate of the state process $X_d(t)$ that is $\tilde{q}_{01}$ and $\bar{\lambda}$. The latter can be realized as a measure whose scale reflects the reaction intensity of the maintenance crew to perform inspections upon switching of $X_d(t)$ from normal state to the degraded state.
ii. the disruption time distribution $\phi_d(t,n)$ satisfies the differential equation (7) with the initial condition (9):

$$\phi_d'(t,n) = \left(\tilde{q}_{01}(t) + \bar{\lambda}\phi_d(t,n)\right)\left(1 - \phi_d(t,n)\right) > 0, \quad (10)$$

where the positive derivative implies increasing trajectories of $\phi_d(t,n)$ between the jumps.
iii. Let $\bar{\lambda} = 0$. This assumption intuitively implies that the maintenance crew (inspection intensity) does respond to the variation of the state process $X_d(t) : 0 \mapsto 1$. From (ii) an explicit solution to the sojourn time distribution of $X_d(t)$ can be given by

$$\bar{\phi}_d(t,n) = \exp\left(-\int_0^t \tilde{q}_{01}(s)\, ds\right).$$

From above argument one can see that by projection on the observed history $\mathcal{F}_t^N$ for $t \in [T_n, T_{n+1})\,(n \ge 0)$ and the use of the disruption time distribution $\phi_d(t,n)$, an $\mathcal{F}_t^N$-adapted estimate of the inspection intensity (7) can be given by

$$\hat{\lambda}_t = \mathbb{E}[\lambda_{X_d(t)} \mid \mathcal{F}_t^N] = \lambda_0 + \bar{\lambda}\phi_d(t,n). \quad (11)$$

To gain a better understanding of the impact of the disruption alert function $\phi_d(t,n)$ and the inspection alert function $\hat{\lambda}_t$ on both the performance of inspections and failures, let the measure of alertness on approaching a disruption, $\phi_d(t,n)$, tend to 1. From (11) we get $\hat{\lambda}_t \to \lambda_1$ $(\lambda_1 > \lambda_0)$ that indicates more frequent inspections to prevent the system failure.

2.4 *Mean time to disruption*

The measure $\bar{\phi}_d(t,n)$ can contribute to determination of the mean time to disruption m_d:

$$m_d = \int_0^\infty \bar{\phi}_d(t,n)\, dt.$$

The mean time to disruption can provide some information regarding the disruption time at which $X_d(t)$ jumps from normal state to the degraded state. The crew will use this insight to perform maintenance in order to timely detect the components failure of the system.

From equations (8) and (9) one can note that the solution of the differential equation (10) based on the initial condition (9) depends on the estimation of inspection times T_n $(n \ge 1)$. In Section 2.5 we devise an inspection scheduling function based on the $\mathcal{F}^N$-adapted inspection intensity. We will see the explored scheduling function incorporating the disruption time distribution $\phi_d(t,n)$ enables us (i) to provide a systematic approach to the determination of non-periodic inspection times and (ii) to estimate the disruption time distribution $\phi_d(t,n)$ over inter-arrival inspection times $[T_n, T_{n+1})\,(n \ge 1)$.

2.5 *Scheduling inspections*

Let $\varphi_n(v)$ for $v \in [0, V_{n+1})$ be the distribution function of the $(n+1)^{\text{th}}$ inter-inspection time $V_{n+1} = T_{n+1} - T_n\,(n \ge 0)$ adapted to the observed information $\mathcal{F}^N$. Then for $t \in [T_n, T_{n+1})$ we have

$$\bar{\varphi}_n(v) = \mathbf{P}(V_{n+1} \ge v \mid \hat{\lambda}_t) = \exp\left(-\int_{T_n}^{T_n+v} \hat{\lambda}_s\, ds\right),$$

where $\bar{\varphi}_n(v) = 1 - \varphi_n(v)$. Since $\hat{\lambda}(t,n) = \lambda_0 + (\lambda_1 - \lambda_0)\phi_d(t,n)$, $t \in [T_n, T_{n+1})$, $\bar{\varphi}_n(v)$ can be expressed as

$$\bar{\varphi}_n(v) = \exp(-\lambda_0 v) \times \exp\left(-(\lambda_1 - \lambda_0)\int_{T_n}^{T_n+v} \phi_d(s,n)\, ds\right). \quad (12)$$

If $\mu_n = \mathbb{E}[V_{n+1} \mid \hat{\lambda}_t]\,(n = 0,1,2,\cdots)$ denote the $(n+1)^{\text{th}}$ expected time between inspections, using the inter-inspection time distribution (12), an $\mathcal{F}^N$-adapted estimate of inter-inspection times can be given by

$$\mu_n = \int_0^\infty \bar{\varphi}_n(t)\, dt \quad (13)$$

This provides a sequence of inspection times $\eta_n = \sum_{k=0}^{n-1} \mu_k\,(n = 1,2,\cdots)$.

2.6 *Example: Examining the model*

To examine the response of the model to threshold's values d = 1,2, consider a 3-component

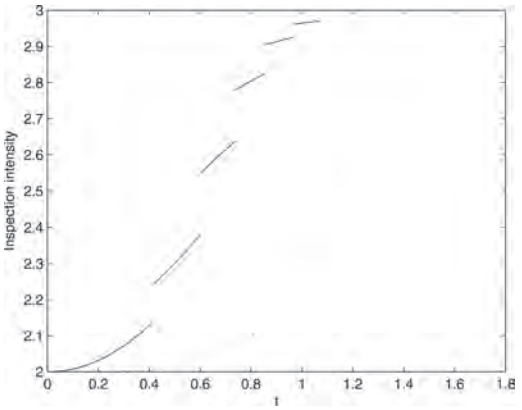

Figure 1. Inspection intensity $\hat{\lambda}_t$ for different $d \in \{1,2\}$.

parallel system whose components lifetime conforms to a Weibull distribution with the failure rate

$$q_{01}(t) = \frac{\alpha}{\beta}\left(\frac{t}{\beta}\right)^{\alpha-1}. \tag{14}$$

In addition let $(\alpha,\beta) = (2,2)$ and $(\lambda_0,\lambda_1) = (2,3)$. Given known parameters, by using the equation (10), an expression for the transition rate $\tilde{q}_{01}$ corresponding to $d = 1,2$ can be given by

$$\tilde{q}_{01} = 1.5t, \qquad \tilde{q}_{01} = \frac{3t \times (exp(0.25t^2) - 1)}{3exp(0.25t^2) - 2}. \tag{15}$$

Figure 1 reveals that the inspection intensity $\hat{\lambda}_t$ in terms of the sojourn time distribution $\phi_d(t,n)$ emerging as solution of the differential equation (10) strongly depends on the threshold's value d: as the threshold's value d decreases to 1 the inspection intensity occurs more frequently. In addition, Figure 1 indicates that the inspection intensity as a measure of alertness reflects the reaction of the maintenance crew. In the sense that they deliver an alert regarding a possibly approaching disruption and this alert is used to make inspections. Thus, the alert is a signal that an inspection has to be performed to detect a failure.

3 COST MODEL

This section aims to jointly determine an optimal replacement policy and an optimal inspection frequency with respect to a state-dependent cost-reward model. The cost structure used here is similar to that of the model proposed by Ahmadi & Wu (2017).

3.1 *Average cycle costs*

A cycle is comprised of a sequence of inspections that ends with replacement scheduled at periodic times $\{t_r, 2t_r, \cdots\}$. Repair and maintenance actions in a cycle incur costs that include: (i) inspection costs to detect the system failures, (ii) a penalty cost associated with undetected failures and (iii) a periodic replacement cost made after every t_r units of time. More precisely, each inspection at time t incurs a time-dependent cost $c_t = ct\ (c > 0)$. Undetected failures within inter-inspection times generate a state-dependent penalty cost per unit time

$$C_{X_d(t)} = C_0 + (C_1 - C_0)X_d(t),$$

$(C_1 > C_0)$. This implies that as the system state shifts to more degraded state $X_d(t): 0 \mapsto 1$, the penalty cost increases from C_0 to C_1. In addition, we assume that the replacement of the system in different states incurs different costs. In other words, the replacement of the system at time t is measured by a state-dependent cost

$$k_{X_d(t)} = k_0 + (k_1 - k_0)X_d(t),$$

$(k_1 > k_0)$. It is noted, as the state process $X_d(t)$ moves from the normal state $(X_d(t) = 0)$ to the degraded state $(X_d(t) = 1)$ the replacement cost increases $k_0 \mapsto k_1$. With respect to the above cost structure, the total cost up to the periodic replacement time t_r termed by $C_d(t_r)$ can be expressed as

$$C_d(t_r) = \underbrace{\int_0^{t_r} c_s dN(s)}_{\text{Inspection cost}} + \underbrace{\int_0^{t_r} C_{X_d(s)} ds}_{\text{Penalty cost}} + \underbrace{k_{X_d(t_r)}}_{\text{Replacement cost}}.$$

The last cost is incurred as the system is found in the state $X_d(t_r)$ at replacement time t_r. Since $\lambda_{X_d(t)}$ is an $\mathcal{F}$-intensity of $N(t)$ and both the $C_{X_d(s)}$ and $k_{X_d(t)}$ are $\mathcal{F}$-measurable, an $\mathcal{F}$-adapted total cost $\mathcal{C}_d(t,n), t \in [T_n, T_{n+1})\ (n \geq 0)$, can be expressed as

$$\mathcal{C}_d(t_r,n) = \mathbb{E}[C_d(t_r) \mid \mathcal{F}_{t_r}] = k_0 + \int_0^{t_r} c_d(s,n)ds,$$

where

$$c_d(t,n) = \left[C_{\lambda_0}(t) + \left(C_{\lambda_1}(t) - C_{\lambda_0}(t)\right)X_d(t)\right] + (k_1 - k_0)dX_d(t), \tag{16}$$

is the total cost rate and $C_{\lambda_i}(t) = C_i + \lambda_i c_t$ for $i = 0,1$.

3.2 *Partial information-based cost model*

Since the term $c_d(t,n)$ depends on the state indicator $X_d(t)$ not directly observed, a projection

on the observation filtration $\mathcal{F}^N$ is needed. As described in Section 2.3.2 such a projection from the $\mathcal{F}$-level to the $\mathcal{F}^N$-level leads to the following expression;

$$\hat{c}_d(t,n) = \Big[C_{\lambda_0}(t) + \big(C_{\lambda_1}(t) - C_{\lambda_0}(t) \big) \phi_d(t,n) \Big] + \big(k_1 - k_0 \big) d\phi_d(t,n). \tag{17}$$

Thus, an $\mathcal{F}^N$-adapted estimate of the expected total cost can be given by

$$\hat{\mathcal{C}}_d(t_r,n) = k_0 + \int_0^{t_r} \hat{c}_d(s,n)\, ds, \tag{18}$$

The integrand $\hat{c}_d(s,n)$ is the conditional expectation of the cost rate at time s given the observations up to time s. In addition, by plugging the derivative of $\phi_d(t,n)$ (see equation (10)) into equation (17), in terms of the sojourn time distribution $\bar{\phi}_d(t,n)$, an $\mathcal{F}^N$-adapted estimate of the cost rate can be given by

$$\hat{c}_d(t,n) = -k_{10}\bar{\lambda}\bar{\phi}_d^2(t,n) + \big(\bar{\lambda}(k_{10} - ct) + k_{10}\tilde{q}_{01}(t) - C_{10} \big) \bar{\phi}_d(t,n) + C_{\lambda_1}(t)$$

where $k_{10} = k_1 - k_0$ and $C_{10} = C_1 - C_0$.

Continuing the example we illustrate an evolution of the maintenance cost rate for both alert parameters d = 1,2 (see Figure 2). One can note that lower threshold value d causes an earlier alert on approaching a disruption which makes inspections more frequent, increases penalty cost and so incurring more maintenance cost.

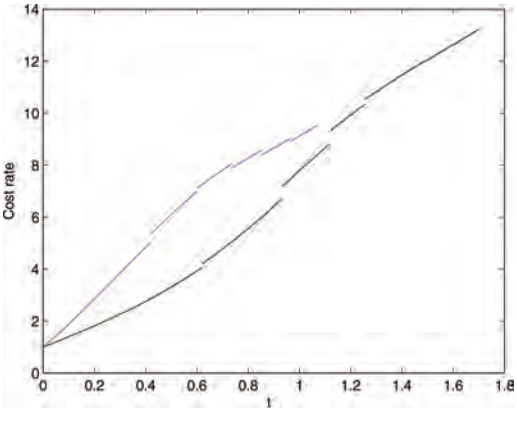

Figure 2. $\mathcal{F}^N$-adapted cost rate for different $d \in \{1,2\}$. Blue and black color correspond to threshold values $d = 1$ and $d = 2$ respectively.

3.2.1 *Long-run average cost rate*

The main objective is to minimize the long-run average cost rate by optimizing the periodic replacement time t_r. To this end, let $\psi_d(n,t_r)$ be the long-run average cost per unit time. Since the sequence of replacement times $\{t_r, 2t_r, \cdots\}$ forms a regenerative process, the time between two consecutive replacements is a renewal cycle. Therefore, by the renewal reward theorem (Ross 1970), the long-run average cost rate is the average per cycle cost divided by the cycle length t_r given by

$$\psi_d(t_r,n) = \frac{\hat{\mathcal{C}}_d(t_r,n)}{t_r},$$

with expression for $\hat{\mathcal{C}}_d(t_r,n)$ provided in (18). We set out to solve the optimization problem

$$t_r^* = \underset{t_r \in \mathbb{R}_+}{\arg\min} \big\{ \psi_d(t_r,n) \big\},$$

along with determining the optimal inspection frequency n^* subject to the optimal replacement time t_r^*.

4 NUMERICAL RESULTS

The aim of the proposed model is to derive a cost-optimal inspection and maintenance policy for a three-component parallel system subject to non-self announcing failures. For this, let the components lifetime be modelled by the Weibull distribution with the failure rate (14). Main numerical results are based on the known degradation parameters $(\alpha,\beta) = (2,2)$ and the inspection parameters $(\lambda_0,\lambda_1) = (2,3)$. The choice for cost parameters are $(C_0,C_1) = (1,3), (k_0,k_1) = (3,6)$ and $c = 2$.

4.1 *Optimal maintenance policy*

To investigate the effect of the alert parameter d on the model, optimal solutions for different threshold values $d \in \{1,2\}$ are obtained (see Table 1 and Figure 2). As noted above, the alert parameter d reflects the attitude of the decision maker towards inspection: changes in d induce changes in the inspection intensity upon disruption time at which dth component of the system experiences failure. Given inspection parameters $(\lambda_0,\lambda_1) = (2,3)$, results reveal insignificant impact of d on the optimal replacement time. On the other hand, the optimal maintenance cost and the optimal frequency of inspection range over several orders of magnitude as the threshold varies. Subject to the results given in Table 1 and Table 2, the sequence of inspections and maintenance actions

Table 1. Optimal parameters and mean time to disruption m_d for different $d \in \{1,2\}$ given $\lambda_1 = 3$.

d	n^*	m_1	t_r^*	m_2	$\psi_d(t_r^*, n^*)$
1	**4**	0.6316	**0.8553**	1.1593	**8.7575**
2	**1**	0.6316	**0.9156**	1.1593	**6.7237**

Table 2. Expected inspection times for different $d \in \{1,2\}$ given $\lambda_1 = 3$.

d	η_1	η_2	η_3	η_4	η_5	η_6
1	0.414	0.6	0.736	0.853	0.936	1.07
2	0.62	0.93	1.115	1.254	1.373	1.484

corresponding to the threshold values $d = 1,2$ are respectively scheduled as follows:

- starting from the normal state, inspections with intensity $\lambda_0 = 2$ are scheduled at times η_i $(i = 0,1)$. Upon failure of the first component at (disruption) time $m_1 = 0.6316$ inspections are considered more often $(\lambda_0 \mapsto \lambda_1)$. Following disruption, inspections to detect the system failures are scheduled at η_i $(i = 2,3)$. To restrain the frequency of inspections and avoid a costly strategy, the model suggests the replacement of the system at $t_r^* = 0.8553$ before disruption time $m_2 = 1.1593$ at which the second component of the system experiences failure. This process incurs the optimal cost $\psi_d(t_r^*, n^*) = 8.7575$.
- starting from the normal state, the first inspection is scheduled at $\eta_0 = 0.62$ just before the first disruption at $m_1 = 0.6316$ and a planned replacement is recommended during inter-disruption times $[0.6316, 1.1593]$ at $t_r^* = 0.9156$. This incurs the optimal cost $\psi_d(t_r^*, n^*) = 6.7237$.

4.2 *Attitude to maintenance*

The inspection model adapts itself to the decision maker's attitudes to maintenance (the value of d) by moving the inspection parameter $\lambda_0 \mapsto \lambda_1$. Increasing the threshold value $d : 1 \mapsto 2$ affects both the inspection intensity and the transition rate of the state process $(\tilde{q}_{01}(t))$ from normal state to more degraded state (see equation (15)) which gives higher value for the mean time to disruption $m_d : 0.6316 \mapsto 1.1593$. The higher threshold d reduces the frequency of inspection and penalty cost which results in reducing overall maintenance cost. As illustrated by Table 1 and Figure 3, the threshold value $d = 2$ leads to more effective strategy as the disruption time $m_2 = 1.1593$ (failure time of the second component) is preceded by

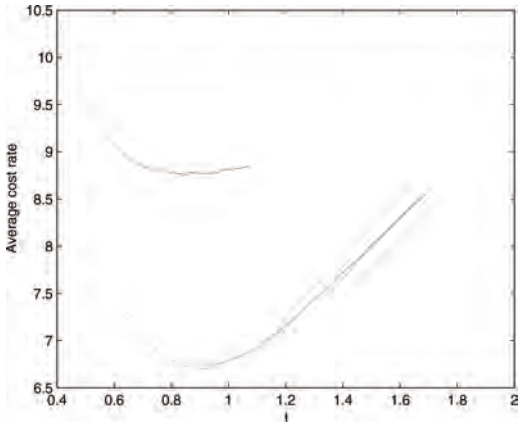

Figure 3. Average cost rate for different $d \in \{1,2\}$ given $(\lambda_0, \lambda_1) = (2,3)$. Blue and black color correspond to threshold values $d = 1$ and $d = 2$ respectively.

Table 3. Optimal parameters and mean time to disruption m_d for different $d \in \{1,2\}$ given $\lambda_1 = 4$.

d	n^*	m_1	t_r^*	m_2	$\psi_d(t_r^*, n^*)$
1	**3**	0.5978	**0.7145**	1.0808	**9.4972**
2	**1**	0.5978	**0.8609**	1.0808	**6.8923**

the replacement time $t_r^* = 0.9156$. On the other hand, the model based on the maintenance threshold $d = 1$ penalizes a costly strategy which favors not only an early replacement, but more frequent inspections (see Table 1 and Table 2).

4.3 *Level of maintenance*

The response of the model to maintenance level is examined with inspection parameter $\lambda_1 \in \{3,4\}$. Given $\lambda_1 = 4$ for $d \in \{1,2\}$ the optimal parameters, the mean time to disruption and inspection times for both threshold values are shown in Table 3 and Table 4. Also, an evolution of average cost rate is illustrated by Figure 4. In both cases the optimal cost increases with λ_1 implying an increase in the amount of maintenance undertaken on the system. On the other hand, with increasing λ_1 or $\bar{\lambda}$ more alert on a possibly approaching disruption is discovered. As discussed in Section 2.3.2, part (ii), this causes a reduction in sojourn time of $X_d(t)$ in normal state hence decreasing disruption time (see Table 3). In addition, given $d = 1$, with increasing inspection intensity $\lambda_1 : 3 \mapsto 4$ inspections will be considered more often but t_r^* decreases to restrain the frequency of inspections. But, in the case $d = 2$, due to insignificant effect of λ_1 on the inspection

Table 4. Expected inspection times for different $d \in \{1,2\}$ given $\lambda_1 = 4$.

d	η_1	η_2	η_3	η_4	η_5	η_6
1	0.405	0.583	0.713	0.827	0.935	1.041
2	0.61	0.904	1.076	1.207	1.322	1.431

times, the optimal solutions (n^*, t_r^*) and the resulting optimal average cost are not particularly sensitive to the inspection parameter λ_1.

5 CONCLUSIONS

The main issue discussed here is to detect the random time of change of the unobservable state (disruption time) based on partial information for systems subject to hidden failures. The approach to estimating the disruption time distribution, which rests on an associated maintenance alert parameter d, helps in two ways: firstly, it delivers an alert or a signal on approaching the components failure of the system and to control the inspection frequency in order to timely detect the system failures. Secondly, it provides insight to perform a replacement in order to avoid typically more costly system failures. The other problem investigated here is the construction and the estimation of a unified cost model based on the available information. The estimated cost model as a measure of policy contributes to the joint determination of an optimal inspection frequency and an optimal replacement time for systems with partial information. The main examples considered are that of a Weibull degradation model for a three-component parallel safety system with the alert parameter *d*. The response of the model to both the threshold and the inspection parameter is examined. Although the numerical results did not reveal a strong influence of the threshold's value *d* on optimal replacement time, but its impact on other parameters including inspection times was more significant. Also, the results provide sensible and realistic inspection policies for such systems and gives insight into the effect of applying various inspection policies.

Two imperfect repair models for a gamma deteriorating system: A comparison

Sophie Mercier
Univ Pau & Pays Adour/CNRS, IPRA-LMAP, 64000 PAU, France

I.T. Castro
Department of Mathematics, University of Extremadura, Spain

ABSTRACT: A system is considered, which is deteriorating over time according to a non-homogeneous gamma process. The point of the presentation is to propose and compare two models of imperfect repairs for the system. For sake of simplicity, only periodic (and instantaneous) repairs are here envisioned. The first model, called the Arithmetic Reduction of Deterioration of order 1 (ARD1), assumes that a repair removes a given proportion of the degradation accumulated by the system from the last maintenance action. The second model, called Arithmetic Reduction of Age of order 1 (ARA1), refers to the virtual age models proposed by Kijima (1989) and further studied by Doyen & Gaudoin (2004) in the context of recurrent events: the ARA1 model assumes that a repair reduces the age accumulated by the system since the last maintenance action, in a given proportion. An ARD1 repair hence lowers the deterioration level, without rejuvenating the system. On the contrary, by an ARA1 repair, the system is put back to the exact situation where it was some time before, which entails the lowering of both its deterioration level and (virtual) age. The two models may hence correspond to different maintenance actions in an applicative context. This presentation focuses on the comparison between the two models, from a probabilistic point of view (moments and stochastic ordering). An application in a maintenance optimization context is also provided, for illustration purpose. A specific case is analyzed, where the two repair models provide identical expected deterioration levels at maintenance times ("equivalent" case). The comparison results can help understanding which among the two models is the best adapted in an applicative context.

1 INTRODUCTION

Many systems suffer a physical degradation before they fail. This degradation is a complex process as it depends of many factors (material, stress loads, temperature, …). To mitigate the effect of the system degradation and to extend the system lifetime, a large volume of maintenance models have been proposed in the literature, with different maintenance actions. Most of these models are limited to perfect repairs (Huynh et al. 2014, Caballé et al. 2015, Hong et al. 2014 among others). However, imperfect maintenance actions describe more realistic situations than perfect repairs. Some advances have been made to include imperfect repairs in a degrading system. Alaswad & Xiang (2017) classified the impact of the maintenance actions over the maintained system into three types. The first type assumes that the maintenance actions return the system to a previous stage of deterioration. In the second type, the imperfect maintenance reduces the degradation level of the maintained system (Castro & Mercier 2016). The third approach is based on the idea that the maintenance action changes the rate of degradation of the system (Zhang et al. 2015). However, as Zhang et al. (2015) claimed, the issue of treating imperfect maintenance in the context of degrading systems remains widely open nowadays.

Following the spirit showed in (Mercier & Castro 2013) and (Castro & Mercier 2016), two models of imperfect repair are here proposed and compared for a system accumulating deterioration over time. The first model, called the Arithmetic Reduction of Deterioration of order 1 (ARD1), assumes that the repair removes the proportion ρ of the degradation accumulated by the system from the last maintenance action (with $\rho \in (0, 1)$). The second model, called Arithmetic Reduction of Age of order 1 (ARA1), refers to the virtual age models proposed by Kijima (1989) and further studied by Doyen & Gaudoin (2004) in the context of recurrent events: the ARA1 model assumes that the repair removes the proportion ρ of the age accumulated by the system since the last maintenance action. An ARD1 repair hence lowers the deterioration level, without rejuvenating the system. On the contrary, by an ARA1 repair, the system is put

back to the exact situation where it was some time before, which entails the lowering of both its deterioration level and (virtual) age. The two models may hence correspond to different maintenance actions in an applicative context.

For a better understanding of the differences between the two models, this paper focuses on their comparison, from a probabilistic point of view. Assuming that the degradation of the system is modeled by a non homogeneous gamma process, stochastic comparisons of both location and spread of the two resulting processes are given. Moreover, a specific case is analyzed, where the two models provide identical expected deterioration levels at repair times ("equivalent" case). Finally, an illustration of the two models is provided, by including them in a global maintenance policy, with replacement of the system when it is too deteriorated.

The paper is organized as follows: The two models of imperfect repair are described in Section 2. The comparison results are given in Section 3 (including the "equivalent" case). Section 4 deals with the application to the global maintenance strategy and concluding remarks are provided in Section 5, together with possible extensions.

2 THE TWO MODELS OF IMPERFECT REPAIRS

2.1 *The intrinsic deterioration and notations*

For $a, b > 0$, let us first recall that the gamma distribution $\Gamma(a, b)$ with parameters (a, b) admits the following p.d.f. (probability distribution function):

$$f_{a,b}(x) = \frac{b^a}{\Gamma(a)} x^{a-1} e^{-bx}, \forall x > 0.$$

The corresponding mean and variance are $\frac{a}{b}$ and $\frac{a}{b^2}$, respectively.

A system is considered with degradation modeled by a non homogeneous gamma process $(X_t)_{t\geq 0}$ with parameters $A(\cdot)$ and b, where $A(\cdot): \mathbb{R}_+ \to \mathbb{R}_+$ is continuous and non-decreasing with $A(0) = 0$, and $b > 0$. We recall that $(X_t)_{t\geq 0}$ is a process with independent increments such that $X_0 = 0$ almost surely and such that each increment $X_{t+s} - X_t$ is gamma distributed $\Gamma(A(t+s) - A(t), b)$ for all $s, t > 0$.

The system is periodically and instantaneously repaired each T units of time. For modeling purpose, we set $X^{(i)}, i \in \mathbb{N}^*$ to be i.i.d. copies of $X = (X_t)_{t\geq 0}$, where $X^{(i)}$ describes the evolution of the deterioration level between the i-th and $(i + 1)$-th maintenance actions. For each imperfect repair model, the maintenance efficiency is measured by an Euclidian parameter $\rho \in (0, 1)$.

2.2 *First model: Arithmetic Reduction of Deterioration of order 1 (ARD1)*

In this model, the maintenance action instantaneously removes the proportion ρ of the degradation accumulated by the system from the last maintenance action (or from the origin). We set $(Y_t)_{t\geq 0}$ be the process that describes the degradation level of the maintained system under this model of repair.

The ARD1 model is sketched in Figure 1 for $\rho = 0.5$. It is developed as follows: At the beginning, the system deteriorates according to $X^{(1)}$. It is first maintained at time T, where the proportion ρ

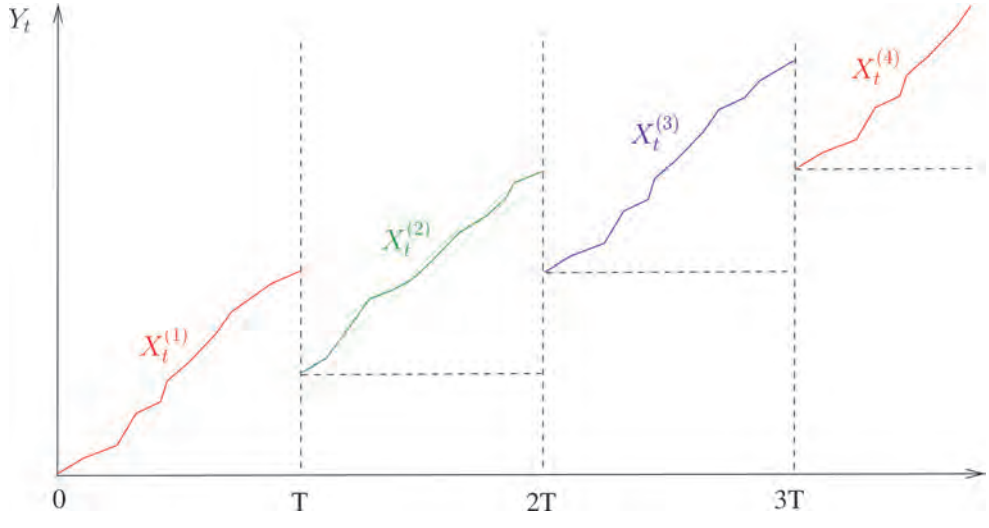

Figure 1. Illustration of the ARD1 policy for $\rho = 0.5$.

of the accumulated deterioration since the origin is removed. This provides:

$$Y_t = X_t^{(1)} \quad t < T, \qquad Y_T = (1-\rho) X_T^{(1)}.$$

Between T and $2T$, the system deteriorates according to $X^{(2)}$. The age of the system is unchanged at time T and we have

$$Y_t = Y_T + \left(X_t^{(2)} - X_T^{(2)}\right)$$

for all $T \le t < 2T$. At the second maintenance time $2T$, the proportion ρ of the degradation accumulated between T and $2T$ is removed, which provides:

$$Y_{2T} = Y_T + (1-\rho)\left(X_{2T}^{(2)} - X_T^{(2)}\right).$$

More generally, we have:

$$Y_t = Y_{nT} + \left(X_t^{(n+1)} - X_{nT}^{(n+1)}\right)$$

for all $nT \le t < (n+1)T$, where $X_t^{(n+1)} - X_{nT}^{(n+1)}$ is gamma distributed $\Gamma\left(A(t) - A(nT), b\right)$ and

$$Y_{(n+1)T} = Y_{nT} + (1-\rho)\left(X_{(n+1)T}^{(n+1)} - X_{nT}^{(n+1)}\right).$$

This provides

$$Y_{nT} = (1-\rho)\sum_{i=1}^{n}\left(X_{iT}^{(i)} - X_{(i-1)T}^{(i)}\right)$$

with $\Gamma(A(nT), \frac{b}{1-\rho})$ as distribution.

When $\rho \to 1^-$, then $Y_{nT} \to 0^+$ and the system is renewed at time nT (As Good As New repair: AGAN). When $\rho \to 0^+$, the repair is ineffective and it is As Bad As Old (ABAO).

Except for the case $\rho \to 0^+$, if $t \bmod T \neq 0$, Y_t is the sum of two independent and gamma distributed random variables (r.v.s) with different scale parameters, and it is not gamma distributed. Its expectation and variance are given by:

$$\mathbb{E}(Y_t) = \frac{A(t) - \rho A(nT)}{b}, \tag{1}$$

$$var(Y_t) = \frac{A(t) - \rho(2-\rho) A(nT)}{b^2}, \tag{2}$$

for $nT \le t < (n+1)T$.

It is easy to check that $\mathbb{E}(Y_t)$ and $var(Y_t)$ are decreasing with respect to ρ, that is, the more efficient the repair, the smaller the expectation and variance of the deterioration level. In this way, the expectation and variance are minimal when $\rho \to 1^-$ that is when the repair is AGAN, and maximal when $\rho \to 0^+$ that is when the repair is ABAO.

2.3 *Second model: Arithmetic Reduction of (virtual) Age of order 1 (ARA1)*

As told in the introduction, the ARA1 model is based on the notion of virtual age, which is reduced by each maintenance action: each repair removes the proportion ρ of the age accumulated by the system since the last maintenance action (or from the origin). This means that, at each maintenance action, the system goes back into its past: the deterioration level is hence reduced (just as for the ARD1 model) but the system is also rejuvenated at the same time (it becomes younger). In case of an increasing deterioration rate ($A(\cdot)$ convex), the rate of deterioration is hence reduced by the repair together with the deterioration level. We set $(Z_t)_{t\ge 0}$ be the process that describes the degradation level of the maintained system under this model of repair.

The ARA1 model is sketched in Figure 2 for ρ = 0.5. It is developed as follows: At the first maintenance time T, the (virtual) age of the system is suddenly reduced of ρT, so that it becomes $T - \rho T = (1 - \rho)T$. This provides:

$$Z_t = X_T^{(1)} \text{ for } t < T, \qquad Z_T = X_{(1-\rho)T}^{(1)}.$$

For $T \le t < 2T$, the age of the system is $(1-\rho)T + (t-T) = t - \rho T$. We get:

$$Z_t = Z_T + \left(X_{t-\rho T}^{(2)} - X_{(1-\rho)T}^{(2)}\right).$$

At time $2T^-$ (just before the repair), the age of the system is $2T - \rho T$ which is reduced of ρT at time $2T$. The age hence is $2(1-\rho)T$ at time $2T$. This provides:

$$Z_{2T} = Z_T + \left(X_{2(1-\rho)T}^{(2)} - X_{(1-\rho)T}^{(2)}\right).$$

More generally, for $nT \le t < (n+1)T$, the virtual age of the system at time t is $t - \rho nT$ (which is just the same as for an ARA1 model for recurrent events, see (Doyen & Gaudoin 2004)). We obtain:

$$Z_t = Z_{nT} + \left(X_{t-\rho nT}^{(n+1)} - X_{(1-\rho)nT}^{(n+1)}\right),$$

for all $nT \le t < (n+1)T$, where $X_{t-\rho nT}^{(n+1)} - X_{(1-\rho)nT}^{(n+1)}$ is gamma distributed $\Gamma(A(t-\rho nT) - A((1-\rho)nT), b)$ and

$$Z_{(n+1)T} = Z_{nT} + \left(X_{(1-\rho)(n+1)T}^{(n+1)} - X_{(1-\rho)nT}^{(n+1)}\right).$$

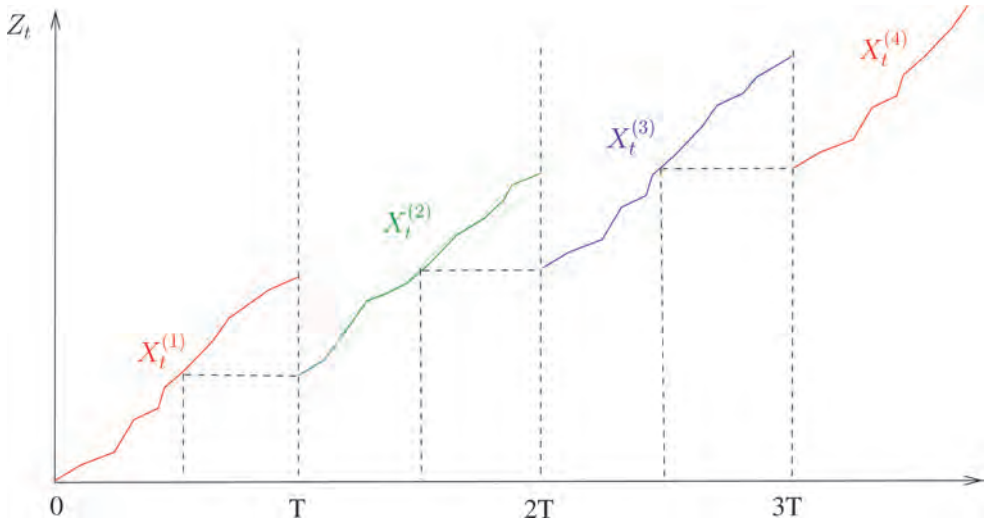

Figure 2. Illustration of the ARA1 policy for $\rho = 0.5$.

Hence

$$Z_{nT} = \sum_{i=1}^{n} \left(X^{(i)}_{(1-\rho)iT} - X^{(i)}_{(1-\rho)(i-1)T} \right)$$

and it is gamma distributed $\Gamma\left(A\left((1-\rho)nT\right), b\right)$. Here, Z_t is the sum of two independent gamma distributed r.v.s which share the same scale parameter b and it is gamma distributed $\Gamma\left(A\left(t-\rho nT\right), b\right)$. Also:

$$\mathbb{E}\left(Z_t\right) = \frac{A\left(t-\rho nT\right)}{b}, \quad var\left(Z_t\right) = \frac{A\left(t-\rho nT\right)}{b^2} \qquad (3)$$

for all $nT \le t < (n+1)T$.

Here again, it is easy to check that $\mathbb{E}\left(Z_t\right)$ and $var\left(Z_t\right)$ are decreasing with respect to ρ. Also, the cases $\rho \to 1^-$ and $\rho \to 0^+$ correspond to AGAN and ABAO repairs, respectively.

3 COMPARISON RESULTS

3.1 *Comparison of the moments*

We now come to the main object of the paper, which is the comparison between the two models of imperfect repairs. Note that, in an applicative context, there is no reason why the estimated repair efficiency should be the same when the impact of the maintenance is modeled by an ARD1 or ARA1 model. Considering two different efficiency parameters $\rho_i, i = 1,2$, our point here is to compare $Y_t^{(1)}$ and $Z_t^{(2)}$, where exponent $^{(i)}$ refers to ρ_i for i = 1, 2. We begin with the comparison of their respective means and variances.

Due to the reduced size of the paper, results on the comparison of moments are provided only in case of a power-law shape function for the gamma process. The interested reader will find general results in an extended version of the paper (Mercier and Castro, submitted), as well as proofs for all the results of the paper.

Proposition 1. *Let* $A(t) = \alpha t^{\beta}$ *with* α, $\beta > 0$. *Assume* $\beta \le 1$.

1. *We have*

$$\mathbb{E}\left(Z_t^{(2)}\right) \ge \mathbb{E}\left(Y_t^{(1)}\right), \forall t > 0$$

if and only if $(1-\rho_2)^{\beta} \ge (1-\rho_1)$.

2. *We have*

$$Var\left(Z_t^{(2)}\right) \ge Var\left(Y_t^{(1)}\right), \forall t > 0$$

if and only if $(1-\rho_2)^{\beta} \ge (1-\rho_1)^2$.

If $\beta \ge 1$, *all results are valid with reversed inequalities.*

For illustration purpose, we consider $A(t) = t^3$, $b = 1$, $T = 1$ and $\rho_2 = 0.5$. As a first case, we take $\rho_1 = 0.3$ so that the conditions of the previous proposition are fulfilled for both expectation and variance. As expected, Figure 3 shows that $\mathbb{E}\left(Y_t^{(1)}\right)$ and $\mathbb{E}\left(Z_t^{(2)}\right)$ are ordered in the same way on the whole real line, the same for the variance. As a second case, we take $\rho_1 = 0.95$ so that the conditions are *not* fulfilled neither for expectation and variance. Figure 4 shows that $\mathbb{E}\left(Y_t^{(1)}\right)$ and $\mathbb{E}\left(Z_t^{(2)}\right)$ are not

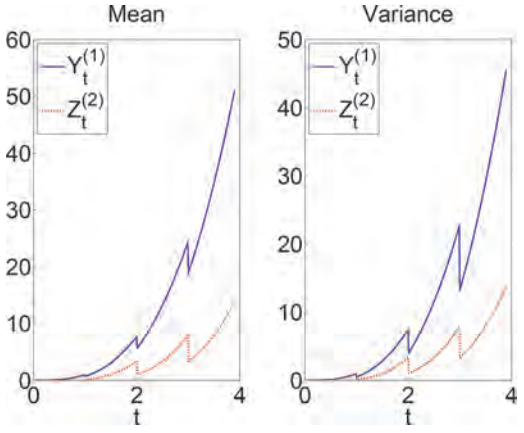

Figure 3. Mean and variance of $Y_t^{(1)}$ and $Z_t^{(2)}$ with respect to t for $A(t) = t^3$, $b = 1$, $\rho_1 = 0.95$, $\rho_2 = 0.5$, $T = 1$.

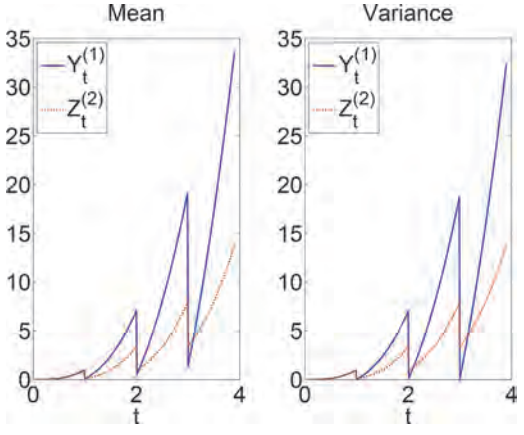

Figure 4. Mean and variance of $Y_t^{(1)}$ and $Z_t^{(2)}$ with respect to t for $A(t) = t^3$, $b = 1$, $\rho_1 = 0.95$, $\rho_2 = 0.5$, $T = 1$.

ordered in the same way on the whole real line, the same for the variance.

3.2 *Technical reminders*

Before providing stochastic comparison results between $Y_t^{(1)}$ and $Z_t^{(2)}$, we here recall a few definitions and results from the literature.

As a first step, let us recall that given two non negative random variables X and Y with probability distribution functions f_X and f_Y, and survival functions $\bar{F}_X$ and $\bar{F}_Y$, respectively, then:

1. X is said to be smaller than Y in the usual stochastic order $\left(X \prec_{sto} Y\right)$ if $\bar{F}_X \le \bar{F}_Y$;
2. X is said to be smaller than Y in the likelihood ratio order $\left(X \prec_{lr} Y\right)$ if $\frac{f_Y}{f_X}$ is non-decreasing;
3. X is said to be smaller than Y in the convex (concave) order $\left(X \prec_{cx(cv)} Y\right)$ if $\mathbb{E}\left(\varphi(X)\right) \le \mathbb{E}\left(\varphi(Y)\right)$ for all convex functions φ (provided the expectations exist);
4. X is said to be smaller than Y in the increasing convex (concave) order $\left(X \prec_{icx(icv)} Y\right)$ if $\mathbb{E}\left(\varphi(X)\right) \le \mathbb{E}\left(\varphi(Y)\right)$ for all increasing convex (concave) functions φ (provided the expectations exist).

The usual stochastic order and the likelihood ratio order compare the locations of random variables whereas increasing convex (concave) orders also compare their variability: $X \prec_{icx} \left(\prec_{icv}\right) Y$ roughly means that $\mathbb{E}(X) \le \mathbb{E}(Y)$ (location condition) plus the fact that X is less (more) "variable" than Y, in a stochastic sense. Also, $X \prec_{cx} \left(\prec_{cv}\right) Y$ is equivalent to $X \prec_{icx} \left(\prec_{icv}\right) Y$ plus $\mathbb{E}(X) = \mathbb{E}(Y)$.

The likelihood ratio order is known to imply the usual stochastic order, which itself implies both increasing convex and concave orders, see Müller & Stoyan 2002 or Shaked & Shanthikumar 2007 for more details.

We finally review known results on the comparison of gamma distributions in the following lemma, see (Müller & Stoyan 2002, p. 62) for instance.

Lemma 1. *Let X and Y be gamma distributed random variables with parameters (a_1, b_1) and (a_2, b_2), respectively, where $a_i, b_i > 0$ for $i = 1, 2$. Then:*

1. *If $a_1 \le a_2$ and $b_1 \ge b_2$, then $X \prec_{lr} Y$;*
2. *If $a_1 \ge a_2$ and $a_1 / b_1 \le a_2 / b_2$, then $X \prec_{icx} Y$;*
3. *If $a_1 \le a_2, b_1 \le b_2$ and $a_1 / b_1 \le a_2 / b_2$, then $X \prec_{icv} Y$.*

The previous lemma is the basis for deriving the stochastic comparison results between the different imperfect repair models given in the next subsection.

3.3 *Stochastic comparison results*

As a first step, the influence of the efficiency parameter ρ on the deterioration level is studied for each imperfect repair model.

Proposition 2. *We have:*

1. *Y_{nT} decreases with respect to ρ in the sense of the likelihood order: If $\rho_1 < \rho_2$, then $Y_{nT}^{(2)} \prec_{lr} Y_{nT}^{(1)}$,*
2. *Y_t decreases with respect to ρ in the sense of both increasing convex and concave orders: If $\rho_1 < \rho_2$, then $Y_t^{(2)} \prec_{icx} Y_t^{(1)}$ and $Y_t^{(2)} \prec_{icv} Y_t^{(1)}$;*
3. *Z_t decreases with respect to ρ for the likelihood ratio order (and hence also for both increasing convex and concave orders): If $\rho_1 < \rho_2$, then $Z_t^{(2)} \prec_{lr} Z_t^{(1)}$.*

In each case, we can see that as expected, the more efficient the maintenance action is (namely

the larger ρ is), the smaller the deterioration level is. Note however that, based on the fact that the likelihood ratio order is stronger than both increasing convex and concave orders, the results for the ARA1 model are stronger than for the ARD1 one. (Counter-examples can be found, which show that that $Y_t^{(1)}$ and $Y_t^{(2)}$ are not comparable for the likelihood ratio order in a general setting).

We now come to the stochastic comparison between the two models.

Theorem 1. *If $A(\cdot)$ is concave and*

$$A\left((1-\rho_2)t\right) \geq (1-\rho_1)A(t) \text{ for all } t \tag{4}$$

(which is true if $\rho_1 \geq \rho_2$), then $Y_t^{(1)} \prec_{icx} Z_t^{(2)}$ for all $t \geq 0$.

If $A(t)$ is convex with a reversed inequality in (4), *then $Z_t^{(2)} \prec_{icv} Y_t^{(1)}$ for all $t \geq 0$.*

As a specific case, if $\rho_1 = \rho_2 = \rho$, then $Y_t \prec_{icx} Z_t$ for all $t \geq 0$ if $A(\cdot)$ is concave, and $Z_t \prec_{icv} Y_t$ for all $t \geq 0$ if $A(\cdot)$ is convex. The concavity/convexity of the shape function $A(\cdot)$ of the underlying gamma process hence deeply infers on the comparison results between the two models: When $A(\cdot)$ is convex, the rejuvenation included in a ARA1 model leads to a lower deterioration level than for an ARD1 model.

Specific results are now summarized in the classical case of a homogeneous gamma process for both moments and stochastic comparisons.

Corollary 1. *Assume that $A(t) = \alpha t$ for all $t \geq 0$, where $\alpha > 0$. We have the following results:*

1. *If $\rho_1 \geq \rho_2$, then $Y_t^{(1)} \prec_{icx} Z_t^{(2)}$ and hence $\mathbb{E}\left(Y_t^{(1)}\right) \leq \mathbb{E}\left(Z_t^{(2)}\right)$ for all $t \geq 0$;*
2. *If $\rho_1 \leq \rho_2$, then $Z_t^{(2)} \prec_{icv} Y_t^{(1)}$ and hence $\mathbb{E}\left(Z_t^{(2)}\right) \leq \mathbb{E}\left(Y_t^{(1)}\right)$ for all $t \geq 0$;*
3. *If $\rho_1 = \rho_2$, then $Y_t^{(1)} \prec_{ex} Z_t^{(2)}$ and $Z_t^{(2)} \prec_{cv} Y_t^{(1)}$ and hence $\mathbb{E}\left(Z_t^{(2)}\right) = \mathbb{E}\left(Y_t^{(1)}\right)$ for all $t \geq 0$;*
4. *$Var\left(Z_t^{(2)}\right) \geq Var\left(Y_t^{(1)}\right)$ for all $t > 0$ if and only if $1 - \rho_2 \geq (1-\rho_1)^2$.*

3.4 *Mostly equivalent imperfect repair models*

In an applied context, parameters ρ_1 and ρ_2 for ARD1 and ARA1 models, respectively, will be estimated from feedback data, which will be typically gathered at maintenance times iT, $i \geq 1$. As a consequence, we can expect that the estimated parameters $\hat{\rho}_1$ and $\hat{\rho}_2$ should be such that the corresponding expected deterioration levels should be very similar at maintenance times, namely such that $\mathbb{E}\left(Y_{iT}^{(1)}\right) \simeq \mathbb{E}\left(Z_{iT}^{(2)}\right)$ for all $i \in \mathbb{N}^*$. Equivalently, the estimated parameters should be such that

$$\frac{(1-\hat{\rho}_1)A(iT)}{b} \simeq \frac{A\left((1-\hat{\rho}_2)iT\right)}{b}, \text{ for all } i \geq 1.$$

There hence is a specific interest for the applications to compare the ARD1 and ARA1 models under the condition

$$(1-\rho_1)A(iT) = A\left((1-\rho_2)iT\right) \text{ for all } i \geq 1, \tag{5}$$

which will lead to equivalent deterioration levels at maintenance times. However, the previous requirement (5) does not seem to have a solution for a general shape function $A(\cdot)$. We hence restrict the study to the power-law case $A(t) = \alpha t^{\beta}$ (with α, $\beta > 0$), for which (5) is just equivalent to

$$1 - \rho_1 = (1-\rho_2)^{\beta}.$$

A homogeneous gamma process corresponds to a power-law shape function with $\beta = 1$. Then the equivalent case just means that the two models share the same efficiency parameters $(\rho_1 = \rho_2)$.

In case of a general power-law shape function, note that the "equivalent" case has a similar spirit to that detailed in Doyen & Gaudoin (2004, Property 4), where the authors match the minimal wear intensities of two imperfect repair models for recurrent events, based on the reduction of either virtual age or failure intensity.

The results for the equivalent case are summarized in the following proposition.

Proposition 3. *Assume that $A(t) = \alpha t^{\beta}$ (with $\alpha, \beta > 0$) and that $1 - \rho_1 = (1-\rho_2)^{\beta}$. Then:*

1. *$Z_{nT}^{(2)} \prec_{cv} Y_{nT}^{(1)}$ and $Y_{nT}^{(1)} \prec_{cx} Z_{nT}^{(2)}$ (which both entail that $var\left(Z_{nT}^{(2)}\right) \geq var\left(Y_{nT}^{(1)}\right)$) for all $n \geq 1$.*
2. *If $\beta \leq (\geq) 1$, then $Y_t^{(1)} \prec_{icx} (\succ_{icv}) Z_t^{(2)}$ (which entails that $\mathbb{E}\left(Y_t^{(1)}\right) \leq (\geq) \mathbb{E}\left(Z_t^{(2)}\right)$) for all $t \geq 0$.*
3. *If $\beta \leq 1$, then $Var\left(Z_t^{(2)}\right) \geq Var\left(Y_t^{(1)}\right)$ for all $t \geq 0$.*

4 APPLICATION

For illustration purpose of the previous results, the system is now supposed to provide some reward per unit time, which decreases when the deterioration level of the system increases. Based on classical functions used in the insurance literature (Rolski et al. 1998), we assume that the reward function is of the shape

$$g(x) = (b_1 - k_1 e^{\alpha_1 x}) 1_{\{0 \leq x \leq c\}} + (b_2 - k_2 e^{\alpha_2 x}) 1_{\{c < x\}}, \tag{6}$$

with $b_1, b_2, \alpha_1, \alpha_2, k_1, k_2, c > 0$. The reward function is supposed to be continuous and positive on $(0, c)$, which implies that

$$b_2 - k_2 e^{\alpha_2 c} = b_1 - k_1 e^{\alpha_1 c} > 0. \tag{7}$$

Also, we assume that $\alpha_1 \le \alpha_2$ and $k_1 \le k_2$ so that level c appears as a critical level, from which the system becomes less performing.

With the previous assumptions, it is easy to check that g is a concave function and that $g(x) > 0$ if and only if $x < L = \frac{\ln(b_2/k_2)}{\alpha_2}$. Level L hence appears as a critical threshold, from where the unitary reward becomes negative.

An example of reward function is plotted in Figure 5 with parameters $\alpha_1 = 0.1, b_1 = 11$ monetary units (m.u.), $\alpha_2 = 0.25, k_1 = 1$ (m.u.), $k_2 = 1$ (m.u.), $c = 4$, and b_2 obtained through (7). With this dataset $L \simeq 10.01$.

The system is assumed to be preventively repaired each T units of time according to an ARD1 or ARA1 model, with efficiency parameters ρ_1 and ρ_2, respectively. The accumulated reward on a time interval [0, t] hence is

$$R^{(1)}_{ARD1}(t) = \mathbb{E}\left(\int_0^t g\left(Y_s^{(1)}\right) ds\right) = \int_0^t \mathbb{E}\left(g\left(Y_s^{(1)}\right)\right) ds$$

with a similar expression for the accumulated reward $R^{(2)}_{ARA1}(t)$ in the ARA1 case.

Considering for instance the equivalent case ($A(t) = \alpha t^{\beta}$ and $1 - \rho_1 = (1 - \rho_2)^{\beta}$) with $\beta \le 1$, we easily derive from point 2 in Proposition 3 that

$$\mathbb{E}\left(g\left(Y_s^{(1)}\right)\right) \ge \mathbb{E}\left(g\left(Z_s^{(2)}\right)\right)$$

for all $s \in [0,t]$, using the fact that $-g$ is an increasing convex function. This immediately entails that

$$R^{(1)}_{ARD1}(t) \ge R^{(2)}_{ARA1}(t) \text{ for all } t \ge 0.$$

As a consequence, even if the "equivalent" case provides similar expected levels at maintenance times, they do not provide the same accumulated rewards on some given time interval. They may hence lead to different decisions in an applied context, for instance for optimizing maintenance strategies.

To better illustrate this difference, we now consider a preventive maintenance strategy, which we next optimize. The assumptions are the following:

- The unitary reward of the system per unit time is given by the reward function g provided in (6). We recall that $L = \frac{\ln(b_2/k_2)}{\alpha_2}$ stands for a "critical" level, from where the reward becomes negative.
- The system is preventively repaired each T units of time according to an ARD1 or ARA1 model (respective efficiency parameters: ρ_1 and ρ_2), up to the first maintenance time KT where the deterioration level is observed to be beyond a given preventive threshold M (with $M < L$). In that case, instead of an imperfect repair (ARA1 or ARD1), a replacement is performed at time KT with cost C_c m.u. when the level is beyond L (corrective replacement) and C_p m.u. when it is between M and L (preventive replacement).

The successive (corrective or preventive) replacements of the system appear as the points of a renewal process, and the long time (operating) profit rate per unit time is given by

$$C_{ARD}(T,M) = \frac{1}{\mathbb{E}(K)T}\left[\mathbb{E}\left(\int_0^{KT} g\left(Y_s^{(1)}\right) ds\right) - C_r\left(\mathbb{E}(K) - 1\right) - C_p\ \mathbb{P}\left(M \le Y_{KT}^{(1)} < L\right) - C_c\ \mathbb{P}\left(L \le Y_{KT}^{(1)}\right)\right]$$

for the ARD1 model with a similar expression for the ARA1 model ($C_{ARA}(T, M)$). Due to the complexity of the model, there is not hope here to find conditions that ensure the dominance of one of the two functions $C_{ARD}(T, M)$ or $C_{ARA}(T, M)$ on the other. The comparison is hence made on a numerical example.

The degradation is modeled by a homogeneous gamma process with parameters $A(t) = 1.3t$ and $b = 0.8$. The parameters of the reward function g are $\alpha_1 = 0.4$, $\alpha_2 = 0.5$, $b_1 = 800$ m.u., $k_1 = 1.05$ m.u., $k_2 = 1.07$ m.u., $c = 8$, which implies $b_2 \simeq 832.66$ m.u. and $L \simeq 13.31$. The repair efficiencies of the ARD1/ARA1 repairs are $\rho_1 = \rho_2 = 0.9$, which corresponds to an equivalent case (homogeneous gamma process and $\rho_1 = \rho_2$). Their common cost is $C_r = 200$ m.u.. The cost of a preventive replacement is $C_p = 1000$ m.u. whereas itis $C_c = 1300$ m.u. for a corrective one. Figures 6a and 6b show the profit rates for the maintained system under ARD1 and ARA1 repairs, respectively. These figures have been computed considering a grid of 10 points for T from 1.14 to 4 and a grid of 13 points for M from 1

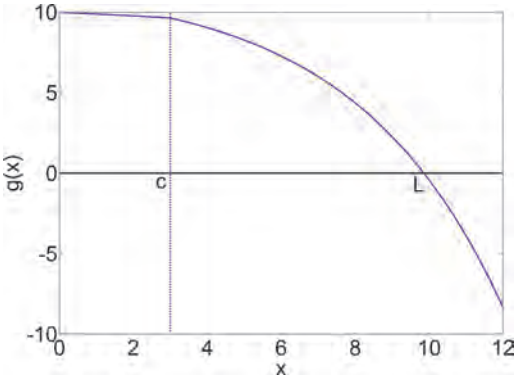

Figure 5. The reward function g for $\alpha_1 = 0.1$, $b_1 = 11$ m.u., $\alpha_2 = 0.25$, $k_1 = 1$ m.u., $k_2 = 1$ m.u., $c = 4$.

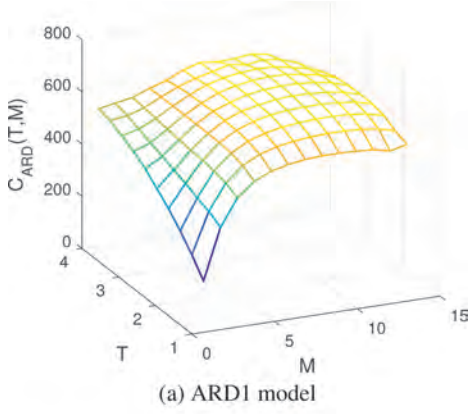
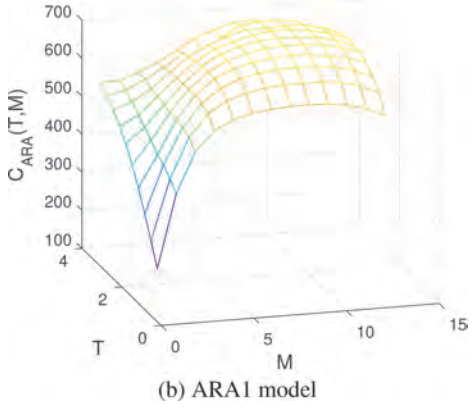


(a) ARD1 model



(b) ARA1 model

Figure 6. Operational profit rates, $\rho_1 = \rho_2 = 0.9$.

to L and 10000 simulations for each pair of points. For both ARD1 and ARA1 cases, the optimal maintenance strategy corresponds to $T^{opt} \simeq 3.05$. However, the corresponding optimal maintenance levels are $M^{opt}_{ARD} \simeq 9.21$ and $M^{opt}_{ARA} \simeq 10.24$, and the optimal unitary rewards $C^{opt}_{ARD} \simeq 673.94$ and $C^{opt}_{ARA} \simeq 684.34$ m.u. per unit time, respectively. There hence is a difference of about 10% between the two optimal preventive levels, which may entail inappropriate decision in an applicative context, when considering one imperfect repair model or the other, whereas the effective behavior of the maintained system is closer to the other one.

5 CONCLUSIONS AND FURTHER EXTENSIONS

Two imperfect repair models for a degrading system have been proposed and compared in this paper. One is based on the reduction of the single deterioration level at maintenance times (ARD1), the other one on the reduction of both deterioration level and age (ARA1). They hence correspond to different maintenance actions, in an applicative context. The comparison of both location and spread have been made in terms of moments and stochastic ordering of the two resulting processes. It has been seen that the concavity/convexity of the shape function of the underlying gamma wear process plays a central role in the comparison results. This corresponds to intuition as a convex shape function (for instance) induces some increasingness property in the rate of deterioration over time. Hence, rejuvenating the system as in an ARA1 one action will decrease the rate of deterioration together with the deterioration level.

As for the stochastic comparison results, the paper focuses on the likelihood ratio order, which is well-known in reliability theory, but also on the (increasing/decreasing) convex/concave orders, which come from the insurance literature and seem a littleless common in papers devoted to reliability theory. Clearly, other stochastic orders might be considered such as Laplace transform order or Excess Wealth order for instance. Other questions of interest concern the comparison of remaining lifetimes, considering the system as failed (or too degraded) when its deterioration level is beyond a fixed failure (critical) threshold. From a theoretical point of view, this seems a difficult issue in a general setting. One could then look at partial results on specific models.

Furthermore, the paper made an attempt for comparing the two types of imperfect repair including them in a global maintenance policy. Clearly, this subject requires further investigation for a better understanding of the practical consequences on the optimal policy of choosing one model of imperfect repair or the other, and typically, this would require a numerical study at a larger scale. Of course, it would also be of interest to consider other types of global maintenance policy (among the numerous ones developed in the literature, e.g. see van Noortwijk (2009)), including one model of imperfect repair or the other.

Finally, a gamma deterioration model has been assumed in this paper. The stochastic comparison results between the two imperfect repair models deeply rely on the comparison properties of the gamma distribution, as summed up in Lemma 1. As noted by the referee, a question of interest would be to revisit the comparison between the two imperfect repair models considering other deterioration models (such as Wiener processes with trend or other subordinators).

ABSTRACT: Both for the manufacturer and the user of industrial vehicles, optimizing simultaneously the maintenance and missions schedule at the fleet level becomes a necessity to improve the profitability. Lots of researches have been realized to optimize either the preventive maintenance schedule or the production planning. Integrating both activities in the same schedule has become a new hotspot. Few researches have been led to schedule both maintenance operations and missions for a fleet of systems which deteriorate over time in a comprehensive predictive approach. As a first step to reach this objective, a single vehicle is considered and we propose a method to jointly optimize its predictive maintenance and its mission planning using the remaining useful life and deterioration information. The vehicle has a set of missions to complete. The aim is to group the missions in blocks and interpose maintenance operations between these blocks. However, the vehicle deteriorates over time and each mission impacts differently the deterioration according to its severity. A stochastic process is used to model the deterioration phenomenon and its parameters are changed for each mission. To obtain the best arrangement between missions and maintenance operations, a genetic algorithm is used. A criterion to minimize the maintenance cost is defined, which takes into account preventive and corrective maintenance costs associated with the missions failure probabilities. The genetic algorithm enables to approach the optimal solution in a reasonable time and avoid considering every possible arrangement.

1 INTRODUCTION

Many researchers have developed methods to optimize the preventive maintenance schedule for multi-component systems (Bouvard et al. 2011) without considering production constraints but taking into account the system availability on a fixed time period (Lesobre 2015). From these previous achievements, a new problematic has arisen aiming at jointly scheduling production and maintenance. Two strategies to solve this problem can be identified.

The sequential strategy consists in scheduling one of the two activities, maintenance or production, and using this schedule as an unavailability additional constraint to solve the joint scheduling. Benbouzid et al. (2003) develop a sequential process to schedule production activities and maintenance in flowshop workshops. The production schedule is generated using heuristic methods. Then, by considering the production tasks order as a constraint, the periodic maintenance operations are added to the initial schedule. This period is determined to reach a trade-off between the maintenance cost and the risk of reducing the machine availability. The same procedure is applied to integrate preventive maintenance in the production scheduling for a single machine to minimize the total expected weighted completion time to do all the jobs (Cassady & Kutanoglu 2005). The exact method, for small size problems, considers all the job sequence possibilities. Then, for each possibility, all the feasible Preventive Maintenance (PM) decisions sets are tested. The job sequence-PM decisions minimizing the objective function is the optimal solution. For larger problems, a two-steps

heuristic method is developed. The first step selects the job sequence having the shortest total weighted completion time. The weigh is an importance factor for each job. The second step identifies the PM decisions minimizing the total expected weighted completion time for the job-sequence established in the first step.

The integrated strategy approach aims at scheduling simultaneously maintenance and production activities. Yalaoui et al. (2014) use a linear programming model to minimize the total production cost. The production is divided in cycles and a preventive maintenance is completed at each cycle beginning to restore the production lines capacities. Each maintenance cycle cost depends on the preventive and corrective maintenance cost. The corrective one is estimated thanks to the failure rate. This exact method is satisfactory for reduced size problem. The following research works apply heuristic methods to solve the integrated scheduling problem. Feng et al. (2016) apply a genetic algorithm to minimize the costs induced by jobs tardiness, corrective and preventive maintenance action. Ladj et al. (2016) suggest an approach hybridizing genetic algorithms and artificial immune systems. A deterministic deterioration model is considered as each job deteriorates the machine of a fixed value and it is assumed that no accidental failure occurs during the time horizon. The maintenance actions are triggered when the deterioration level oversteps a failure threshold. These approaches are single-objective optimization methods but multi-objective methods exist. Da et al. (2016) choose to minimize both the maintenance cost rate and makespan.

A comparison between the sequential approach and a new integrated strategy to minimize the manufacturing system cost for a single-unit system has been drawn by Li et al. (2010). The maintenance operations are imperfect and an improvement factor is defined to quantify each operation effectiveness. The integrated approach uses a heuristic method to find the optimal schedule and enables to save about 12% of the manufacturing costs with respect to the sequential approach. The terms sequential or integrated only refer to the way of solving the scheduling problem. In both cases, the result is a single simultaneous schedule for production and maintenance.

In the previous contributions, the deterioration modelling considers either the machine age or a deterministic model where each job deterioration is exactly known. Li et al. (2010) do not consider the failure risk or any reliability based constraints to obtain the joint schedule.

The objective of this paper is to develop a new integrated strategy to schedule both missions and maintenance for a deteriorating vehicle using deterioration information. Firstly, the joint scheduling problem is defined. Then, the adopted approach to solve it is explained. The models for the vehicle deterioration evolution and for the missions impact on the deterioration are developed and the optimization method is exposed. Finally, performances and sensitivity studies are presented on application examples to illustrate the algorithm behaviour.

2 PROBLEM FORMULATION

A single vehicle has a set of missions to complete. It is modelled as a single-unit system which deteriorates over time according to its activity. The vehicle operates in missions with different severity levels, characterized not only by their duration but also by several environment parameters as road condition, topography. The vehicle usage modelling is then adapted and takes into account the mission severity level.

The objective of the present work is to jointly optimize the vehicle predictive maintenance and its mission planning using the deterioration information (Figure 1). The preventive maintenance operations have to be well planned to prevent immobilizing failures, maximize the vehicle availability and not disturb the missions progression. According to these conditions, the schedule is defined as a

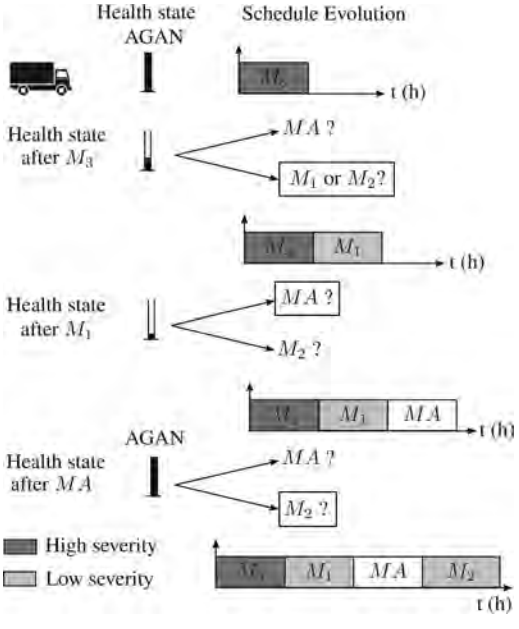

Figure 1. Framework to schedule the three missions M_1, M_2 and M_3 and the maintenance actions MA according to the health state. Their durations and deterioration severities are respectively defined by the boxes lengths and colors.

series of mission blocks interrupted by maintenance operations to restore the vehicle deterioration state to an As Good As New (AGAN) state.

The schedule optimization is based on the total maintenance cost and aims at maximizing the vehicle activity between two consecutive preventive maintenance operations while considering its health state. The total maintenance cost is then based on the preventive maintenance costs C_{pt}, for which each operation costs C_0, and the costs C_{ct} associated with corrective maintenance. To estimate C_{ct}, the missions failure risks and the corrective maintenance cost C_f for each operation are considered.

3 RESOLUTION APPROACH

3.1 *Vehicle deterioration model*

3.1.1 *Deterioration evolution*

The vehicle is characterized by a global health indicator. Its deterioration evolution is modelled by a stationary Gamma process. The choice of this stochastic continuous deterioration process is motivated by its ability to represent observable and gradual deterioration phenomena in industrial systems (Lesobre 2015, Van Noortwijk 2009). A Gamma process $X(t)$, $t > 0$ is defined by its shape and scale parameters respectively denoted α and β. A failure occurs when the cumulated deterioration $X(t)$ exceeds the failure threshold L. The distribution function F followed by the time to failure T is then given by Eq. 1. The failure probability for a mission whose duration is equal to t_m is equal to $F(t_m)$.

$$F(t) = P(T \leq t) = \frac{\Gamma(\alpha t, L\beta)}{\Gamma(\alpha t)}, \quad (1)$$

where $\Gamma(.)$ is the Gamma function and $\Gamma(\alpha,L\beta)$ is the incomplete Gamma function defined by $\Gamma(\alpha t, L\beta) = \int_{L\beta}^{\infty} u^{\alpha t-1} e^{-u} du$.

3.1.2 *Missions impact on the deterioration*

The missions correspond to the deliveries the truck has to complete. They are described by their durations and they affect the vehicle deterioration evolution. Indeed, the vehicle evolves in a dynamic environment influencing its deterioration. The environment evolution results from changes in the missions characteristics during the vehicle lifetime. The deterioration-threshold failure model used in this work allows one to integrate the mission characteristics through the modification of the deterioration parameters. It is thus assumed that these changes have a time-related impact on the deterioration process, modelled by a change in the deterioration speed. The deterioration is then modelled by a Gamma process with varying parameters. Each mission is associated with a pair of parameters.

Thanks to the deterioration model, the failure probabilities can be estimated based on the distribution function followed by the time to failure. An optimization method to jointly schedule mission and maintenance can then be developed.

3.2 *Optimization method for joint scheduling*

A genetic algorithm based approach is developed to find the optimal joint schedule for maintenance and missions minimizing the total maintenance cost. The optimization criterion definition is one of the major point to discuss.

3.2.1 *Criteria definition*

The schedule is composed of mission blocks separated by preventive maintenance operations. The optimization criterion is then based on the maintenance cost associated with the schedule. This criterion relies on two elements:

- The preventive maintenance cost C_0 corresponding to the maintenance operations scheduled at each block end.
- The corrective maintenance cost C_f related to the failure occurring within each mission block.

An optimal balance is to be found between preventive and corrective maintenance i.e. the number of blocks and the blocks filling. To determine the possible mission number in the blocks, the deterioration process is used to estimate the failure probabilityfor a block. This failure probability considers the parameters characterizing the missions in the block.

For p missions in a block, p environment changes, representing the missions severity levels, occur. Figure 2 presents an example with 3 missions and 3 environment changes. The only known information are that the deterioration level is equal to 0 at the block beginning. No information on

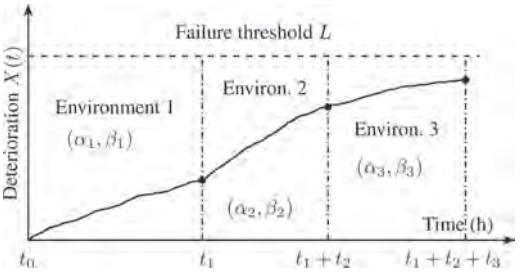

Figure 2. Deterioration evolution in a block with 3 missions.

its deterioration evolution are available when the vehicle is completing the schedule.

The cumulated deterioration between t_0 and $t_1+t_2+t_3$ corresponds to the deterioration increments sum between t_0 and t_1, t_1 and $t_1 + t_2$ and between $t_1 + t_2$ and $t_1 + t_2 + t_3$. The increments probability densities of the missions are respectively denoted f_1, f_2 and f_3. The increments deterioration density for the block is the increments densities convolution for the missions in the block. The more numerous the environment changes are, the more complex the reliability expression is to compute (Khoury 2012). Based on the Gamma process properties and the environment changes, an approximation for the block deterioration process can be given by an equivalent Gamma process $Ga(\alpha_e, \beta_e)$. Its average value and variance are respectively weighted mean values of the average values and variances related to the Gamma processes of the missions. The different weights are the proportions of the block duration spent in each environment. For Figure 2, the equivalent Gamma process parameters are defined as follows:

$$\frac{\alpha_e}{\beta_e}=\frac{1}{T}\sum_{i=1}^{p} t_i \frac{\alpha_i}{\beta_i} \quad \text{and} \quad \frac{\alpha_e}{\beta_e^2}=\frac{1}{T}\sum_{i=1}^{p} t_i \frac{\alpha_i}{\beta_i^2}, \tag{2}$$

where $p = 3$ and $T=\sum_{j=1}^{p} t_j$. Note that if all the Gamma processes related to the missions have the same scale parameter β and the same duration, the resulting convolution density is exactly the one for a Gamma process $Ga\left(\sum_{i=1}^{p}\alpha_i,\beta\right)$.

The block failure probability is obtained based on the equivalent Gamma process. It is the probability that the cumulated deterioration exceeds the failure threshold L, knowing that $X(t_0)$, the deterioration at t_0, is equal to 0.

$$P(X(T)-X(t_0)\geq L)=\frac{\Gamma(\alpha_e(T-t_0),L\beta_e)}{\Gamma(\alpha_e(T-t_0))} \tag{3}$$

The criterion C_1 (Eq. 4) is defined to estimate the maintenance costs for a joint schedule π composed of N_b blocks. It considers only one failure by block.

$$C_1(\pi)=\sum_{k=1}^{N_b}(C_0+C_f\mathbb{P}_f(k)), \tag{4}$$

where $\mathbb{P}_f(k)$ is the probability to have one failure in the block k as explained in Eq. 3. Variations can then be defined to accept multi failures in the blocks. We define another criterion C_2 which considers that in a block composed of m missions, no more than m failures can occur. Only one failure by mission could happen. Considering multi failure in a block corresponds to estimate the expected failure occurrences in a block.

The replacement process is such that once the deterioration exceeds the failure threshold L, a corrective maintenance is completed and the deterioration level is back to 0. Based on the equivalent Gamma process, the deterioration evolution in the block can be characterized. The probability to have two failures in the block defined in Figure 2 can then be estimated by $P(X(T) - X(t_0) \geq 2L)$. The principle is the same as the replacement process but without the deterioration level reset after a failure. The criterion C_2 for a joint schedule π composed of N_b blocks is:

$$C_2(\pi)=\sum_{k=1}^{N_b}\left(C_0+C_f\sum_{i=1}^{N_m(k)}\mathbb{P}_{fk}(D\geq iL)\right), \tag{5}$$

where $N_m(k)$ is the number of missions in the block k, D the deterioration level and $\mathbb{P}_{f_k}(D\geq iL)$ the probability to exceed the failure threshold L for the i^{th} time in the block k.

The two criteria C_1, C_2 are used as optimization criteria for the genetic algorithm developed to solve the joint scheduling problem.

3.2.2 *A genetic algorithm based method*

A genetic algorithm (GA) is developed to solve the joint scheduling problem for missions and maintenance using a maintenance cost based criterion defined in the section 3.2.1. The choice of this heuristic method is justified by its adaptability regarding the individuals and operators definitions as well as its performances to reach a good solution in a satisfying computation time. The genetic algorithm principle is based on the hybrid genetic-immune algorithm proposed by Ladj et al. (2016). The operators are adapted to be applied in a random deterioration case as Ladj et al. (2016) develop it for a deterministic deterioration case. Its general main principle is illustrated in Figure 3. The different stages are explained in the following paragraphs.

A parameter is defined to condition the block filling. As the deterioration evolution is stochastic, the exact deterioration level reached at a mission block end cannot be known. However, a failure probability can be estimated according to the missions in the block. This parameter acts on the maximum admissible failure probability for a block. It is more likely to dispatch a vehicle on a mission block whose failure probability is not too high to avoid at best corrective maintenance. This parameter is denoted $\mathbb{P}_{f_{max}}$ and its values is between 0 and 1. The closer to 1 it is, the more flexible the genetic algorithm is to generate individuals. Acting on this parameter guides the genetic algorithm towards the best joint schedule.

Individual representation: The individuals correspond to candidate schedules for both maintenance

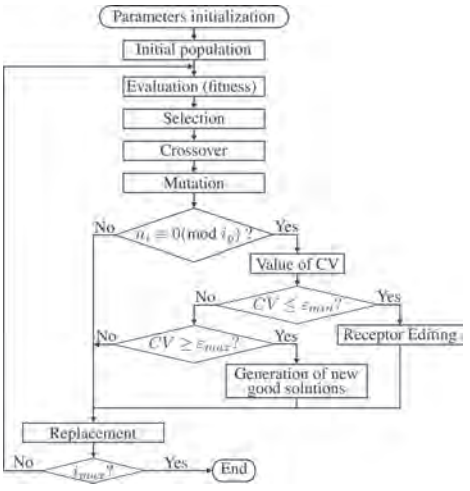

Figure 3. Genetic algorithm principle.

and missions. In the GA, the genotype is obtained by sequencing the mission set into different blocks. In a block, the missions are supposed to be completed one after the other. The preventive maintenance operations occurs at each block end. For instance, in case of a problem with $n = 6$ missions to schedule, a possible candidate schedule is $\pi = \{(6,2)(5,3,4)(1)\}$.

Initial population: The initial population is composed of N_{pop} individuals. 60% of them are randomly generated. Each mission is randomly put in a block while respecting the block filling condition. For the remaining individuals generation, special techniques are applied. 20% of the population is generated using the First Fit (FF) method (Coffman et al. (1996)). This method is applied on random missions sequences to form candidate solutions by assigning the missions to the blocks. The last 20% is generated using to heuristic methods called First Fit Decreasing (FFD) and Best Fit Decreasing (BFD) (Coffman et al. (1996)). Then, block permutations are performed on these solutions to generate other individuals. Note that the individuals generated by these techniques still respect the block filling condition.

Evaluation: The evaluation stage consists in applying the fitness function *Fit* to evaluate the quality of an individual in the population. The fitness function is related to the maintenance cost based criteria defined in section 3.2.1. Two fitness functions for a individual π are defined in Eq. 6. The best individuals are the ones for which the maintenance costs are the lowest.

$$Fit_1(\pi) = \frac{1}{C_1(\pi)} \quad \text{and} \quad Fit_2(\pi) = \frac{1}{C_2(\pi)} \tag{6}$$

Selection: The selection operator is a 2-tournament selection operator (Michalewicz 1996). It randomly chooses two individuals in the current population and selects the fittest one. When the selected individuals number reaches N_{pop}, the selection stage is over.

Crossover: The crossover operator crosses two parent individuals to obtain new offspring individuals. A crossover probability P_{cross} defines whether or not the parents will procreate. The principle is to randomly select a pair of parents. Both parent blocks are listed and a random selection is done to copy non-overlapping blocks to both offspring individuals so that no missions are duplicated. Then, for each offspring, the remaining missions are randomly added to blocks, either an existing one while respecting the block filling condition or a new one. This principle is inspired from the crossover operator developed by Rohlfshagen and Bullinaria (2010).

Mutation: The mutation operator is based on Swap mutation (Michalewicz 1996) and consists in exchanging two randomly selected missions from two different blocks while respecting the block filling condition. This swapping occurs with a probability P_{mut}.

Population dispersion: This stage periodically evaluates the total population dispersion which is of great importance to avoid converging towards a local optimal solution. The total population includes the parents and their children with their possible mutations and contains $2N_{pop}$ individuals. As explained by Ladj et al. (2016), diversification and intensification are two major issues when building effective search algorithms. Diversification refers to the capacity to explore different regions of the search space while intensification refers to the ability to generate high fitted solutions in those regions. A balance between these two notions has to be obtained. When the iteration number n_i is a multiple of the iteration period i_p, the population dispersion is estimated through the Coefficient of Variation (CV), also known as the Relative Standard Deviation (RSD) (Ladj et al. 2016). CV considers the fitness value of each schedule π_i in the total population *Pop* (Eq. 9). According to its value, different decisions are adopted to enhance either the diversification or the intensification.

$$CV = \frac{\sigma}{\mu} \cdot 100\% \tag{7}$$

$$\text{with} \quad \mu = \frac{1}{2N_{pop}} \sum_{\pi_i \in Pop} \frac{1}{Fit(\pi_i)} \tag{8}$$

$$\text{and} \quad \sigma = \sqrt{\frac{1}{2N_{pop}} \sum_{\pi_i \in Pop} \frac{1}{(Fit(\pi_i) - \mu)^2}} \tag{9}$$

Receptor editing: When the population dispersion CV is lower than a minimum dispersion threshold ε_{min}, individuals are very similar and focused on a limited search space region. The receptor editing operator aims at reducing the risk of premature convergence (Ladj et al. 2016). A part of the least fitted individuals (α% of the population) are eliminated and replaced by random new individuals to possibly explore new search space regions.

Generation of new good solutions: When the population dispersion CV is higher than a maximum dispersion threshold ε_{max}, individuals cover distinct search space regions. To promote the most promising regions, a part of the least fitted individuals are replaced by mutations of the most fitted individuals (α% of the population).

Replacement: Individuals for the next generation are selected among the total population formed by the parents and the children. A part of the least fitted individuals (β%) is directly added to the next generation while the fittest members among parents and children complete the next generation until it contains N_{pop} individuals.

Termination condition: The genetic algorithm terminates after i_{max} iterations and a joint schedule for missions and maintenance operations minimizing the corrective and preventive maintenance costs can be obtained. The results are illustrated through application examples.

4 APPLICATION EXAMPLES

4.1 *Simulated data*

Two datasets of $n = 6$ missions represent two scenarii (Tables 1 & 2). The difference between them comes from the mission failure probabilities range. For the dataset A, the maximum mission failure probability is 1% while for the dataset B, it is 19%.

The dataset A further emphasizes the influence of the missions variances changes while the dataset B better illustrates the sensitivity studies for the impact of the ratio between the preventive and corrective maintenance costs and for the effect of $\mathbb{P}_{f_{max}}$.

Table 1. Dataset A.

Missions	Durations (h)	α_m	β_m	Failure probabilities
1	21	0.13	0.1	0.002
2	21	0.18	0.1	0.009
3	8	0.4	0.1	0.004
4	8	0.33	0.1	0.002
5	2	1.33	0.1	0.002
6	3	1.32	0.1	0.01

Table 2. Dataset B.

Missions	Durations (h)	α_m	β_m	Failure probabilities
1	9	0.85	0.1	0.189
2	4	1.85	0.1	0.163
3	3	1.34	0.1	0.011
4	6	0.93	0.1	0.048
5	6	0.90	0.1	0.041
6	2	3.81	0.1	0.184

Table 3. Parameters definition.

Parameter	Value	Parameter	Value
C_0	1000	C_f	3000
L	100%	N_{pop}	30
P_{cross}	0.7	P_{mut}	0.1
i_p	4	i_{max}	100
α	20%	β	20%
ε_{min}	10	ε_{max}	60

Table 4. Performance results.

	Dataset A		Dataset B	
Criterion	C_1	C_2	C_1	C_2
C_m	3787.2	3788.3	7898.4	7905
GA: T_c (s)	2.34	2.90	3.02	3.24
EM: T_c (s)	7.79	7.76	3.47	3.48

The preventive and corrective maintenance costs C_0 and C_f, the failure threshold L and the genetic algorithm parameters have to be initialized (Table 3). The maximum failure probability $\mathbb{P}_{f_{max}}$ is fixed at 0.95 for all the studies except for the one on the variance changes (4.3.3) for which $\mathbb{P}_{f_{max}}$ is equal to 0.1.

4.2 *Performances analysis*

The performance analysis is realized for both datasets and both criteria defined in section 3.2.1. It is performed on a computer with Intel© Xeon© CPU E3-1240 v5 @ 3.50 GHz and 16.0 GB RAM. For each dataset, 1000 realizations are generated to compare the maintenance cost and computation time results between the Genetic Algorithm (GA) and an Exact Method (EM). The exact method considers all the possible schedules respecting the block filling condition and their associated criterion values to find the schedule minimizing the criterion. The maintenance cost and the computation time are respectively denoted C_m and T_c. The study results are explained in Table 4.

Dataset A: The optimal joint schedule obtained with the exact method is the same for both criteria. This schedule is $\pi^{12}_{opt_1} = \{(1,3)(2,5)(4,6)\}$. The computation time gains with the genetic algorithm are quite significant: 70% forthe criterion C_1 and 62.6% for the criterion C_2.

Dataset B: The optimal joint schedule obtained with the exact method differs according to the chosen criterion. For the criterion C_1, the optimal schedule is $\pi^1_{opt_2} = \{(1)(2)(4)(6)(3,5)\}$ while for the criterion C_2, it is $\pi^2_{opt_2} = \{(1)(2)(3)(4)(5)(6)\}$. The computation time gains are lower than with the dataset A. They are respectively of 13.1% with C_1 and 7% with C_2. This difference comes from the number of feasible schedules when respecting the block filling condition. Indeed, the feasible schedule number for the datasets A and B are respectively 199 and 80. It explains why the exact method is faster for the dataset B.

For all the 1000 realizations with both datasets and criteria, the genetic algorithm converges towards the same schedule as the one obtained with the exact method. The only differences that can occur are permutations between the blocks or permutations of missions in the same block. As the criteria are computed based on the equivalent deterioration process for each block, the mission order does not have an influence on the block failure probabilities. The maintenance costs for the criterion C_2 are slightly higher because multi failures are considered in the blocks. It increases the associated corrective maintenance cost.

The genetic algorithm computation time for the criterion C_2 has increased with respect to the computation time for the criterion C_1. For the datasets A and B, the increases are about 24% and 7.4%. As the criterion C_2 considers multi failures probabilities, there are more calculations to do when computing the fitness values for the candidate schedules.

The results show the interest of using a genetic algorithm based method instead of an exact method to converge towards an optimal joint schedule for missions and maintenance while saving computation time. After showing the genetic algorithm performances, it is essential to study its sensitivity to several parameters to analyse its behaviour.

4.3 *Sensitivity study*

This section studies the influence of some parameters on the genetic algorithm behaviour, on the obtained joint schedule and on its associated performance. For each study, the dataset is selected to illustrate at best its behaviour.

4.3.1 *Impact of the ratio R_c*

The first study is interested in the impact of R_c, the ratio between the preventive and corrective maintenance costs respectively denoted C_0 and C_f. It is realized with the dataset B. R_c varies between 0.1 and 1 with a step fixed at 0.1 and the value for the preventive maintenance cost C_0 is the one defined in Table 3.

For both criteria, the block number in the schedule decreases when R_c decreases, i.e. when the corrective maintenance cost decreases (Table 5). When the corrective cost is very high with respect to the preventive one, the best schedule favours a high block number because grouping missions increases the failure risk in each block and leads to a significant maintenance cost inflation. On the contrary, when the two maintenance costs are quite similar, grouping the missions in few blocks is less expensive with respect to the maintenance costs.

Note that the reduction of the number of blocks is faster for the criterion C_1. When R_c is equal to 0.5, the optimal schedule for the criterion C_1 is composed of 4 blocks while the one for the criterion C_2 has 5 blocks.

4.3.2 *Effect of the variations of $\mathbb{P}_{f_{max}}$*

This section studies the effect of the maximum admissible failure probability for a block on the optimal schedule computation. This probability aims at guiding the genetic algorithm to converge faster towards the optimal solution. The smaller the probability is, the stricter the constraint on the block filling is.

This part is illustrated for the dataset B with the criterion C_1. Table 6 shows that when $\mathbb{P}_{f_{max}}$ increases, the number of blocks decreases. For most

Table 5. Optimal schedule when R_c varies (Criterion C_1).

R_c	Maintenance cost	Optimal schedule
0.1	12350	{(2)(6)(4)(1)(5)(3)}
0.2	9175	{(6)(2)(3)(1)(4)(5)}
0.3	8116.7	{(4)(3)(5)(2)(1)(6)}
0.4	7415.4	{(4)(1)(6)(5,3(2)}
0.5	6901.5	{(2)(1)(6)(5,4,3)}
0.6	6345.4	{(2)(6,1)(3,5,4)}
0.7	5867.4	{(5,3,4)(1,6)(2)}
0.8	5509	{(1,6)(5,4,3)(2)}
0.9	5230.2	{(1,6)(2)(5,3,4)}
1	5007.2	{(5,3,4)(2)(1,6)}

Table 6. Optimal schedule when $\mathbb{P}_{f_{max}}$ varies (Criterion C_1).

$\mathbb{P}_{f_{max}}$	Maintenance cost	Optimal schedule
0.2	7905	{(3)(4)(5)(6)(1)(2)}
0.3	7905	{(6)(5)(2)(1)(4)(3)}
⟦0.4;0.9⟧	7898.4	{(4)(2)(1)(3,5)(6)}
1	4000	{(1,5,6,4,3,2)}

of $\mathbb{P}_{f_{max}}$ values, the optimal schedule is composed of 5 blocks. When $\mathbb{P}_{f_{max}}$ is equal to 1, the optimal schedule groups all the missions in the same block because it is less expensive for the maintenance.

As expected, when the block filling constraint is relaxed, the optimal schedule is composed of less blocks. Note that when $\mathbb{P}_{f_{max}}$ is equal to 1, the optimal schedule not necessarily counts one block. For the dataset A, it is composed of 3 blocks for both criteria.

4.3.3 *Influence of missions variance changes*

In this part, the influence of the missions variance changes are studied to evaluate the genetic algorithm behaviour. For this specific study, the block filling condition $\mathbb{P}_{f_{max}}$ is fixed at 0.1. It is to be sure to illustrate only the effects due to the variance changes.

The initial dataset is the dataset A. As $\mathbb{P}_{f_{max}}$ is reduced with respect to the part 4.2, the optimal joint schedule differs. With both criteria, it is $\pi_{opt} = \{(2)(6)(5,1)(4,3)\}$. Based on this dataset missions, three datasets are generated. The missions durations are identical but the deterioration processes parameters are modified so that the increments expected value for each mission remains the same from one dataset to another. For each mission, the variance of the deterioration increment is either increased or decreased with respect to the initial variance (Tables 7 & 8). $\mathbb{P}$ denotes the mission failure probability.

Table 7. Datasets when increasing the variance by 2 or 5.

	Variance × 2			Variance × 5		
Missions	α_m	β_m	$\mathbb{P}$	α_m	β_m	$\mathbb{P}$
1	0.07	0.05	0.02	0.03	0.02	0.05
2	0.09	0.05	0.04	0.04	0.02	0.09
3	0.20	0.05	0.02	0.08	0.02	0.07
4	0.16	0.05	0.01	0.07	0.02	0.05
5	0.66	0.05	0.01	0.27	0.02	0.05
6	0.66	0.05	0.04	0.26	0.02	0.09

Table 8. Dataset when decreasing the variance by 2.

	Variance/2		
Missions	α_m	β_m	$\mathbb{P}$
1	0.27	0.2	4.2×10^{-5}
2	0.37	0.2	5.8×10^{-4}
3	0.79	0.2	1.1×10^{-4}
4	0.66	0.2	2.5×10^{-5}
5	2.65	0.2	2.7×10^{-5}
6	2.64	0.2	7.2×10^{-4}

When the variances are increased by a factor 2 and 5, the optimal joint schedules are respectively $\pi_{i_2} = \{(5,4)(6)(1)(3)(2)\}$ and $\pi_{i_5} = \{(5)(6)(1)(2)(4)(3)\}$. Increasing the variances increases the number of blocks in the optimal joint schedule. Indeed, increasing the variances also increases the probability to have a failure for each mission. It is then harder to group the missions into blocks. On the contrary, when the variances are reduced by a factor 2, the optimal joint schedule is $\pi_{d_2} = \{(4,6)(3,1)(2,5)\}$. The number of blocks is reduced. If the variances continue to decrease, the optimal schedule remains π_{d_2} because reducing more the block number lead to failure probabilities exceeding $\mathbb{P}_{f_{max}}$. The results are explained by the fact that the failure uncertainty increases when the variance increases.

4.4 *Larger size problems*

The higher the missions number to schedule is, the harder it becomes to compare the genetic algorithm results with the exact method results owing to the exact method computation time. The number of feasible schedules becomes too numerous. When considering $n = 9$ missions with $\mathbb{P}_{f_{max}}$ equal to 0.95, the exact method needs more than 11 days to reach the optimal schedule. With the genetic algorithm, the average computation times for the criteria C_1 and C_2 are respectively 2.63s and 3.77s. Note that when using C_1, 16% of the 1000 realizations do not reach the optimal solution and the maintenance cost deviation represents 1.45% of the optimal maintenance cost. Considering several failures by blocks gives a better maintenance cost estimation and a more coherent cost surface from one iteration to another. The convergence is then improved and when using C_2, all the schedules are identical to the optimal one.

To improve the genetic algorithm convergence, the population size N_{pop} and the maximum iteration number i_{max} can be increased, but the convergence is not guaranteed. But it will be to the detriment of the computation time. Indeed, increasing the population size and the iteration number also increase the computation time.

5 CONCLUSION

A static method based on a genetic algorithm is proposed to schedule missions and preventive maintenance for a vehicle by optimizing a maintenance cost based criterion. Two criteria consider either one or multi failures in the blocks and include the vehicle deterioration model, evolving due to the different mission severity. Its performances and sensitivity are described through

application examples. The genetic algorithm converges towards the optimal schedule in a satisfying computation time.

The obtained results are promising and offer improvement perspectives. Dynamic information, such as the deterioration level or the failure occurrences, could be integrated to update the schedule and reduce the maintenance costs even more. New missions could be added during the schedule completion. These different points will be further investigated to evolve towards a dynamic scheduling method.

A concept for a holistic risk-based operation and maintenance strategy for wind turbines

Christian T. Geiss & Christian U. Grosse
Technical University of Munich, Munich, Germany

ABSTRACT: Operational wind turbines are highly loaded structures. Especially the high amount of load cycles-up to 10^9 –, leads to the conclusion that these renewable energy structures are in need of a suitable structural health monitoring and management strategy. In times of energy transition from conventional power plants to renewable power plants a safe and reliable operation of these assets is a premise. The paper presented here introduces an approach on determining risk-based operation and maintenance strategies for wind turbines. The approach combines Bayesian decision analysis with the concepts known in structural reliability analysis. Information from sensors can be used in probabilistic models to update the incomplete knowledge of the state of nature. They are a cost-effective risk-reduction measure and can be used for uncertainty quantification and reduction of uncertainties. Therefore the combination of the described methods is able to optimize maintenance and inspection activities according to the associated costs.

1 INTRODUCTION

A design lifetime of 20 years is generally assumed for modern wind turbines. The extension of service life beyond those 20 years has to be justifiable from a technical, safety, and economic point of view. Especially important are all load-transferring components that are relevant for the structural integrity of the wind turbine and the control and protection system.

The supporting structure of a wind energy systems is a large capital expenditure (CAPEX), on average between 20 to 30% of the overall capital expenditures. During the service life of wind energy systems, the structural supporting structure is particularly important and at risk. While drive train, generator and rotor blade systems already are monitored for structural health, this is not the case for the structural supporting structure.

As shown in the failure statistic in Figure 1 failures in the supporting structure cause the highest and most expensive downtime events. From both a technological and economical point of view it is worthwhile to use the supporting structure of a wind turbine systems as long as safety and reliability levels can be fulfilled at reasonable cost (Geiss 2014).

As shown in Figure 4, currently about 1.000 wind turbine systems already have exceeded their 20 year designed service life. The overall capacity of the German wind energy installation already in its second half of service life is 41%.

The described situation stresses the need for new maintenance strategies and life cycle assessments

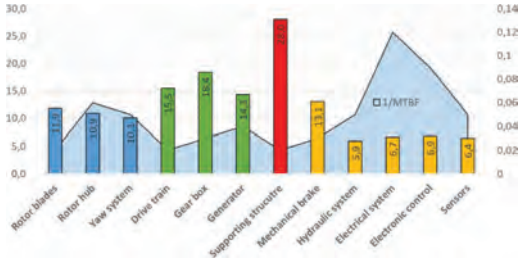

Figure 1. Wind turbine damage statistic (WInD-Pool 2017).

of onshore wind turbines. Especially challenging for existing wind turbine structures is that the original design documents cannot often be used as a reference for a remaining useful lifetime analysis.

According to the DNV GL guideline (DNV GL AS 2016) there exist four methods of lifetime extension analysis:

1. Lifetime extension inspection
2. Simplified approach
3. Detailed approach
4. Probabilistic approach

The assessment shall always be based on a combination of an analytical part and a practical part. The analytical part incorporates an assessment based on new or additional calculations for the wind turbine, considering the site-specific conditions. The lifetime calculation of the analytical part should be supplemented with relevant field experience of the wind

turbine model concerning weak points, known failures or retrofits. Figure 2 gives an overview of the different life cycle phases of a wind turbine system.

The probabilistic approach integrates the use of stochastic methods in the assessment of structural integrity. Alternatively, rather than use of deterministic values in the simplified and detailed approach, the probabilistic approach uses appropriate probability distributions to characterize the uncertainty in models and model inputs. The stochastic parameters—such as probability distribution types, expected values, coefficients of variation, or correlation coefficients—in the limit state formulations have to justify that they do not introduce errors into the analyses. A structural reliability analysis (SRA) in the following course of actions has to be carried out according to DNV GL:

1. Selection of a target reliability level
2. Identification of failure modes in the system
3. Development of limit state functions (g-functions) for each failure mode based on engineering theory
4. Quantification of the deterministic and stochastic variables within the limit state function and their correlations
5. Use of appropriate methods (e.g. first order reliability method—FORM) to compute reliability indices or probabilities of failure for the structural components
6. Comparison of the computed component reliability with target reliability level for each component
7. Analysis of results using sensitivity analysis

The aleatory and epistemic uncertainty in mathematic models and input parameters are to be described by appropriate probability distributions, and the nature of uncertainty has to be clarified. Any type of measurement can be used to update the probability models. If aero-elastic models or component resistance are not available, generic load and resistance models can be used. Based on the probabilistic approach, risk-based inspection methods may be developed.

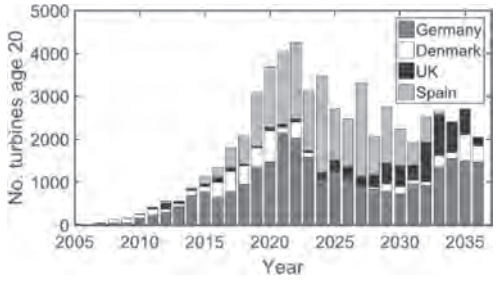

Figure 2. Wind turbine age structure (Ziegler et al. 2018).

The two most relevant deterioration mechanisms for a wind turbine supporting structure are corrosion mechanisms and fatigue crack growth mechanisms. The current research approach focusses on the fatigue crack-growth mechanism, as the most critical deterioration mechanism of the structural system.

Theoretical models exist that describe the specific fatigue mechanisms causing wear of a structural element. However, these models inherit implied model uncertainties, which can be reduced by in-field inspection data. Non-destructive testing (NDT) methods are therefore effective risk mitigation measures for existing structures.

2 DETERIORATION MODELLING

All deterioration mechanisms are time-dependent and consequently all reliability problems in fatigue are time dependent (JCSS 2002). A failure event of a deteriorating structure can be modelled as a first passage problem. The limit state function is then also a function of time. Failure occurs when the limit state function becomes negative for the first time, given that it was positive at $t = 0$. In that case, the probability of failure between time $t = 0$ and time $t = T$ can be expressed by the following equation:

$$p_F(T) = 1 - P(g(\underline{X}(t)) > 0 \tag{1}$$

For most deterioration processes the problem is simplified by the fact that damage is monotonically increasing with time. If the modelled deterioration problem has a fixed damage limit—failure occurs when damage reaches a constant limit—the deterioration problem can be solved as a time-independent problem. The time variable t is then a simple parameter of the model and deterioration is treated as a monotonously increasing process.

E.g., if failure has not occurred at time t_1, failure has also not occurred at time $t < t_1$. For the definition of a failure rate of the modelled system, several definitions are possible. In this case the annual failure probability of the modelled system

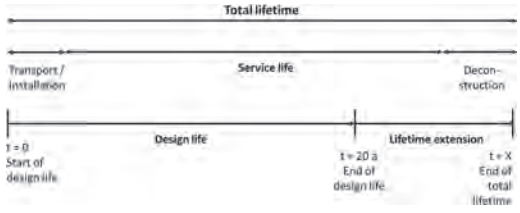

Figure 3. Life cycle phases of wind turbines.

is best fitting. This circumstance enables to evaluate the reliability problem at fixed time intervals $t = t_1; t_2 \quad ; t_n$.

$$t = t_{i-1} + 1yr \tag{2}$$

Consequently, the annual probability of failure in year t_i can be expressed as follows:

$$\Delta p_F(t_i) \approx \frac{p_F(t_i) - p_F(t_{i-1})}{1 - p_F(t_{i-1})} \tag{3}$$

Very typically this is a SN fatigue modelling problem. Failure is defined to occur when the accumulated damage has reached Δ or commonly defined as $\Delta = 1$.

In practical engineering application the computation of probabilities is done with Monte-Carlo-simulations and FORM-algorithms, e.g., (Strurel 2017).

3 STEEL FATIGUE PROCESS

Generally, fatigue arises at points of local stress concentrations; so-called hot spots can be represented by welds, cut-outs and a wide variety of mechanical connection types—e.g., bolts. Due to inhomogeneities, welds are especially relevant as local hot spots and stress concentrations. State of the art engineering theory uses specific steel fatigue models for the description of the fatigue process caused by fluctuating stresses. Fundamentally the steel fatigue models are sub-divided into S-N models—based on experiments- and fracture mechanic models.

A classic formulation is represented by the Basquin equation, which describes a linear relationship between lnN_F and $ln\Delta S$.

$$N_F = C_1 \cdot \Delta S^{-m_1} \tag{4}$$

C_1 and m_1 are material parameters and are defined by experiments.

The theory of linear damage accumulation goes back to Palmgren (Palmgren 1924). The Palmgren-Miner law is based on the assumption of linear and interaction-free damage accumulation. The damage accumulated after N cycles is independent of the order in which the stress cycles occur. The damage increment for each cycle has the stress range ΔS_i.

$$\Delta D_i = \frac{1}{N_{F,i}} \tag{5}$$

$N_{F,i}$ is the number of cycles to failure for ΔS_i as given by the associates SN-curve. The total accumulated damage after N cycles can be described as follows:

$$D_{tot} = \sum_{i=1}^{N} \Delta D_i \tag{6}$$

Fatigue failure is reached when D_{tot} reaches a specific value, here expressed as Δ. Generally, Δ is modelled with the mean value 1. Subsequently, the SN fatigue limit state function can be described:

$$g_{SN} = \Delta - D_{tot} \tag{7}$$

The particular stress ranges and number of stress cycles are commonly application specific. Considering the distribution those two parameters can often be approximated by a Weibull or Rayleigh distribution. The Weibull distribution is a good description for natural processes related to dynamic response of elastic system—e.g. marine structures (Almar-Naess 1984) or wind turbines (Ziegler, Muskulus 2016a).

Generally, the described empirical fatigue design laws and models inherit obviously many uncertainties. The three general uncertainties in the empirical fatigue design approach are:

- Uncertainty of the fatigue model (SN-curve)
- Uncertainty of the fatigue resistance (uncertainty on the applied SN curve)
- Uncertainty about the loading and monitoring sensors

An applicable limit state function for the fatigue design state of a steel structure can be found in (Straub 2014) and is expressed as follows:

$$g_{SN} = \Delta - \nu TE\left[\Delta D_i\right] \tag{8}$$

The fracture mechanic approach is opposed to the SN-model approach. The theory implies the initiation and gradual development and propagation of small cracks in the microstructure due to cyclic loads. In practice, the crack propagation mechanism is often combined with corrosion mechanisms.

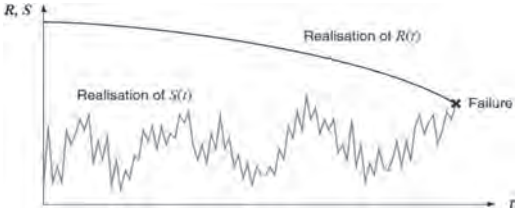

Figure 4. Stress and resistance of a structural system in time.

Table 1. Generic steel SN-fatigue model (Straub 2014).

Param.	Dimension	Distrib.	Mean	COV
Δ	–	LogN	1	0,3
v	yr^{-1}	Det	10^7	
T_{SL}	yr	Det	40	
$k_{\Delta S}$	Nmm^{-2}	Det	7,448	
B_S	–	LogN	1	0,25
$\lambda_{\Delta S}$	–	Det	0,9	
C_1	$(Nmm^{-2})^{m1}$	Lognormal	4,48e12	0,51
m_1	–	Det	3	
m_2	–	Det	5	
N_q	–	Det	10^7	
N_0	–	Det	∞	
d	mm	Det	16	

($FDF = 2$).

The fracture mechanic fatigue models introduce a stress intensity factor, which is derived from load intensity and crack length, and is the predominant control of crack propagation. Fatigue crack growth models are usually based on the linear elastic fracture mechanic theory.

The evolution or lifetime of a crack can be divided in three stages:

- Initiation → Number of cycles spent in that phase → N_I
- Propagation → Number of cycles spent in that phase → N_P
- Failure → Total number of cycles N_F → analogous to the SN-approach

$$N_F = N_I + N_P \tag{9}$$

For the purpose of deterioration control, an innovative concept for wind turbine structures is to combine the SN-model approach with the fracture mechanics approach to a hybrid probabilistic model, which describe the fatigue crack dimension at any time during the service life of a wind turbine.

The SN-model approach represents all the design assumptions that have been made to design the structural element resistant to fatigue damage. On the other hand, the fracture mechanics approach is basically suitable for in-service deterioration control of structural elements, crack width and crack length can be measured by non-destructive testing methods—e.g. ultrasound or magnaflux.

In every model calibration, a measure of how well a particular calibration fits has to be introduced. The SN-model gives information on whether a hot spot has failed or survived, whereas the FM-model gives the crack dimension after any number of cycles. Therefore, the FM-model has to be calibrated to the SN-model after the number of cycles to failure the critical crack size is reached in the FM-model.

The parameters to which the model should be fitted are random. In engineering theory there exist already a few calibration algorithms as state of the art.

Considering the described facts Straub (Straub 2014) developed a hybrid solution for a calibration of the SN-model to the FM model. The probability distribution of $F_{N_F}(N)$ is equivalent to the probability of failure p_f as a function of the number of cycles.

$$p_F(N) = F_{N_F}(N) \tag{10}$$

The actual calibration is performed by a least-square fitting in β-space.

$$\beta = -\Phi^{-1}(p_f) \tag{11}$$

A minimization with respect to the parameters of the fracture mechanics model $x_1 \ldots x_N$ is carried out.

$$\min_{x_1 \ldots x_N} \sum_{t=1}^{T_{SL}} \left(\beta_{SN}(t) - \beta_{FM}(t; x_1 \ldots x_N)\right)^2 \tag{12}$$

with

- $\beta_{SN}(t)$ as the reliability at time t using the SN-model
- $\beta_{FM}(t; x_1 \ldots x_N)$ as the reliability at time t using the FM model

The evaluation of reliability indexes is performed by a FORM or SORM algorithm. The choice of parameters to be calibrated depends on the applied FM-model. Generally, two parameters have to be calibrated. First, the crack growth rate parameter, which has a large influence on crack growth, and the second parameter for which least information is available, but influences the structural reliability.

A solution for the one-dimensional crack growth model can be expressed as follows:

$$C_P \cdot \Delta S^{m_{fm}} \cdot (N - N_I) = \int_{a_0}^{a} \frac{dz}{Y_G(z)^{m_{fm}} (z \cdot \pi)^{m_{fm}}} \tag{13}$$

It follows:

$$a(N) = \left(a_0^{(2-m_{f_m})/2} + \frac{2 - m_{f_m}}{2} C_P \left(Y_G \pi^{1/2} \Delta S\right)^{m_{f_m}} (N - N_I) \right)^{2/(2-m_{f_m})}, m_{f_m} \neq 2 \tag{14}$$

Ziegler (Ziegler, Muskulus. 2016b) is also conducting research in analyzing the application of risk-based inspection methods for deterioration control of offshore supporting structures.

4 CONCRETE FATIGUE PROCESS

In the field and onshore a tremendous amount of hybrid supporting structures currently exists, which combine a pre-stressed concrete part as lower tower section with a conical steel part as tower top; a holistic research approach also has to consider fatigue performance indicators of concrete elements, which can be measured by NDT techniques in field.

Thiele (Thiele 2016) conducted a study on suitable fatigue performance and damage indicators for concrete specimen in the framework of his doctoral thesis. A main finding relevant for the research here is, that the E-Modulus tends to fit as a fatigue performance indicator for concrete structures. Besides the E-Modulus Thiele investigated deformations, cycle counts, and micro cracks as potential fatigue performance indicators. Ultrasound amplitudes showed a high sensitivity to the damage evolution in the concrete specimen. In both cases scattering in the measurement campaign was relatively low compared to other measurement principles, e.g. sound emission measurements.

Ultra sound measurement has the advantage as an in-service inspection technique since measurements can be carried out while the structural element is in service without a special load slope or any other special preparations. However, it must be assured that the coupling of the ultrasound sensors is appropriate.

In a current research project—called MISTRAL-WIND – at the Chair of Non-Destructive Testing at the Technical University of Munich, more sophisticated experiments considering those findings will be run in January 2018 (Geiss, et al. 2017).

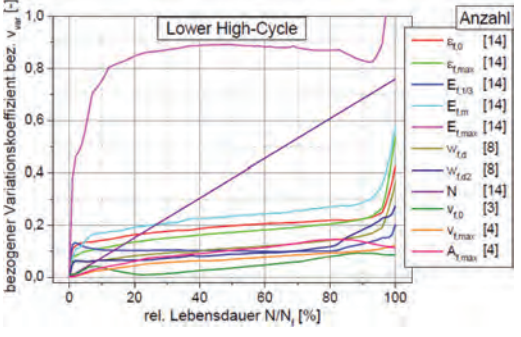

Figure 5. Variation coefficient of several physical fatigue damage indicators over the relative life time of a concrete specimen (Thiele 2016).

5 RISK-BASED INSPECTION PLANNING

The concept of risk based inspection planning inherits the primary goal of quantifying the effect of inspections on the risk condition of a component and thus enables cost optimal inspection planning. Given the fact that design deterioration laws represent imperfect knowledge considering the component's in-service deterioration process, risk-based inspection planning is a suitable method for deterioration control. Madsen showed one of the first applications of the concept (Madsen, Krenk, Link 1986).

The method of uncertainty quantification has two main objectives, first the quantitative characterization of uncertainties, and second the reduction of uncertainties. Inspections can reduce uncertainties and update the incomplete knowledge of the structural state, which can be described as an epistemistic uncertainty. In many applications in structural asset management, inspections can be a cost-effective risk reduction measure. Empirical statistics for structural systems are rarely available since every structure is more or less unique. Therefore professional experience with structural failures is scarce. A first approach in this direction is represented by the WInD-Pool project (WIndPool 2017). Qualitative estimations of the probability of failure are not suitable. Eventually risk-based inspection planning has to seek the equilibrium between a desired level of reliability and the cost optimal allocation of maintenance activities in a holistic life cycle asset management framework.

6 RISK-BASED INSPECTION ALGORITHM

In many practical situations, the conditional probability of specific events is of interest, meaning the probability of occurrence of event E2 given the occurrence of Event E1. This classical probabilistic dependency is generally handled with Bayes' rule (Faber 2007):

$$P(E_2 \mid E_1) = \frac{P\left(E_1 \cap E_2\right)}{P\left(E_1\right)} = \frac{P(E_1 \mid E_2)P\left(E_2\right)}{P\left(E_1\right)} \qquad (15)$$

From this basic equation, one can derive basic and important definitions for the RBI framework:

- $P(E_1|E_2)$ is the likelihood measure for the amount of information on E_2 gained by knowledge of E_1. The likelihood measure is typically used to describe the quality of an inspection.

- $P(E_2|E_1)$ is known as the posterior probability of occurrence of E_2 or its updated occurrence probability.
- $P(E_2)$ is the prior probability of Event E_2, prior to the knowledge of E_1.

In the probabilistic RBI framework different inspection outcomes or results are possible. Those different inspections results will trigger different maintenance actions, which are also described by limit state functions.

As relevant inspection outcomes in the RBI framework the following outcomes can be defined:

- Event of indication of a defect I
- Event of detection of a defect D
- Event of false indication FI
- Event of a defect measurement with a measured size s_m

7 INSPECTION MODELLING

The number of inspection performance models today is limited, because round-robin tests for empirical models are expensive and empirical models for one application cannot be transferred to other applications. Straub and Faber (Straub, Faber. 2002a, Straub, Faber. 2002b, Straub, Faber. 2003) developed quantitative models for a risk-based inspection framework using Bayesian updating techniques.

The performance of a non-destructive inspection is dependent on many parameters.

- Defect size and geometry
- Defect orientation
- Environmental condition
- Sensitivity of the inspection method
- Sensitivity of the sensors
- Sensor placement
- Accessibility of the structure tested
- Inspector performance
- etc.

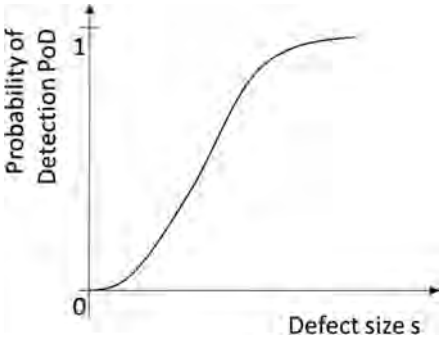

Figure 6. Probability of detection vs. defect size.

The probability of detection (POD) is the mean rate of success when the specific inspection technique is performed and is exposed to various sources of uncertainties. One and two dimensional POD models are typically used for the analysis.

Because the POD-function is a monotonically increasing function, the probability of detecting a crack smaller than or equal to the size s is $POD(s)$. $POD(s)$ becomes 1 for very large crack sizes.

The classical approach of the POD formulation has some shortcomings. The POD-function must be a distribution function, which is not always the case in reality. Furthermore it is difficult to integrate the two dimensional POD-functions.

Uncertainties inherited in the inspection performance models are:

- Variability due to scatter in the response signal (aleatory uncertainty)
- Statistical uncertainty due to limited set of trials in experimentally determined POD/POI models (epistemic)
- Model uncertainty due to empirical nature of the parametric model (epistemic)

Straub and Faber (see citations above) analyzed the aleatory and epistemic uncertainty sources in such models in more detail. Jüngert and Kurz (Kurz, et al. 2011) conducted a research study concerning the POD performance of ultrasound NDT tests. POD performance test represent a considerable bottleneck in bringing probabilistic approaches in practical and reliable applications.

8 DECISION ANALYSIS

The ultimate goal in the decision analysis process is the identification of optimal decisions on maintenance actions for deteriorating structures. The decision environment is subjected to uncertainty under the following aspects:

- Uncertainty on the state of the system; state of deterioration
- Uncertainty on the performance of the inspection; probability of detection (POD)
- Uncertainty on the performance of repair actions
- Uncertainty on the consequences of failures

One method of evaluating such decision problems is through the deployment of so-called decision trees. Each path of the decision tree is assigned with a utility value and its probability characteristics. Considering the point in time and informational characteristics of the decision problem three basic situations can be defined.

1. The prior analysis represents a decision analysis with given information. At this state, the utility

function and the probabilities of the various states of nature corresponding to the different consequences have been defined. The decision analysis is reduced to the computation of the expected utilities and finding the optimal point of the optimization problem.
2. The posterior decision analysis represents a decision analysis problem with additional information on the state of nature. If additional information becomes available—e.g. through inspections—the probability structure in the decision problem can be updated. The probability update is carried out using Bayes' rule.
3. The pre-posterior analysis represents a decision analysis situation dealing with unknown information. The decision maker has the possibility to buy additional information through an experiment. If the cost of this information is small in comparison to the potential value of information, the experiment should be performed. If several experiments are potentially suitable, the decision maker has to choose the experiment yielding the overall largest utility for his decision problem.

As a first step a set of possible events will be defined, E_1 to E_n. Those events can be compared with different outcomes of a game. Events with a large index are preferred over other events with a lower index. The decision maker can choose different actions also called lotteries. Each action will lead to probabilities of occurrence for different events. E.g., action a will lead to Event E_1 with the probability $p_1^{(a)}$ and to Event E_2 with the probability $p_2^{(a)}$. Action b will lead to event E_1 with the probability $p_1^{(b)}$ and so forth.

All probabilities of occurrence have to fulfill the basic condition: $p_1^i + p_2^i + p_n^i = 1$.

The utility index is used to express specific preferences of the decisionmaker, in such a way that one decision is preferred to another if the expected utility of the former is larger than the utility of the latter. A utility index u can be assigned to the different basic events E_1 to E_n.

The final optimization criterion is the expected cost criterion. The utility index u is linearly assigned to monetary for the considered range of events. The indirect costs associated with the failure events and repair and inspection are included in the probabilistic modelling. Thus, all consequences of an event have to be expressed in monetary terms, which can also introduce weakness in the approach due to lack of reliable information on monetary consequences,.

The pre-posterior decision analysis has the intention to identify the optimal decision on possible inspection actions, enabling optimal maintenance planning.

Concerning the inspection actions it has to be determined:

- Where to inspect → location of inspection
- What to inspect → indicator of the system state
- How to inspect → what kind of inspection technique
- When to inspect → time of inspection

The inspected costs of an inspection strategy have to be determined. Initially, the number of decision tree branches to consider is evaluated:

$$n_b = n_a^{n_{Insp}} + \sum_{i=0}^{n_{Insp}} n_a^i \tag{16}$$

9 INSPECTION COST MODEL

The inspection cost model integrates the following cost parameters

- Expected costs of failure C_F
- Cost of inspection as a function of inspection technique e_i at time t
- Cost of repair C_R
- Interest rate r

The total expected costs during the service life period T_{SL} is computed as the summation of the expected failure costs, the expected inspection costs and the expected repair costs:

$$\begin{aligned} E\left[C_T\left(\underline{e},d,T_{SL}\right)\right] &= E\left[C_F\left(\underline{e},d,T_{SL}\right)\right] \\ &+ E\left[C_I\left(\underline{e},d,T_{SL}\right)\right] + E\left[C_R\left(\underline{e},d,T_{SL}\right)\right] \end{aligned} \tag{17}$$

The decision rule has a significant influence on the cost function. A short compilation of possible maintenance decision rules can look like:

1. Repair all defects indicated at the inspection
2. After indication perform a measurement and repair only cracks deeper than a_R
3. Etc.

For the optimization procedure a maximum annually probability of failure is allowed Δp_F^{max}:

$$\begin{aligned} &min_{e,d} E\left[C_T\left(\underline{e},d,T_{SL}\right)\right] s.t. \\ &\Delta p_F\left(\underline{e},d,t\right) \le \Delta p_F^{max} \; t = 0,\ldots T_{SL} \end{aligned} \tag{18}$$

However, this optimization procedure inherits to major restrictions:

- The minimum analysis period is one year
- The calculation of total service life is prohibitive

To level out the latter restriction, two simplification approaches are possible, the constant threshold approach and the equidistant inspection time approach (Straub 2004).

Applying the constant threshold approach, the optimization parameter is the annual probability of failure $\Delta p_F{}^T$ and inspection is always performed in the year before $\Delta p_F{}^T$ is exceeded. It follows as new optimization problem:

$$min_{e,d,\Delta p_F{}^T} E\left[C_T\left(\underline{e}, \Delta p_F{}^T, d, T_{SL} \right) \right] s.t. \Delta p_F{}^T \leq \Delta p_F^{max} \tag{19}$$

In that way an RBI-based approach can be deployed a holistic and effect structural health monitoring and management strategy, which combines design information with realistic in situ performance measurements using non-destructive testing techniques.

10 OUTLOOK

The author's future research will focus on integrating the RBI-approach into the overall asset management strategy of wind turbine systems as well as developing, validating and maturing the approach in in situ and laboratory tests. Laboratory experiments will be undertaken on broadening the understanding of applicable fatigue performance indicators of concrete structures under the influence of fatigue loading, which can be measured with ultrasound based NDT techniques.

Furthermore, validated methods and concepts can be broadened to other civil engineering structures that have a high demand of cost-optimal allocation of maintenance activities, such as bridges.

Last but not least it has to be considered how far such models are capable of integrating combined effects of deterioration mechanisms, e.g., corrosion and fatigue deterioration and their interaction.

ACKNOWLEDGEMENT

This research was partly funded by the Federal Ministry for Economic Affairs and Energy. Furthermore, the help of Prof. Grosse as co-author and Prof. Glaser from UC Berkeley through the preparation of this article is gratefully acknowledged.

Optimising the maintenance strategy for a multi-AGV system using genetic algorithms

R.D. Yan, S.J. Dunnett & L.M. Jackson
Loughborough University, Loughborough, Leicestershire, UK

ABSTRACT: Automated Guided Vehicles (AGVs) are playing increasingly vital roles in a variety of applications in modern society, such as intelligent transportation in warehouses and material distribution in automated production lines. They improve production efficiency, save labour cost, and bring significant economic benefit to end users. However, to utilise these potential benefits is highly dependent on the reliability and availability of the AGVs. In other words, an effective maintenance strategy is critical in the application of AGVs. The research activity reported in this paper is to realise an effective maintenance strategy for a multi-AGV system by the approach of Genetic Algorithms (GA). To facilitate the research, an automated material distribution system consisting of three AGVs is considered in this paper for methodology development. The movement of every AGV in the multi-AGV system, and the corrective and periodic preventive maintenances of failed AGVs are modelled using the approach of Coloured Petri Nets (CPNs). Then, a GA is adopted for optimising the maintenance and associated design and operation of the multi-AGV system. From this research, it is disclosed that both the location selection of the maintenance site and the maintenance strategies that are adopted for AGV maintenance have significant influences on the efficiency, cost, and productivity of a multi-AGV system.

1 INTRODUCTION

AGVs are increasingly used in modern society attributed to their high efficiency, accuracy, low cost and therefore significant economic benefit (Tuan, 2006).

However, with the emerging trend in modern society for AGVs designed for more complex tasks they have become larger and larger in size, where the reliability and maintenance issues in recent years are receiving increasing concern. However, to the author's best knowledge, so far there has not been sufficient research being conducted in this area except a few preliminary researches (Vis, 2006). For example, three major hazards, i.e. collision, tilting over and falling, have been identified during the operation of AGVs (Trenkle, 2013); as well as a combined Markovian model and a neural network were applied to maximise the reliability of AGVs and minimise their repair cost at the same time (Fazlollahtabar, 2013). Little research has been conducted to deal with the maintenance issue of failed AGVs except using a control method for enhancing the failure control management of both loaded and unloaded AGVs in an underground transportation system (Ebben, 2001). For this reason, the purpose of this research is to fill this technology gap through developing an optimal maintenance strategy for a typical multi-AGV system. At present, preventive and corrective maintenance are two basic strategies that are popularly adopted in engineering practice (Smith et al., 1973). In the past decades, there have been a number of research studies conducted to optimise the maintenance strategies dedicated to various kinds of industrial applications. For example, a simulation was carried out to evaluate the performance of manufacturing production lines with different maintenance policies (Lei, 2010); The maintenance cost and availability of an aircraft system was optimized using a mathematical replacement model (Fornlöf, 2016) and so on.

In this paper, both preventive and corrective maintenance strategies dedicated to a multi-AGV system are studied by the combined use of a Coloured Petri nets (CPN) simulation model and a specifically designed Genetic Algorithm (GA) model.

The remaining part of the paper is organised as follows. A brief description of the multi-AGV system considered in the paper is given first in Section 2; the potential of the CPN in describing the paths, routing and maintenance issues of the AGVs is explored in Section 3; the maintenance strategy of the multi-AGV system is optimised with the aid of GA in Section 4; and the paper is finally ended with a few key research conclusions in Section 5.

Table 1. Presumed time duration of every phase.

Phase	Phase length (hours)
1	0.02
2	0.2
3	0.02
4	0.2
5	0.02
6	0.2

2 CONFIGURATION OF THE MULTI-AGV SYSTEM

The AGV transport system described in (Yan, 2017) is also considered in this research. However, instead of considering a single AGV, a more complicated transport system consisting of three AGVs will be investigated in this paper. This will allow the investigation of the interactions between different AGVs and the impact of the failure of either one or more AGVs on the operation of the others in the same transport system. In addition, it is worth noting that in this research the subsystems of the individual AGVs are assumed to fail 12 times every year, as cited in (Yan, 2017). The mission of the AGVs is divided into six phases, namely (1) mission allocation and route optimization, (2) dispatch to station, (3) loading of item, (4) travelling to storage, (5) unloading and (6) travelling back to base. In order to facilitate the research, the time duration of every phase is presumed and listed in Table 1 for demonstration purpose. They would be different when the AGV is requested to deliver different types of missions.

In the model, it is assumed that the AGV will be taken away from the system immediately to prevent deadlock and conflicts as long as it fails, so that the downtime of the system due to AGV failures can be minimised. To meet such a need, it is essential to optimise the location of the maintenance site in the system to enable the recycle vehicle (the vehicle collecting the failed AGV) to reach and recycle the failed AGV in the shortest time.

3 SIMULATION MODELLING

3.1 *Coloured Petri Nets (CPNs)*

Attributed to the unique efficiency and cost-effectiveness features, modelling has been identified as one of the most important approaches to improve the design and operation of a system. In particular, a Petri net (PN) is regarded as one of the most economic and effective tools to model AGV systems (Wu, 1999; Nishi, 2010). The concept of a PN was developed by Petri (1962), which is a direct bipartite graph. It consists of four types of symbols, i.e. circles, rectangles, arrows and tokens, as shown in Figure 1. Where, circles represent the places, which may be conditions or states (e.g. mission failure, phase failure, or component failure); rectangles represent the transitions, more abstractly actions, or events which cause the change of condition or state; Arrows connect places and transitions; Tokens are small marks that gives dynamic properties of the PN. They move via transitions if the enabling condition is satisfied. It provides an intuitive graphical representation of a system and allows flexible description of events.

What Figure 1 shows is an example explaining how the tokens move through a net. From Figure 1a, it is seen that there are two inputs and one output place connected to a timed transition with a time delay t. The input places have arcs with weights 2 and 1, respectively. Once the transition is enabled after the time delay, t, the arc weight number of tokens will be taken out from the corresponding input place to fulfil the transition after the time delay t associated with the transition. For the example, as Figure 1b shows, one more token will appear in the output place.

However, conventional PN methods are found inefficient in describing complex systems or describing a system that is designed to carry out complex tasks or missions (Jensen, 2015). To address this issue, a more advanced PN method, namely Coloured Petri nets (CPN), was proposed by Rene (1994). In comparison with the conventional PN, each individual token in the CPN is designed with a specific colour, which either has different identities or carries different information. Therefore, they are more informative than those present in the conventional PN.

3.2 *System modelling*

In a multi-AGV system, every AGV need to be distinguishable as they may be located at different positions in the transport system and may fail at different times. In view of the powerful capability of CPNs in describing the kind of complex situations (Wu, 2002; Aized, 2009), CPN is employed in the following research.

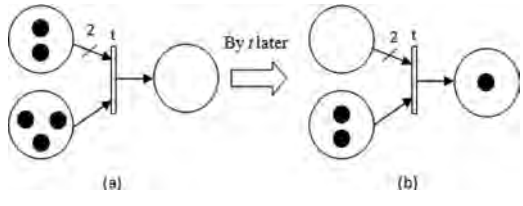

Figure 1. Enabling and switching of transition, (a) before enabling transition, (b) after enabling transition.

To correctly describe the operation and maintenance activities in a multi-AGV system, three types of CPN models are purposely developed and detailed below:

1. Path Petri nets (PPN) – for describing the layout configuration of the system;
2. Corrective maintenance Petri nets (CMPN) – for defining the corrective maintenance of failed AGVs in the system;
3. Periodic maintenance Petri nets (PMPN) – for defining the periodic maintenance of all AGVs in the system.

Herein, the CMPN and PMPN share the AGV failure information and feed their responses into PPN.

3.2.1 *PPN*

A three-AGV dispatching system is considered in this paper. It consists of 1 AGV base, 1 pickup station, 1storage site, 1 maintenance site, and a number of transport paths. The base is for storing and recharging the AGVs; the pickup station is the place where items are collected; and storage is the destination for unloading the items. All these places are assumed to have sufficient space for parking multiple AGVs. To demonstrate the significant influence of layout configuration on the efficiency of recycling failed AGVs from a multi-AGV system, three different layout configurations are considered, as shown in Figure 2. Where, MS indicates the location of the maintenance site.

From Figure 2, it is seen that different layout configurations are distinguished by the different locations of maintenance site and the extra paths for recycling failed AGVs. For example, in Figure 2a the maintenance site shares the same space with the base; in Figure 2b the maintenance site is located between the base and the storage. In addition, an extra path between the pickup station and the maintenance site is designed to prevent deadlock caused by the breakdown of AGVs; in Figure 2c the maintenance site situates at the centre of the system. Accordingly, three extra paths are designed to assure its accessibility to the AGVs that could fail at anywhere of the system. Based on the aforementioned designs, the PPN models for these three different layout configurations can be readily constructed by defining the movement directions of the AGVs. For example, the PPN for the configuration in Figure 2b is shown in Figure 3, where only one direction of movement is enabled, and the dotted arrows represent the information flows coming from other CPNs. The tokens in the figure represent AGVs. Once the required action is completed a token from other CPN enables the corresponding transitions.

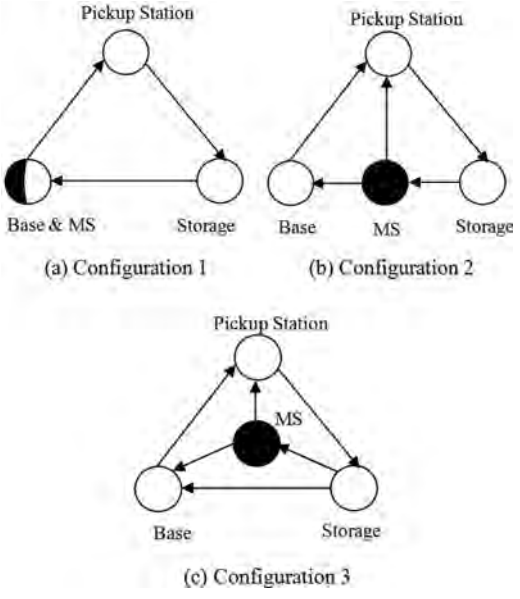

Figure 2. Three layout configurations.

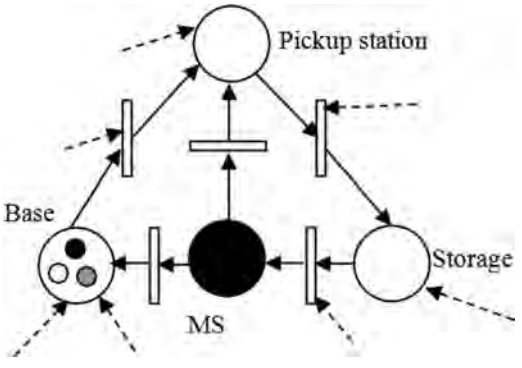

Figure 3. PPN for the configuration in Figure 2b.

Then, the AGV token with the same colour can move to the place of the next station.

3.2.2 *Corrective Maintenance Petri Nets (CMPN)*

Once the failed AGVs are recycled and towed back to maintenance site, the corrective maintenance will be implemented immediately if the maintenance engineers are available to work on the failed AGV. However, once the maintenance engineers are unavailable, the failed AGVs will have to queue. On completing the corrective maintenance, the recovered AGV will be assumed having a perfect condition as a brand new one does. In the meantime, the maintenance engineer who undertakes

the repair of this AGV will be released. They will become available to undertake the repair of other failed AGVs. In the model, a normal distribution function is employed to describe the repair time of the failed AGVs. The developed CMPN model is shown in Figure 4. Once a token exists in both 'Failed AGVs recycled' and 'Available engineering' places, the token will be produced in 'under repair' place. Following the repair process, the AGV will be back to the healthy state. This will be indicated by a token produced in the 'Up' place.

3.2.3 *Periodic Maintenance Petri Nets (PMPN)*
A PMPN model that considers periodic maintenance has been developed and is shown in Figure 5. Likewise, in this model the recovered AGVs are assumed having perfect health condition as a new one does.

It is worth noting that in the model shown in Figure 5 the three transitions with different colours indicate the failure time of the three AGVs in the system. For the simplification, a simple corrective maintenance policy is taken in this research, i.e. all AGVs in the system will receive periodic maintenance in spite of their actual health condition. Moreover, the corrective maintenance will last only for 2 days regardless of the actual condition of the AGVs. For example, in Figure 5 it is assumed there are *m* AGVs in healthy condition and n AGVs in faulty condition. The healthy AGVs are in 'Up' place and faulty AGVs are in 'Failed AGVs recycled' place. Regardless the actual health status, all AGVs will receive periodic maintenance. Therefore, there will be *m+n* tokens in 'Periodic Maintenance' place. Accordingly, all AGVs in the system will not start to work until the 2-day period of corrective maintenance expires. On the expiry of the period of corrective maintenance, all AGVs in the system are assumed to have perfect health condition as a brand new one does.

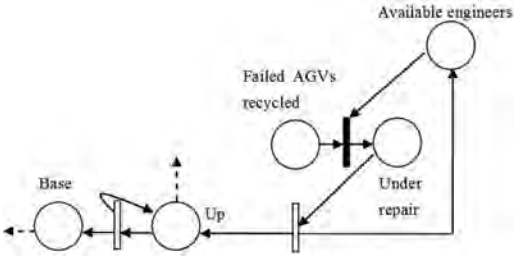

Figure 4. CMPN model.

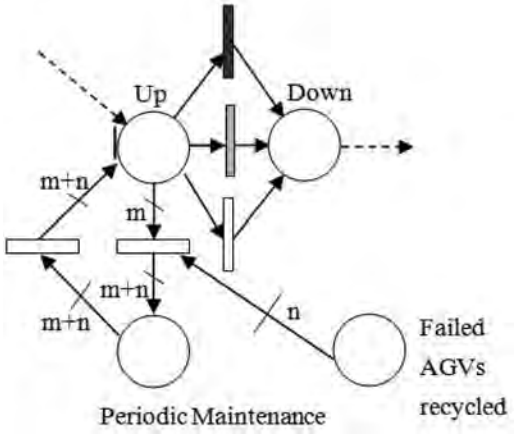

Figure 5. PMPN model.

3.3 *Simulation results*

By integrating the above CPN models, a more comprehensive model can be readily obtained, which not only considers the specialities of the layout configuration but also considers the maintenance processes of the AGVs. In order to verify the model and investigate the influences of different maintenance strategies on the operational performance of a multi-AGV system, an algorithm has been developed to simulate the comprehensive model, the input variables of which include the failure rate and repair rate of all AGVs, the time taken to perform periodic maintenance, and phase lengths that are required by the AGVs to deliver assigned tasks.

Firstly, the influence of different layout configurations on the recycle time of failed AGVs is investigated. In the layout configurations described in Figure 2b and c, separate maintenance sites are designed. Such a design significantly reduces the risk of conflict and deadlock and therefore improves the efficiency of the recycle process, although with the cost of extra space and extra routes to enable the operation of such a design. The simulations considering all three types of layout configurations are performed and the corresponding recycle time calculation results are listed in Table 2. From the table, it is found that when the maintenance site is placed in the centre (see Figure 2c), the recycle time will be the minimum.

Subsequently, the influence of different maintenance strategies on the performance of the multi-AGV system is investigated. Assume the operation time of the system is 10 hours per day, the corresponding simulation results obtained for the layout configuration illustrated in Figure 2b are listed in Table 3. In the table, the number of missions completed is employed as a criterion for performance assessment.

From Table 3, it is found that if without applying any maintenance strategy within the period of

Table 2. Recycle time.

Location indicated by	Recycle time (hours)	Extra space (unit)	Length of extra route required (unit)
Figure 2a	0.132	0	0
Figure 2b	0.128	1	$\sqrt{3}/2$
Figure 2c	0.101	1	$3\sqrt{3}/4$

Table 3. Number of completed missions.

T	P	N1	N2
7 days	0.03	11518	11840
1 month	3.93	12840	15264
3 months	36.32	9372	15972
6 months	77.34	6084	16142
12 months	98.06	3280	16234

Note: T—Time interval of periodic maintenance; P—Percentage of AGVs failed within the time interval if there is no maintenance (%); N1—Number of missions completed per year with periodic but without corrective maintenance; N2—Number of missions completed per year after taking both periodic and corrective maintenance.

12 months, 98% of AGVs will fail after completing 3280 missions. This fully highlights the added value and the necessities of conducting appropriate maintenance to the AGVs during their service life. Moreover, the larger values of N2 than the corresponding values of N1 prove that the corrective maintenance can actually enhance the performance of the multi-AGV system, i.e. the corrective maintenance can help to keep long-term high efficiency of the system, although it could cause extra financial and labour costs.

4 OPTIMISATION OF MAINTENANCE STRATEGY

4.1 *Genetic algorithm*

The results obtained from the CPN simulations can be used as factors for optimising the maintenance strategy of the AGV system. Since the resultant optimal maintenance strategy is desired to lead to a cost effective and time efficient operation of the multi-AGV system, the optimisation considered in this research becomes a typical multi-objective optimisation problem. In the paper, Genetic Algorithm (GA) is employed to carry out the optimisation. Nowadays, the GA has been regarded as one of the most popular tools to solve this kind of multi-objective optimisation problem attributed to its powerful capability of conducting optimisation in a global range regardless of initial conditions and other derivative factors. Inspired by the biological evolution of living species, GA was first introduced by John Holland in 1970s (Holland, 1975). GA has been well applied for solving the scheduling and dispatching problems to AGV systems. For example, Reddy and Rao applied GA to minimise the makespan, mean flow time and mean tardiness at the same time (2006). A GA based simulation approach was proposed to find the optimal dispatching rules in complex environments (Chang et al., 2013).

To implement the GA optimisation, an initial population of individuals (also known as chromosomes consisting of genes) will be generated. The fitness of each chromosome is evaluated subject to the predefined objective functions. By selecting pairs of parents in the population, new chromosomes or children can be generated. This is known as crossover. The chromosomes with the higher fitness are more likely to be selected so that their genes can be passed on with higher probability. A mutation might also be involved to prevent early convergence of the solution. Through repeating such a process, the chromosomes with larger fitness values can be obtained until an optimal solution is reached.

4.2 *Fitness functions*

Following this idea, a GA program is developed in the research to optimise the multi-AGV system. The flowchart of the GA program is shown in Figure 6. The parameters used in the calculation are listed in Table 4. The following two objective functions are defined to optimise the system design:

Objective function 1: The maximum number of missions completed within a given time

$$Mission = \max\left(N_m \cdot N_p - T_{rc} \cdot N_f / T_m\right) \tag{1}$$

Objective function 2: The minimum cost for completing the missions

$$Cost = \min\begin{pmatrix} N_a \cdot N_p \cdot C_p + N_f \cdot C_c + N_e \cdot C_e + \\ C_{ms} + N_m \cdot C_a + L_r \cdot C_r + C_{lm} \end{pmatrix} \tag{2}$$

where $N_P = 365/T$ is based on the assumption that there are 365 days in a year.

Based on the aforementioned two objective functions, a fitness function is developed as

$$fitness = \frac{Mission}{Cost} \tag{3}$$

The maintenance strategy is optimised subject to:

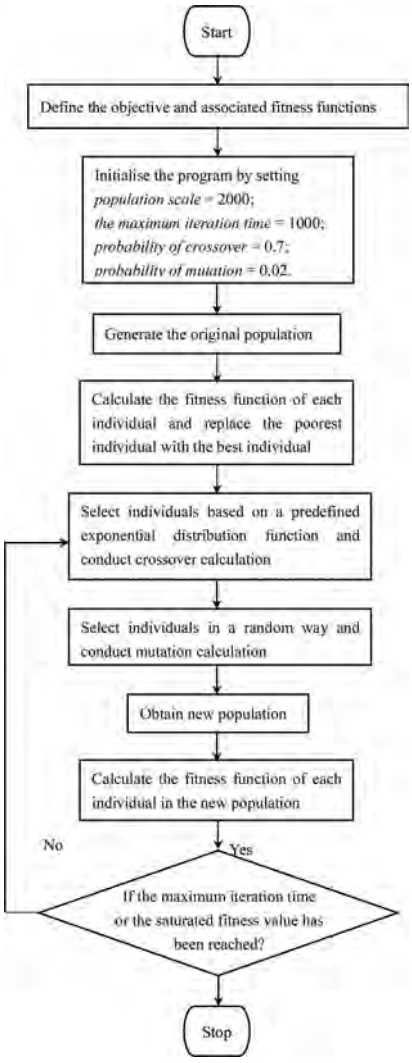

Figure 6. Flowchart of the GA based optimisation program.

$$number\ of\ mission\ completed \geq 10000 \quad (4)$$

$$probability\ of\ all\ AGVs\ failed \leq 0.1 \quad (5)$$

where, equation (4) means that the number of missions required to complete within one year is not less than 10,000; equation (5) means that the probability of all AGVs fail is not larger than 10%.

4.3 *Selection*

In the program, an exponential function is specifically defined for simulating the 'survival of the fittest' principle in natural evolutionary process. For the i-th individual, its probability P_i being selected for participating in GA crossover calculation can be expressed as:

$$P_i = \frac{e^{w(f_i - f_{\min})}}{\sum_{j=1}^{N} e^{w(f_j - f_{\min})}} \times 100\% \quad (6)$$

Table 4. Parameters used in GA program.

Parameters	Symbol	Value
Number of AGVs	N_a	3
Operation cost of an AGV to complete a single mission	C_a	8
Business costs of maintenance site per year	C_{ms}	10000 – with corrective maintenance 5000 – without corrective maintenance
Land cost for maintenance site per year	C_{lm}	1000 – Share site with AGV base 5000 – Separate site
Number of missions competed per year	N_m	See the values of N1 and N2 in Table 3
Time interval of periodic maintenance	T	See the values of T in Table 3
Periodic maintenance cost per AGV	C_p	400
Recycle time	T_{rc}	See the values of recycle time in Table 2
Average time to complete a mission	T_m	0.66
No. of maintenance engineers on site	N_e	1
Cost of one Engineer in a year	C_e	25000
Total number of failures occurring in the system with corrective maintenance per year	N_f	14 (results obtained using PN)
Average cost for conducting corrective maintenance of an AGV failure	C_c	200
Extra route length	L_r	See the values of Length of extra route required in Table 2
Cost of per unit length extra route	C_r	1000

where N denotes the size of population scale; f_i is the fitness of i-th individual; f_{min} is the fitness of the poorest individual; and w is a constant for controlling the efficiency of population evolution. It is worth noting that the larger the value of w, the more efficient the evolution tends to be. But it should be aware that too large a value of w would lead to risk of failure to obtain global optimisation results. In this research, w is taken to be 100.

4.4 *Coding*

It should be noted that there are three major factors, namely the period of periodic maintenance, the system configurations and the adoption of corrective maintenance. Their values are obtained from the CPN simulations. Hence the variation ranges of these factors need to be controlled by constraints. These three parameters are coded into binary numbers and then connected together to create a single 'chromosome'.

4.5 *Crossover operator and mutation operation*

The crossover operation is applied to two randomly selected chromosomes with the crossover rate of 0.7. A one-point crossover is adopted with an illustrative example shown in Figure 7.

The alternating position can be chosen at any point within the chromosomes. By combing two sets of genes from both parent generations, an offspring chromosome can be produced. The operation of mutation illustrated in Figure 8, maintains genetic diversity of the population and prevents the solutions trapping to the local best. It is also implanted with a fixed mutation rate of 0.02.

4.6 *GA results and discussion*

Using the developed GA program the location of maintenance site and the maintenance strategies of the multi-AGV system are optimised through integrating the two objective functions into one fitness function, i.e. the unit mission cost shown in equation (3). To illustrate the effectiveness of the GA optimisation, a numerical example has been taken. By applying the parameters defined in Table 4 to the program, the population starts to evolve gradually. The resultant variation tendency of average fitness against the number of evolution times is shown in Figure 9.

From Figure 9, it is found that after the population is evolved for about 200 times, the average fitness reaches a saturated value. That means the optimal design of the multi-AGV system is achieved through 200 times of evolution calculations. The optimised results are listed in Table 5.

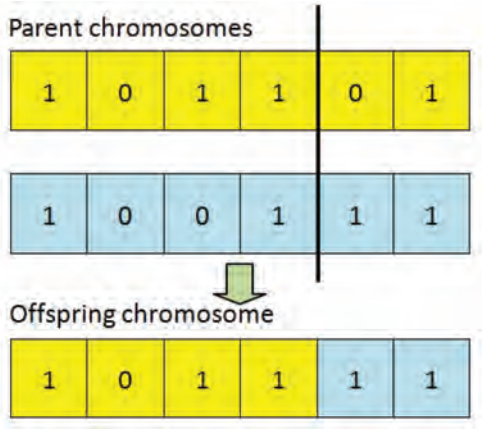

Figure 7. One-point crossover operator.

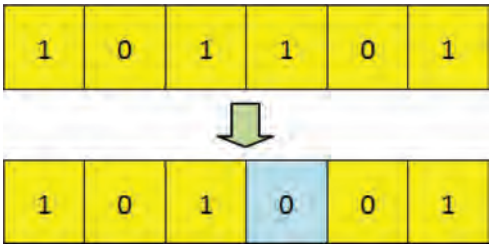

Figure 8. Mutation operator.

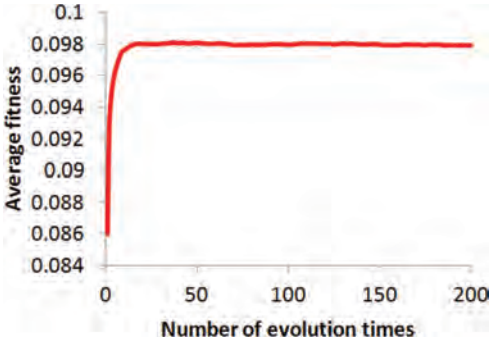

Figure 9. Evolution of GA population.

Table 5. Optimal results obtained from GA.

With corrective maintenance?	Yes
Location of maintenance site	In the AGV base
Time interval of periodic maintenance	12 months
Total cost (£)	164872
Mission completed per year	16231

From Table 5, it is found that

- The corrective maintenance is indeed essential for maintaining the long-term high efficiency of a multi-AGV system;
- Arrange the maintenance site to share the same place with the AGV base will save the cost on land, therefore result in the minimum unit mission cost;
- The positive influence of periodic maintenance on improving the performance of the system cannot be demonstrated if the ageing issue of the AGVs is not taken into account in the optimisation.

5 CONCLUSIONS

In order to develop a feasible and efficient approach to optimising the design, operation, and maintenance of a multi-AGV system, the CPN simulation models and the GA-based optimisation approach are developed in this research. From the research results described above, the following conclusions can be drawn:

1. The combined use of CPN and GA has been demonstrated an effective approach to assessing the performance of multi-AGV systems;
2. This hybrid approach enables the prediction to the optimal time interval of periodic maintenance and the assessment of the influence of correct maintenance on system efficiency;
3. The optimisation of the location of maintenance site and maintenance strategies can be skilfully converted to be a simple single objective optimisation problem with the fitness function of unit mission cost;
4. The corrective maintenance is an effective measure to maintain the long-term high efficiency of the system, although it may lead to extra maintenance costs.

Future work of this research will focus on dealing with more complex AGV systems.

ACKNOWLEDGEMENT

The work reported in this paper aligns to the working being researched as part of the EPSRC grant EP1K01413711.

A modelling methodology for the assessment of preventive maintenance on a compressor drive system

Y. Zhang, A. Barros & A. Rauzy
Department of Mechanical and Industrial Engineering, Norwegian University of Science and Technolgy, Trondheim, Norway

E. Lunde
Research and Technology, Statoil ASA, Trondheim, Norway

ABSTRACT: Huge rotary machines are commonly used in oil and gas processing plants for separation, compression and boosting. Their reliability is of high importance to avoid operation downtime and production loss. In this paper, we present a modelling methodology, based on the AltaRica 3.0 modeling language and stochastic simulation, to assess the average production level of a compressor drive system. This system consists of six trains, where each of them contributes to one sixth of the total production capacity. It runs under two operation modes (full and reduced capacity) corresponding to seasonal demand periods (winter and summer). The problem at stake is to design a model at system level that captures the various degradation processes, monitoring policies, and maintenance rules involved in the system under study. The aging of units is represented by means of multiple degradation levels. Given units information provided by monitoring and inspection, preventive and corrective maintenance interventions are decided locally to each unit. Performance indicators such as the cumulative production and production loss over a certain mission time can then be assessed. This paper contributes to the development of engineering models for maintenance assessment based on framework and patterns designed to architecting some typical oil and gas systems.

1 INTRODUCTION

Huge rotary machines are commonly used in oil and gas processing plants for separation, compression and boosting. Ensuring a high reliability of these machines is of primary importance to avoid operation downtime and production loss. As of today, this high reliability is achieved thanks to robust-by-design machines, and by rigorous preventive maintenance policies (DNV-GL-RP-002 2014, API-RP-7L 2006). Nevertheless, rigorous preventive maintenance comes with a high cost. This is the reason why the oil and gas industry is currently moving to the so-called condition-based approach (Gustavsson and Eriksen 2005, Markeset et al. 2013). In order to deploy a condition-based maintenance policy, one needs to assess its potential benefit and risk over more traditional approaches.

In this paper, we present the results of a preliminary study we made on a compressor drive system. This system consists of six trains, where each of them contributes to one sixth of the total production capacity. The system runs under two operation modes (full and reduced capacity) corresponding to two distinct seasonal demand periods (winter and summer). Maintenance interventions have to be scheduled during the low demand season where some of the trains can be stopped while still fulfilling the demand.

We present here the modelling methodology we used, together with modelling patterns and simulation experiments. This methodology relies on the AltaRica 3.0 language Rauzy (2008) and Prosvirnova (2014) and stochastic simulation. It aims at developing models that make it possible to answer questions like "Will the system survive in the coming winter without loss of production? How much can we gain/lose by changing inspection interval of this component or group of components?" and so on. The key performance indicator is the expected production loss due to failures and maintenance operations over a given time period.

The object-oriented language AltaRica 3.0 makes it possible to handle the various modelling challenges at stake: It provides mechanisms to represent faithfully the various degradation processes, monitoring policies, and maintenance rules involved in the system under study. It makes it possible to represent implicitly very large state spaces;

It facilitates information propagation through the network of components and therefore the calculation of key performance indicators; It supports the reproduction of basic patterns in order to develop models of large systems by assembling seamlessly models of components; …

The main purpose of this paper is to present this modelling framework and to illustrate its application. We report here the results of a number of experiments we performed on the model in order to run what-if scenarios. We show the various possibilities to refine and optimize inspection/maintenance policies as well as to asses their impact on the production.

The use of this study is not limited to onshore installations with given maintenance problems. It helps to improve the knowledge and decisions making with a tool for future subsea installations, as there will be more and more seabed compression with equivalent and even more complex maintenance problems.

The remainder of this paper is organized as follows. Section 2 presents state of the art of Preventive Maintenance PM in compressor drive system. Section 3 describes the use case of compressor train system and its assumptions. Section 4 introduces the modelling methodology and design of components and system. Section 5 shows numerical experiments for assessing various inspection and maintenance policies. Section 6 concludes the work and discusses future research.

2 STATE OF THE ART

Compression is a common practice in Q&G processing technology. Due to the complex configuration of a compression drive system, the control over such a system turns to be of paramount importance. This section is thus dedicated to the state of art investigation on compressor drive system which is normally composed of VSD, pump, compressor, valves and so on. Findings from for instance (Andersen et al. 2006, Eriksson and Staver 2010, Eriksson and Konstantinos 2014) and interviews with industrial partners are summarized as a preparation for our model.

2.1 *Health indicator and degradation modelling*

A typical compressor drive system is arranged with multiple trains in parallel where each train consists of a number of components (e.g. VSD, gear, compressor, valve etc.). Each of them is subject to different aging processes (e.g. fouling, wear, harmonics, unbalance) which could be revealed in several condition monitoring sources as described previously. An option to aggregate these sources to formulate a single health indicator is Technical Condition Index (TCI) (Nystad 2008, Nystad & Rasmussen 2010). It is defined to represent the degree of degradation with respect to production availability. The overall TCI value of a compressor, for instance, is aggregated from bottom-level TCI for each degradation symptom revealed by its monitoring source. Its aging measurement includes but not limited to: vibration, seal wear, bearing temperature, compressor efficiency and so on. Each of them is assigned a weight based on expert judgement about its criticality, and it is further merged upwards in the hierarchy for the total TCI of the compressor. Besides, previous maintenance actions and their impact (mainly missing or incomplete working log) can be included in the model as left truncated censoring data. Given all these inputs, a parametric hazard regression model Weibull PHM model is applied in Nystad & Rasmussen (2010) to estimate parameters in the degradation model by maximum likelihood method. Once the parameters are available, the expected Remaining Useful Lifetime (RUL) given a specific time point is tractable with certain confidence.

In this paper, we rely on an alternative solution proposed by Moholt (2016). The health indicator is a discrete variable with a finite number of possible values from new to fail. It is used by guidelines to assess the health of an equipment in a more qualitative way. Such a simplified model is aligned with the amount of data that are currently available for the case under study in this paper. Moreover, it is more adapted to our modelling framework based on discrete states.

2.2 *Intervention and maintenance modelling*

Often maintenance programs are established by project teams by each companies. They propose alternative solutions, demonstrate the advantages/disadvantages for the maintenance strategies and discuss an optimal solution with manufactures. Most components are under calendar-based maintenance together with condition-based maintenance program.

For calendar-based maintenance, the frequency, content, duration and required preparations for maintenances vary in the user manual by equipment type, size and application. The components are analysed in design phase and assigned maintenance levels (L1-L4) according to their criticality (ABB 2013). Periodic maintenance is implemented according the plan.

For condition-based maintenance, there is short term preventive maintenance plan scheduled for the next low demand season based on the input from condition monitoring and inspection. Such decisions are mainly based on experience and

expert judgement. Notice that for both maintenance interventions, there is no possibility to react immediately on any degradations/failures in the systems due to the time for preparing maintenance kits.

A risk based simulation approach (RBI) has been applied to develop maintenance strategy for subsea systems in Ormen Lange field (Gustavsson & Eriksen 2005). The lifetime scenario of the system is represented by discrete degradation/failure events happen for each component. The cost model quantifies intervention cost and production loss due to unexpected failures for the mission time. Then a variety of maintenance strategies are fed into the model to calculate desired performance indicators (e.g. average lost production, average repair cost) and help to assess the impact of different maintenance strategies for the subsea systems. However, it is not clear how this model is implemented technically and whether the modelling language and simulation tool are open to external users.

In our paper, we illustrate our method to model maintenance planning on a system-size compressor drive system. The model presented in this paper is authorized by integrated modelling environment AltaRicaWizard in the framework of OpenAlta Rica project. We show the possibilities to develop various maintenance strategies in the model, and demonstrate the loss/gain of these alternatives.

3 USE CASE: COMPRESSOR TRAIN

3.1 *System description*

We focus on 6 electrical trains that are used to compress the gas. Each of them contributes to one sixth of the total production capacity. Each compressor drive system consists of, from the left: a Variable Speed Drive (VSD), a Motor (M), a Gear box (G) and the compressor (C), see Figure 1.

During winter (6 months), full capacity is required and all the 6 trains are supposed to be used. During the summer, only part of the total capacity is required, for instance 1/2. Then only 3 trains are needed. The switch from full capacity to reduced one and then backwards is operated once a year (e.g. 01/10 and 01/04). At system level, once one train is failed, it is revealed naturally by production capacity. Similarly, at train level if one of the component is degrading, it reduces production capacity immediately.

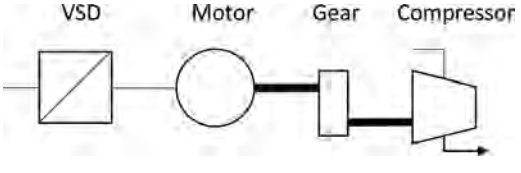

Figure 1. Diagram of one compressor train.

3.2 *Assumptions of each unit*

3.2.1 *VSD and gear*

VSD and Gear are much more reliable than motor and compressor. They have only binary states: Working (W) and Failed (F) (Figure 2). The failure time follows exponential law with low failure rate.

Both components are continuously monitored. In addition, they are easy to repair so the maintenance time is short. Only corrective but no preventive maintenance is planned on these units. The intervention can occur at any time during operation of the system.

Concerning production, it depends on working state of the unit and production flow plug into it.

3.2.2 *Compressor*

Compressor is subject to indirect continuous monitoring on the degradation process. It has four states: Working (W), Degraded 1 (D1), Degraded 2 (D2) and Failed (F). The time to change between these states follows exponential laws where the rate is respectively λ_{d1}, λ_{d2} and λ_f (Figure 3). In W state, the compressor runs at full capacity 100%; in D2 state, the compressor has fouling and it consumes more power to maintain the full production capacity; in D2 state, fouling is accumulated and compressor capacity decreases below an acceptable threshold 80%; in F state, the compressor cannot operate any longer and its capacity sinks to 0%.

When compressor reaches its D1 state, a preventive minor maintenance (e.g. cleaning) is arranged; when it reaches D2/F state, a spare part is ordered and the preventive/corrective major maintenance (e.g. replacement) will be implemented. The duration of minor and major maintenance is respectively δ_{mn} and δ_{mj}. Delay time to prepare corresponding maintenance interventions is ρ_{mn} and ρ_{mj}.

The actual production of the compressor depends on its degradation level, the operation phase and also the input production passing to it.

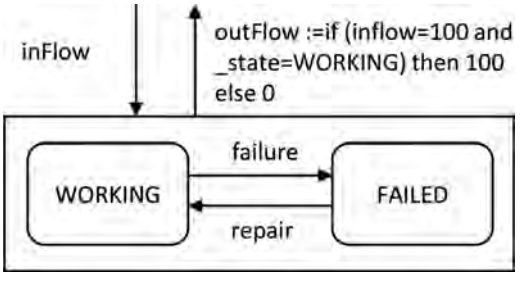

Figure 2. Automaton for VSD and Gear.

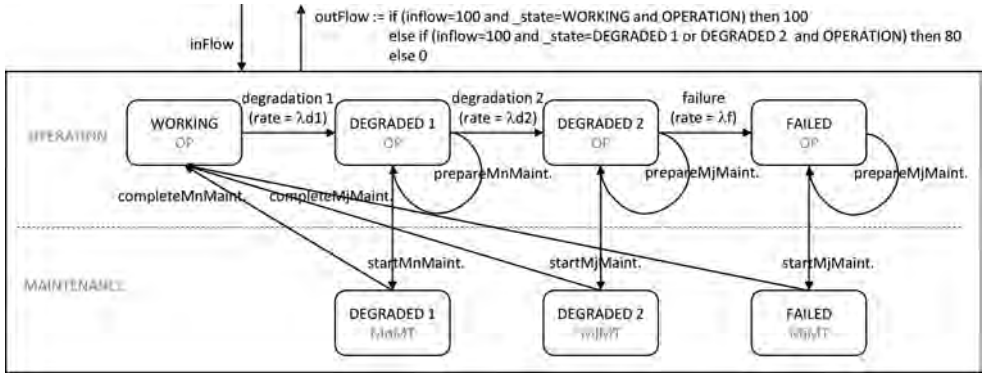

Figure 3. Automaton for compressor.

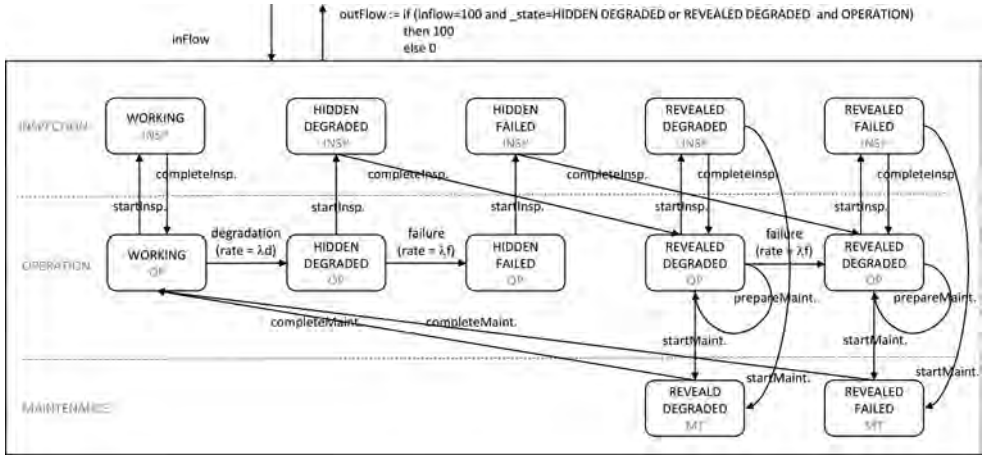

Figure 4. Automaton for motor.

3.2.3 *Motor*

Motor is under periodic inspection. It has six states: Working (W), Hidden Degraded (HD), Revealed Degraded (RD), Hidden Failed (HF), Revealed Failed (RF) (Figure 4). A periodic inspection is perfect and it reveals all the hidden degradations and failures. The inspection occurs every τ and it lasts for Δ unit time. After detection of degradation (RD), the condition can deteriorate further to a failure (RF).

There could be discrepancy between observed state and actual state of the unit. However, the maintenance planning is made based on observed state of the unit. In W/HD/HF, no action is taken; in RD/RF, a spare unit is ordered and the proactive/corrective maintenance is implemented which lasts for δ. The delay to prepare the intervention is ρ.

The actual production of the motor depends on its working state, the operation phase together with the upstream production passing to it.

As a first study of the compressor drive system, we simplify the model by saying that we have enough maintenance teams. We do not consider system-level diagnosis neither maintenance planning. For the mentioned units, any maintenance and inspection stops the production of the intervened train, but do not interfere behaviours of the units on the same line or the other trains. All the components are independent of each other and interventions are decided locally.

4 MODELLING METHODOLOGY

The modelling formalism that we use here is Alta Rica 3.0 and its underlying mathematical framework, Guarded Transitions Systems (GTS). For formal presentation see (Rauzy 2008, Prosvirnova 2014). The formalism can handle complex systems with four main Modules as explained in (Zhang et al. 2017):

1. description of individual behaviours of units
2. description of the actual state of the system
3. diagnosis on the state of the system
4. description of maintenance planning and actions

In our case, we simplify the situation by saying that components are independent and maintenance decisions are made local. Therefore, there is no system-level diagnosis netiher decision making. We only use part of the framework (Module 1, 2) while Module 4 can be further embedded into Module 1. The model constituting two parts: modelling units and modelling system are explained as follows:

4.1 *Modelling units*

The first part describes behaviours of each unit. The purpose is to translate finite state automata as Figures 2, 3 and 4 into AltaRica language. GTS of each unit describes indigenous events that happen locally by itself, for example degradation and failure. Meanwhile, it can embed foreign interventions that posed on top when the local condition or clock reaches certain trigging point, for instance start maintenance and start inspection. To clarify the mechanism, we use motor (Figure 4) as an example. The AltaRica code implementing the GTS for the motor is given in Figure 12.

The class of a generic inspected unit is designed and named as `Motor` (line 5). The motor can be in one of the following states: Working (W), Hidden Degraded (HD), Revealed Degraded (RD), Hidden Failed (HF) and Revealed Failed (RF) (line 1). It experiences three alternating stages in its life cycle: Operation (OP), Inspection (INSP) and Maintenance (MAINT) (line 2). In addition, it runs under winter and summer profile (line 3). Line 10–16 assign names to events and declare their duration by keyword `delay`.

The definition of a `transition` (line 20–33) starts with the name assigned to it, then comes several pre-conditions of the transition with are connected by logic operators `and,or`. After a transition sign comes the final effect of the event, e.g. state or phase values are modified. Under such mechanism, the fireable events and their transitions mimic the behaviour of the component as time elapses.

Figure 5. A map of maintenance optimization scenarios.

According to the assumptions, motor degrades and fails only in operation phase. Therefore the state changes are preconditioned with `_phase==OP` (line 20–22). The initiation of an inspection follows fixed interval. Upon completion, a hidden degradation or failure is detected and meanwhile a clock starts to count the time for maintenance preparation (line 26–29). The counting, however, does not stop further degradation of the motor, so the event `prepareMaint` is defined by state indicator `_clock` independent of motor `_state` (line 30). Once the preparation is ready, all the maintenance resources are ready for use but we have to check that it is the low demand season (e.g. summer) to launch an actual campaign. If the `_season==SUMMER`, the maintenance starts immediately and the completion brings state back to working and resets clock again (line 31–33).

The assertion part (line 35–36) describes how to update flow variables after each transition firing. The production of the motor is 100% when it is in operation and not failed, otherwise it produces nothing.

In summary, classes of generic automata can be designed for each unit (VSD, Gear, Motor, Compressor) and season demand following the same routine.

4.2 *Modelling system*

The codes in section 4.1 defines actually several classes of continuously monitored (VSD, Gear, Compressor) and periodically inspected units (Motor) that can be reused for many times. Instantiations of these classes provide the basic elements for constructing a class or prototype of a bigger system. For instance, one train of a CDS can be described in Figure 10.

The code declares a class of `Train` which consists of two instances of the basic `RepairableUnit`, one instance of `COMPRESSOR` and one instance of `MOTOR` (line 2–5). Similarly, for a complete CDS with 6 identical trains, the class `Train` can be recalled for 6 times (`Train T1, Train T2,...`) to instantiate the real structure. The production of one train is determined by input and output flows passing through the series of the units. Namely, the input of a unit is plugged, by the equation `sign:=`, into the output of the precedent unit (line 9–13). Therefore, the equation means that the production of one train depends on the upstream production and availability of each unit in series.

4.3 *Performance indicators*

In practice, maintenances have a cost, just as shutdowns of systems due to failures. It is however very difficult to get realistic figures for these costs, because they depend on too many factors. More obviously, there is a discrepancy between the production expectation and the actual production of the system throughout the mission time. Here, we consider the average production and the loss of the system (per unit time) as relevant performance indicators. The GTS representation of these indicators are shown in Figure 11.

The defined observers are real numbers. Potential capacity of the CDS is normalized summation of each train (line 8–9). It is then compared with the actual demand according to the season. If the potential capacity satisfies the demand, then there is no production loss; otherwise the production loss equals the demand minus potential capacity of the CDS.

5 NUMERICAL EXPERIMENT

The mentioned modelling methodology is applied to the use case of CDS. A set of illustrative data (Table 1) is fed into the model. The mission time is 87600 h (10 years). We set the maximum production capacity for all six working trains to 100 per hour. For 10 years that would add up to $8.76e+6$, and with nominal seasonal production profile in summer (*0.5) we get $4.38e+6$. We assume that at the beginning of simulation, the production capacity of each unit is 100% per hour and the operation starts from winter.

The GTS model can thus be able to run a variety of what-if scenarios and the result can be assessed by the stochastic simulator embedded in AltaRicaWizard. The map in Figure 5 shows possible experiments that we can simulate with the model. Due to scientific focus of this paper, only selected experiments are discussed in the following subsections.

Table 1. Input parameters for each unit.

Component	VSD	Motor	Gear	Compressor
λ_{d1}		$1.0e-6$		$1.0e-6$
λ_{d2}				$1.0e-5$
λ_f	$1.0e-7$	$1.0e-5$	$1.0e-7$	$1.5e-4$
ρ_{mn}		4380		2190
ρ_{mj}				4380
δ_{mn}	6	365	6	182.5
δ_{mj}				365
τ		730		
Δ		12		

5.1 *Inspection interval*

Figure 6 plots 1 million realizations of the process for accumulated production and loss versus different inspection interval values $730 \leq \tau \leq 11680$ (1 to 16 months). When inspection interval is less than 4 months, the production loss increases dramatically. This is because with too frequent inspections, operations are dominated by unnecessary shutdowns to check still functioning components. After this point, the total production approaches a stable high level and it reaches the peak value when τ is around 12 months. Notice that the curve is almost flat when τ is from 4 to 16 months. It implies that the total production may be not so sensitive to the inspection interval in such range given our assumptions and input parameters.

5.2 *Time horizon*

Figure 7 shows Monte Carlo simulation for accumulated production and production loss from 1 to 10 years with 1 million realizations at each year. As time elapses, the production and loss increase almost linearly. It quantifies the provided overall production and revenue reduction over a period of mission time and thus gives decision makers a look-ahead horizon of the production profile of the whole CDS system.

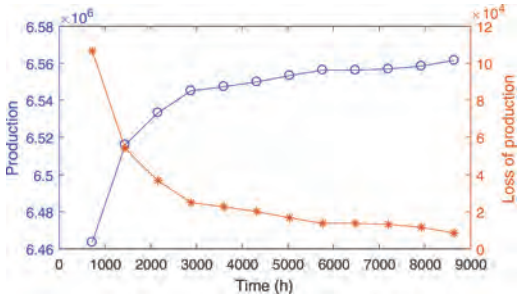

Figure 6. Production and loss versus inspection interval τ.

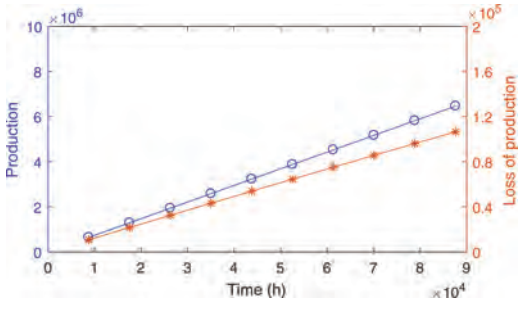

Figure 7. Production and loss versus mission time.

5.3 *Maintenance delay*

Figure 8 presents consequence of reducing minor PM preparation time (delay). Here, we assume that delay of major preventive/corrective maintenance interventions remain as it was ρ_{mj} and the changes only apply to ρ_{mn} of inspected components. From the figure we see that as minor preventive maintenance delay decreases from 10 to 1 year, the total production increases around 0.045%. The production loss with (ρ_{mn} < 87600) and without minor PM (ρ_{mn} = 87600) does not differ much. The link between instant reaction and increased production is obvious, but the gain of having maintenance resource immediately ready can be questionable. This is relevant for deciding an optimal spare parts strategy, when the cost of contracting maintenance service and storing spare parts has to be evaluated against the benefits of income.

5.4 *Seaon profile*

Figure 8 presents consequence of extending low demand period (i.e. summer) from 1 to 12 months. This time corresponds to the window when maintenance intervention is allowed. As the window extends, the system spends more time in reduced operation mode, and thus the total production decreases. Yet, production loss is reducing rather than increasing because the potential loss is compensated by relaxed requirement of production in the extended summer period. As such, we quantify the effect of a changing season profile on the accumulated production of the system.

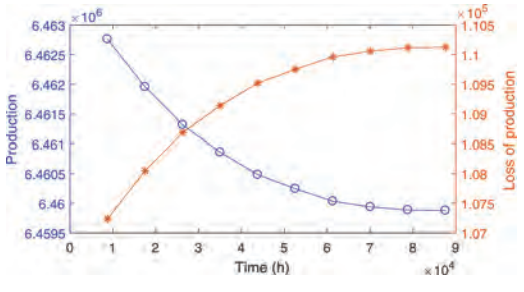

Figure 8. Production and loss versus maintenance delay.

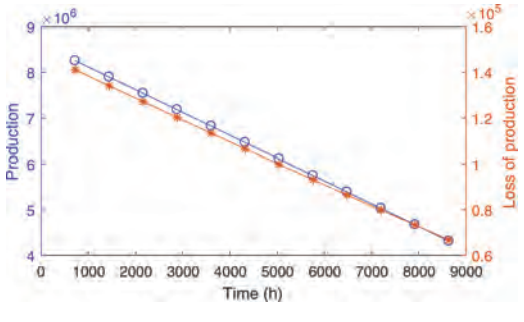

Figure 9. Production and loss versus low demand duration.

6 CONCLUSIONS

In this paper, we present a preventive maintenance model on a compressor drive system. The model relies on the formal modelling formalism AltaRica 3.0 and its mathematical framework guarded transitions systems. They provide mechanisms to represent state and transitions of local units, enable composition of multi-unit systems and allow information flows (e.g. production, observed condition) circulating through them. We illustrate how our modelling methodology handle the various modelling challenges in our CDS case, like multiple unit types, huge state space, monitoring together with inspection policies, multi-level maintenance actions and so on. We pose on top of the model different maintenance and inspection policies and perform numerical experiments using Monte Carlo simulations. The simulator, as a decision support tool, demonstrates how the health of components in the system affect the kind of intervention decisions need to make now/soon. The model calculates accumulated production and its loss in a certain mission time. It can provide practitioners motivation with respect to, for instance, intensifying/relieving work on condition monitoring so that interventions become efficient and necessary.

However, this work is very preliminary and there are several directions that can be further investigated.

Direction 1. Degradation profile We assume that components deterioration follow exponential laws with its respective degradation or failure rate lambda. However, if the plant data is available and tractable for more accurate estimation of component degradation, we may introduce multiple degradation states, or fit the data with other laws (e.g. Weibull, empirical distribution). In addition, if the operation mode changes, we may need to consider different degradation profiles (e.g. failure rate) under normal production, increased production, decreased production.

Direction 2. Season profile The current season profile is simplified with only two modes and constant production requirement for each mode. However, there could be fluctuations of production requirement given that it follows a mean within each season. For instance, in summer the production demands is 52% for 20 days, 65% for 40 days, and then 43% for 7 days and so on. Such

fluctuations in the seasonally demand profile can be introduced if a general abstraction of time dependent plant data is available.

Direction 3. Monitoring policy In practice, the inspection dates cannot be freely fixed, because they depend on many factors external to system such as the availability of the maintenance crew. Inspection may be destructive to the component. Certain inspections may take some predictable time and the system may be partly or totally shutdown during inspections. Meanwhile, other inspections do not interrupt operation. In addition, as we have 6 trains in parallel, the inspection can be conducted for all at the same time or only certain pieces at a time. These situations can be further introduced to the model to make it more realistic as implemented in O&G industry.

Direction 4. Maintenance policy It is important to sustain production all the mission time, especially in summer period when window is open for interventions. Therefore, in the occurrence of several degradations or failures in a system, we may need to decide when to react and which ones to intervene in priority. For instance, we can decide to maintain when we lose 3 compressors, or 2 compressors plus 1 motor, or wait for more failures and so on. When there are 1 working, 3 degraded, and 2 failed trains, we can decide to repair the 2 failed trains first and then repair the 3 degraded ones later to ensure highest possible production capacity. System level maintenance planning can be considered in these cases.

A maintenance time estimated method based on virtual reality

Juan Wu, Dong Zhou & Pengyan Liu
State Key Laboratory of Virtual Reality Technology and System, Beihang University, Beijing, P.R. China

ABSTRACT: Traditional method of maintenance time estimation is based on the time regular obtained from large statistical data. However, this method requires physical prototypes, which is much more difficult during design and development stage. Moreover, to obtain accurate data, a large amount of experiments need to be conducted to calculate maintenance time and eliminate the error. A method is proposed in this paper, which uses maintenance platform based on virtual reality to avoid the necessity of physical prototype. In this method, based on maintenance simulation analysis under virtual reality environment, Methods Time Measurement (MTM) and compensation-based time prediction are integrated. Then, according to difference between the actual repair time and the estimated time from virtual simulation, time compensation model is built considering the factors of proficiency, fatigue and maintenance environment. Finally, a real case is used to validate the model. This method could give suggestions of the evaluation of quantitative maintenance factors in the early design stage of the product.

1 INTRODUCTION

Maintenance time is an important quantitative parameter in the analysis of maintenance. However, it is usually hard to get in the development and manufacturing stages. Traditional maintenance time estimation mainly through time-accumulated method (Griswold 1970) or similar product comparative time analysis (Pliska et al. 1987), which are based on massive data. Physical prototypes are necessary in traditional methods, while in the early stage of development and manufacturing it is hard to meet this necessity. Moreover, to obtain accurate data, a large amount of experiments need to be conducted to calculate maintenance time and eliminate the error.

Given these issues above, the main problems that traditional methods faced are the lack of physical prototypes and the large amount of experiments.

While the application of virtual reality in maintenance can fix these problems. Virtual prototypes are used in virtual maintenance, which avoids the use of physical prototype. And the analyst can make virtual simulation which contains all the motions of a maintenance task. This reduces the number of the experiments.

The application of virtual maintenance has been increased in early stage of development and manufacturing during the last few decades. Real-time immersive virtual environments, such as the CAVE (Cruz-Neira et al. 1993) and the Workbench (Cutler et al. 1997) have been used to evaluate the maintainability of virtual prototypes. A novel assembly optimization framework based on genetic algorithm was proposed in 2009 (Christiand et al. 2009).

Except of the use of virtual environment, a lot of studies analyze virtual simulation which consists of a series of virtual human motions. And many methods have been proposed based on these motions, including work force, methods time measurement, modular arrangement of predetermined time standard and so on (Genaidy et al. 1989, Kanai et al. 1996, Genaidy et al. 1990, Laurig et al. 1985, Dossett 1992, Laringa et al. 2002, Fischer et al. 1991, Wygant et al., 1993, Hoffmann et al. 1993). These methods classify different types of human motion and give the relevant motion-time principles. Except for those methods, maintenance time estimated based on system maintenance work procedure through Monte Carlo simulation (LIU et al, 2014). Similarly, maintenance time predicted through structural complexity metric model was proposed in 2014 (Owensby et al, 2014). While the average repair time could be also estimated by failure rate (Shen et al, 2017). While in this paper, author uses methods time measurement as the basic method to estimate maintenance time and gives some compensation principle.

The rest of the paper is organized as follow. Section 2 shows the overview of methods time measurement. Section 3 discusses the details of the compensation principle. Section 4 presents a case study for the implementation of the methodology. While section 5 gives a conclusion of the study.

2 OVERVIEW OF METHODS TIME MEASUREMENT

The maintenance process is consists of a series of human motions. While in methods time measurement, these motion are divided into three parts, including human work, posture adjustment and hand operations (Geng et al. 2014). The following paragraphs will discuss each part in detail.

2.1 *Human walk*

Human walk simply means the walk motion in the virtual maintenance, such as approaching the object. And the time of human walk is decided by walking distance and the weight of the object in the hand if the operator need to carry something to somewhere.

2.2 *Posture adjustment*

Posture adjustment contains 5 parts, which are leg adjustment, position, pick, place and collision. Leg adjustment is the movement of leg, while pick and place are the motion of human arm and hand. Position is the combination of leg and upper limbs, while collision is the movement of all human limbs.

2.3 *Hand operations*

In this part, hand operations contain only hand motion with tools. Bare-handed operation belongs to posture adjustment. Connector operation and maintenance tool operation are the two section of hand operations.

3 TIME COMPENSATION METHODOLOGY

As shown in Figure 1, the overall framework consists of 2 parts: human motion time and compensation time. Human motion time is estimated by methods time measurement that have been discussed in Section 2, while compensation time will be fully discovered in Section 3.

In the study of field maintenance work, the author have found that the proficiency and the fatigue of the operator have great impact on maintenance time. While other qualitative maintainability parameters, such as visual accessibility, do have some influence on maintenance time; but they are not important as the factors of proficiency and fatigue are. Therefore, the author takes proficiency and fatigue as two main compensation part, while other qualitative maintainability parameters are integrated into maintenance environmental factor.

$$T = T_0 \cdot \alpha_i \cdot \left(1 + \beta_j\right) \cdot \gamma_k \tag{1}$$

where T = final estimated time; T_0 = human motion time measured by methods time measurement; α_i = proficiency ratio; β_j = fatigue rate; γ_k = maintenance environmental ratio.

3.1 *Proficiency*

Proficiency refers to the degree to which the operator does the maintenance work. A high proficiency means that the operator is skilled at the maintenance work including the maintenance process, tools used during maintaining, which are operating objects, where to put dissembling items and other maintenance matters. An operator with high proficiency would start his work in order and finish them one by one. While without high proficiency, a maintainer would need more time to look at the maintenance manual to see what to do next, which would waste a lot of time.

This paper classifies proficiency in three levels. Below are detailed rules describing the degree to proficiency in each level:

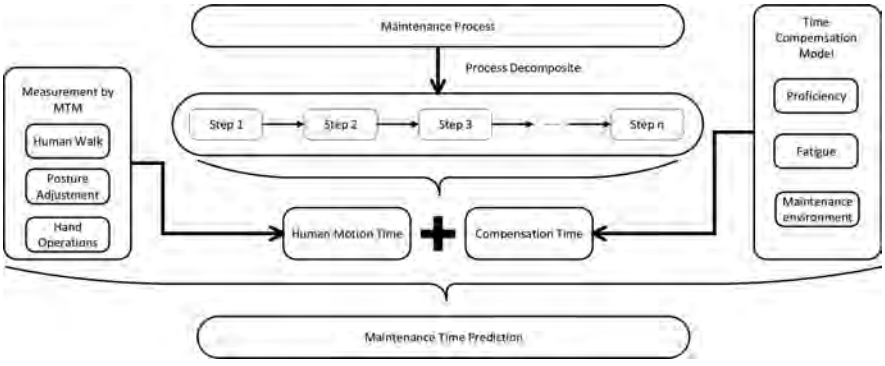

Figure 1. Framework of the time compensation methodology.

Level 1 – The operator knows the whole maintenance process including steps, tools, objects and he masters this operation.
Level 2 – The operator knows the whole maintenance process, but he have never done it or he only have done it once before this operation. He may need to look at the maintenance manual when he forgets what to do next, but it is not often.
Level 3 – The operator doesn't know how to maintain the object. He needs to look at the maintenance manual while operating.

The relationship between proficiency level and its ratio is shown in Table 1.

3.2 *Fatigue*

Fatigue is common especially in long time maintenance. After long time maintaining, operators would feel tired, which causes the decline of mental concentration. Less concentration results in the increase in maintenance time. Fatigue would also cause the decrease in moving speed including hand moving, walking and turning.

The detailed rules are shown as follow:

Level 1 – The operator doesn't feel tired. He is in the same mood as beginning. Therefore, his motion would not be affected.
Level 2 – The operator feels a little tired. His motions are also affected by his fatigue. He may take a little break or slow down his operation, but it wouldn't be long. His efficiency may also reduce due to tiredness.
Level 3 – The operator feels tired. He need to take a break or he would make mistakes. In this mood, he should have a rest or something dangerous may occur.

The relationship between fatigue level and its rate is shown in Table 2.

Table 1. Proficiency ratio.

Proficiency level	Ratio
Level 1	α_1
Level 2	α_2
Level 3	α_3

Table 2. Fatigue rate.

Fatigue level	Rate
Level 1	β_1
Level 2	β_2
Level 3	β_3

3.3 *Maintenance environment*

Due to the limit of virtual maintenance environment, it is hard to simulate the working environment same with the actual one in the aspect of temperature, humidity, illumination condition. But it still has other maintenance environmental factors that will influence maintenance time.

Visual accessibility means the extent or visibility that can be seen from the operator's current location. A good visual accessibility refers to that during maintaining, the operator could directly see the working area, objects and tools. A bad vision could result in the increase of maintenance time because the maintainer would need more time to search for tools or others.

Operating space refers to area of an operator touching objects and getting tools. A good operating space could provide the maintainer a comfortable working place. While a bad operating space would increase human motion time.

Those two maintenance environmental factor could be examined in virtual maintenance which are shown in Figure 2. The upper one shows the operator's visual accessibility, while the other presents the operating space.

In this paper, the author presents three rules of maintenance environment:

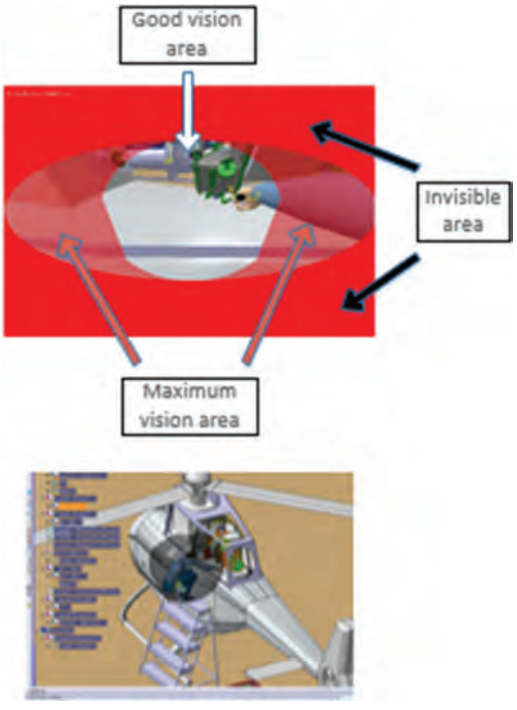

Figure 2. Visual accessibility and operating space in virtual maintenance.

Table 3. Maintenance environmental ratio.

Maintenance environmental level	Ratio
Level 1	γ_1
Level 2	γ_2
Level 3	γ_3

Level 1 – The operator is in a natural posture, which means he could easily get what he want or touch what he want to operate, and at the same time all maintenance objects and tools are right in the his sight.

Level 2 – Either the operator is in a narrow space that he could not be so easy to get or touch what he want, or he doesn't have a good vision that some are out of his sight, which means he needs to turn to a certain angle to touch the object or the tool.

Level 3 – The operator is in a narrow space and most or all maintenance objects and tools are out of his view.

The relationship between maintenance environmental level and its ratio is shown in Table 3.

3.4 *Time estimation*

Before doing the final calculating, the analyst should check the integrity of the virtual simulation. If there is any simplification, the analyst should take that into calculation. After checking, the analyst could choosing different ratio according the different situation and the final value is the result of this time estimation.

4 CASE STUDY

Using the methodology above, the author uses the maintenance of an electric fan as example. The virtual model of the fan is shown as Figure 3. While the process of its maintenance is presented in Table 4. The author uses DELMIA (Digital Enterprise Lean Manufacturing Interactive Application) as the virtual maintenance platform, where the simulation is made exactly based on steps showing in Table 4. While in the simulation, time is estimated by PTS, which refers to Predetermined Time Standards. And the actual time is collected through several surveys.

Table 4 show the detailed process of this maintenance work. And the time of each task is listed in Table 5, which including data from methods time measurement, proposed method and actual work. Time of methods time measurement only consider human motion, while proposed method not only

Figure 3. Virtual model of a fan.

Table 4. Maintenance process.

Number	Detailed task	Component of motion
1	Pick up the tool	Pick
2	Remove 2 nuts on the two sides	Pick, screw × 2 and place
3	Put down the tool and take out the body part of the fan	Pick, place
4	Pick up another tool	Pick
5	Remove 3 nuts on the upper side	Arm raise, screw × 3, arm fall
6	Put down the tool	Place
7	Remove the front cover of the body part	Pick, place

Table 5. Maintenance time calculation.

Motion	Methods time measurement	Proposed method	Actual time
Pick	1.1	1.1	2.5
Screw 1	12.4	18.6	17.8
Pick	1.1	1.1	1.1
Place	1.4	1.4	1
Screw 2	12.6	18.6	18
Place	1.4	1.4	1.3
Pick	1.1	1.1	2.7
Arm raise	0.5	0.5	0.9

Screw 4	12.2	17.0	14.2
Screw 5	12.8	17.0	23
Arm fall	0.5	0.5	2.1
Place	1.4	1.4	2.5
Pick	1.1	1.1	1.7
Place	1.4	1.4	1.6
Total	73.2	100.8	108.7

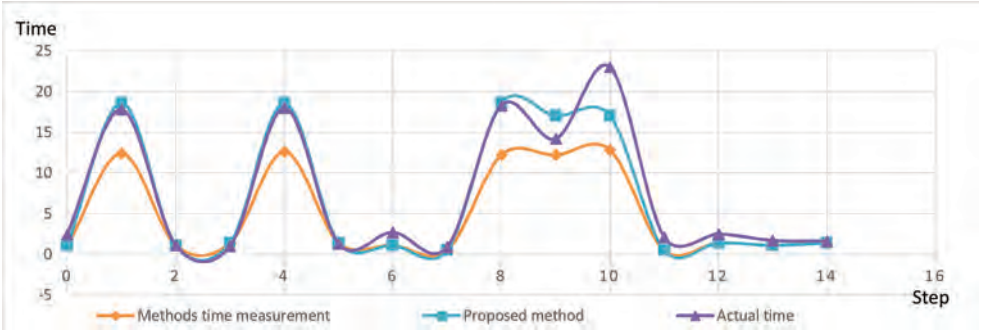

Figure 4. Comparison between two methods.

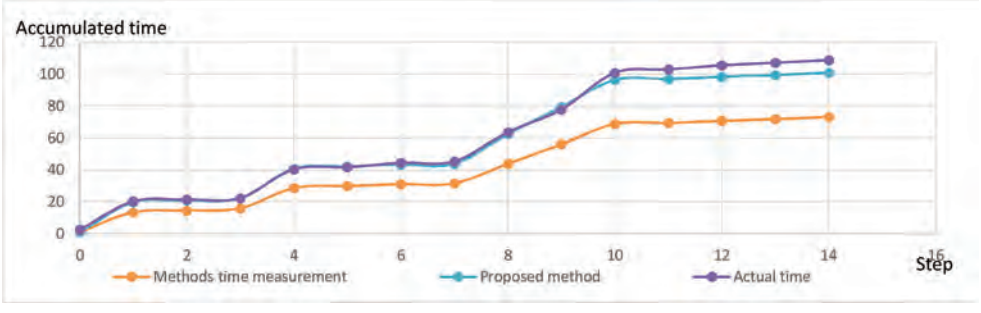

Figure 5. Accumulated time comparison.

uses human motion, but also time compensation rules.

As can be seen from Figure 4 and Figure 5, the orange line stands for methods time measurement, while the blue one represents proposed methods and the actual result shows in purple line. It is clearly that compared to methods time measurement (the orange line), time estimated by proposed method is closer to practice. And result also shows that proficiency is the main factor that influences maintenance, which fits in with the actual survey result the author have gotten in field maintenance.

In real maintenance, operators are often unfamiliar with the maintenance process because the failure rate of the equipment is extremely low, especially in the field of aeronautics and astronautics. Therefore, proficiency is the key factor in time estimation.

5 CONCLUSION

This paper presents a methodology for maintenance time estimation based on virtual reality, where methods time measurement and time compensation model are discussed. The advantages of this methodology is that it provides a time estimated way without physical prototype and it is more accurate than methods time measurement. By analyzing the comparison result, the author finds that proficiency is much more important in maintenance time estimation, and by actual survey the author also finds that qualitative maintainability parameters may not play an important role in time prediction. The author must admit that they do have some influence, but they do not have as much as I have thought before, which is only the author's opinion.

Future work will focus on the importance of qualitative maintainability and the simplification of the proposed method. Moreover, with the development of virtual reality, more methods will be found based on methods time measurement and the proposed method, which may be more simple and useful in real life.

ABSTRACT: The Original Equipment Manufacturers (OEMs) nowadays face the need of establishing an optimized maintenance plan from the design stage of the assets. Up to date, the production-centered business model has limited their after-sales maintenance strategy, and accordingly their knowledge about the assets operational behaviour. Furthermore, the added difficulty of the assets operating in different contexts (increasing the variability of their behavioural patterns) contributes to the misalignment of the maintenance plan with the assets' actual needs. Therefore the purpose of this paper is to propose a methodology based on the proportional hazards model for assessing the behaviour of the assets and the influence of the different operational context variables in their reliability. This methodology aims to provide support information to a better customization of the maintenance plans in the offer stage. Likewise, the proposed methodology has been verified and validated through a real case study with data provided by a leading company in the railway sector.

1 INTRODUCTION

Traditionally Original Equipment Manufacturers (OEMs) have focused their efforts on asset production and sale, however, the highly demanding market has imposed the need of maintaining their competitiveness levels through the after sales service, which might become a profitable source of income. Since the business approach of the OEMs has shifted to this new paradigm, it can be identified in the literature a growing body of publications recognizing the importance of optimizing the maintenance plans.

Nevertheless, the OEMs have not achieved a desirable optimization level in their after sales service. To date, because of these inefficient maintenance plans, the after sales service has incurred into avoidable costs and excessive resources consumption. This becomes a major issue when the maintenance strategy is designed at the offer stage of the asset, where the customization of maintenance actions and frequencies is difficult due to the lack of available information to characterize the asset failure mechanisms. Furthermore, the operational environment of products can change, requiring reliable operation in unfamiliar circumstances, or uncertain asset's operators' behaviour (de Rocquigny et al. 2008).

Nowadays, to face the mentioned problem, the OEMs follow a holistic approach supported by information provided by the suppliers and by information regarding similar assets' patterns. The customization degree of the resulting maintenance plans does not properly integrate information regarding the operational context in which the assets will perform. Thus, in order to avoid the misalignment of expected and actual assets' maintenance needs, it is crucial to develop capabilities and tools to assess the influence that the different operational context variables have in the behaviour of the asset. To this aim, a novel methodology is developed and presented in this paper, with its

corresponding application to a real case study in the railway sector.

The Proportional Hazards Model (PHM) plays a key role in the proposed methodology by being a valid approach to relate survival analysis and the impact of operational context variables. The main advantage of the model is the possibility of considering the impact of more than one variable simultaneously (Tang et al. 2014). The PHM was first introduced by Cox (1972) in a seminar paper in the Royal Statistical Society, not only has it been proposed for medical studies but for reliability analysis by Cox himself and by other authors in the literature (Bendell et al. 1986, Wightman & Bendell 1986, Lawless 1983).

A critical review of the existing literature in the beginnings of this new methodology can be seen in Bendell (1985) where the complexities of the model are enumerated along with the proper way of applying it to reliability studies. Baxter et al. (1988) presented it as a powerful tool for examining reliability data-sets where the failure data may be inhomogeneous due to the presence of risk factors. Through the literature various examples of its applications can be found, in these applications, it is used as an exploratory tool in Bendell et al. (1986) and in Wightman & Bendell (1986); but also as a reliability prediction model for, among others, rail diesel engines (Jardine et al. 1989), marine and aircraft turbines (Jardine et al. 1987), traction transformers (Lin et al. 2016), vitrified clay pipes (Xie et al. 2017), electromagnetic relays (Li et al. 2015) and mobile handsets (Tiwari & Roy 2013).

As stated by Li et al. (2010), the PHM lays a mathematical foundation for predicting the failure occurrence and developing optimal maintenance policy. Thus, in this paper the application of the PHM to a real case study in the railway sector is presented and discussed, having the obtained results been validated by a leading company in the sector. More precisely, several components of the Heating Ventilating and Air Conditioning (HVAC) System have been analyzed through the study of a database that gathered failure information from different operational contexts. The intention is to provide a case study in the application of the PHM and its potential for the maintenance plan design at the beginning of the asset's lifecycle, where no information to characterize its behaviour is available.

The structure of this paper is as follows. Firstly the HVAC system and the several aspects to be taken into account regarding its maintenance are presented, besides the failure data to be analyzed is also discussed in section 2. In sections 3 and 4 the Cox model, along with its main equations, and the proposed methodology are explained correspondingly. Once the main concepts are introduced, in section 5 the application to a real case study is performed, where several components of the HVAC systems with their individual resulting PHMs are analyzed. Finally, in section 6, the conclusions and benefits resulting from the application of the proposed methodology to the real case study are presented.

2 HVAC SYSTEM

The railway sector is a growing industry that provides good mobility for a reasonable price. Transportation systems' complexity is increasing, as well as its number of users; hence it is necessary both, to improve their availability and to guarantee high levels of security and comfort whilst ensuring reasonable maintenance costs (Foulliaron et al. 2014). There exists a trend towards a cost-efficient and performance-based system, this trend is highly influenced by political, economic and environmental motivations (Umiliacchi et al. 2011). One of the main pillars within the trend is the asset management discipline, and the importance of a proper asset management strategy is supported by the vast amount of literature focused on optimizing the maintenance plans for rolling stock.

As previously stated, in order to optimize the maintenance actions, customization to operational context is required. This paper discusses the application of PHM to the HVAC system in the railway sector, which has been chosen because it plays a key role in comfort levels of the passengers. The HVAC system in a train, metro or tramway provides an air flow in order to maintain proper and comfortable room environmental conditions. Among the functionalities of the HVAC system several comfort-related aspects are taken into account, these functionalities include (1) temperature adjustment, (2) refreshing of room air, (3) filtration of the outside air, (4) ensuring proper noise levels and (5) avoiding pressure waves (in high-speed trains).

To regulate the inside comfort environment, it is necessary to take into account that the setpoint temperature depends on the outside temperature in order to avoid excessive thermal shock. However this is not the only parameter to be considered when designing an HVAC system; the indoor relative humidity level should be maintained below 60% on average, and it is important to remark that passengers are heat and humidity sources. Accordingly, HVAC system should be designed to maintain desirable levels of inside temperature and humidity; the technical solution adopted should endure the outside conditions, as well as the coach maximum occupancy.

As stated in Bendell (1985), the proportional hazards modeling techniques for reliability analysis are useful when the analyzed data correspond

to failures of non-repairable items whose times to failure are completely independent and equally distributed. Following these concerns, for the case study three different components of the HVAC system have been selected: the control panel, the electronic control (as a subcomponent of the control panel) and the compressor unit.

The database has been provided by a leading company in the sector, it includes the work orders of maintenance services for HVAC systems in rail projects working in different European cities. The full study considered the HVAC systems running from 1st January 2015 to 31st August 2017, since the quality of the data is more consistent in this period. From the maintenance work orders record, the Time Between Failures (TBFs) has been calculated, and then the information regarding the operational context has been associated with each of the TBFs.

3 PROPORTIONAL HAZARDS MODEL

The PHM assumes that the hazard function of an asset decomposes into the product of a baseline hazard function and an exponential term incorporating the effects of the explanatory operational context's variables (covariates) (Cox 1972). The most extended PHM is given by Equation 1,

$$h(t, X_1 \ldots, X_p) = h_0(t) \exp\left(\sum_{j=1}^{k} \beta_j X_j \right) \quad (1)$$

where $h(t, X_1, \ldots, X_k)$ represents the hazard rate at time t for an asset with covariates $(X_1, \ldots, X_k)$; $\mathbf{X} = (X_1, \ldots, X_k)$ is the vector containing the values of the explanatory variables where $X_i (\forall i = 1,2,\ldots,k)$ can be either a naturally variable or an indicator variable; $h_o(t)$ represents the baseline hazard function, it would be the hazard function for the null vector $\mathbf{X} = \mathbf{0} \in \mathbb{R}^k$ – it can be parametric following certain distribution or of a unspecified form; and $\beta = (\beta_1, \ldots, \beta_k)$ is the vector of the parameters of the model which describe the effects of each of the covariates.

Given two identical assets operating in two different operational contexts, that would be $\mathbf{X} = (X_1, \ldots, X_k)$ and $\mathrm{X}' = (\mathrm{X}'_1,\ldots,\mathrm{X}'_k)$, being the X' one with a higher risk; it is defined the Hazard Ratio (HR) between the two of them as:

$$HR = \frac{h(t,\mathbf{X}')}{h(t,\mathbf{X})} = \frac{h_0(t)\exp\left(\sum_{j=1}^{k} \beta_j X'_j\right)}{h_0(t)\exp\left(\sum_{j=1}^{k} \beta_j X_j\right)} \quad (2)$$

$$HR = \exp\left(\sum_{j=1}^{k} \beta_j \left(X'_j - X_j \right) \right) \quad (3)$$

It can be observed in Equation 3, that the Hazard Ratio is independent of time t, being that the property which gives the model its name of Proportional Hazards Model.

A special case of the HR would be when comparing an asset operating in an environment where the covariates take mean values $\overline{\mathbf{X}} = (\overline{X}_1 \ldots, \overline{X}_k)$ with an asset operating in a context $\mathbf{X_i} = (X_{i1}, \ldots, X_{ik})$; given this HR let the hazard function of the asset operating in $\mathbf{X_i}$ be expressed by Equation 4,

$$h(t,\mathbf{X_i}) = h_{\overline{\mathbf{X}}}(t) exp\left(\sum_{j=1}^{k} \beta_j \left(X_{ij} - \overline{X}_j \right) \right) \quad (4)$$

where the hazard function is decomposed into a baseline hazard function in the mean values of the covariates $(h_{\overline{\mathbf{X}}}(t))$, and into the exponential part where the deviations from the mean value of each covariate are taken into account, instead of the covariates values themselves.

The baseline hazard function in the mean values of the covariates can be estimated in the model and it can also be either an unspecified form function, or a function following certain distribution. In this paper it has been fitted to follow a two-parameter Weibull distribution, thus the obtained model would be expressed by Equation 5,

$$h(t,\mathbf{X_i}) = \frac{\gamma}{\alpha} \cdot \left(\frac{t}{\alpha} \right)^{\gamma - 1} \cdot \exp\left(\sum_{j=1}^{k} \beta_j \left(X_{ij} - \overline{X}_j \right) \right) \quad (5)$$

where:
α is the characteristic life (scale parameter).
γ is the shape parameter.
T is the time.

4 METHODOLOGY & PROPORTIONAL HAZARDS MODEL

The proposed methodology for assessing the impact of operational context variables is shown in the flowchart of Figure 1. It consists of two modules, the first one is oriented to data treatment and preparation, and the second one mainly comprehends the model fit and tests of the PHM. In the next paragraphs, a detailed explanation of both is presented.

4.1 *Module 1. Data treatment and preparation*

In this first module, the work is directed towards two focus of interest, the identification of the operational context variables and the treatment of the maintenance data. On the one hand, for identifying the variables that affect the reliability of the

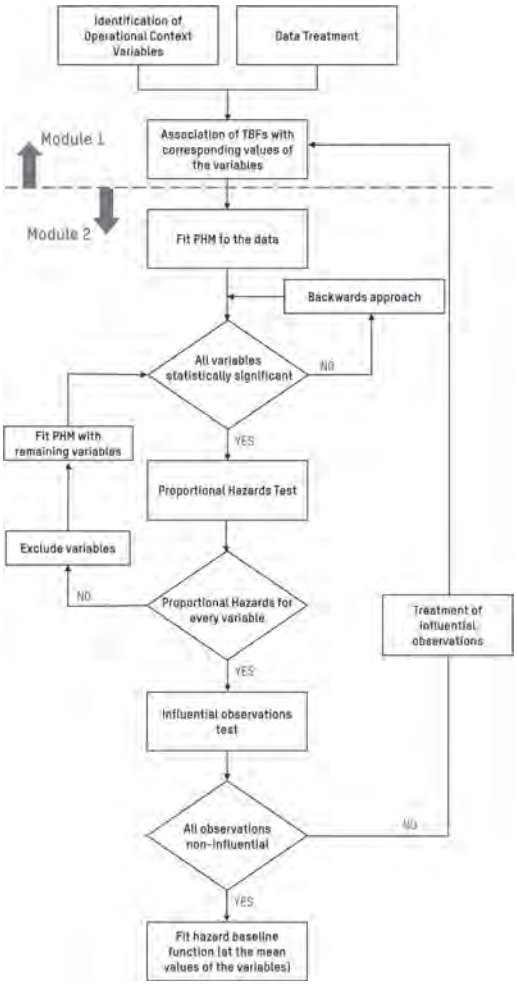

Figure 1. Flowchart of the proposed methodology.

asset it is essential to cooperate with maintenance workers in order to translate their know-how into valuable feedback that helps in the integration of every environmental aspect influencing the failure mechanisms. On the other hand, following the general framework in a reliability improvement study proposed by Louit et al. (2009), the work orders are treated to calculate the TBFs taking into consideration the diverse issues such as scarce data, censoring (only right is contemplated) or data pooling. Likewise, it is important to check and minimize as much as possible potential human errors and noise, such as double imputed work orders or non-failure related work orders.

Having calculated the TBFs, as well as the variables that might influence the reliability, the linkage between both should be performed. To this aim, it is necessary to define a way of associating a value of the variables to every TBF; nonetheless, the procedure to follow for each of the variables should be ad-hoc designed depending on the available information and the characteristics of the variable.

4.2 *Module 2. Valid PHM fit*

With the data set containing the failure times associated with the appropriate context variable value, it is the next step to seek for a valid PHM fit using the method of partial likelihood. In this paper's case study the fit has been performed with the Cox Proportional Hazards regression in R, but there are many software solutions for this regression. The way to proceed should be to try to fit a PHM that includes all the identified covariates, however, it is very likely that many of them will not result influential with enough statistical significance. Significance levels have to be arbitrary set for the null hypothesis contrast where every $\beta_i = 0 (\forall i = 1,2,\ldots,k)$, in the case study a p-value <0.1 was considered significant.

Moreover, it also exists the possibility of having identified collinear variables, i.e. covariates which can be linearly predicted from any of the others. When in the results appears either a not statistically significant or a collinear covariate, they are eliminated following the backward approach proposed by Bendell et al. (1986) until a PHM is reached, where each variable is influential with a p-value lower than the selected one, and no collinearity is detected.

Already the model contains the proper covariates, it is required to check the proportional hazards hypothesis under which the model has been fit. To this aim, a test and a graphical analysis for each significant variable are performed based on the Schoenfeld residuals obtained from the regression. If a covariate performs well in neither the analytical test, nor the graphical one, it needs to be excluded from the PHM model and the regression performed again with the remaining covariates.

When the proportional hazards hypothesis has been tested and validated, the next phase is to spot any possible influential observations that may have biased the estimation of the regression parameters. In case any is identified, it is examined to consider how it should be treated before proceeding in the fit of a more accurate PHM.

Since by default $h_{\bar{x}}(t)$ is a free distribution function estimated in the regression, the last step of the methodology consists of fitting it to a suitable probability distribution. So the resulting Proportional Hazards Model will be a completely parametric function (see Equation 5), that can be decomposed in two terms:

- A hazard baseline function following certain distribution, in the case study a two-parameter

Weibull, in the mean values of the covariates. Thus it will depend on the parameters of the chosen distribution and it will depend on the time (t) as well.

- An exponential function that integrates the information regarding the operational context, since the deviation from the mean of each influential variable is multiplied by its corresponding estimated parameter.

5 REAL CASE STUDY RESULTS & DISCUSSION

The system to study is the HVAC system integrated into different projects of the railway sector, however, the PHM is not applied to the system as a whole unit but to selected subsystems. In order to select the subsystems several criteria have been followed but firstly a Failure Mode and Effect Analysis has been performed to fully understand the failures mechanisms of the HVAC system. Having formalized the knowledge about HVAC failure modes, an approach based on the CIB-framework proposed by Waeyenbergh and Pintelon (2004), is applied. To identify both the Most Important Systems (MIS) and the Most Critical Components (MCCs), the know-how of the company workers is documented and implemented in the Maintenance Cost Matrix in Figure 2.

Every MIS, at different indenture levels, is included in the matrix where in the vertical axis Corrective Costs (CC) are represented and the horizontal axis corresponds to preventive costs (PC). However this cost classification is based on a Pareto qualitative approach since for each component both have been calculated by Equations 6 and 7,

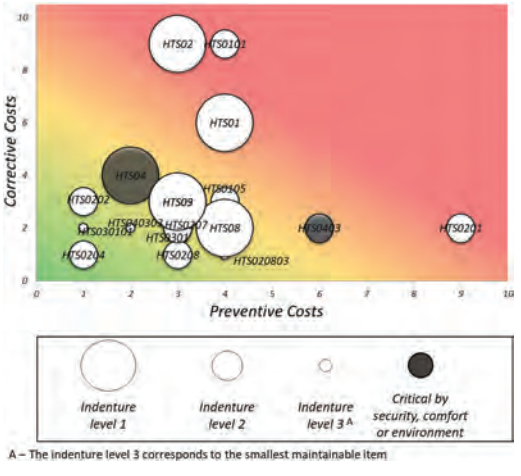

Figure 2. Maintenance cost matrix.

$$CC = PI_{CorrectiveCost} \cdot PI_{FailureFrequency} \quad (6)$$

$$PC = PI_{PreventiveCost} \cdot PI_{PreventiveFrequency} \quad (7)$$

where PI is the Pareto Index being: 1 for low, 2 for medium and 3 for high.

In the Matrix of Figure 2, four MIS can be seen in the red area of the matrix representing high maintenance costs. It also shows two MIS whose criticality is due to security, comfort or environmental issues. These six MIS are the ones that are categorized as MCC and thus are the ones that have been analyzed by the PHM. The identified MCCs are shown in Table 1, with their reference, description and indenture level.

Once the items to be analyzed have been defined, their corresponding failure data have been extracted from the database and treated as proposed in the methodology (see subsection 4).

The next step is to identify what are the influential variables that are going to be integrated into the analysis. By cooperating with the company, 11 covariates have been selected as possible risk factors, some of them are defined by the project specifications and the others are exogenous uncertainty variables. In Table 2, the criteria for selecting every variable are explained.

When applying the proposed methodology only three out of the six MCCs provide a valid PHM model, the control panel (HTS01), the control electronics (HTS0101) and the compressor module (HTS04). The evaporator module (HTS02) can be adjusted to a PHM where the maximum temperature and the relative humidity have influence in the hazard function, however, they do not pass the proportional hazards test.

For neither the HTS0403 nor the HTS0201, a valid PHM can be adjusted; this is due to data scarcity. Both of them have been selected because their preventive maintenance cost was high (bottom-right position in the matrix). As a matter of fact, is this over-maintenance that causes failures absence, and therefore data scarcity.

In every case, the integration of the same 7 variables was problematic due to collinearity problems, these variables correspond to X_1, X_2, X_3, X_4, X_6, X_7

Table 1. Identified MCCs.

Reference	Indenture Lv.	Description
HTS01	1	Control panel
HTS0101	2	Control Electronics
HTS02	1	Evaporator Module
HTS0201	2	Air filter
HTS04	1	Compressor Module
HTS0403	2	Compressor

Table 2. Covariates.

Variable	X_i	Selection criteria
Number of passengers	X_1	People is a source of humidity and heat so the company believes that the annual average of passenger for every project has to be included since it might affect the reliability
Refrigerant	X_2	The kind of refrigerant the HVAC system of every project is using modify the pressure it works
Number of stops	X_3	The bigger the number of stops of every project is the more the HVAC system is exposed to heat loss or gain and therefore the more it has to work.
Intensity of use	X_4	For every project the contractual available trains working is different as well as the fleet to provide that availability and therefore the HVAC system work load differ from every project
Relative humidity	X_5	As one of the functions of the HVAC system is to provide comfortable room humidity levels the outside atmospheric humidity will condition its work load
Maximum distance between stops	X_6	The distance between stops its equivalent to the time the HVAC is working and its capability to reach working permanent regime. To incorporate the deviation of this variable the maximum and the minimum distances for every project are also taken into account.
Minimum distance between stops	X_7	
Average distance between stops	X_8	
Maximum temperature	X_9	As the main function of the HVAC system is to provide comfortable room temperature the outside temperatures will condition its work load. To incorporate the deviation of this variable the maximum and the minimum temperatures is also taken into account
Mean temperature	X_{10}	
Minimum temperature	X_{11}	

and X_8. Most of them are project specifications and therefore the value of one of them determines the value of the others since it corresponds to a certain project. As a result of the variables demeanor, it is impossible to distinguish in the regression the individual effects of every one of them.

Due to this problem, it has been only possible to fit into the models the uncertainty variables corresponding to the relative humidity and the temperature, which are X_5, X_9, X_{10} and X_{11}.

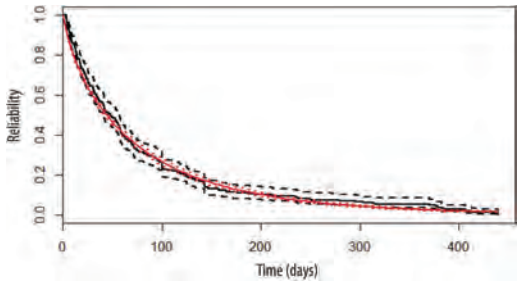

Figure 3. HTS01 survival baseline fit (Weibull, 95% CI).

5.1 *HTS01: Control panel*

In the analysis of this MCC, two covariates are found to be statistically significant, with a default p-value of 0.01 for the hypothesis contrasts. These two covariates are the relative humidity and the minimum temperature (X_5 and X_{11}) with coefficients $\beta_5 = -0.008$ and $\beta_{11} = -0.041$. Both of the coefficients are lower than zero meaning that the higher the variables' values are, the lower the asset's failure rate.

Due to the resulting values of the coefficients, a unitary increase in the relative humidity (at a constant minimum temperature) provides a 0.8% lower failure rate; and a unitary increase in the minimum temperature (at a constant relative humidity) provides a 4.02% lower failure rate.

With a valid PHM, the fit of the baseline function in the mean values of the two covariates has been performed. A Weibull Distribution has been fitted to the non-parametric baseline function, it can be seen in Figure 3 with the 95% confidence intervals for both functions. These results have been contrasted with the collaborating company and there is one major conclusion about the component and its resulting PHM.

It is worth to highlight how the higher the minimum temperature is the better the component performs. After discussion with the HVAC technicians, a likely explanation for this phenomenon has been found. The technicians point out that there is not forced ventilation for the electronic components, thus their temperature is not controlled and the outside temperature will have more influence on their behaviour. It also has been long noticed how the failure rate of the control panel increases when there are important temperature fluctuations

within the day. Thus it is believed that the modeled positive impact of the minimum temperature increase, reflects the observed negative impact of temperature fluctuation. This discussion has lead to future conjoint works.

5.2 *HTS0101: Control electronics*

This component is a subsystem of the HTS01 previously studied, and it is reasonable to think that its resulting PHM will share some features with the one from the HTS01 analysis. As it was thought, they do share properties; the minimum temperature is the only variable that allows fitting a valid Cox model and therefore a single-covariate PHM is obtained. The coefficient associated with this variable is $\beta_{11} = -0.045$ and it provides a 4.44% lower failure rate by a unitary increase of the minimum temperature.

It can be seen that the effect of the minimum temperature is defined by a negative coefficient, meaning that the higher the minimum temperature, the better reliability the asset will have. The technicians have validated this result through the same reasoning applied to HTS01. The fit of its undefined baseline function, in the mean value of the covariate, to a Weibull distribution can be seen in Figure 4.

It is important to notice that the effect of the minimum temperature is almost equal in HTS01 and HTS0101. However not only is this coefficient similar, but the fits to Weibull distributions result in very similar shape parameters. It is also important to mention that the scale parameter of HTS01 is smaller which is reasonable since HTS01 includes HTS0101 whose scale parameter is over 65% higher.

Therefore the control panel and the control electronics are both affected by the same risk factor, and their behaviour is also similar because of their shape parameters. However, the reliability of the HTS01 is lower because it depends on the failure rate of HTS0101, and on other components' failure with a serial arrangement as well.

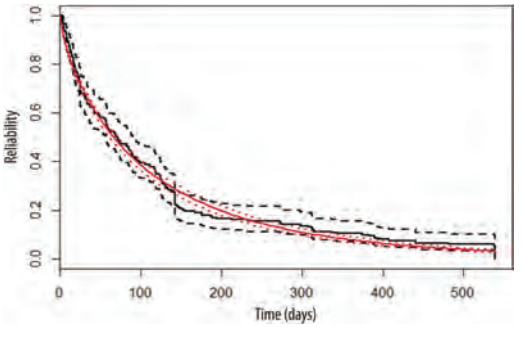

Figure 4. HTS0101 survival baseline fit (Weibull, 95% CI).

5.3 *HTS04: Compressor module*

The number of data available for this MCC was not very large, in spite of this inconvenience, a proper Proportional Hazards Model has been found to describe the behaviour of the component with enough statistical significance. The influential variables for this MCC are the relative humidity and the mean temperature, with their corresponding coefficients equal to $\beta_5 = 0.0547$ and $\beta_{11} = 0.1316$. In this case, both of the covariates are associated with positive coefficients meaning that the higher values of the covariates, the higher risk of failure. Being more specific, if the relative humidity increases one unit (at a constant mean temperature) it provides a 5.62% increase of the hazard function; and if the unitary increase happens in the mean temperature (at a constant relative humidity value), the increase in the hazard function equals 14.07%. Once the PHM has been adjusted and validated, the hazard function in the mean values of the covariates is fitted as proposed in the methodology. It can be seen in Figure 5, and it is important to notice how the fitted curve is not as accurate as in the previous MCC because of the data scarceness.

It is remarkable the major effect of the mean temperature, it reveals that it is an important risk factor to take into account when designing the maintenance strategy of this critical component. The collaborating company validates this results, and they have been dealing with a problem that backs up the results here obtained.

6 BENEFITS & CONCLUDING REMARKS

In this paper, a failure rate model for different components of the HVAC system is proposed considering different risk factors of the operational context. The main contribution of this paper is the PHM approach following an established methodology that set a number of steps for a proper application of the Cox model. It has been demonstrated

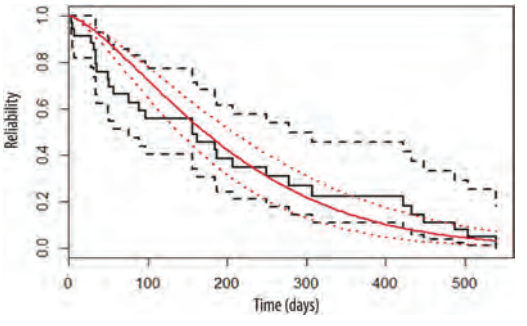

Figure 5. HTS04 survival baseline fit (Weibull, 95% CI).

that as thought, the temperature and the relative humidity influence the behaviour of the asset.

In the last step of the methodology, by fitting the baseline hazard function in the mean values of the covariates, a Weibull PHM is obtained. The obtained failure rate model consists of a completely parametric equation (see Equation 5). The parametric equation has three important advantages:

- In the offer stage it allows to know the asset reliability before it starts to operate, and therefore it is possible to develop an optimized maintenance plan that better fits the reality of the asset operation improving the efficiency and effectiveness of the maintenance activities. The customized reliability enables a more accurate Life Cycle Cost (LCC) analysis that may be a competitive advantage in tender processes, setting the company a step forward their competitors.
- From the after-sales service's point of view, one of the most significant advantages is the improvement of the management of an assets fleet in which every one of them is working in different operational conditions and shows a different failure mechanism. This improvement in the management will result in higher availability rates, and accordingly a revenue from the decreased costs due to non-availability, and in savings derived from the enhanced customization of maintenance frequencies. It is remarkable that not only is the OEM making profit of the new reliability model, but the assets users as well.
- Depending on the arrangement of the components of the asset, it is possible that in certain operational contexts the criticality of the components will increase due to a higher failure rate caused by one or more variables of the context. The proposed model allows to foresee this criticality increase and to anticipate its consequences by identifying the components in which the maintenance service should focus its efforts.

As a future work, it is necessary to study a way of modeling the impact of project specifications, since it is not possible to integrate their information in the proposed PHM due to collinearity problems.

It is interesting to remark that some uncertainty variables, such as the number of passengers, could be integrated into the model if a more detailed record of the variable were available.

The work here presented can serve as basis approach to future predictions of HVAC systems reliability, and also as a tool to integrate external information into the assets managers decision-making process. The authors reckon that by further work it will be possible to extrapolate the methodology here proposed to reliability modeling for several assets, and it will enable a more efficient asset management by a better customized and accurate maintenance plan design in the offer stage.

Opportunistic maintenance strategy for a train fleet under safety constraints and inter-system dependencies

H. Ghamlouch & A. Grall
ICD/LM2S – UMR CNRS 6281, Université de Technologie de Troyes, Troyes, France

ABSTRACT: The aim of this work is to propose a modeling framework to call into question the maintenance regulations of a train fleet and improve an enforced maintenance policy without disrupting its main structure. The considered fleet is constituted of identical trains. A fixed periodic preventive maintenance planning is imposed by the manufacturers for safety and operational quality requirements. Each overhaul includes a set of pre-defined tasks such as inspection, minimal repair activities and preventive replacement of some components. During inspection if the degradation level of a component exceeds a primary replacement threshold it is precautionary replaced. In case of failure of at least one component when the train is in operation, it is immediately replaced. In this paper we propose the introduction of opportunistic maintenance activities to improve the periodic maintenance strategy while operating within the constraints of imposed planning. Opportunistic maintenance can include early revisions or precipitate preventive replacements of some component (with respect to scheduled preventive replacement or their primary replacement threshold). Dynamic maintenance task can be applied additionally during corrective activities or pre-scheduled revisions. Dependence matrices are used in order to consider stochastic dependencies between the system's components. Economic dependence is basically derived from a tree-like set-up model. A specific replacement threshold dedicated to opportunistic preventive replacement as well as a flexibility degree of revision dates are introduced. Multiple constraint are also considered for optimization: availability, work hours and number of simultaneously revised systems. A comparison between the periodic maintenance strategy with and without opportunistic tasks is presented.

1 INTRODUCTION

In transportation industry, production, operation and maintenance costs along with system's reliability and safety can be very decisive in the business success and continuity. In this context, management tools adopted by manufacturing and operators companies are continuously enhanced in order to increase systems' reliability as well as passengers safety and comfort. These tools specially allows to determine operation scheduling methods and maintenance strategies.

The optimization of maintenance policies in manufacturing organization is not a recent subject for researchers (Barlow and Hunter 1960). A first review of issues and results concerning maintenance scheduling problems and how crucial this later can be on the productivity and competitiveness of both manufacturing and service organization was pointed out by Paz and Leigh 1994. Ever since, maintenance strategies development and optimization have been considered in different domains, for instance: energy production systems (Sikos and Klemes 2010), (Shafiee 2015), transportation (Fritzsche et al. 2014, Liden 2015), networks (Morcous and Lounis 2005), infrastructures (Rios-Mercado and Borraz-Sánchez 2015), etc.

Maintenance strategies are usually classified in two categories: 1) corrective maintenance where maintenance is held when the system fails and 2) preventive maintenance where maintenance is held in a precautional way in order to prevent system failure. This later is usually adopted for systems with severe failure consequences. In a preventive maintenance strategy the systems components are maintained or replaced according to specific rules that usually consider system's age, deterioration level, operation time, etc. Depending on the system nature, different criteria can be considered for maintenance policy assessment and optimization such as mean cost rate, availability, downtime or combined economic and reliability criteria. A detailed survey of maintenance policies and deterioration modeling as well as optimization criteria is given by Wang (2002). A recent review of past and current research on optimal maintenance policy selection issues in manufacturing domain is given by Ding and Kamarudding (2011). Maintenance mathematical models as well as numerical algorithms for optimization were respectively reviewed by Vasili et al. (2011) and Alrabghi and Tiwari (2015).

Most of maintenance optimization studies in railway field have been focused on railway infrastructure maintenance Liden (2015), Bianchini Ciampoli

et al. (2017). This later can consume very large budgets has numerous challenging planning problems. Besides of the railway infrastructure, the main part of railway system is the rolling stock. Time spent in the maintenance of rolling stock may disrupt the operation and can cause financial losses as well as customers dissatisfaction. A major challenge for trains operators is to ensure required train service with limited rolling stock units. An operator should also respect the requirements of the trains manufacturer and security norms. This can be achieved if the correct maintenance strategy is adopted.

Despite the increasing efficiency of sensors and on line monitoring devices most of the maintenance strategies recommended by rolling stock manufacturers and adopted by railway operators are based on traditional periodic scheduling of maintenance operations, Eisenberger and Fink (2017). Classical periodic preventive maintenance strategies often lead to incorrect maintenance work, unnecessary maintenance tasks and often revert to corrective maintenance or breakdown maintenance (Rezvanizaniani et al. 2008). Different levels of inspections are defined and scheduled in a periodic manner according to a specified number of operation time or kilometers Sriskandarajah et al. (1998). Significant improvement in operation and maintenance cost could be obtained by implementing condition-based or predictive maintenance strategies which allow to anticipate system failure (Giacco et al. 2014). In complex systems the interaction between different components plays a major role in system deterioration and failure prediction and should be considered when setting the decision rules. Dependencies can offer more opportunities to group maintenance activities and reduce maintenance costs. Maintenance optimization for multi-component systems with internal dependencies is an important subject in maintenance optimization scholars (Nicolai and Dekker 2007). The main aim of this paper is to investigate the possibility to take advantage of opportunities to improve a traditional maintenance policy based on regulatory obligations.

This paper considers constraints of manufacturer and security instructions which are controlling the existing maintenance planning and cannot be modified easily. An opportunistic maintenance strategy is proposed for tram trains considering system dependencies. This work is a part of DIADEM project (Dynamic Diagnosis and Predictive Maintenance for Train Onboard Systems) which handles the case of Rennes's tram fleet. The company KEOLIS which is operating the Rennes's tram fleet is currently adopting a systematic preventive maintenance strategy that is scheduled according to manufacturer instruction and security norms. Tram fleet system description as well as the existing actual maintenance strategy are detailed in section 3. The approach proposed to add flexibility is presented in section 4. First the system and maintenance model are presented with strict maintenance rules. Then two new parameters are introduced: 1) the flexibility degree which allows the operator to modify the scheduled systematic replacement activities and 2) the secondary replacement threshold which allows the operator to anticipate replacement activities when it is beneficial. Finally, empirical results from numerical simulation are given and discussed.

2 COMPLEX SYSTEMS AND DEPENDENCIES

In order to manage system health and maintenance scheduling for multi-component systems a good understanding of components interactions and dependencies is essential. According to Thomas (1986) components dependencies can be classified as economic, structural or stochastic dependencies. Economic dependence implies that grouping maintenance activities causes variation of the maintenance cost. Stochastic dependence means that the conditions (or status) of two or more components are related either in a deterministic or probabilistic way. In case of structural dependences the maintenance of one component requires the maintenance or at least dismantling of others. In this section a brief review of system dependencies and their modeling in maintenance optimization is presented.

2.1 *Economic dependence*

Economic dependence means that the cost of a joint maintenance on several components is not equal to the sum of their individual maintenance costs.

In this paper we consider positive economic dependence which usually refers to economies of scale. It takes into account the reduction of setup activities and costs when several components are maintained simultaneously (Papadakis and Kleindorfer 2005). The economies of scale have been introduced to maintenance optimization in multiple forms. A single setup model is considered by Schouten et al. (1998) in order to evaluate preventive and opportunistic maintenance policies for traffic control lights. "Single setup" means that for simultaneous maintenance of two or more components a specific setup cost is paid only once. The single setup model is commonly used in maintenance optimization, see for example (Castanier et al. 2005), (Scarf and Deara 2003) and (Budai et al. 2004). Different setup activities can also be considered, leading to multiple setup models. In this case dif-

ferent components may or not share one or more setup activity. This model has been used by van Dijkhuizen (2000) where a tree-like setup structure was developed in order to reduce maintenance cost for an industrial production system. Another form of positive dependence is the downtime opportunity. Some components failures can be considered as an opportunities for preventive maintenance e.g. because they cause a system shutdown. The downtime required for corrective maintenance allows preventive maintenance and/or inspection in shared time which reduces the total downtime costs. This model is basically used in transportation field because of the nature of the system operation and maintenance (Sheu and Jhang 1997, Higgins 1998 and Sriskandarajah et al. 1998).

2.2 *Stochastic dependence*

Stochastic dependence occurs as the result of physical or operational interaction between components. The status of one component may influence the deterioration level or the lifetime of others. Stochastic dependence can be classified into three different types (Murthy & Nguyen 1985). The first type (type I) is when the failure on component i may introduce complete failure of component j with a certain probability p. In this case the failure of component i is called natural failure, while the failure of component j is considered as induced failure. This model has been considered for maintenance e.g. in (Scarf & Deara 2003) and (Jhang & Sheu 2000). Type II is defined when the failure of component i can induce a failure of component j with probability p but failure of component j induces a direct failure of component i. In case of deteriorating components, failure of component i acts as a shock to component j increasing its deterioration level with a random amount. Component j fails when the total deterioration level exceeds a failure level. This model has been e.g. used in context of maintenance optimization in Satow & Osaki (2003). The third type of stochastic dependence considers that failure of each components acts like a shock on other components, inducing a random increase on their failure rate or deterioration levels. It was first used by Özekici (1988).

2.3 *Structural dependence*

Structural dependence between multiple components implies that the maintenance of these components should always be applied simultaneously. Related components can not be maintained individually. For systems with structural dependence both opportunistic maintenance policy and preventive maintenance policy seems to be advantageous (Nicolai & Dekker 2007).

3 DIADEM PROJECT AND THE CASE OF RENNES' TRAM TRAIN

DIADEM project focuses on the development of diagnostic and prognostic tools for sensitive components of railway rolling stocks. The final aim is to develop new decision-making tools for maintenance management. This paper focuses on one collateral objective which is to question an actual current maintenance policies and to propose improvements while preserving the same rules. A fleet of 12 identical trains is considered. The tram fleet is operating in an alternative way in order to ensure the requested service availability of $P = 8$ out of $N = 12$ trains. During stand-by phase the non operating trains can be held in the main station in order to cover any additional load, for example in the case of a train failure, or are brought to the workshop in order to undergo maintenance activities.

The operation of different units (trains) is controlled by a special management tool which accords daily services to the train fleet according to three activity profiles (intense, medium or low activity profile). Note that different operation modes for different trains implies that, some trains will undergo faster deterioration process than the others. Thus, preventive maintenance scheduling and probability of failure are distributed with respect to the time interval which prevents the overcrowding of the maintenance workshop.

3.1 *The applied maintenance strategy*

The actual maintenance strategies adopted by the operator of Rennes' tram fleet is described hereafter. A sequence of periodic revisions is imposed by the manufacturer for safety and operational quality requirements.

Additionally, online monitoring system is available on each train and connected to a control room in the workshop. The monitoring system notifies the operator of any malfunction in any of the train's monitored equipment. No matter of how serious or dangerous the malfunctioning can be or not, the operation of the faulty train is immediately interrupted. The train is temporary replaced and directed to the workshop for corrective maintenance. Revisions and preventive maintenance activities are not allowed during the corrective maintenance period. No matter how short is the time before the expiry of the next revision period, the faulty train should be returned to operation mode directly after the application of corrective maintenance.

3.2 *System components and subsystems*

The considered tram system consists of 12 identical trains. Each train is composed of two cars

connected by a coupling system. Referring to trains operational and maintenance manuals given by the manufacturer, trains subsystems are defined according to their operational function. Thus a single subsystem may include several components that are physical distributed in one or both cars.

Nine types of embedded subsystems are considered. Each subsystem consists of multiple components which can be physically distributed in different locations of the trains. 16 different types of components are recorded. The list of components and subsystem under consideration as well as their quantities and other characteristics are presented in Table 1.

The lifetime law of the components are derived from both manufacturing maintenance manuals and the results of the first step of DIADEM project where historical data on trains maintenance activities and failures are collected. For each component type a set of useful information including replacement cost and the total lifetime probability parameters (considered to follow a Weibull function) is available.

In the next section a description of inter-system dependencies and their modeling is presented.

4 THE PROPOSED OPPORTUNISTIC MAINTENANCE APPROACH

As explained in previous section, the adopted maintenance strategy is based on the application of periodic preventive maintenance activities that are strictly scheduled and are coupled with corrective maintenance activities in case of failure. Maintenance activities are performed in the company's maintenance workshop with limited capacities in terms of space and manpower.

According to the company records, and under the current maintenance and operation policies, the tram system ensures a global availability of 0.98. Nevertheless, improvements can be reported on the current maintenance strategy in order to reduce operation costs and because of future requirements on transportation system capacities and availability.

In this paper we show that the consideration of inter-system dependencies and the addition of some flexibility degrees to the preventive maintenance schedule may introduce gains on maintenance costs without harming system reliability and availability. Our proposed approach relies on the addition of opportunistic maintenance actions to the mandatory mixed maintenance strategy. Opportunistic maintenance requires that earlier revisions or precipitate preventive replacements may be permitted under specific rules.

In order to cover the continuity of transportation service at the required frequency, 8 trains out of 12 must be operating simultaneously at any time. Non-operating trains are put on stand-by mode or sent to the workshop for maintenance operations. Note that the operator's workshop dispose of exactly $n = 4$ tracks where non-operating trains can be received. As for today, limitation on financial, technical and human resources of the operator company have not caused any obstruction on tram service and trains availability.

4.1 *The modeling of system operation and dependencies*

Trains operation scheduling is devoted to a special software that uses a selection algorithm designed for this purpose. According to this algorithm, the running schedule of different trains is established so that the dates of systematic maintenance interventions would be distributed in order to avoid the overcrowding of the maintenance workshop.

Because of their physical locations and functional interactions, different components from

Table 1. List of trains' subsystems and components.

different subsystems may present several types of dependencies. Noting that components with structural dependence are considered as a single part, we are only interested by the modeling of stochastic and economic dependencies.

Economic dependence: Setup levels tree
Economic dependence is the natural result of the physical installation of different components. According to system and components description given by the manufacturer manual as well as technical experience of the maintenance team, the setup level of each component is deduced as follows.

We first consider that each train is composed of two main blocks represented by car A and car B. Then each car is divided into smaller block that includes different components and equipment from different subsystems. Block definition and components grouping are done according to their position inside the car. Thus, components of different subsystem may belong to the same block while the components of one subsystem are not necessary belonging to a single block. One simple example is the position of pads and iscs from the braking system which are distributed into 4 blocks, along the two cars. However, pads and discs of one car are installed on one side and the other of its bearing system.

The division of systems components into blocks facilitates the definition of setup activities required for reaching each component. Components requesting the same setup activities in order to be reached and maintained are said to be on the same setup level. Different setup levels can be related according to a sequential order. However the division of setup levels is not straightforward. Setup levels are divided according to a tree-like model. The root of setup tree is considered as the simple activity of bringing the train into the workshop. Disassembling activities of different blocks and components are then classified into their correct position inside the setup levels tree. For each setup level basic setup time and costs are then assigned. Information about the setup levels required by each component are also included in a setup information table. During revision or corrective maintenance activities and in order to reach to specified component, setup activities of its associated setup levels must be applied.

The effect of economic dependence appears when two components having a shared setup level or belonging to the same block are jointly maintained. In this case, to reach both components during the maintenance session, common setup activities should be applied only once. Thus, the setup cost and downtime time of the concerned train can be reduced.

Stochastic dependence matrix
Depending on their physical or operational relationship, stochastic dependences between components may exist or not. The considered dependence are as follows: after failure of one component a shocks occur on the health condition of dependent components. The shock is considered as a random amount of additional damage which follow a normal distribution. Hence a stochastic dependence matrix is proposed to gather cross dependences between the components of the system. The element *(i,j)* of the stochastic matrix represents the effect of failure of a component of type *i* on the component of type *j*. This element consists of four parameters:

- The first parameter is defined as a boolean variable that determines either or not the failure of a component *i* will affected the status of other components of type *j*.
- The second parameter is also defined as a boolean variable that specifies whether the stochastic relation between components of types *i* and *j* is conditioned by the fact that both components belongs to same block or car.
- Parameters 3 and 4 represent the mean and variance of the normal distribution that quantifies the additional damage caused by the failure of component *i* on the deterioration level on the component of type *j*.

One can notice that the definition of the stochastic matrix allows the representation of different stochastic dependence types for different components by simply changing the parameters of its element. The parameters of the stochastic matrix in our case study are estimated according to component interaction represented in the manufacturer manual as well as historical records of components failure.

4.2 *Flexibility degree and secondary replacement parameters*

As described in section 3.1, the currently adopted maintenance strategy is a combination of preventive and corrective strategies. Preventive maintenance activities are grouped into 3 types of systematic revisions which are periodically scheduled for each train according to its rolling distance. At each revision the specified train should be directed to the maintenance workshop and a list of different inspections, cleaning, minimal maintenance activities and components replacements should be applied. For each type of revision a different list of maintenance tasks is defined. Maintenance tasks are carefully selected according to the manufacturer's specifications, components lifetime estimation as well as feedback from the workshop technicians experience. During revision, replacement of non-defected components should be applied if the inspection activities reveal that the deterioration level of this component exceed a predefined replacement threshold (which we will call the pri-

mary threshold). Each revision type requires a minimal revision cost and minimal downtime of the system which are both registered in association of the maintenance tasks list. The total cost of a revision is the sum on minimal revision cost setup costs and the eventual cost of parts replacement.

According to the actual maintenance strategy, corrective maintenance is applied to the faulty train immediately after the detection of faulty behavior. However revisions and preventive maintenance activities are not allowed during corrective maintenance period. Thus, the total corrective maintenance cost includes setup costs, replacement costs as well as any penalty costs in the case of availability loss.

Opportunistic maintenance

An opportunistic maintenance policy is proposed in order to take better advantage of corrective downtime and setup of the system. Early revisions and preventive activities will be allowed according to specified rules. This can be done by adding two new parameters to the maintenance decision rule:

- Flexibility degree: it is applied to revisions periods and allows the operator to perform early revisions. When a faulty train is directed to the workshop for corrective maintenance, the technical team is required to perform the next planned revision if the expiry date of the revision period is close enough.
- Secondary replacement threshold: during the corrective maintenance of a given component, technical team is allowed to inspect and replace other components on the same setup level if their deterioration level exceeds a secondary replacement threshold. The application of this rule may introduce savings on setup costs and also prevents future failure of the system.

In next sections, the addition of these two parameters and the application of the two additional rules is described and discussed.

4.3 *Simulated operation and maintenance: An empirical example*

In this step we are going to test the new opportunistic maintenance approach for the case of Rennes's tram system using numerical and simulation methods. Simulation are based on the following system description: (i) Train fleet consist of 12 trains; (ii) The maintenance workshop dispose of 4 maintenance tracks; (iii) 8 trains must be in service mode continuously in order to ensure the required load.

As explained previously, three types of periodic revisions are defined. Trains are directed to the workshop for revision when their running distance reach one of the periodic revision distance. Running and maintenance of different trains are scheduled by specific software in order to ensure the continuity of transport service and correct scheduling of required revisions. If the load is not handled because of a low number of available trains, a penalty charge is imposed. Penalty costs are calculated per day according the number of lacking trains.

Different data and parameters are required, especially about dependencies and revisions.

- About maintenance baseline: for each type of revision a revision periodicity, maintenance operations as well as minimal cost and duration are imposed.
- About trains states: information about the last revision of each type, running distance, total time spent in the workshop, time and cost spent for all maintenance activities are registered as well as all historical information about failures.
- About components: the type of the component, the block and car it belongs to and its deterioration level are recorded.
- About dependencies: the Stochastic dependence matrix is given.
- About maintenance costs: the setup matrix includes information about duration and cost of each setup level.

According to the maintenance strategy, two different cases are compared. The first case present the imposed maintenance policy as it is currently adopted by the train operator. The second one takes advantage of opportunistic maintenance as described in section 4.2 by introducing flexibility degree and secondary replacement threshold. In both cases trains operation and revisions are scheduled using the same method. When the monitoring system detects a malfunctioning on one of the trains, the operation of this train is interrupted and the train is directed to the workshop for corrective maintenance. Components deterioration and lifetime probabilistic rules are also the same. The two algorithms differ in the following:

First results

Simulation of trains operation and maintenance is held for 60 years. And the empirical results regarding preventive and corrective maintenance as well as setup total costs of the train fleet are given in Table 1. The first column of this table represent the case of initial maintenance policy without opportunistic maintenance. The rest of the table presents the case where opportunistic maintenance actions are introduced with different flexibility degrees and secondary replacement threshold. Note that secondary replacement threshold is represented in % with respect to the primary replacement threshold. Results in this table show the advantage of opportunistic maintenance policies in mixed maintenance

strategy for the case of Rennes' tram fleet. The major advantage is due to savings on setup costs which leads to a smaller cost for operation per train.

The best result is found with no flexibility degree on revisions periods but introducing a secondary replacement threshold of 85% of the primary replacement threshold. Secondary replacement threshold identifies when non-defected components can be replaced during corrective maintenance of other components. This preventive maintenance activity introduce no cost on preventive setup cost because it benefits from corrective setup activities to reach all related components.

Figure 1. Operational information and costs for one train simulated with mixed and opportunistic maintenance strategy using different maintenance secondary threshold and flexibility degrees.

A very close result is found for the opportunistic maintenance with 5% of flexibility degree and secondary replacement thresholds of 80% and 85%. This is also due to savings on setup cost and failure costs. Looking at unavailability durations and average failure rate of trains we also notice that the addition of opportunistic maintenance policy does not introduce any harm to the system availability. However, results in this table suggest that the relation between economic gains and additional decision parameters (flexibility degree and secondary threshold) is not linear nor straightforward. Numerical optimization methods should be implemented for each special case in order to choose the best flexibility parameters to be used.

5 CONCLUSION

Maintenance strategy and optimization is a major concern of operators company in transportation industry. Due to security and safety reasons, the flexibility with maintenance activity planning is very low on the considered fleet which is derived from Rennes' tram train fleet. Additional constraints are due to high request on availability and limitation on maintenance facilities and labor. Trains are maintained according to a strictly scheduled preventive maintenance planning which involves three types of periodic preventive revisions. This paper considers new degrees of freedom in the maintenance policy which are related to additional opportunistic maintenance actions based on dependencies. A dependence matrix and a setup "tree like" model are considered in-order to characterize stochastic and economic dependencies between different components of trains. Two "flexibility parameters" are introduced in the maintenance decision rule. The first one is the flexibility degree which allows the operator to perform earlier revisions. And the second one referred as "secondary maintenance degree" allows the operator to perform preventive replacement of non-defective parts during corrective maintenance of other components.

The effect of introducing flexibility parameters into maintenance strategy has been tested numerically. The results show the interest of opportunistic maintenance and suggest that it could be very advantageous in terms of maintenance cost savings without harming system availability. However, the choice of flexibility parameters is not obvious. Advanced numerical methods should be used in order to optimize the decision variables. The effects of different failures on system security and passengers safety have not been considered in this study. A fixed penalty cost is used to quantify the unavailability cost caused by the failure of any of the train's components. Further studies may focus

on types and effects of system failures in order to take them into consideration in maintenance optimization process.

ABSTRACT: The quality and reliability of road infrastructure and its equipment play a major role in road safety. This is especially true for autonomous car traffic guided mainly by a GPS system that is, unfortunately, neither precise nor reliable. In order to improve the guidance systems, one option could be to equip the vehicle with a camera reading road markings. Such solution require maintenance strategies guaranteeing markings' perceptibility to the human eye or the autonomous car camera. Currently, the retroreflection luminance of markings is measured for evaluating marking degradation. An important remaining step is a life time analysis depending on the inspection strategy. Since the exact failure time isn't generally observed, feedback database contain many censured data: the left-censure corresponding to a marking failing before the first inspection, the interval-censure that corresponds to markings failing between two inspections, and the right-censure corresponding to a marking that never fails. In the literature, a Weibull analysis was proposed to estimate the markings reliable distributions using the Maximum Likelihood through the Newton-Raphson method. Facing with censored data, this approach couldn't be computed without introducing strong bias in the reliability estimation. For generic interval-censored data, Pradhan and Kundu proposed an alternative, based on the EM algorithm. In our study an extension of the EM algorithm processing left and right censures is proposed. Finally, this algorithm is applicable for all kind of observations, whatever the censure nature. After introducing this EM extension, the paper focuses on the fact that computations are simpler than the Newton-Raphson methods and censored-data are directly estimated. The French National Road 4 markings case is considered to illustrate the proposed approach. Moreover, the proposed algorithm being generic, its application is, of course, not limited to our road marking case study.

1 INTRODUCTION

The quality and reliability of road infrastructure and its equipment play a major role in road safety. This is especially true for autonomous car traffic. Currently, autonomous vehicles are guided mainly by a GPS system. Unfortunately, GPS systems are neither precise nor reliable. For example, GPS signals couldn't work in urban canyons or tunnels. In order to improve autonomous vehicle guidance systems, one option would be to equip the vehicle with a camera able to "read" road markings. However, this solution requires a maintenance strategy guaranteeing that road markings remain perceptible to a human eye or an autonomous car camera.

According to both the AFNOR rules (AFNOR 2009) and the available inspection devices, the retroreflection luminance of markings is the only measure used for evaluating marking degradation. A retroreflective marking reflects light from a vehicle headlight back in the direction of the driver. For waterborne markings, the retroreflective property is guaranteed by glass spheres mixed into the paint during application. The retroreflection luminance is measured in millicandela per square meter and by lux ($mcd/m^2/lx$). A minimum threshold of 150 $mcd/m^2/lx$ is required for a new marking (AFNOR 2009).

Several decay models for retroreflective marking exist in the current literature which mainly calculate retroreflective luminance based on a regression model. For example, Lu (1995) proposed an exponential regression model function of age of markings, Abboud & Bowman (2002) developed exponential models as a function of the Annual Average Daily Traffic (AADT) and the age of markings, Sarasua, Clarke, & Davis (2003) calculated the difference in reflectivity over time,

Sitzabee et al. (2009) proposed the most complete decay multilinear model as a function of time, the initial retroreflection, the AADT, the lateral locations of markings and marking color. All decay models have a common weakness: they are difficult to apply directly to a given road network. For example, consider a single road. The road is not systematically maintained in its entirety. For safety reasons, road managers maintain only specific areas at a time. This is especially true for road surface maintenance.

In a previous study, a clustering approach able to segment a road network according to past inspections was proposed (Redondin et al. 2017). Each cluster was interpreted with respect to a specific area of the road network and admits its own retroreflective luminance evolution over time. This fact leads to each cluster having its own optimum maintenance strategy. An important remaining step is to do a life time analysis. This work could confirms the necessity of one maintenance strategy by cluster and is the first step to develop any maintenance model.

Currently, road markings are monthly or yearly inspected by a retroreflectometer. Thus, such a periodical approach isn't able to determine the exact failure time for any marking. Moreover, in feedback database, three kinds of censure are observed: the left-censure corresponding to a marking failing before the first inspection, the interval-censure that corresponds to markings failing between two inspections, and the right-censure corresponding to a marking that never fails.

A Weibull analysis was proposed by Sathya narayanan et al. (2008), which consists of estimating the markings reliable function using a Weibull distribution. Its parameters are estimated according to the Maximum Likelihood Estimator (MLE). In attendance of censored-data, the likelihood function depends on the probability density, the cumulative distribution and the reliable function of a Weibull distribution. For interval-censored data, Pradhan and Kundu (2014) found instances where the Newton-Raphson does not compute. An alternative, based on the EM algorithm (McLachlan & Krishnan 2008) has been proposed.

Section 2 proposed an extension of the EM algorithm processing left and right censures. The proposed algorithm is applicable for all observation vectors, independently of the nature of the censure. After introducing this EM extension, this paper will focus on a simpler computations than the Newton-Raphson methods (Bain & Englehardt 1975). Morever, censored-data are directly estimated. Then, the proposed approach could be applied for other cases studies and are not restricted to roadmarkings considered in this paper.

As in, the French National Road 4 inspection database is considered to illustrate the proposed approach and its use for analysing maintenance cycles. Two applications are proposed: on the one hand, the first take into account the whole maintenance cycle and the EM Algorithm produces one global Weibull analysis. On the other hand, the second segements first the cycle according to a clustering approach (Redondin et al. 2017). Each cluster admits its own Weibull analysis taking into account different decay profiles.

2 IMPROVED EM ALGORITHM

2.1 *Censored Weibull distribution*

In this paper, a Weibull distribution $\mathcal{W}(\alpha,\beta)$ is defined by its associated probability density function (1) where $\alpha > 0$ and $\beta > 0$ are respectively the associated scale and shape parameters.

$$f(t) = \begin{cases} \frac{\beta}{\alpha}\left(\frac{t}{\alpha}\right)^{\beta-1} e^{-\left(\frac{t}{\alpha}\right)^{\beta}} & \text{if } t > 0 \\ 0 & \text{if } t \leq 0 \end{cases} \quad (1)$$

The observed data $(t_1,...,t_n)$ is assumed independent identically distributed. In this paper, an observed failure is a failure established according to a given inspection strategy. $\forall i = 1,...,n$, t_i is assumed to be the first observed failure moment of i. Three censorship cases are assumed.

- If a failure has occurred before the first inspection, then it is called left-censored.
- If a failure has occurred between two inspections, then it is called interval-censored.
- If a failure hasn't been observed, then it is called right-censored.

If t_i is interval-censored, then its associated interval is $[l_i, r_i]$. The interval is clearly defined according to the current inspection strategy. A censor detector is associated for each observation as follows $\forall i = 1,..,n$.

$$\delta_i = \begin{cases} 0 & \text{if } t_i \text{ is uncensored} \\ 1 & \text{if } t_i \text{ is left-censored} \\ 2 & \text{if } t_i \text{ is interval-censored} \\ 3 & \text{if } t_i \text{ is right-censored} \end{cases} \quad (2)$$

From now, the observed data is subdivided according to the censor detector.

$$\mathcal{T} = \left\{ t \in \left((t_1, \delta_1),...,(t_n, \delta_n) \right) / \delta_i = 0 \right\} \quad (3)$$

$$\mathcal{X} = \left\{ x \in \left((t_1, \delta_1), ..., (t_n, \delta_n) \right) / \delta_i = 1 \right\} \quad (4)$$

$$\mathcal{Y} = \left\{ y \in \left((t_1, \delta_1), ..., (t_n, \delta_n) \right) / \delta_i = 2 \right\} \quad (5)$$

$$\mathcal{Z} = \left\{ z \in \left((t_1, \delta_1), ..., (t_n, \delta_n) \right) / \delta_i = 3 \right\} \quad (6)$$

In the case of an uncensored Weibull distribution, the MLE is the couple (α, β) which maximizes the associated likelihood function (7). This couple annuls also symultaneously the two partial derivates of the log-likelihood function. For the specific case of a Weibull distribution, the solution of this non-linear equations system is currently done by a Newton-Raphson approach (Bain & Englehardt 1975).

$$L(\alpha, \beta) = \prod_{i=1}^{n} f(t_i) \quad (7)$$

The likelihood function associated to a censored Weibull distribution (8) depends on the reliable function S for interval and right censorship cases and it also depends on the cumulative function $F = 1 - S$ for the left censorship case.

$$L(\alpha, \beta) = \prod_{t \in \mathcal{T}} f(t) \prod_{x \in \mathcal{X}} F(x) \prod_{y \in \mathcal{Y}} R(r) - R(l) \prod_{z \in \mathcal{Z}} R(z) \quad (8)$$

Reminder: let's take W a Weibull distribution $\mathcal{W}(\alpha, \beta)$, the reliable function (9) is the probability that the time of failure is later than some specified time $t > 0$.

$$R(t) = P(W > t) = e^{-\left(\frac{t}{\alpha}\right)^{\beta}} \quad (9)$$

For the road markings study, Sathyanarayanan et al (Sathyanarayanan, Shankar, & Donnell 2008) chose this classic approach for a Weibull analysis. In a breast cancer case study and restricted only to interval-censored data, Pradhan and Kundu (Pradhan & Kundu 2014) showed different examples where this approach does not compute. Specifically, the Newton-Raphson approach isn't able to estimate (α, β). An alternative based on a EM Algorithm is proposed. This paper proposed an extension of the algorithm, processing left and right censures.

The EM algorithm interprets censored data like missing data to estimate and computes iteratively into two steps:

1. The Expected Step estimates censored data according to a given Weibull distribution $\mathcal{W}(\alpha, \beta)$.
2. The Maximization Step estimates a Weibull distribution $\mathcal{W}(\alpha, \beta)$ by the MLE according to both uncensored and completed data.

The algorithm computes until one distribution converges. This point is detailed in section 2.4. First, sections 2.2 and 2.3 present the extended algorithm through one given iteration.

2.2 *Improved expected step*

Let's take W a Weibull distribution $\mathcal{W}(\alpha, \beta)$. To simplify the EM formalism, the substitution $\alpha \leftarrow 1/\alpha^{\beta}$ is suggested by Pradhan and Kundu (Pradhan & Kundu 2014). According to that, the density function is done by (10) in this section.

$$f(t) = \begin{cases} \alpha\beta t^{\beta-1} e^{-\alpha t^{\beta}} & \text{if } t > 0 \\ 0 & \text{if } t \leq 0 \end{cases} \quad (10)$$

The Expected Step calculates the estimated likelihood function defined as the maximized expectation of the likelihood function (7) conditioned to uncensored data (11).

$$L_c(\alpha, \beta) = E[L(\alpha, \beta) \mid \mathcal{T}] \quad (11)$$

This conditional expectation leads to produce three estimators $\forall x \in \mathcal{X}, y \in \mathcal{Y}, z \in \mathcal{Z}$. Each one is a conditional expectation adapted for one specific censure: (12) and (14) estimates respectively the left and right censures and (13) is proposed by Pradhan and Kundu (Pradhan & Kundu 2014) for the interval-censures case.

$$\hat{x} = E[W \mid W < x] = \frac{\alpha\beta \int_0^x t^{\beta} e^{-\alpha t^{\beta}} \, dt}{1 - e^{-\alpha x^{\beta}}} \quad (12)$$

$$\hat{y} = E[W \mid l < W < r] = \frac{\alpha\beta \int_l^r t^{\beta} e^{-\alpha t^{\beta}} \, dt}{e^{-\alpha l^{\beta}} - e^{-\alpha r^{\beta}}} \quad (13)$$

$$\hat{z} = E\left[W \mid W > z \right] = \frac{\alpha\beta \int_z^{+\infty} t^{\beta} e^{-\alpha t^{\beta}} \, dt}{e^{-\alpha z^{\beta}}} \quad (14)$$

Finally, the completed likelihood function associated to a censored Weibull distribution is defined by (15).

$$L_c(\alpha, \beta) = \prod_{t \in \mathcal{T}} f(t) \prod_{x \in \mathcal{X}} f(\hat{x}) \prod_{y \in \mathcal{Y}} f(\hat{y}) \prod_{z \in \mathcal{Z}} f(\hat{z}) \quad (15)$$

2.3 *Improved maximization step*

According to the MLE formalism, the couple (α,β) annuls simultaneously the two partial derivates of the completed log-likelihood function.

$$\partial_\alpha L_c = \frac{n}{\alpha} - \sum_{t\in\mathcal{T}} t^\beta - \sum_{x\in\mathcal{X}} \hat{x}^\beta - \sum_{y\in\mathcal{Y}} \hat{y}^\beta - \sum_{z\in\mathcal{Z}} \hat{z}^\beta \tag{16}$$

$$\partial_\beta L_c = \frac{n}{\beta} + \sum_{t\in\mathcal{T}} \ln\, t + \sum_{x\in\mathcal{X}} \ln\, \hat{x} + \sum_{y\in\mathcal{Y}} \ln\, \hat{y} + \sum_{z\in\mathcal{Z}} \ln\, \hat{z} - \alpha\left[\sum_{t\in\mathcal{T}} t^\beta \ln\, t + \sum_{x\in\mathcal{X}} \hat{x}^\beta \ln\, \hat{x} + \sum_{y\in\mathcal{Y}} \hat{y}^\beta \ln\, \hat{y} + \sum_{z\in\mathcal{Z}} \hat{z}^\beta \ln\, \hat{z} \right] \tag{17}$$

This non-linear equations system doesn't admit an obvious solution. Restricted to interval-censored data, Pradhan and Kundu (Pradhan & Kundu 2014) solved this non-linear equations system by a fixed point approach. This choice is due to an estimation of α done by the equation $\partial_\alpha L_c = 0$. Processing left and right censures, the extending estimator is:

$$\alpha = \frac{n}{\sum_{t\in\mathcal{T}} t^\beta + \sum_{x\in\mathcal{X}} \hat{x}^\beta + \sum_{y\in\mathcal{Y}} \hat{y}^\beta + \sum_{z\in\mathcal{Z}} \hat{z}^\beta} \tag{18}$$

This estimator (18) is completely dependent on β: an estimation of β is enough. Furthermore replacing α by (18) in (17), a function $g(\beta)$ as $\partial_\beta L_c = g(\beta) - \beta$ is extracted (19). To simplify, let's take $\mathcal{S} = \mathcal{X} \cup \mathcal{Y} \cup \mathcal{Z}$.

$$g(\beta) = \frac{1}{\dfrac{\sum_{t\in\mathcal{T}} t^\beta \ln t + \sum_{s\in\mathcal{S}} \hat{s}^\beta \ln \hat{s}}{\sum_{t\in\mathcal{T}} t^\beta + \sum_{s\in\mathcal{S}} \hat{s}^\beta} + \dfrac{\sum_{t\in\mathcal{T}} \ln t + \sum_{s\in\mathcal{S}} \ln \hat{s}}{n}} \tag{19}$$

The fixed point of g is the point β as $g(\beta) = \beta$ also defined as the convergence point of the sequence (20). The initial value is arbitrary. This point is detailed at section 2.4

$$(u_n)_{n\geq 0} = \begin{cases} u_0 > 0 & \text{arbitrary} \\ u_n = g(u_{n-1}) & n > 0 \end{cases} \tag{20}$$

To conclude, α is finally deduced from (18).

2.4 *Iteration process and convergence*

The Weibull distribution estimated at the algorithm iteration $k > 0$ is denoted $\mathcal{W}(\alpha_k, \beta_k)$. The initial distribution $\mathcal{W}(\alpha_0, \beta_0)$ is arbitrary. In this paper, α_0 and β_0 are the MLE where the censorships not taken into account.

Sections 2.2 and 2.3 show that one algorithm iteration could be reduced to an estimation of β done by the convergence point of (20) depending on the function g (19) conditioned by estimated data (12–14). As α_k is directly defined both by β_k and (18), the next sequence $(\beta_k)_{k\geq 0}$ is clear-defined as:

$$(\beta_k)_{k\geq 0} = \begin{cases} \beta_0 > 0 \\ \beta_k = \lim\limits_{n\to+\infty} \begin{cases} u_0 = \beta_{k-1} \\ u_n = g(u_{n-1}) \end{cases} \end{cases} \tag{21}$$

$|\beta_k - \beta_{k-1}| < 10^{-4}$ is the selected stopping criterion. Finally, the EM Algorithm convergence is defined both by the convergence of the sequence $(\beta_k)_{k\geq 0}$ and (18):

$$\begin{cases} \beta = \lim\limits_{k\to+\infty} \beta_k \\ \alpha = \dfrac{n}{\sum_{t\in\mathcal{T}} t^\beta + \sum_{x\in\mathcal{X}} \hat{x}^\beta + \sum_{y\in\mathcal{Y}} \hat{y}^\beta + \sum_{z\in\mathcal{Z}} \hat{z}^\beta} \end{cases} \tag{22}$$

Again, the stopping criterion is $|\beta_k - \beta_{k-1}| < 10^{-4}$. To conclude, the substitution $\alpha \leftarrow 1/\sqrt[\beta]{\alpha}$ returns the current Weibull distribution (1).

3 MAINTENANCE CYCLE 2008–2012

3.1 *Presentation of the French National Road 4*

The broken centerline of the French National Road 4 (NR4) is considered to illustrate the proposed approach. The NR4 runs between Paris and Strasbourg. Since 2007, the section of this road between Courgivaux and Vauclerc (~102 km) has been managed by the DIR Est, which inspects this section of the road once a year. Inspections are organized in September in collaboration with CEREMA Est. The selected retroreflectometer is an Ecodyn.

The maintenance cycle selected is composed of 73 measures annotated with a PR. To simplify, each measure is interpreted as one marking. Markings laid in March 2008 and replaced in March 2012. The marking material chosen is supposed be the same. The cycle is localized around three cities: Courgivaux, Sommesous and Vitry-le-François. The direction heading toward Vauclerc is chosen.

Four inspections are available: 6, 18, 30 and 42 months (after March 2008). The retroreflection luminance of a given marking i at the inspection point t is denoted $RL_t(i) \in \mathbb{N}^*$. If $RL_t(i) \leq 150\ mcd/m^2/lx$ then the marking i is failed at t. Let's take τ be the first time when a given marking is observed failing.

$$\tau = \min\{t \in \{6,18,30,42\} / RL_t(i) \leq 150\} \tag{23}$$

According to τ, t_i is the first time when the marking $i = 1,...,73$ is observed failing. If a marking i hasn't been observed, then the marking is right-censored and $\tau = \varnothing$. In this situation, $t_i = 42+$ tentatively.

$$t_i = \begin{cases} \min \tau & \text{if } \tau = \varnothing \\ 42+ & \text{else} \end{cases} \quad (24)$$

The adapted censor detector is deduced (25). From now on, if $t_i = 42+$ them $t_i = 42$. This formalism assumes three censorship intervals ([6,18], [18,30] and [30,42]) and t_i isn't an uncensored observation. Finally, the observed data is finally defined as $\left((t_1,\delta_1),...,(t_{73},\delta_{73})\right)$.

$$\delta_i = \begin{cases} 1 & \text{if } t_i = 6. \\ 2 & \text{if } t_i = 18,30,42. \\ 3 & \text{if } t_i = 42+. \end{cases} \quad (25)$$

According to inspection campaigns, the monitoring of the retroreflective luminance is presented by the Figure 1. All censor case are presented: two failures are observed during the 6th month (September 2008), a group of markings which never failed until the 42nd month (September 2011) exists and the majority of failure is interval-censored. At least two decay models are also presented.

Two approaches could be produced: a global and a clustering Weibull analysis. The global analysis consists in selecting the whole monitoring and estimating one global Weibull distribution. This approach is interesting if the observed data is small. This situation could happen for two reasons. Firstly, current retroreflectometer like the Ecodyn produce generally one average measure every 100 m. This fact reduces considerably the data set size. Secondly, current maintenance strategy could concern only one specific area. The clustering analysis consists in segmenting first the whole monitoring and estimating one Weibull distribution by cluster. This approach is interesting to produce one specific maintenance strategy by cluster over time, but the observed data must be large and must present a diversified censorship case.

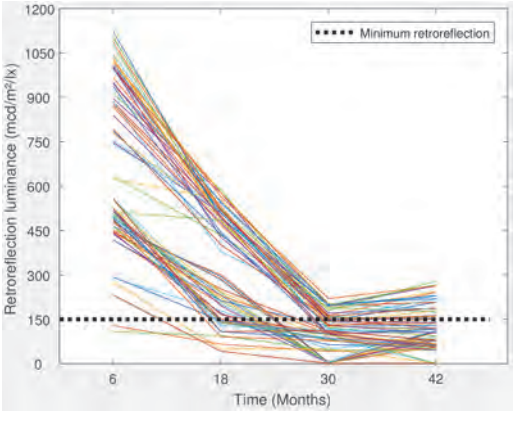

Figure 1. Maintenance cycle on the NR4 brocken centerlines between September 2008 and September 2011.

3.2 *Global Weibull analysis*

The Table 1 presents the Weibull analysis. The first column indicates the observed data associated to the censor indicator. For example, (6,1) corresponds to failures observed during the 6th month (September 2008) and the left-censored case. The second column indicates the number of observation: for example, there are 2 left-censored data and they correspond to 3% of the observed data. The last column indicates the failure time (in month) estimated by the EM Algorith. For example, according to the Weibull distribution $\mathcal{W}(31.65,2.20)$, left-censored data are estimated at 4.12 months (July 2008).

Table 1 confirms observations made on the monitoring. An important case of interval-censored data (74%) is presented. Particularly the main failure is emerged between 18 and 30 months (53%). Right-censored data are the second most important case (23%). Only two markings are left-censored.

The EM Algorithm converges after 12 iterations to the Weibull distribution $\mathcal{W}(31.65,2.20)$. According to this distribution, several estimated failures are proposed. Interval-censored failures are estimated 12.94, 24.01, 35.44 months (March 2009–2010, February 2011). This period corresponds to the average of each interval. Left and right censored failures are respectively estimated to 4.12 months (July 2008) and 50.41 months (May 2012). The maintenance campaign in March 2012 is finally warranted.

Finally, the EM Algorithm is able to produce one Weibull analysis adapted to the whole monitoring.

Table 1. Weibull analysis of the 2008–2012 maintenance cycle.

Observed failure	Numbers	Estimated failure $\mathcal{W}(31.65,2.20)$
(6,1)	2 (3%)	4.12
([6,18],2)	13 (18%)	12.94
([18,30],2)	39 (53%)	24.01
([30,42],2)	2 (3%)	35.44
(42,3)	17 (23%)	50.41

3.3 *Clustering Weibull analysis*

Based on an Agglomerative Hierarchical Clustering, the clustering process proposed in the previous ESREL conference could be restricted to the maintenance cycle (Redondin, Bouillaut, Daucher, & Faul 2017). Two clusters are proposed: Sommesous and other cities. Figure 2 distinguishes clusters on the monitoring. Sommesous (red) represents markings which admit a strong retroreflection luminance, a fast decay between 6 and 30 months and finally a stationary decay until the 42 Months (September 2011). Other cities (blue) present a fast decay between 6 and 18 months and a slow decay until the 42 Months.

The Table 2 presents the Weibull analysis by clusters. The structure is similar to Table 1 excepted the added first column to indicate both the cluster and the Weibull distribution estimated. The EM Algorithm proposed the Sommesous Weibull distribution $\mathcal{W}(41.35,3.5)$ and the Other Weibull distribution $\mathcal{W}(18.83,6.61)$ respectively after 19 and 38 iterations.

Sommesous markings failed mainly between 18 and 30 months and focused all right-censored data. Their failure are respectively estimated at 24.95 months (March 2010) and 49.84 months (April 2012). Other markings failed mainly between 6 and 18 months or 18 and 30 months and focused all left-censored data. Their failures are respectively estimated at 15.23 months (June 2009), 20.14 months (November 2009) and 5.21 months (August 2008).

The clustering process clearly separated the monitoring into two decay profiles. Sommesous markings had a strong retroreflectivity and failed either within 30th month or after the 42nd month while Others markings had a weaker retroreflectivity and failed before the 30th month. Finally, the EM Algorithm is also able to produce one specific Weibull analysis by cluster.

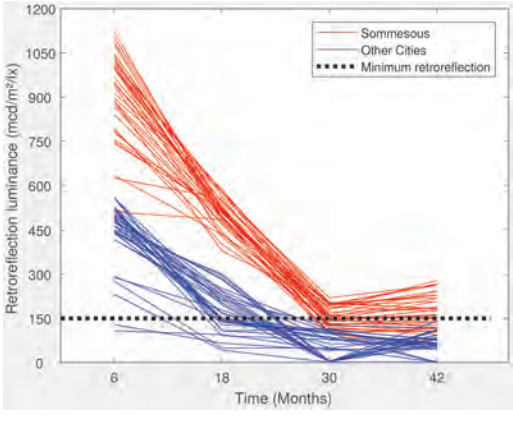

Figure 2. Maintenance cycle 2008–2012 by clusters.

Table 2. Weibull analysis of the maintenance cycle 2008–2012 by clusters.

Cluster	Observed failure	Numbers	Estimated failure
Sommesous	([18, 30], 2)	18 (25%)	24.95
	([30, 42], 2)	2 (3%)	35.11
$\mathcal{W}(41.35,3.5)$	(42,3)	17 (23%)	49.84
Other Cities	(6,1)	2 (3%)	5.21
	([6, 18], 2)	13 (18%)	15.23
$\mathcal{W}(18.83,6.61)$	([18, 30], 2)	21 (29%)	20.14

3.4 *Comparison*

Estimated failures between the global and the clustering models are equivalent to one month. Markings failed between 18 and 30 months in Other Cities are the main difference. The global model estimated the failure in March 2010 and the clustering model estimated the failure in November 2009. The difference is due both to the EM Algorithm computation and the current inspection strategy. First, the September 2010 inspection observed that 53% of markings failed since September 2009 and the associated interval-censored data is ([18, 30], 2) for all markings. Second, the global approach ignores different decay profiles. Therefore in this case, the EM-Algorithm produced one global estimation.

The Figure 3 compares reliable functions according to the global model and the two clusters. The global reliable function (green) underestimates Sommesous over time (–0.12 in average). Other Cities is slightly underestimated the 14th first months (–0.03 in average) and overestimated next months (+0.12 in average) in particular after the 23rd months. Finally, the global reliable function is an average estimation.

The global model is a compromise estimation according to different observations: two left-censored observations, important failure between 18 and 30 months, the quarter of observations is right-censored... The clustering model suggests first several clusters according to the decay profile and each one admit its own Weibull distribution. Therefore the Sommesous Weibull distribution is estimated according to two facts: without failures before the 18th month and all right-censored observations.

The clustering model admits two main disadvantages. First, the clustering process tends to isolate markings which admit one specific censure. For example, all right-censored observation could be gathered into a third cluster extracted from

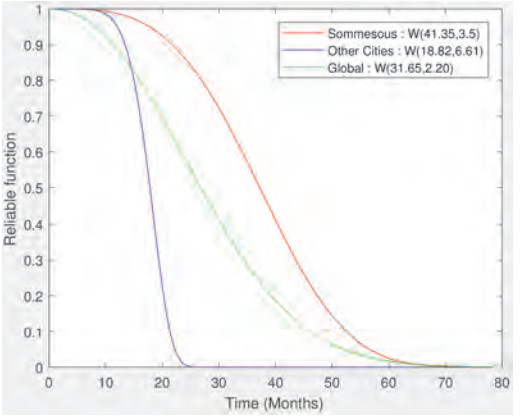

Figure 3. Associated reliable functions according to the maintenance 2008–2012.

Sommesous. In this situation, the MLE is based on the only observation (42, 3) and doesn't compute. The second problem is each cluster admits its own Weibull analysis. The model admits a total of 57 EM Algorithm iterations, whereas the global model admits only 12.

However, the global reliable function concludes to a poor compromise: Sommesous and Other markings reliable are respectively underestimated and overestimated.

Finally, the clustering model has done a more reliable Weibull analysis but the clustering process and the number of EM Algorithm iteration should be monitored.

4 CONCLUSIONS

The current literature presents a first Weibull analysis for road markings (Sathyanarayanan, Shankar, & Donnell 2008). Censored Weibull distributions are estimated by the current approach based on the MLE upgraded by a Newton-Raphson approach. Restricted to interval-censored data, Pradhan and Kundu (Pradhan & Kundu 2014) discoved several limits to this method and proposed a first alternative based on a EM Algorithm.

The introduced extended EM Algorithm is a credible alternative to the MLE of a censored Weibull distribution. This is specially true on the censored data management. Indeed, the EM Algorithm replaces censored data by a failure iteratively estimated at once the Weibull distribution. Furthermore, the EM Algorithm is upgraded by a fixed point approach. This method is simpler than the Newton-Raphson. Indeed, the fixed point depends only to uncensored data and estimated data and doesn't need any upstream verification.

The introduced algorithm isn't limited to our case study. Pradhan and Kundu themselves presented a breast cancer case study for example. The extension accepts a greater variety of situations: uncensored and right-censored data, no-uncensored data, no-interval-censored data. From the moment the decay monitoring over the time and the maximum decay level are both clear, the EM Algorithm is able to produce and rank all censored data.

The EM Algorithm is able to estimate several Weibull distribution in our road markings study. Two approach is proposed. The global model is interesting in the case where the observed data is small. However, the estimated Weibull distribution is an average compromise between different decay profiles. In the NR4 case, the global reliable function overestimates Other markings and underestimates Sommesous markings. The clustering analysis segments first the whole monitoring and estimates one Weibull distribution by cluster. This situation is interesting if the observed data is large and could distinguishes different decay profiles. In the NR4 case, reliable functions are more reliable.

This paper shows that the clutering approach is more reliable that the global model. However, this approach needs a monitoring of the clustering process. Indeed, the current process tends to isolate one specific censure by cluster. Consequently, the MLE could be based on only one observed data and it formalism cannot compute. An alternative based on a mixture model also produces by an EM Algorithm is currently investigated. This approach could estimate directly the optimum segmentation and associated it in one mixture Weibull distribution.

Finally, the Weibull analysis completed by an EM approach is adapted in a road markings study. Furthermore, for given sections of the road network, reliable functions are able to indicate directly each section admits a premature aging for example. These facts lead to the development of a probabilistic opportunistic maintenance model adapted to a whole road network or a segmented road network.

Time-dependent unavailability model integrating on demand-caused and standby-related failures addressing positive and negative effects of testing and maintenance

P. Martorell, S. Martorell, I. Martón & S. Carlos

ABSTRACT: In recent years, many authors have proposed alternative approaches to modelling the effect of ageing and test and maintenance activities. Some authors have proposed approaches to modelling the unavailability of safety-related components associated with standby-related failures that explicitly addresses all aspects of the effect of ageing, maintenance effectiveness and test efficiency. Recently, other authors have proposed a new reliability model for the demand failure probability that explicitly addresses all aspects of the effect of demand-induced stress, maintenance effectiveness and test efficiency. In this context, the paper presents a whole time-dependent unavailability model for a safety component, regarding time-dependent unreliability contributions for each failure mode addressing ageing, degradation stress by demand and effectiveness of maintenance and testing as well as the downtime contributions related to maintenance and testing activities. An application case of a motor-operated valve of a pressurized water reactor nuclear power plant is included. A set of sensitivity cases are presented to show how this model can be used, for example, in the planning of maintenance and surveillance test activities with the aim of minimizing equipment unavailability.

1 INTRODUCTION

The safety of Nuclear Power Plants (NPPs) depends on the availability of safety-related components that are normally on standby and only operate in the case of a true demand. These components typically have two main types of failure modes that contribute to the probability of failure on demand: by demand-caused and standby-related failure.

Both are generally associated with constant values in a standard Probabilistic Risk Assessment (PRA) models. However, both failure modes are often affected by degradation such as demand-related stress and ageing, which cause the component to degrade with chronological time and ultimately to fail. Maintenance and test activities are performed to control degradation and the unreliability and unavailability of such components, although this has both positive and negative effects.

Initial studies reported in Kim et al. (1994) already provided a well-organized foundation to account for ageing as well as positive and adverse effects of testing components for both by demand-caused and standby-related failure modes. However, this model does not take into account the positive effect of maintenance activities as a function of their effectiveness in managing component degradation due to demand-induced stress and ageing.

In recent years, many authors have proposed alternative approaches to modelling the effect of ageing and test and maintenance activities (Kančev et al 2016, Shin et al. 2015, Volkanovski 2012). Martón et al. (2015) proposes an approach to modelling the unavailability of safety-related components associated with standby-related failures that explicitly addresses all aspects of the effect of ageing, maintenance effectiveness and test efficiency. Recently, Martorell et al. (2017) have proposed a new reliability model for the demand failure probability that explicitly addresses all aspects of the effect of demand-induced stress, maintenance effectiveness and test efficiency.

This paper presents a whole time-dependent unavailability model for a safety component, regarding time-dependent unreliability contributions developed by Martón et al. (2015) and Martorell et al. (2017) for each failure mode as well as the downtime contributions related to maintenance and testing activities.

An application case of a motor-operated valve of a nuclear power plant is included. A set

of sensitivity cases are presented to show how this model can be used, for example, in the planning of maintenance and surveillance test activities with the aim of minimizing equipment unavailability.

2 UNRELIABILITY MODELS UNDER IMPERFECT MAINTENANCE

In this paper the model of demand and failure probability standby failure rate, proposed by Martorell et al. (2017) and Martón et al. (2015), respectively, have been joined to develop a whole time-dependent reliability model taking into account the related preventive maintenance and testing activities performed.

On the one hand, demand failure probability of a component normally in standby depends on the number of demands on the component, which depends of performing the planned and unplanned surveillance and functional test, operational demands and test after corrective actions. So, surveillance testing not only introduce a positive effect, but also and adverse one, which is usually compensate by performing maintenance activities to eliminate or reduce the accumulated degradation.

On the other hand, standby failure rate depends on its age, which is a function of the chronological time elapsed since its installation and the effectiveness of the maintenance activities performed on it.

In both models, in order to introduce the effect of preventive maintenance, two imperfect maintenance models are considered: Proportional Age Reduction (PAR) and Proportional Age Setback (PAS).

In the PAR approach, each maintenance activity is assumed to reduce proportionally, in a factor ε, only the component degradation gained from the previous maintenance, while the rest remains unaffected, where ε represents the maintenance effectiveness that ranges in the interval [0,1]. Nevertheless, in the PAS approach, each maintenance activity is assumed to reduce proportionally, in a factor ε, the degradation that the component has immediately before it enters maintenance.

2.1 *Demand failure probability addressing maintenance effectiveness*

The time-dependent demand failure probability could formulated in terms of a time-dependent degradation function, $f(t)$, as follows:

$$\rho(t) = \rho_0 + \rho_0 * f(t) \tag{1}$$

where ρ_0 is the residual demand failure probability and $f(t)$, assuming that the degradation factor is the same for all types of demands and is equal to p_1, $f(t)$ can be formulated as follows:

$$f(t) = p_1 * n(t) \tag{2}$$

where $n(t)$ should include the number of demands performed up to time t. When only test-induced stress is considered, $n(t) = [t/T]$, where T represents the test interval and [x] the floor function that gives the largest integer less than or equal to x.

A time-dependent demand failure probability model that addresses the demand-induced stress and the effect of *m-1* maintenance activities can be formulated for the period *m* as follows:

$$\rho_m(f) = \rho_0 + \rho_0 . f_m(t) \tag{3}$$

being ρ_0 the residual demand failure probability and $f_m(t)$ the degradation function.

This equation can be particularized for $t = t_m = m \cdot M$, immediately after performing maintenance number *m*, and the PAR model, to obtain the formulation of the time-dependent demand failure probability immediately after maintenance *m* (P. Martorell *et al.*, 2017):

$$\rho_m(t = t_m) = \rho_0 + \rho_0 . p_1 \cdot \frac{M}{T} \cdot (1 - \varepsilon_D) . m \tag{4}$$

where p_1 is the degradation factor associated with demand failures, T is the test interval, M is the preventive maintenance interval, m is the number of maintenances performed and ε_D is the preventive maintenance effectiveness associated with demand failures.

Analogously, the time-dependent demand failure probability immediately after maintenance *m* for PAS model can be expressed as follow (P. Martorell *et al.*, 2017):

$$\rho_m(t = t_m) = \rho_0 + \rho_0 . p_1 \cdot \frac{M}{T} \cdot \frac{(1 - \varepsilon_D)}{\varepsilon_D} \cdot \left\{ 1 - (1 - \varepsilon_D)^m \right\} \tag{5}$$

2.2 *Standby failure rate addressing maintenance effectiveness*

In this paper, the linear ageing failure rate model has been considered to model the reliability model of standby—related failures. This model assumes that the failure rate has a linear behaviour with component age departing form an initial reliability, inherently by design, which can be expressed as (Martorell et al., 1999):

$$\lambda(t) = \lambda_0 + \alpha.w(t) \quad (6)$$

where t represents the chronological time, α is the linear ageing factor and $w(t)$ is the component's age after maintenance $m+1$. In Equation 6 component inherent failure rate by design is given by the term λ_0, which represents random failures, while the second term $\alpha \cdot w(t)$ represents the degradation of the equipment failure rate due to equipment ageing, which is counterbalanced by the effectiveness of the maintenance policy.

This equation can be particularized for $t=t_m = m \cdot M$, immediately after performing maintenance number m, and the PAR model, to obtain the formulation of the time-dependent standby failure rate immediately after maintenance m (Martón et al., 2015):

$$\lambda_m(t = t_m) = \lambda_0 + \mathrm{M} \cdot (1 - \varepsilon_s).m \quad (7)$$

where, ε_S is the preventive maintenance effectiveness associated with standby failures.

Analogously, the time-dependent standby failure rate immediately after maintenance m for PAS model can be expressed as follow (Martón et al., 2015):

$$\lambda_m(t = t_m) = \lambda_0 + \mathrm{M} \cdot \frac{(1 - \varepsilon_s)}{\varepsilon_s} \cdot \left\{1 - (1 - \varepsilon_s)^m\right\} \quad (8)$$

3 UNAVAILABILITY MODELLING

The average unreliability contribution to the unavailability of a component normally in standby over its renewal period can be formulated as follows (Martón et al. 2015, Martorell et al. 2017):

$$u_R = u_{R,S} + u_{R,D} \quad (9)$$

where the $u_{R,S}$ is the standby-related unreliability contribution and $u_{R,D}$ is the demand-caused unreliability contribution.

On one hand, adopting the PAS model to represent the behavior of the imperfect maintenance for the standby-related failures of the component according to the results in the previous section, $u_{R,S}$ is given by (Martón et al, 2015):

$$u_{R,S} \approx \frac{1}{2}\left(\lambda_0 + \frac{1}{2}\alpha M\left(\frac{2 - \varepsilon_s}{\varepsilon_s}\right)\right)T \quad (10)$$

On the other hand, adopting the PAS model to represent the behavior of the imperfect maintenance for demand caused failures of the component according to the results in the previous section, $u_{R,D}$ is given by (P. Martorell *et al.*, 2017):

$$u_{R,D} = \rho_0 + \frac{1}{2}\rho_0 . p_1 . \frac{M}{T} . \left(\frac{2 - \varepsilon_D}{\varepsilon_D}\right) \quad (11)$$

In accordance with Martón (2015), the averaged unavailability of a component is the sum of the average unreliability contributions and the unavailability contributions due to detected downtimes for performing testing and maintenance activities with the plant at power, which can be formulated as follows:

$$u = u_R + u_T + u_M + u_C + u_O \quad (12)$$

where u_T represents the unavailability contribution due to testing, u_M is the unavailability contribution due to performing preventive maintenance, u_C is the unavailability contribution due to performing corrective maintenance conditional to detecting a failure during a previous test, and u_O is the contribution due to replacement of the equipment, if any.

For sake of simplicity, the last two contributions, u_C and u_O, are not included as contributions of total average unavailability due to both are negligible as compared with the downtime effect of preventive maintenance and testing activities.

Thus, the downtime contributions considered in this paper can be evaluated using the following equations (Martón et al. 2015):

$$u_T = \frac{\tau}{T} \quad (13)$$

$$u_M = \frac{\sigma}{M} \quad (14)$$

where τ is the downtime for testing and σ is the downtime for preventive maintenance.

Thus, the averaged unavailability of the component is given by:

$$u = u_{R,S} + u_{R,D} + u_T + u_M \quad (15)$$

Substituting Equations 10, 11, 12 and 14 into Equation 15 yields the following formulation of the total average unavailability of a component:

$$u = \frac{1}{2}\left(\lambda_0 + \frac{1}{2}\alpha M\left(\frac{2 - \varepsilon_s}{\varepsilon_s}\right)\right)T + \rho_0 + \frac{1}{2}\rho_0 p_1 \frac{M}{T}\left(\frac{2 - \varepsilon_D}{\varepsilon_D}\right) + \frac{\tau}{T} + \frac{\sigma}{M} \quad (16)$$

4 CASE STUDY

In this section, an example of application of the model is presented that focuses on a Motor-Operated Valve (MOV) of a nuclear power plant.

Table 1 and Table 2 shows reliability parameters estimated obtained from the plant operational data, i.e. historical failure, maintenance and test data. The imperfect maintenance reliability model that best fit the plant data for by demand caused failures and standby-related failures is the PAS model in both cases. These results are extracted from (Martorell et al. 2017).

The estimates obtained are used to predict the performance of the MOV as a function of test and maintenance intervals. In particular, the MOV average unreliability contribution of each failure mode and the total MOV unavailability are computed and plotted as a function of maintenance and test intervals for a 10 years horizon.

Figure 1 shows the evolution of $u_{R,S}$ and $u_{R,D}$ as a function of the test interval, regarding different preventive maintenance intervals for a 10 years horizon renewal period. It can be seen that $u_{R,S}$ increases significantly for high T and M values.

Table 1. Parameters of the reliability model of standby related failures under PAS model.

Parameter	Value	[Units]
λ_0	5.860E-06	$\mathbf{h^{-1}}$
α	3.424E-10	$\mathbf{h^{-2}}$
ε_S	0.716	–

Table 2. Parameters of the reliability model of demand caused failures under PAS model.

Parameter	Value	[Units]
ρ_0	6.420E-03	–
p_1	5.415E-3	–
ε_D	0.886	–

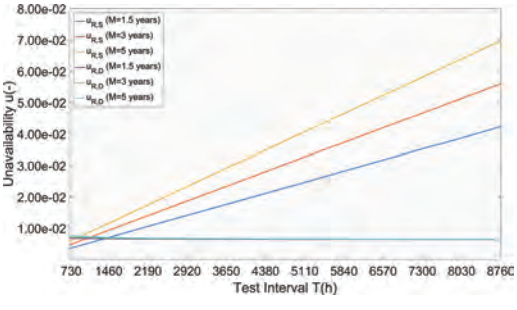

Figure 1. $u_{R,S}$ and $u_{R,D}$ as a function of the test interval for different maintenance periods.

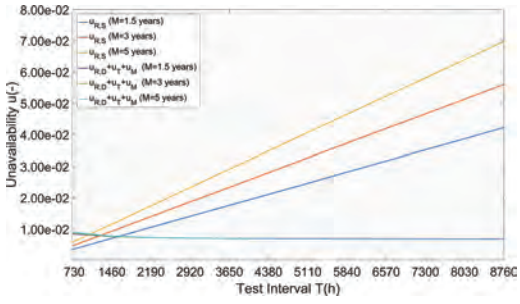

Figure 2. $u_{R,S}$ and $u_{R,D} + u_T + u_M$ as a function of the test interval for different maintenance periods.

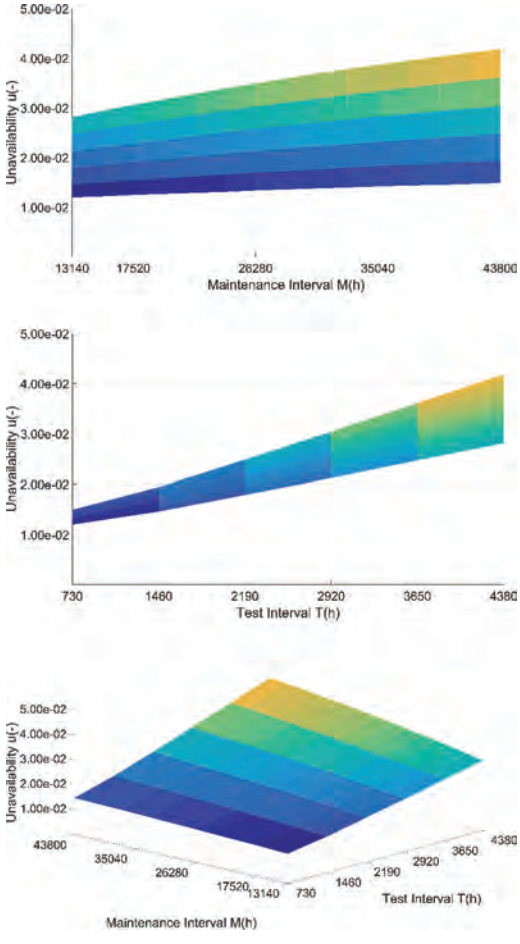

Figure 3. Unavailability for different maintenance and test intervals under PAS model.

Nevertheless, the effect of maintenance is positive for both unreliability contributions. Moreover, an increase on test frequency between maintenances, i.e. low T values, have a very negative effect on $u_{R,D}$ for very low T intervals.

Figure 2 shows the evolution of $u_{R,S}$ versus $u_{R,D} + u_T + u_M$ as a function of the test interval considering different preventive maintenance intervals for a 10 years horizon renewal period. The term $u_{R,S}$ allows quantifying the benefit of developing test and maintenance activities on the total component unavailability while the sum of contributions $u_{R,D} + u_T + u_M$ represents their negative effect.

The last study involves the analysis of the total average unavailability of the component as a function of the couple $\{M, T\}$ for a 10 years horizon, which is shown in Figure 3. The highest values of u are reached adopting the highest maintenance and test intervals. The main contributor to the total unavailability, u, see Equation 15, is the standby-related unreliability contribution given by Equation 10 as it can be seen in Figure 2. This explains the direct and proportional dependence between u and T and M. Nevertheless, the sum of the demand unreliability contribution and downtime effects considered, i.e. downtime effect of preventive maintenance and testing activities, become more relevant for very low T values. This fact is appreciated in Figure 2 too.

5 CONCLUDING REMARKS

This paper presents a whole time-dependent unavailability model for a safety component, regarding time-dependent unreliability contributions for by demand caused failures and standby-related failures as well as the downtime contributions related to maintenance and testing activities. Regarding imperfect maintenance effects, two models are considered: Proportional Age Reduction (PAR) and Proportional Age Setback (PAS).

A practical and realistic case study is included facing the parameters estimation of a typical motor-operated valve in a nuclear power plant. Equipment RAM is quantified based on the best model fitted to make it clear the impact of such an estimation in a testing and maintenance-planning context.

Thus, the results of a whole time-dependent unavailability model may help to plan in a more efficient way the test and maintenance program, which should provide appropriate balance among the different contributions to the unavailability of the MOV, with the aim of minimizing its unavailability assuring a low level of unreliability.

ABSTRACT: In the literature related to reliability and maintainability analysis on reparable equipments, a great number of studies have been published about modelling and analyzing their failure times. However, there are no so much studies which analyze the behavior of these equipments when failures happen at demand. In this case, models are completely different since the failure distribution is discrete. In this work, the model is performed from the real behavior of equipments without any a priori probability distribution. From this model, discrete probability function and cumulative distribution function, needed for the subsequent parameters estimation, are obtained. By combination of these functions and imperfect maintenance models, likelihood function for reliability analysis is constructed to jointly estimate its parameters, that is, the failure at demand probability and the maintenance effectiveness, and their variability. Then, an application case performs the estimation procedure applied to a database of a safety equipment of a Nuclear Power Plant, where the obtained estimations together with their variability can be used to plan optimal test and maintenance intervals.

1 INTRODUCTION

From the end of the last century, studies related to improvement of safety in industrial plants in general, and in nuclear power plants in particular, have acquired special relevance in order to optimize both, the safety of these plants and the resources spent for this purpose. In this context, analyzing reliability through a failure model that adequately represents the behavior of safety equipments is an essential task to which many authors have been devoted (Martorell et al. 1999, Busacca et al. 2001, Nakamura et al. 2004). First problem to solve in these kind of studies is modeling the behavior of these equipments and, consequently, estimating the parameters of such models for a later exploitation of results, fundamentally in terms of optimizing some objectives (Shin et al. 1996, Mullor et al. 2006). Although initially models used were excessively simple, exponential distribution with null or perfect maintenance, the classic Bad As Old (BAO) and Good As New (GAN) models, in order to improve the fit of the model to reality, more complex models, both in terms of failure distribution and maintenance models, have been considered. Weibull, Gamma, linear… failure distributions are currently used since they allow a better fit to reality, simultaneously, imperfect maintenance models, as Proportional Age-Setback (PAS) or Proportional Age Reduction (PAR), which better reproduce the influence of maintenance activities in the components aging process are combined with the previous failure distributions obtaining like this, models more adequate to the objectives.

Even though a high degree of utility in the exploitation of the information obtained from the combination of previous models has been achieved in several applications (Lapa et al. 2000, Mullor et al. 2007), the standby condition in most of safety equipments to which this methodology is applied requires periodic verification of their availability to ensure a high probability of their correctly operation when they are called for performing their task. Mentioned verification of availability generates another problem, each such verification of the state of safety components degrades the said state due to the stress generated by the test, so, in addition to the previous age-dependent failure model for standby equipments, the probability of failure at demand generated by checking their status must be also analyzed. The demand-induced stress has been modeled by an stochastic degradation jumps (Yang et al. 2017) considering that random shocks occur according to a Non Homogeneous Poisson Process, or addressing the effects of test strategies on the probability of failure at demand for safety instrumented systems (Torres-Echeverría et al. 2009).

However, most of these models are not close enough to the true behavior of safety equipments in terms of tests degradation. So this paper focuses

on modeling the probability of failures related to the influence of tests and maintenance activities without assuming any a priori distribution, that is, constructing the probability and the cumulative functions of a discrete probability distribution directly by observed data, that combined with the imperfect maintenance models PAS and PAR provide the needed elements to construct the likelihood function which allows us to jointly estimate the probability of failure due to tests and the effectiveness of each maintenance activity, through the well known Maximum Likelihood Estimation (MLE) method based on the Nelder-Mead Simplex (Nelder & Mead 1965).

Finally, a practical and realistic case study of a typical motor-operated valve in a nuclear power plant is presented. Estimations of probability failure at demand and maintenance effectiveness are obtained through the new discrete model presented adapting its expressions to the MLE functions.

The rest of this paper is organized as follows: Section 2 presents the discrete failure at demand model. Section 3 describes the parameter estimation method in these kind of reliability models. The above methodology is applied in Section 4 to the observed data from a set of High-Pressure Injection System (HPIS) motor valves of a NPP. Finally, Sections 5 and 6 present the conclusions and references.

2 DEMAND-CAUSED FAILURE MODEL

The construction of this model is, in essence, simple, but somewhat more complex in its formalization. We start from a null initial failure probability, which means that the probability of failure at demand is zero until the first test. When this first test is performed, the probability of demand failure becomes p, and remains constant until the instant of the next test in which increases, again, by p, becoming from that moment $2p$, and so on until the test immediately before the first maintenance, in which has been reached a failure probability of

$$p_1^- = kp \tag{1}$$

where k is the number of test performed in the first maintenance interval. Next action will be the first maintenance in which previous probability of failure will be reduced, depending on its effectiveness, ε, up to

$$p_1^+ = p_1^-(1-\varepsilon) = kp(1-\varepsilon) \tag{2}$$

and the same process is repeated from this point. Starting, in this case, from p_1^+, each test increases the failure probability in a constant p, until reaching, in the test immediately before the second maintenance, a failure probability of

$$p_2^- = p_1^+ + kp = kp(1-\varepsilon) + kp \tag{3}$$

At this instant, the reduction of failure probability after the second, and following, maintenance will depend on the imperfect maintenance model applied.

In the case of implementing the PAR model, where the reduction affects only the failure probability increased in the last maintenance interval, we obtain

$$p_2^+ = kp(1-\varepsilon) + kp(1-\varepsilon) = 2kp(1-\varepsilon) \tag{4}$$

In the case of selecting PAS as maintenance model, the reduction affects the total failure probability reached before performing the maintenance, so this probability, after the said maintenance, will became

$$p_2^+ = \left(kp(1-\varepsilon) + kp\right)(1-\varepsilon) \tag{5}$$

Apart from simplifications or different representations for subsequent treatment and applications, the previous one is the evolution of the failure probability at any instant of the useful life period of the analyzed component, that is represented in Figure 1.

Then, the construction of probability functions, that determine the likelihood functions which allow as estimating the objective parameters under models that really represent the behavior of the equipment in terms of the occurrence of failures at demand, are showed.

2.1 *Proportional age reduction model*

If a PAR model is considered, the maintenance only reduces the increase of probability from the previous maintenance, we would obtain that, for

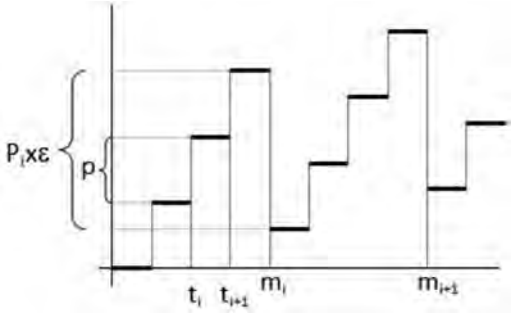

Figure 1. Evolution of the failure probability vs time.

any maintenance m, the failure probability before and later applying it will be

$$\begin{aligned}\rho_m^- &= (m-1)kp(1-\varepsilon)+kp \\ \rho_m^+ &= mkp(1-\varepsilon)\end{aligned} \tag{6}$$

Since, for the construction of the likelihood function we will only need the probability function, $p(t)$, at failure times and the cumulative distribution function, $F(t)$, at failure and maintenance times, from the previous expressions, and denoting by $k_{f,m}$ the instant, the number of test in maintenance m, in which the failure is observed, the probability function in said failure will be

$$p\left(t_{f,m}\right) = (m-1)kp(1-\varepsilon)+k_{f,m}p \tag{7}$$

and adding the probability functions in the test and maintenances until the maintenance m we obtain the cumulative distribution function in each maintenance

$$F\left(\tau_m\right) = m\frac{k(k+1)}{2}p+\left((k+1)\frac{m(m+1)}{2}-km\right)kp(1-\varepsilon) \tag{8}$$

finally, the cumulative distribution function in each failure is obtained adding to the cumulative distribution function in the previous maintenance, the probability function in each test until the failure, applied in the maintenance interval where the said failure is observed

$$\begin{aligned}F\left(t_{f,m}\right) &= F\left(\tau_{m-1}\right)+k_{f,m}(m-1)kp(1-\varepsilon) \\ &\quad +\frac{k_{f,m}\left(k_{f,m}+1\right)}{2}p\end{aligned} \tag{9}$$

2.2 *Proportional age-setback model*

If the imperfect maintenance model is the PAS one, which reduces the failure probability that each component has accumulated until the time before that maintenance activity is performed, we find, obviously, the same situation in the first maintenance, but this will not happen in the following ones. The failure probability before the second maintenance will continue to be the same than in the PAR model, but after then it will be

$$\rho_2^+ = \left(kp(1-\varepsilon)+kp\right)(1-\varepsilon) = kp\left((1-\varepsilon)+(1-\varepsilon)^2\right) \tag{10}$$

and, by generalizing the process again, we obtain the failure probabilities before and after the *m-th* maintenance, which will be given by

$$\begin{aligned}\rho_m^- &= kp\left(1+(1-\varepsilon)+(1-\varepsilon)^2+\ldots+(1-\varepsilon)^{m-1}\right) \\ &= kp\sum_{i=0}^{m-1}(1-\varepsilon)^i \\ \rho_m^+ &= kp\left((1-\varepsilon)+(1-\epsilon)^2+\ldots+(1-\varepsilon)^m\right) \\ &= kp\sum_{i=1}^{m}(1-\varepsilon)^i\end{aligned} \tag{11}$$

Although, again, what we want to obtain are probabilities of failure and their cumulated sums or distribution function, we can get, proceeding in a similar way to the previous model, the equivalent expressions

$$p\left(t_{f,m}\right) = kp\sum_{i=1}^{m-1}(1-\varepsilon)^i + k_{f,m}p \tag{12}$$

$$F\left(\tau_m\right) = kp\left(\sum_{i=1}^{m}((k+1)(i-1)+1)(1-\varepsilon)^{m-i+1} + \frac{mk(k+1)}{2}\right) \tag{13}$$

$$\begin{aligned}F\left(t_{f,m}\right) &= F\left(\tau_m\right)+k_{f,m}kp\sum_{i=1}^{m-1}(1-\varepsilon)^i \\ &\quad +\frac{k_{f,m}(k_{f,m}+1)}{2}p\end{aligned} \tag{14}$$

It should be noted that, unlike what it happens with continuous models of failure distributions, these expressions, and their subsequent contribution to the likelihood function, do not depend on the instant in which the failure is observed but on the number of tests and maintenance, and type of maintenance, which have been carried out until the observed failure. Finally, it should be pointed that, although these expressions seem very complex, in fact they are, when substituting k, $k_{f,m}$ and m by their values in a particular problem as in our application case, they become much clearer and very useful for their implementation.

3 ESTIMATION PROCEDURE

The construction of the likelihood function for proposed reliability models under imperfect maintenance is presented below. For a given model and a set of observed data, the likelihood function, L, is the product of probabilities that the observed data will occur as a function of the parameters that must to be estimated

$$L\left(\xi \mid observed\ data\right) = \prod_{events} p_i \tag{15}$$

This expression can be applied to the age dependent failure models formulated previously by considering the probability function as probabilities of failures and the reliability function to

model probabilities after maintenances, both normalized on the time interval in which the events are observed, obtaining in this way the general expression for the likelihood function in reliability models with imperfect maintenance that will be given by

$$L(\xi \mid observed\ data) = \prod_{failures} h(t) \cdot \prod_{maintenances} R(t) \tag{16}$$

which applied to discrete models becomes

$$L(\xi \mid observed\ data) = \prod_{failures} \frac{p(t)}{1-F(t)} \cdot \prod_{maintenances} (1-R(t)) \tag{17}$$

From these expressions, the maximum likelihood estimation (MLE) method provide estimates of the parameters of reliability and maintenance models. The maximum likelihood estimations of these parameters are those values that maximize the likelihood function, that is, that maximize the probability that the observed events occur. Although sometimes direct methods can be applied to obtain the solution, this is not usually the situation in reliability models. In our applications, to maximize the likelihood function of each model, we use the Nelder-Mead Simplex method.

Let r_m be the number of failures observed in the maintenance interval m, which occur at instants $t_{m_1}, t_{m_2}, \cdots$ and let τ_m be the instant when maintenance m is performed, with $m \in \{1, 2, \ldots, M\}$. The likelihood function under imperfect preventive maintenance will be given by

$$L(\xi) = \prod_{m=1}^{M} \left[\prod_{j=1}^{r_m} h_m\left(t_{m,j}\right) \cdot R_m\left(\tau_m\right) \cdot R_M\left(\tau^*\right) \right] \tag{18}$$

where ξ is the vector of unknown parameters, M is the number of maintenances performed in the observation period τ^*, with $h_m(t)$ and $R(t)$ being the failure rate and the reliability function in the maintenance interval m, and $R(\tau^*)$ the reliability function in the censor time τ^*. Since the logarithm is an increasing function, the likelihood function and its logarithm achieve their maximum at the same value of the objective parameters vector. So, in order to simplifying the computational process, we will use the log likelihood function given by

$$log\ L(\xi) = \sum_{m=1}^{M} \sum_{j=1}^{r_m} \log(h_m(t_{m,j})) - \sum_{m=1}^{M} H\left(\tau_m\right) - H_{m+1}\left(\tau^*\right) \tag{19}$$

This expression will be useful when we have a probability distribution of failures that provides in closed form the failure rate and the cumulated failure rate, $H(t)$, as in the case of the continuous distributions. However, in the above presented discrete model we do not dispose of failure rate and cumulated failure rate functions in closed form, so we construct the likelihood function, and its logarithm, from the probability function and the cumulated distribution function, or one minus it, the reliability function, $R(t)$, in each failure and maintenance times

$$log\ L(\xi) = \sum_{m=1}^{M} \sum_{j=1}^{r_m} log\left(\frac{p_m\left(t_{m,j}\right)}{R\left(t_{m,j}\right)} \right) + \sum_{m=1}^{M} log\left(R_m\left(\tau_m\right)\right) + log\left(R_{M+1}\left(\tau^*\right)\right) \tag{20}$$

Again, by replacing the probability and cumulate functions obtained in the previous section for PAR and PAS maintenance models, the corresponding log likelihood functions are obtained.

Maximizing these functions by applying Nelder-Mead simplex method provide the maximum likelihood estimations of the parameters of each age dependent failure model. The optimization process itself provides, in addition to the vector of punctual estimations, information about its variability through the Fisher information matrix, which is defined as the opposite of the matrix of partial second derivates. So if the parameters vector is of dimension n, the information matrix will be given by

$$I(\xi) = \begin{bmatrix} \frac{\partial^2 \log L(\xi)}{\partial \xi_1^2} & \cdots & \frac{\partial^2 \log L(\xi)}{\partial \xi_1 \partial \xi_i} & \cdots & \frac{\partial^2 \log L(\xi)}{\partial \xi_1 \partial \xi_n} \\ \vdots & \ddots & \vdots & & \vdots \\ \frac{\partial^2 \log L(\xi)}{\partial \xi_i \partial \xi_1} & \cdots & \frac{\partial^2 \log L(\xi)}{\partial \xi_i^2} & \cdots & \frac{\partial^2 \log L(\xi)}{\partial \xi_i \partial \xi_n} \\ \vdots & & \vdots & & \vdots \\ \frac{\partial^2 \log L(\xi)}{\partial \xi_n \partial \xi_1} & \cdots & \frac{\partial^2 \log L(\xi)}{\partial \xi_n \partial \xi_i} & \cdots & \frac{\partial^2 \log L(\xi)}{\partial \xi_n^2} \end{bmatrix} \tag{21}$$

then, we can obtain, for each model, the variance-covariance matrix as the inverse of the information matrix divided by the sample size.

To conclude this section, we must comment that an inconvenient of the application of the Nelder-Mead simplex method to the optimization of our log likelihood functions to estimate the objective parameters is that this is an optimization method without restrictions. Obviously, the parameters in our models have a limited space of definition and these restrictions must be introduced in some way in the optimization process. Fortunately, the restrictions of the parameters can be included through transformations of themselves. These

restrictions are $0 \le p, \varepsilon \le 1$, so the parameters, in the optimization process are defined as $p = \exp(x_1)/(1 + \exp(x_1))$ and $\varepsilon = \exp(x_2)/(1 + \exp(x_2))$, which ensures that solutions will be obtained within the domain of the decision variables. In addition, since the method only provides local optimum, its search must be repeated several times from different initial points, selected in a random way, to ensure obtaining a global optimum.

4 APPLICATION CASE

The application case presented below concerns the analysis of data collected from a High-Pressure Injection System (HPIS) consisting of a set of motor operated valves, normally in stand-by, reason why they must be checked periodically which causes some deterioration that increases the probability of failure at demand. Given the set of available data, failures, tests and maintenance activities, the objective of this application is the joint estimation of effectiveness of maintenance, ε, and probability of failure at demand, p, under the assumption of imperfect maintenance models PAR or PAS.

The available database presents the monitoring of the described equipment during 5100 days, in which 195 tests and 9 maintenances have been applied, and 3 failures have been observed. Since more information is not available, and this is usually the real situation, we assume that both maintenance and testing are time uniformly distributed so that all intervals between tests and maintenances have the same length, what means that finally we have tests every 25 days and maintenances every 525 days, which provides 9 maintenance activities in 14 years and 20 tests in each maintenance interval.

Once constructed the logarithm of the likelihood function presented in Section 3, the sum of the logarithm of probability function divide by reliability function in failure times and the logarithm of this reliability function in maintenance and censor times, Maximum Likelihood Estimation is performed through the Nelder-Mead Simplex method obtaining the results, about parameter estimations and their variability, showed in Table 1.

The variance-covariance matrix for the PAR and PAS models is given respectively by:

Table 1. Parameter estimation results.

Parameter	PAR model	PAS model
$\hat{p}$	4.63E-4	4.19E-4
$\hat{\varepsilon}$	0.9824	0.9056
L	0.024	0.005

$$PAR \qquad \widehat{\Sigma^2} = \begin{pmatrix} 8.24E-10 & 1.04E-7 \\ 1.04E-7 & 9.48E-5 \end{pmatrix}$$

$$PAS \qquad \widehat{\Sigma^2} = \begin{pmatrix} 1.23E-9 & 1.31E-6 \\ 1.31E-6 & 2.81E-3 \end{pmatrix}$$

The results of this application, together with those obtained in applications of these models to other databases, provide interesting conclusions. Firstly, and focusing in the presented case, we obtain the estimation of both, failure probability at demand and maintenance effectiveness. We can realize that results do not differ too much between both models, which is due to the fact that, since the maintenance effectiveness is in both cases close to one, the two models are very similar, providing very close estimations. However, we can conclude that the model which better represent the behavior of this equipment is the PAR one, since the value of its likelihood function in the obtained optimum is greater than in the PAS one, which means, under the same number of parameters, as it happens, that the probability of occurrence of the observed data is greater in the PAR model than in the PAS one. Additionally, when obtaining together with punctual estimations, its variance-covariance matrix that provides, in addition to their covariance, the standard deviation of the estimation of each parameter as the square root of its main diagonal, we can construct confidence intervals for each parameter, which provides us with a very usefulness information about their variability for further applications.

$$PAR \qquad CI_{95\%}(p) = (4.07E-4, 5.19E-4)$$
$$CI_{95\%}(\varepsilon) = (0.9633, 1)$$

$$PAS \qquad CI_{95\%}(p) = (3.50E-4, 4.88E-4)$$
$$CI_{95\%}(\varepsilon) = (0.8018, 1)$$

We also note that confidence intervals are narrower in the PAR model, that is, their estimates show less variability, which is consistent with the previous selection as the most appropriate model. Finally, it must be pointed that, in general, the maintenance effectiveness in PAR model is greater than in the PAS one, as it happens in our application. Since PAS maintenance provides better results, it reaches the same state as the PAR one with less effort.

5 CONCLUSIONS

This paper presents the construction of a model which really represent the behavior of an equipment which requires of periodic test, which deteriorate at each realization. This model allows us to

jointly estimate, via Maximum Likelihood Estimation, both the failure probability at demand and the maintenance effectiveness, when imperfect maintenance is, as really occurs, incorporated to the age dependent model.

Results obtained in the application case, which are in accordance with those usually verified in its context, validate the usefulness of this model and expand the field of the optimization of efforts aimed at improving the reliability of this kind of equipment.

ABSTRACT: Planning maintenance over a large, distributed and ageing power infrastructure is a challenge. Interruptions in power supply cost large amounts of money in terms of undelivered energy and therefore maintaining the infrastructure to deliver at all times is imperative. This paper presents a novel method developed to model the risk of power line infrastructure. The user is presented with a visual risk picture and the associated expected costs based on the user's maintenance strategy of choice. Visual risk presentation overlaid on map data allows the decision-maker to understand the risk picture and make appropriate investment decisions based on the same. The developed model is currently being used in-house at various grid operators in Norway. Users can test out the effect different maintenance strategies and its effect on the risk picture.

1 INTRODUCTION

1.1 *Background*

Every year there are thousands of planned and unplanned interruptions on the electrical power grid in Norway. These disconnections result in undelivered energy that cost the society millions each year. The year 2016 saw a total of 25,777 incidents totaling a loss of 8,239 MWh undelivered energy (Statnett 2017). Assuming an average interruption of 1.3 hours (Kjølle 2011), the cost of undelivered energy is approximately 30.7 NOK per kWh. This equals 253.2 million NOK, or over 32 million USD.

Norway as a country is characterized by large energy differences from region to region. Some areas are under producers and others, over-producers (Fornybar.no). In general, transporting energy over large distances is imperative in ensuring a robust power distribution network in the country.

Planning maintenance of such a large power distribution infrastructure is a challenge. A large portion of the infrastructure is aging, pushing for significant re-investment costs from year to year. In such a situation, the challenge is identifying where efforts should be focused and where money should be invested.

Furthermore, expanding infrastructure within renewables, creates challenges with respect to resource availability and utilization. This places more pressure on power grid companies to improve strategies while simultaneously reducing costs.

1.2 *Objective*

Paragraph §2–13 in the regulations for electrical power distribution (FEF 2006) states that the power distribution grid owner shall have an overview of their infrastructure such that they can decide where to focus maintenance effects and which areas require more focus/investment that others. This is with regard to reputation, Health Safety and Environment (HSE), technical condition and of course reliability of power supply. RENblad ((Norwegian: Rasjonell Elekstrisk Virksomhet)) claims that todays' choice of maintenance strategy often results in components being replaced much earlier than they must. Therefore, risk-based maintenance is a pre-requisite to enable better maintenance decisions. This is the objective of the approach and model developed.

This paper presents a simulation model developed, and results from a case study. Furthermore, preliminary feedback from pilot users are also discussed. The developed risk model quantifies the technical, HSE and economic-risk condition of a given power line and puts this in a financial context.

The approach simulates line degradation over multiple years and models the effect of different maintenance strategies. The result is a risk picture and cost associated with a chosen maintenance strategy.

2 STATE-OF-THE-ART

2.1 *Maintenance practice in the industry*

Moving from a reactive to a proactive maintenance approach is a demanding change for a power company. Grid owners systematically document results from physical inspections on their power lines from year to year. Certain operators perform limited visual inspections from the ground level yearly. More detailed inspections examining each utility pole for internal damage, rotting etc., is performed at 10-year inspection intervals. The data collected from these inspections is used to a very limited extent in planning maintenance. Deciding on a maintenance plan purely based on "age of infrastructure" and "total number of findings from inspections" is not optimal. Such a strategy is not risk-based and can result in significant investments made on infrastructure that has a very limited risk connected to power supply reliability.

Maintenance and reinvestment is a necessity to maintain the functionality of the power distribution grid. As components age and are exposed to external factors such as wind, lightning, vegetation, etc., their functionality may weaken or fail. Furthermore, parts of the power grid are so old that lines are associated with the need for reinvestments. Driving maintenance versus reinvestment decisions is a fine balance between economy and risk. "*When is it economically beneficial to replace/reinvest in infrastructure versus performing periodic maintenance on the same?*". Recent trends (Nordgård and Samdal 2009) point towards developing strategies by looking at the balancing of cost effectiveness with other risks, such as economy, HSE, reputation, supply reliability etc. Thus, bringing the advent of risk-based maintenance.

A well-known technique for the same is Reliability Centered Maintenance (RCM) (IEC 60300-3-11). RCM is primarily a qualitative approach which involves a systematic consideration of system functions, where they may fail and a consideration of safety vs. economy to decide on an appropriate maintenance strategy, e.g. preventive maintenance vs. corrective run-to-failure maintenance (Moubray 1997). The outcome of applying RCM on a set of systems including a number of components, on which reliability measurements can be done, would be a maintenance program pointing to a set of components or sub-systems to be maintained at different timeslots.

In Norway, the RENblad is a set of guidelines universally followed by most electric power distribution companies. These guidelines cover standardized material and methods for the power distribution business. One such guidebook is the "Distribution Network – Maintenance Strategy" (Norwegian: Distribusjonsnett – Vedlikeholdsstrategi"). This guidebook focuses on "condition-based maintenance management".

2.2 *Available decision-support methods and tools*

The available decision support methods and tools, vary with the size and ambitions of the power companies. The project "Smarter Asset Management using Big dAta" (SAMBA) is a 3-year industry innovation project headed by Statnett, partially founded by the Norwegian Research Council and involving several partners such as SINTEF Energy Research, GE Grid Solutions, ABB and IBM. Their ambition is to add value by activating more online, automatically collected condition and system operation data. These data will be combined with maintenance data collected on site, and then be used for estimating asset's condition, probability of failure and remaining lifetime. Some research questions are:

- What is the condition of the components now?
- How will the condition of a component develop over time?
- Do I do the right maintenance at the right time?
- When should a component be replaced?
- What is the consequence of a component break?

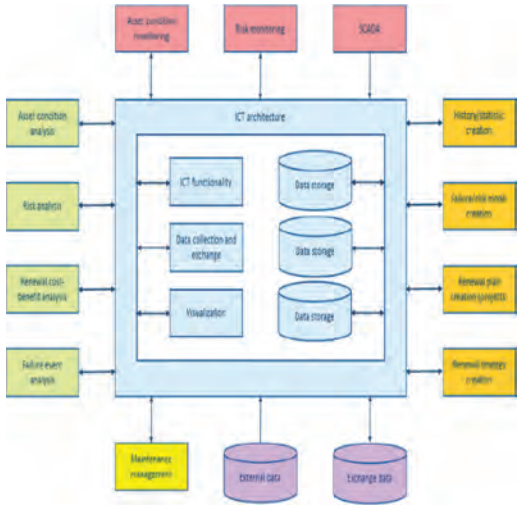

Figure 1. The SAMBA approach (Downloaded from Statnett: www.statnett.no/Global/Smarte%20Nett.pdf).

The SAMBA approach is described by the following figure:

Connected Drone is another project approved by the Norwegian Research Council and The Norwegian Water Resources and Energy Directorate (NVE). The goal of the project is to create an efficient and secure system for inspection of power lines using drones. By utilizing deep learning to analyze data obtained from sensors mounted on drones, the project seeks to give power grid utilities insights into the state of their infrastructure. The system will be delivered as an integrated, total solution and is specially adapted to the monitoring and control of power grids. The project is managed and led by eSmart Systems in close collaboration with 12 network companies and several technology partners. The first commercially available product—Connected Drone and The Intelligent Assistant, is capable of analyzing massive amounts of image data.

In the other end of the scale one can find the small net grid companies where the maintenance strategy is based on yearlong collection of experience. Through the human capital in the companies they have learned what causes degradation of their specific net, and they know the status of their components.

In between there are the big group of power companies which do their inspections, record and assess the data through Excel sheets, and perform both reactive repairs and proactive maintenance. One often-used strategy seems to be that they inspect 10% of their net (Guidelines requires a full inspection at least every 10 years). Thereafter they do repair or replacement on those components that fail according to the maintenance strategy (RENblad).

2.3 *Risk modelling and decision support*

Operational safety has over the years received more and more attention in many industries. Within the nuclear field and in the offshore industry large accidents such as Three Mile Island (US, 1979), Piper Alpha (UK, 1988) and Texas City (US, 2005) has contributed to this attention. One reason for this is that the focus in the future for the offshore industry is on operation of existing installations, extending the operational life of some of these installations as well as tying in new subsea installations.

As a way forward to understand, model and predict large accidents many risk models or barrier models has been developed, for example the BORA (Vinnem et al. 2003), OTS (Sklet et al. 2010) and Risk OMT model (Gran et al. 2012), or through master thesis works such as "Activity-based Modelling for Operational Decision-support" (Edwin 2015). Common for these models and works are that they build a model containing of target objects and background indicators.

3 WISELINE MODEL

3.1 *A pole and a line*

The Wiseline model has at its basic element an electric pole. The pole itself can be constructed by timber or by steel (as shown in Figure 2) and consist of a number of components with the mean to stabilize the pole, carry the power line, or provide as a barrier against different unwanted incidents. One such is lightning (as shown in Figure 2), thereby the need of isolators to avoid high current to spread. For a timber pole the top-hat is a component to protect the top of a pole from water impregnation and consequent decay.

At a specific geographic spot, there might be a single pole, or a number of poles. The number of poles at a single location depends on for example the need to stabilize the line when the line shifts direction. Another reason for more poles at a single location is the number of power lines the line carries. In Wiseline we call this location a "*pole site*".

Finally, a row of such pole sites forms a *line*. Typically, a line runs from one switch to another switch, i.e. representing a part of the line which can be isolated during for example maintenance.

Figure 2. An electric pole (Photo: wiseline.no).

3.2 *Inspection data*

Collection of data on a set of lines are done through inspection. A grid owner is required to do a complete inspection of every pole every 10 years. This involves an inspection of all parts of a pole, both at earth level and in the air. This is typically performed by professional inspectors using advanced tools and methods.

In between, at more frequent intervals, simpler inspections are recommended and performed. Here the poles are only inspected from a distance, and the observer can for example fly along with a helicopter or travel along using a skidoo, small engine or on foot. These methods are now being replaced by the use of drones with camera. This allows the observer to analyse the photos afterwards or also apply intelligent computer image processing methods to automatically register any abnormalities. Finally, inspections are also performed every time there is an outage. In these cases, both an inspection as well as a repair must take place.

There are in total about 30–40 inspection points for a given pole site. Some components have only one inspection point, e.g. if the top hat is intact, damaged or missing. While for others there are several inspection points, e.g. for a timber pole the following inspection points are recorded—external rot, internal rot, woodpecker holes, pole damage etc. The format of inspection data varies depending on the company that has performed the inspection. Each inspection is mostly recorded in terms of a textual description fitting with the damage categories listed in the REN-blad.

Deviations per indicator are associated with a character running from 1 to 5 (or 0 to 4), where 1 is "no finding", also equivalent to "as good as new" and 5 corresponds to "non-functioning". For this exercise of translating inspection data to character scales, input from the Energi Norge handbook (Energi Norge 2011) is used. For instance, if a "top-hat" at the top of the utility pole is missing, it translates to a 5 on the character scale. On the other hand, the character setting on a slightly bent or misoriented pole may be nuanced from between 2 to 5 depending on the degree of damage. The inspections records of such grades are used as input in the Wiseline model for each pole.

3.3 *Risk model*

In the Wiseline model each grade is translated to a value between 0.0 and 1.0, where 1 is the best. A grade 1 is always translated to the value 1.0. However, a grade 5 is translated differently depending upon the role of the component. If the component is critical it may be given a value 0.01, while if it is not critical it may be given a value 0.9. This can be illustrated by the component "warning sign". It provides no barrier in terms of delivering power, therefore a missing sign (with grade 5) will in this case be translated to 0.9. On the other hand, it provides a barrier in terms of HSE and will be translated to 0.01. Note, the numbers 0.9 and 0.01 are here only illustrative.

In real cases, the values to be used in the translation are set by the grid owner to reflect their interpretation of the importance of the inspections. The risk model is developed for three top-events – "technical condition", "HSE" and "power supply ability". Dependent on the top-event being modelled, the various components and their corresponding indicators are weighted differently in the underlying risk model. For instance, the "power transmission" subfunction will be weighted with a higher importance for the "power supply ability" model as compared to in the "HSE" model. Similarly, the high-voltage signage on utility poles will be weighted higher for the HSE model in comparison to the other two risk models. Criticality tables are established for the various components, as shown in Table 1.

The combination of the values within each group is done by a weighting function. Thereafter the groups are combined up to a risk value for the pole, the risk values at poles are combined to a risk value for the pole site (see illustration in Fig. 3). Finally, the risk values for pole sites are combined to a risk value for the line. This combination can be viewed upon as a factor model as applied in various risk models. In the current model the poles are handled independently, but obviously further work on the model will also take into account that the state of on pole will have influence on the state of its neighboring poles.

3.4 *A set of risk values*

The outcome of applying the Wiseline model is a set of risk values for each pole and for each line,

Table 1. Example—Component criticality specification.

Function/Sub function	Component	Technical condition	HSE	Power supply ability
Earthing/Protection	Voltage Signage	Medium	Important	Insignificant
Structural	Common Brace	Medium	Very Important	Very Important
Transmission	Insulator	Medium	Important	Important

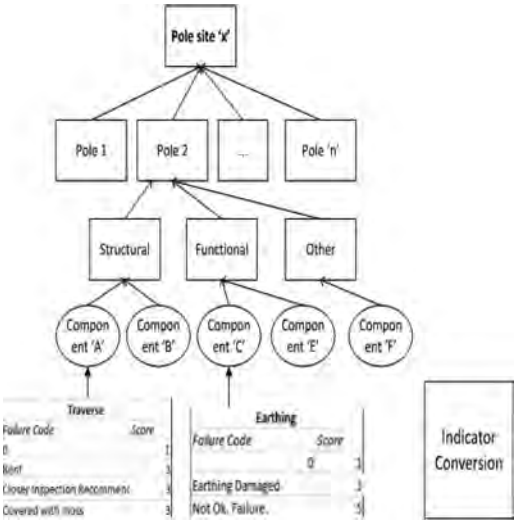

Figure 3. Combining the translated inspection values on components up to a risk value for a pole and a pole site.

Table 2. Risk values for a demo-line.

Risk factor	Risk value
Technical state	0.98
Power ability	0.99
HMS	0.96

as shown in Table 2 for demo line. The set of risk values contains of one risk value for the "technical condition" (where all components are treated equal in the combination), one for the "ability to deliver power" and one for "the HMS". For some clients, with classification of poles and lines according to, the set is extended with a fourth risk value related to the economical consequence.

The same is done for each pole. This can be used to visualize for example the HMS risk value along a line, as shown in Figure 4. Here also the translated component values for some components are included, as well as a red and yellow line representing different acceptance levels. The two lines at the bottom represents height above see and vegetation at the spots (here flat and equal vegetation all along).

3.5 *Predicting the future*

The next step in the Wiseline method is to do predictions of the future. This is done by allowing each component to degrade from its current inspected state according the reliability figure yielding for that type of component. Monte Carlo simulation is used to simulate the degradation of component condition over time and calculate the associated costs connected to the chosen maintenance strategy.

The developed risk model provides the user with significant flexibility in choosing a maintenance strategy. Examples of strategies include:

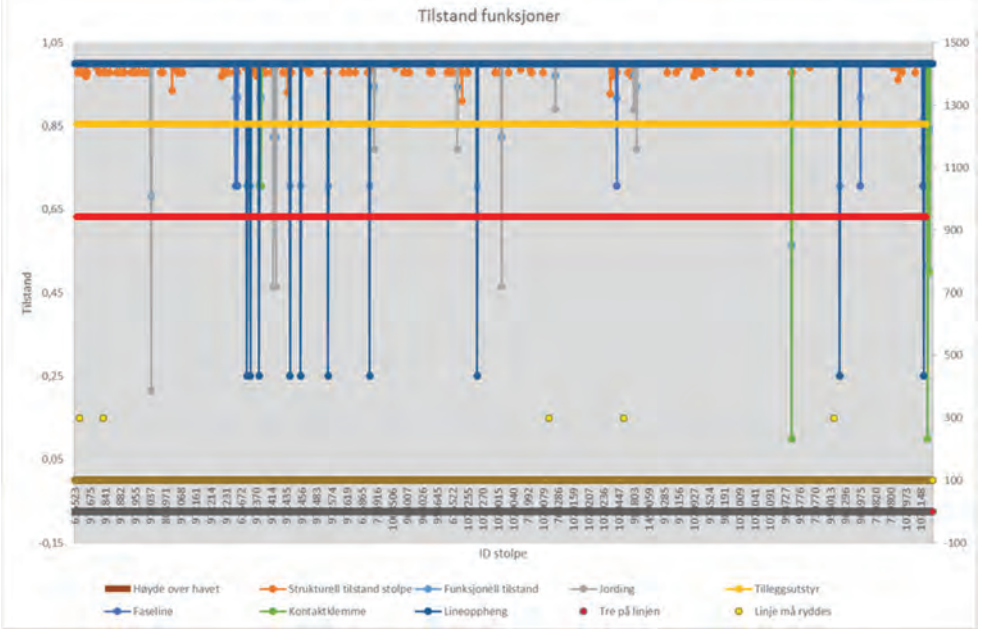

Figure 4. The risk value for HMS for the poles along the demo line. The red and yellow line represents different acceptance levels.

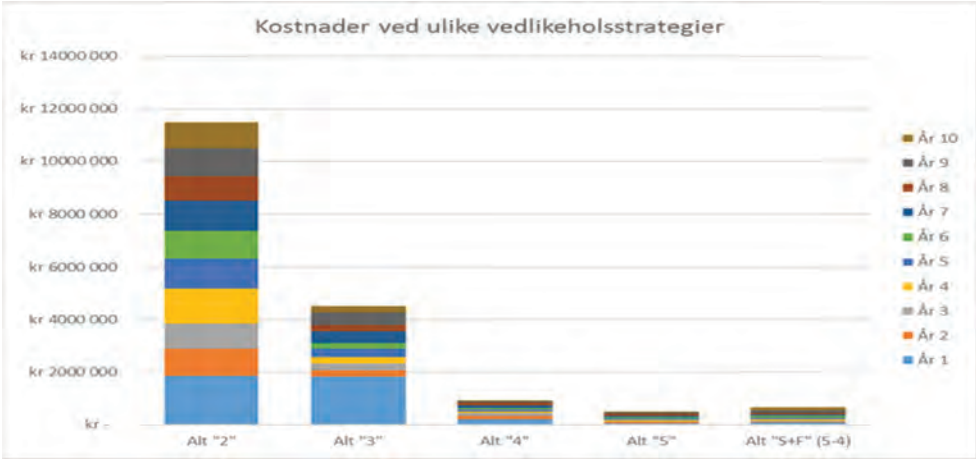

Figure 5. The cost per year for 5 different maintenance strategies.

1. No maintenance. Run-to-failure.
2. Preventive maintenance (Fix when component condition > = indicator score 'x')
3. Overhaul selected utility poles based on specified criteria at t = 'x' and run-to failure thereafter.

In the current Wiseline model the same reliability model is applied for a component independent of its age, type, producer, location etc. In the future this can be exchanged with more specific models. One such model is under development by Sintef, power grid companies and inspection companies to model how fast a timber pole will rot, and thereby provide an estimate also of the rest life time. In another project, Statnett and Sintef (Solheim et al, 2016) aims at establishing wind dependent failure rates for overhead transmission lines using reanalysis data and a Bayesian updating scheme.

3.6 *Estimating the cost of a maintenance strategy*

The final step in the Wiseline method is to associate each maintenance strategy with an investment cost. This investment cost includes both the cost of the component repaired or replaced, and the labor cost. These costs are specific for each grid owner.

The result is that decisions can be made by balancing the costs towards the acceptable risk for the different top events. In Figure 5 the cost per year for 5 different maintenance strategies are shown for a demo-case. Visual risk presentation overlaid on map data allows the decision-maker to understand the risk picture and make appropriate investment decisions based on the same. A demonstration of this shown in Figure 6 for the client Vesterålskraft.

4 CASE STUDY

To demonstrate the functionality of the developed risk model, anonymized inspection data from power lines across different Norwegian electric power distribution owners were used in the following. The data input basis included inspection points from a total of more than 300 power lines, where each line included from 10 to up to 300 utility poles. These include power voltage distribution lines right from 230V to 22kV. As discussed in Section 3, input inspection data was first mapped to the indicator set in the risk model. As the inspection data were collected in different years, the next step was to degrade each component from its current inspected state according the reliability figure yielding for that type of component up to the predicted state in 2017.

The Wiseline model was then run using the 2017 data as the starting-point for the simulations. An outline of the results is shown in Table 3. Here the results for HSE is shown, first for the calculated 2017 value, then the predicted risk value applying two different maintenance strategies: maintenance when grade 4 is predicted (VG4) and maintenance when grade 3 is predicted (VG3). Here the cost estimates are left out for simplification. However, only by observing at the lines in the table, one sees that there is a low correlation between the number of deviations and the predicted risk values. Furthermore, one also sees that the risk value does not correlate with the age of the poles either.

Figure 6. The risk value displayed on a map (Vesterålskraft).

Table 3. Outline of the results for the case study.

Line	KV	# Poles	Inspected	Pole year (min)	Pole year (max)	Deviations	HSE (2017)	HSE (2027) VG4	HSE (2027) VG3
Wiseline003	22	11	aug. 14	1963	1964	8	94.59	98.71	98.23
Wiseline006	22	6	aug. 14	1962	1985	9	94.98	99.14	99.49
Wiseline192	22	8	jun. 16	1990	1992	4	96.34	99.81	96.71
Wiseline002	22	34	aug. 14	1955	1994	22	96.53	99.35	99.82
Wiseline045	0.23	19	aug. 14	1950	2000	11	96.59	99.03	96.78
Wiseline025	0.23	12	aug. 14	1954	1978	2	97.30	99.11	99.65
Wiseline026	0.23	14	aug. 14	?	1968	9	97.42	99.23	99.58
Wiseline337	0.23	27	aug. 11	1900	1959	38	97.48	98.81	99.01
Wiseline339	0.23	15	jun. 11	1900	1990	38	97.51	98.83	99.63
Wiseline097	22	17	okt. 15	1955	2008	17	97.55	98.77	98.24
Wiseline141	22	1	jun. 16	1957	1957	3	97.58	95.88	99.76
Wiseline336	22	36	aug. 11	1974	1974	32	97.65	98.37	99.56
Wiseline046	0.23	16	aug. 14	?	2010	1	97.71	99.02	99.30
Wiseline159	22	1	jun. 16	1960	1960	2	97.79	97.79	99.34
Wiseline301	0.23	34	nov. 13	1900	2004	80	97.83	97.98	99.49

In two clients cases the degradation has been run up to 2027. At this stage, the end-user can select appropriate risk acceptance criteria for each of the risk models. By looking at the lines that do not meet the risk acceptance criteria in 2027, the clients get a proposal for which lines to address first. For the same line the associated cost by maintenance is calculated, so that a risk-based approach can be applied for the decision.

5 DISCUSSION

5.1 *Application for decision-support*

As the Wiseline model now is implemented, it applies a number of simplifications in the modelling. One such simplification is to apply the same reliability model independent of both geography and age of a component. Furthermore, the risk

model applies a limited set of component criticality values. In the next versions of the Wiseline model the intention is to extend the different parts, and also to include the effect of causes for deviation, such as lightning, wind, trees, woodpeckers etc. In its current state, the Wiseline model runs by applying Excel, and transferring the data from a client into the model, and from the model into result visualization. The plan is to address these aspects through a development and innovation project together with partners from the beginning of 2018.

5.2 *Limitations*

Two limitations in the model is of course the quality of the inspection data, and errors in the translation of the inspection data into the input data. The more manual steps there are in this process, the more influence it can have. On the other hand, when the inspection data is professional collected and exported directly from an inspection data base, like the database of NordiConsult, this problem is minimized.

Another limitation lays in the interpretation of the risk factors. The technical state, where all indicators are treated equal, is a construct. The HSE factor should probably be split into inspector/skilled laborer and third party (animals and general public). Finally, the "ability to deliver power" is not the same as "causing an outage" and do not say much about how long an outage will be. Thereby the Wiseline model do not say much about expected costs due to outage.

6 CONCLUSION

Planning maintenance over a large, distributed and ageing power infrastructure is a challenge. This paper has presented a novel method developed to model the risk of power line infrastructure. The model uses inspection data, reliability models for the aging of components and associated maintenance costs to present a risk picture and the associated expected costs based on the user's maintenance strategy of choice. Visual risk presentation overlaid on map data allows the decision-maker to understand the risk picture and make appropriate investment decisions based on the same. The developed model is currently being used in-house at various grid operators in Norway. Here the Wiseline model has demonstrated that there is no single maintenance strategy that fits all cases. What the Wiseline model do is to enable the grid operators to do risk-based decisions.

The real-time reliability evaluation and sequential inspection decision based on Wiener process

Senyang Bai, Zhijun Cheng, Yong Yang & Bo Guo
College of Systems Engineering, National University of Defense Technology, Changsha, Hunan, P.R. China

ABSTRACT: Due to the complexity and high reliability requirements of aerospace equipment, it's a significant challenge to establish the efficiency maintenance management in terms of little failure data or even no failure data in the actual operation or storage environment. This paper investigates the issue of real-time reliability and sequential inspection policy for aerospace equipment based on a Wiener process-based degradation model. Firstly, the stochastic characteristics of the equipment's degradation is described by the Wiener process. The product-to-product variability and the temporal uncertainty of the degradation can be characterized by the random drift parameters. Secondly, the expression of reliability distribution is obtained with close form by use of the first-hitting time theory. An adaptive method is proposed to evaluate the unknown parameters with the optimal smoothing algorithm (RTS) and the Expectation Maximization algorithm (EM). Once the new degradation information is available, the parameters should be updated with Bayesian equation. Moreover, the historical information of the same type product can also be integrated in the selection of the initial parameters to ensure the convergence in the iterative updating. Thirdly, a sequential inspection model is discussed to determine the optimal intervals to satisfy the requirements for the real-time reliability at the certain time. Finally, an example of fatigue crack growth in an aerospace aluminum alloy is given to illustrate the validity of the proposed method.

1 INTRODUCTION

The majority of aviation products are high reliability products, such as aircraft engines, satellites, gyroscopes, which need to maintain a certain degree of reliability during long storage or operation process. Due to a variety of factors (such as temperature stress, fatigue, corrosion, etc.), their internal material properties will change, including the corrosion of mechanical parts, rubber materials, aging and so on. It results in a reduction in the reliability of the product. Therefore, to improve the reliability and minimize the times of inspection or maintenance, it is of vital significance to optimize the inspection and maintenance policy.

The Wiener process-based degradation model is a statistical data driven method, it has been extensively utilized in modeling degradation paths both academically and practically. Its biggest advancement is that the distribution of failure time can be formulated as an inverse Gaussian distribution. Ray (2002) and Ye (2015) et al. successfully applied Wiener process to fatigue crack growth analysis. Gebraeel (2005) et al. described the degradation path of rotating element bearing by Wiener process. Aiming at the effect of the non-stationary feature and the delay of state detection caused by discrete inspection on long-run operation cost, Zhang (2016) proposed an optimal inspection-based maintenance policy for three-state mechanical components subject to competing failure modes. A maintenance optimization model for mission-oriented systems based on Wiener degradation is proposed by Guo (2013). These all demonstrate that Wiener process model can achieve satisfactory result by using large sample data. However, most aviation products are costly and high reliability, it is almost impossible to obtain enough data of the failure life through the life test or accelerated life test, and even "zero failure" phenomenon may occur. Therefore, we will consider establishing the degradation model based on Wiener process by using the small sample data, so as to be more suitable for aviation products.

Besides, in order to ensure the normal operation of products and preventive maintenance, variation in reliability under different conditions should be considered. Real-time reliability evaluation is ideal because the factors that affect reliability change continuously with time for dynamic systems. Yan (2016) developed a two-phase Wiener degradation model to evaluate the real-time reliability of devices. Xu et al. (2008) proposed a real-time reliability prediction method for a dynamic system that suffers from a hidden degradation process. Wang et al. (2014) investigated the issue of real-time

reliability evaluation based on a general Wiener process-based degradation model. Faghih-Roohi et al (2014) developed a dynamic model for availability assessment of multi-state weighted k-out-of-n systems using the universal generating function and Markov process. Each method has its advantages and disadvantages. For example, Markov models have state space explosion problems (Tanrioven (2004)). The major limitation of stochastic simulation is that the monitoring value has to be a scalar. However, there are usually many monitoring values exist in real situations. The hidden degradation process identification is unsuitable for a situation in which the characteristics of the degradation processes are time varying, or the path function of the fault process is nonlinear. Therefore the temporal uncertainty of the degradation will be characterized by the random drift parameters in the model of this paper, which is defined as a random walk model, thus we can improve the degradation model.

It is a significant challenge for engineers to define the appropriate inspection interval in term of uncertainty in product deterioration and environment change. Fewer inspections will lead to lower reliability, and frequent inspection will lead to higher cost, so the optimal inspection policy should be set up and tradeoff between the reliability and operation cost. For the long-storage products, Feng (2011) proposed a sequential inspection method based on Weibull distribution, and the sequential inspection time is confirmed based on storage reliability request. Cui (2004) developed a sequential inspection policy for multiple systems under availability requirement. And considering the optimization of alarm threshold, a sequential inspection scheme is determined by Jiang (2010). For systems subject to stochastic deterioration, Zhu (2017) proposed a sequential condition-based maintenance policy. The above sequential inspection methods are based on the constraint of the degradation threshold, availability, cost and so on to optimize the maintenance and inspection decision. But for the aviation products studied in the paper, real-time reliability is more necessary to be assessed. Therefore we will focus on improving the related sequential inspection and maintenance policy by using the real-time reliability model, which will ensure the high reliability of the aviation products.

The aim of this paper is to find the optimal maintenance policy for the aviation products. The model of this paper can makes full use of the mathematical properties of Wiener process, and the uncertainty of stochastic model parameter estimation is also taken into consideration. To ensure the convergence of parameters in the iterative updating, the historical information of the same type product is integrated in the selection of the initial parameters. Moreover, a variety of algorithms are used to iteratively update the model parameters, which realize the real-time updating of parameter estimation and the adaptive prediction of remaining life. Combined with the requirement of real-time reliability, the sequential inspection policy is determined for the aviation product, thus reducing the number of inspection and maintenance effectively.

The remainder of this paper is organized as follows. Section 2 describes the model assumptions and maintenance policy. In Section 3, the real-time reliability model of the product is established and the unknown parameters are estimated. Section 4 presents an optimal model for sequential inspection. In section 5, a numerical example of fatigue crack growth in an aerospace aluminum alloy is given to illustrate the validity of the proposed method. Conclusions and some future works are drawn in Section 6.

2 MODEL DESCRIPTION

2.1 *Model assumptions*

1. It is assumed that the performance of the product is recovered as new after replacement

Nomenclature	
μ	drift coefficient
μ_0	initial drift coefficient
σ	diffusion coefficient
w_0	preventive maintenance threshold
w	failure threshold
η	the random walk parameter of μ
a_0	the mean of normal distribution about μ_0
D_0	the variance of normal distribution about μ_0
$D_{k\|k}$	the updated variance of μ
$D_{k\|k-1}$	the conditional variance of μ
$\boldsymbol{\theta}$	set of the model parameter$(a_0, D_0, Q_0, \sigma_0^2)$
R_s	requirement of the real-time reliability for the product (constant)
Δt_{ik}	inspection interval
t_i	time of the i-th maintenance
t_{ik}	time of k-th inspection after i-th maintenance
x_{ik}	degradation data of k-th inspection after i-th maintenance
$x_{i(0:k)}$	set of degradation data after i-th maintenance
l_{ik}	remaining life of the profuct at the time t_{ik}
$p(\mu_k \| X_{0:k})$	the conditional PDF of μ_k for the given $X_{0:k}$
$f_{T\|x_k}(l \mid x_k)$	the PDF of the remaining life when the inspection data is x_k
$f_{T_{ik}\|X_{0:k}}(l_{ik} \mid X_{0:k})$	the PDF of the remaining life for the product when the inspection data is $X_{0:k}$
$R_s(t \mid x_k)$	real-time reliability of the product at time t
$R_s(l_{ik} \mid X_{0:k})$	real-time reliability of the remaining life for the product

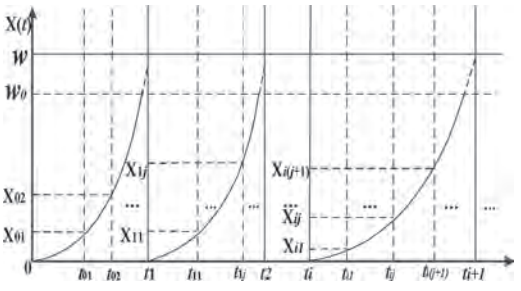

Figure 1. Inspection and maintenance cycle diagram for the product.

2. According to the actual requirement of engineering, R_S is generally set to be a constant.
3. Failures are observed only by inspection, and if degeneration data of inspection exceed the preventive maintenance threshold w_0, the maintenance should be carried out and the component will be replaced.
4. The inspection time and replacement time are negligible.

2.2 *Deterioration and maintenance process*

In this paper, a metal material of an important component from the aviation product is taken as the research object. It is found that the degradation processes of many aviation products performance are random and uncertain. The Wiener process can well describe the time uncertainty of the degradation process, and it is also easier to deal with the error of data measurement. Due to the long service life and high cost of maintenance for aviation products, periodic inspection or real-time monitoring is generally required. If the performance degradation is found to exceed the preventive maintenance threshold w_0, the component will be replaced immediately. The diagram of inspection and maintenance cycle is shown in Figure 1.

The Wiener process is used to establish the degradation model of aviation products. $R_S(t \mid x_k)$ is defined as the real-time reliability at time t. And according to the definition of real-time reliability, the value of $R_S(t \mid x_k)$ would gradually decreases from 1 after each inspection as time goes on. And the process can be divided into three steps based on the sequential inspection policy. Firstly, the real-time reliability model is established based on Wiener process; then, the model parameters are estimated by using the degradation data $x_{i(0:k)}$, so the PDF expression $f_{L_k|X_{0:k}}(l_{ik}|X_{0:k})$ of the remaining life for the product can be obtained, furthermore the expression $R_S(l_{ik} \mid X_{0:k})$ of the real-time reliability can be derived. Finally, the inspection interval Δt_{ik} is determined to satisfy the requirement of R_S, so the next inspection time is $t_{i(k+1)} = t_{ik} + \Delta t_{ik}$.

3 REAL-TIME RELIABILITY

If the aviation product is known to have not failed at the current moment, a conditional probability can be used to express its reliability level. When new degradation data is obtained, the real-time reliability is further updated.

3.1 *The model of real-time reliability*

For the actual operation or storage of aviation products, the degradation process is described by the Wiener process, so we can get the following expression by using the Markov property of $\{B(t), t \geq 0\}$:

$$X(t) = x_k + \mu(t - t_k) + \sigma B(t - t_k) \tag{1}$$

It is assumed that $x_k < w$ at the time t_k, otherwise, the device is considered invalid. In this study, the definition of product life is based on the first-hitting time theory for random process proposed by Lee (2007), then the PDF of the product life can be obtained:

$$f_{T|x_k}(t \mid x_k) = \frac{w - x_k}{\sqrt{2\pi(t - t_k)^3 \sigma^2}} \exp\left\{-\frac{(w - x_k - \mu(t - t_k))^2}{2\sigma^2(t - t_k)}\right\} \tag{2}$$

Due to the small sample of the degradation data for the aviation product, it is important to integrate all the data from each inspection into degradation modeling. In this study, μ is defined as a random walk model, which can be updated as the new inspection data is obtained, that is $\mu_k = \mu_{k-1} + \eta$, and $\eta \sim N(0, Q)$. Then based on the state-space model framework, the degradation process of the aviation product can be constructed by a linear state-space model as:

$$\mu_k = \mu_{k-1} + \eta \tag{3}$$

$$x_k = x_{k-1} + \mu_{k-1}(t_k - t_{k-1}) + \sigma\varepsilon_k \tag{4}$$

where $t_0 = 0$, $x_0 = 0$, $\varepsilon_k \sim N(0, t_k - t_{k-1})$ and $t_k - t_{k-1}$ is the variance of ε_k based on the characteristics of Brownian motion.

It is assumed that the initial drift coefficient follows $\mu_0 \sim N(a_0, D_0)$, and the drift coefficient μ can be regarded as an implicit "state" estimated from the inspection data $X_{0:k} = \{x_0, x_1, x_2, ..., x_k\}$. Therefore, the above state-space model establishes the relationship between the drift coefficient and all inspection data from the beginning to the present time t_k. In equation (3), once the new degradation data is obtained, the probability distribution of μ_k can be calculated from all the inspection data by using recursive filtering method. And the posterior estimation expectation of μ_k can be defined as $\hat{\mu}_k = E(\mu_k \mid X_{0:k})$, the corresponding variance

can be defined as $D_{k|k} = \mathrm{var}(\mu_k \mid X_{0:k})$. In order to obtain $\hat{\mu}_k$ and $D_{k|k}$, we need to get the PDF of μ_k for a given $X_{0:k}$, which denoted by $p(\mu_k \mid X_{0:k})$, and $p(\mu_k \mid X_{0:k})$ can be recursively calculated from $p(\mu_{k-1} \mid X_{0:k-1})$ using Bayesian rules. According to the stochastic filter theory and the strong tracking filtering technique, the conditional PDF of μ_k can be obtained:

$$p(\mu_k \mid X_{0:k}) = \frac{1}{\sqrt{2\pi D_{k|k}}} \exp\left\{-\frac{(\mu_k - \hat{\mu}_k)^2}{2D_{k|k}}\right\} \tag{5}$$

According to the first-hitting time theory of random process, we can use equation (6) to measure the real-time reliability of the product:

$$R(t; X_{0:k}, \boldsymbol{\theta}_k) = P(X(\tau) < w, \forall\, \tau \in [t_k, t] \mid \boldsymbol{\theta}_k, X_{0:k}, x(t_j) < w, j = 1,2,\cdots,k) \tag{6}$$

where $\boldsymbol{\theta}_k = \left(a_k, D_k, Q_k, {\sigma_k}^2\right)^T$. In order to get the expression of $R(t; X_{0:k}, \boldsymbol{\theta}_k)$ the definition of the remaining life for the product is given firstly:

$$L_k = \inf\{l_k : X(l_k + t_k) \geq w \mid X_{0:k}, x(t_j) < w, j = 1,2,\cdots,k\} \tag{7}$$

So $R(t, X_{0:k}, \boldsymbol{\theta}_k)$ can be expressed as follows:

$$R(t; X_{0:k}, \boldsymbol{\theta}_k) = P(L_k > t - t_k) \tag{8}$$

According to the literature (Si (2016), Peng (2009)), and combined with the state-space models of equation (3) and equation (4), the PDF of remaining life L_k can be obtained as follows:

$$f_{L_k|X_{0:k}}(l_k \mid X_{0:k}) = \frac{w - x_k}{\sqrt{2\pi {l_k}^3 (D_{k|k} l_k + \sigma^2)}} \times \exp\left\{-\frac{(w - x_k - \hat{\mu}_k l_k)^2}{2l_k(D_{k|k} l_k + \sigma^2)}\right\}, l_k > 0 \tag{9}$$

Then when $t - t_k = l_k$, the real-time reliability of the remaining life l_k can be obtained:

$$\begin{aligned} R_S(l_k \mid X_{0:k}) &= \int_{l_k}^{\infty} f_{L_k|X_{0:k}}(l_k \mid X_{0:k}) dl_k \\ &= \Phi\left(\frac{w - x_k - \hat{\mu}_k l_k}{\sqrt{D_{k|k} {l_k}^2 + \sigma^2 l_k}}\right) \\ &\quad - \exp\left\{\frac{2\hat{\mu}_k (w - x_k)}{\sigma^2} + \frac{2D_{k|k}(w - x_k)^2}{\sigma^4}\right\} \\ &\quad \times \Phi\left(-\frac{2D_{k|k}(w - x_k) l_k + \sigma^2(\hat{\mu}_k l_k + w - x_k)}{\sigma^2 \sqrt{D_{k|k} {l_k}^2 + \sigma^2 l_k}}\right) \end{aligned} \tag{10}$$

The parameters a_k, D_k, Q_k and ${\sigma_k}^2$ of the random degradation model are unknown in equation (8), (9) and (10), which need to be estimated based on the inspection data $X_{0:k}$. Therefore, Section 3.2 mainly describes the adaptive estimation method of unknown parameters.

3.2 *The adaptive estimation method of parameters*

In order to sequentially evaluate the unknown parameters, it is necessary to use all the inspection data of the product from the start of the operation or storage to the current time. Once the new inspection data is acquired, the previous parameters can be updated recursively. The unknown parameter vector is denoted as $\boldsymbol{\theta} = (a_0, D_0, Q, \sigma^2)^T$. When new degradation data x_k is obtained, the maximum likelihood estimation method is used to estimate $\boldsymbol{\theta}$. The log-likelihood function based on $X_{0:k}$ can be expressed as:

$$L_k(\boldsymbol{\theta}) = \log[p(X_{0:k} \mid \boldsymbol{\theta})] \tag{11}$$

where $p(X_{0:k} \mid \boldsymbol{\theta})$ is a joint PDF of degradation data $X_{0:k}$. Then, based on the likelihood function of the degradation data $X_{0:k}$, the maximum likelihood estimation value $\hat{\boldsymbol{\theta}}_k$ of $\boldsymbol{\theta}$ can be obtained by maximizing the likelihood function, which can be expressed as:

$$\hat{\boldsymbol{\theta}}_k = \arg\max_{\theta} L_k(\boldsymbol{\theta}) \tag{12}$$

The EM algorithm can be used to approximate the maximum likelihood estimation value of the parameter by maximizing the likelihood function $p(X_{0:k}, \boldsymbol{U}_k \mid \boldsymbol{\theta})$ $\left(\boldsymbol{U}_k = \left(\mu_0, \mu_1, ..., \mu_k\right)\right)$. According to the relationship between $p(\mu_k \mid X_{0:k})$ and $p(X_{0:k}, \boldsymbol{U}_k \mid \boldsymbol{\theta})$, $L_k(\boldsymbol{\theta})$ can be divided into two parts, namely:

$$L_k(\boldsymbol{\theta}) = \ell_k(\boldsymbol{\theta}) - \log p(U_k \mid X_{0:k}, \boldsymbol{\theta}) \tag{13}$$

where

$$\ell_k(\boldsymbol{\theta}) = \log p(X_{0:k}, U_k \mid \boldsymbol{\theta}) \tag{14}$$

According to the adaptive estimation method proposed by Si (2016), the unknown parameters of the model can be divided into the following steps:

- Step 1: The joint log-likelihood function in the EM algorithm can be expressed as:

$$\begin{aligned} \ell_k(\boldsymbol{\theta}) &= \log p(\mu_0 \mid \boldsymbol{\theta}) + \log \prod_{j=1}^{k} p(\mu_j \mid \mu_{j-1}, \boldsymbol{\theta}) \\ &\quad + \log \prod_{j=1}^{k} p(x_j \mid \mu_{j-1}, \boldsymbol{\theta}) \end{aligned} \tag{15}$$

As a result, the conditional expectation $E[\ell_k(\boldsymbol{\theta} \mid \hat{\boldsymbol{\theta}}_k^i)]$ of $\ell_k(\boldsymbol{\theta})$ is as follows:

$$E[\ell_k(\boldsymbol{\theta}\mid\hat{\boldsymbol{\theta}}_k^i)] = E_{U_k|X_{0:k},\hat{\theta}_k^i}[\ell_k(\boldsymbol{\theta})]$$
$$= \frac{1}{2}E_{U_k|X_{0:k},\hat{\theta}_k^i}[-\log D_0 - (\mu_0 - a_0)^2 D_0 - \sum_{j=1}^{k}(\log Q + (\mu_j - \mu_{j-1})^2 Q) - \sum_{j=1}^{k}(\log\sigma^2 + (x_j - x_{j-1} - \mu_{j-1}(t_j - t_{j-1}))^2 / (\sigma^2(t_j - t_{j-1})))] \tag{16}$$

- Step 2: The Rauch-Tung-Striebel (RTS) optimal smoothing algorithm is used to calculate the conditional expectations $E_{U_k|X_{0:k},\hat{\theta}_k^i}(\mu_j)$, $E_{U_k|X_{0:k},\hat{\theta}_k^i}(\mu_j^2)$ and $E_{U_k|X_{0:k},\hat{\theta}_k^i}(\mu_j\mu_{j-1})$:
- Step 3: Substituting the results of $E_{U_k|X_{0:k},\hat{\theta}_k^i}(\mu_j)$, $E_{U_k|X_{0:k},\hat{\theta}_k^i}(\mu_j^2)$ and $E_{U_k|X_{0:k},\hat{\theta}_k^i}(\mu_j\mu_{j-1})$ into equation (16), the specific expression of $E[\ell_k(\boldsymbol{\theta}\mid\boldsymbol{\theta}_k^i)]$ can be obtained. This completes the E step in the EM algorithm.
- Step 4: Followed by the M step, according to the literature (Si (2016)), the parameter $\hat{\theta}_k^{(i+1)}$ estimated from the i+1 step iteration in M step is the global unique optimal solution of the equation(12), there is $\hat{\theta}_k^{(i+1)} = (a_{0k}^{(i+1)}, D_{0k}^{(i+1)}, Q_k^{(i+1)}, (\sigma^2)_k^{(i+1)})^T$. Specific proof of the process and convergence analysis of the algorithm can be found in the literature (Si (2016)).

Thus the parameter estimation value $\hat{\boldsymbol{\theta}}_k = (a_{0k}^{(i+1)}, D_{0k}^{(i+1)}, Q_k^{(i+1)}, (\sigma^2)_k^{(i+1)})^T$ is obtained, which will be used as the model parameter of the real-time reliability in the next inspection time.

4 DETERMINATION OF SEQUENTIAL INSPECTION INTERVALS

In order to make the model parameters estimation converge faster and obtain higher accuracy, we can use the historical data of similar aviation products to estimate the approximate initialization parameters $\boldsymbol{\theta}_0 = (a_0, D_0, Q_0, \sigma_0^2)^T$. For an important component of aviation product, it is generally necessary to set the real-time reliability R_S (constant) according to the task requirement, so as to ensure the reliability of the product before inspection or maintenance.

4.1 *Determination of the initial inspection time t_{01} and t_{02} for the new product*

In order to estimate the parameter $\hat{\theta}_k$ more accurately, and make parameter estimation converge more quickly, two state information of product are required at least. Conservatively, the interval for the first inspection is set to be the same as the second inspection considering the product safety and reliability, i.e. t_{01}=$t_{02}/2$. Since the real-time reliability should be guaranteed before the next inspection, there is following expression based on equation (10):

$$R_S(l_k \mid X_{0:k}) = \Phi\left(\frac{w - x_k - \hat{\mu}_k l_k}{\sqrt{D_{k|k}{l_k}^2 + \sigma^2 l_k}}\right) - \exp\left\{\frac{2\hat{\mu}_k(w - x_k)}{\sigma^2} + \frac{2D_{k|k}(w - x_k)^2}{\sigma^4}\right\} \times \Phi\left(-\frac{2D_{k|k}(w - x_k)l_k + \sigma^2(\hat{\mu}_k l_k + w - x_k)}{\sigma^2\sqrt{D_{k|k}{l_k}^2 + \sigma^2 l_k}}\right) \geq R_S \tag{17}$$

Thus, the second inspection time t_{02} satisfies the following formula:

$$\Phi\left(\frac{w - x_0 - \hat{\mu}_0 t_{02}}{\sqrt{D_0{t_{02}}^2 + \sigma_0^2 t_{02}}}\right) - \exp\left\{\frac{2\hat{\mu}_0(w - x_0)}{\sigma_0^2} + \frac{2D_0(w - x_0)^2}{\sigma_0^4}\right\} \times \Phi\left(-\frac{2D_0(w - x_0)t_{02} + \sigma_0^2(\hat{\mu}_0 t_{02} + w - x_0)}{\sigma_0^2\sqrt{D_0{t_{02}}^2 + \sigma_0^2 t_{02}}}\right) \geq R_S \tag{18}$$

Based on the monotonicity of the distribution function, it is easy to get the solution $\hat{t}_{02}$ of the unary equation by using MATLAB, then:

$$t_{02} \leq \hat{t}_{02}$$

According to engineering practice, the second inspection time can be set as t_{02}= $\hat{t}_{02}$, so the first inspection time is t_{01}=$t_{02}/2$=$\hat{t}_{02}/2$. then the product can be respectively inspected at t_{01} and t_{02} to obtain new degradation data x_{01} and x_{02}.

4.2 *Determination of the inspection time $t_{i(k+1)}(i \geq 0, k \geq 0)$*

After obtaining the product degradation data x_{01} and x_{02}, the new parameter $\hat{\boldsymbol{\theta}}_{\mathbf{01}}$ can be determined by using the adaptive estimation method to integrate x_{01} and $\boldsymbol{\theta}_0$. Similarly, the parameter $\hat{\boldsymbol{\theta}}_{\mathbf{02}}$ is adaptively estimated by integrating the degradation data x_{01}, x_{02} and parameter $\hat{\boldsymbol{\theta}}_{\mathbf{01}}$, then the inspection interval $\Delta\hat{t}_{02}$ can be determined according to the requirement of R_S, so the third inspection time is $t_{03} = t_{02} + \Delta\hat{t}_{02}$.

If the degradation data of the next inspection still does not exceed the preventive maintenance threshold w_0, the new inspection data w_{0k} and parameter $\hat{\boldsymbol{\theta}}_{\mathbf{0(k-1)}}$ will be integrated to estimate the parameter $\hat{\boldsymbol{\theta}}_{\mathbf{0k}}$ recursively, then the interval after each inspection can be determined. Similarly, the next inspection time will meet the following condition:

$$t_{0(k+1)} = t_{0k} + \Delta\hat{t}_{0k} \tag{19}$$

For further consideration, if the degradation data x_{0n} exceeds the preventive maintenance threshold w_0 during the inspection, this important component will be replaced. Then all the degradation data $x_{(i-1)(0:n)}$ of inspections after the $(i-1)$-th $(i \geq 1)$ maintenance is used to estimate the parameter $\hat{\boldsymbol{\theta}}_{i0}$ adaptively, and $\hat{\boldsymbol{\theta}}_{i0}$ will be taken as the initial parameter of the model after the i-th maintenance. Similarly, all the inspection data $x_{i(0:k)}$ is used to estimate the model parameters $\hat{\boldsymbol{\theta}}_{ik}$ adaptively, then the interval Δt_{ik} can be determined, and the interval Δt_{ik} satisfies the following condition:

$$\begin{aligned}&\Phi\left(\frac{w-x_{ik}-\hat{\mu}_{ik}\Delta t_{ik}}{\sqrt{D_{ik}\Delta t_{ik}{}^2+\sigma_{ik}^2\Delta t_{ik}}}\right)\\&-\exp\left\{\frac{2\hat{\mu}_{ik}(w-x_{ik})}{\sigma_{ik}^2}+\frac{2D_{ik}(w-x_{ik})^2}{\sigma_{ik}^4}\right\}\\&\times\Phi\left(-\frac{2D_{ik}(w-x_{ik})\Delta t_{ik}+\sigma_{ik}^2(\hat{\mu}_{ik}\Delta t_{ik}+w-x_{ik})}{\sigma_{ik}^2\sqrt{D_{ik}\Delta t_{ik}{}^2+\sigma_{ik}^2\Delta t_{ik}}}\right)\\&\geq R_S\end{aligned} \tag{20}$$

Similarly, $\Delta\hat{t}_{ik}$ can be easily obtained by using the MATLAB, so there is:

$$t_{i(k+1)} = t_{ik} + \Delta\hat{t}_{ik} \tag{21}$$

5 NUMERICAL EXAMPLE

In this section, a certain type of aluminum alloy material (Meeker (1998)) commonly used in aviation products is taken as an example, the quality of this material is generally evaluated by the length of its fatigue crack. The initial crack length of the material is 0.9 inches, and the failure threshold is set to be $w = 1.6$ inches, the preventive maintenance threshold is set to be $w_0 = 1.58$ inches.

5.1 *Evaluation of the real-time reliability model*

In the experiment, firstly the approximate initial parameter $\hat{\boldsymbol{\theta}}_0 = (a_0, D_0, Q_0, \sigma_0^2)^T = (6.5, 0.5, 0.5, 0.1)^T$ is obtained by integrating the fatigue crack growth data of the same type product. In order to verify the effectiveness of the model proposed in this paper, we select the crack length information corresponding to time $\boldsymbol{t}_{1:28}$ as the degradation data. And for each inspection time, the degradation information $\boldsymbol{X}_{1:h}$ before the inspection time is set as the history degradation information, thus the parameter of degradation model can be updated by using the proposed method, then the future crack length of the material can be predicted by the formula $\hat{x}_{k+1} = x_k + \hat{\mu}_k(t_{k+1} - t_k)$ step by step. Finally, the result is compared with the real curve

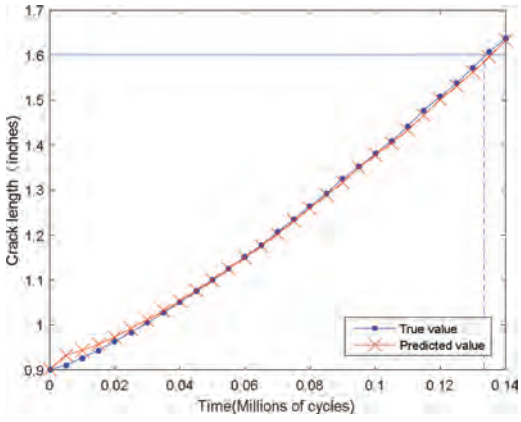

Figure 2. The comparison plot of crack growth curve.

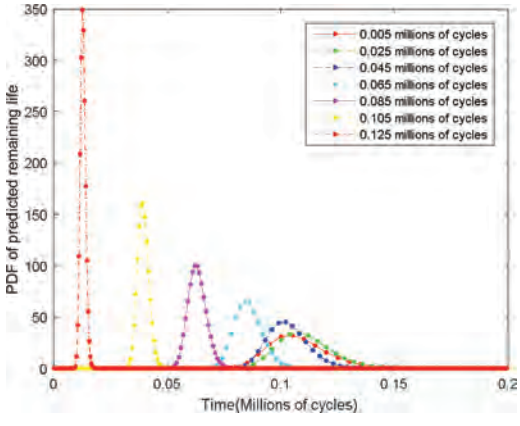

Figure 3. PDF of predicted remaining life at seven different inspection points.

of fatigue crack growth for the aluminum alloy. The comparison plot is shown in Figure 2.

According to the result of the experiment, the theoretical failure time of crack length reaches the failure threshold is about 0.13343 million cycles, and the mean square error between the predicted value and the true value is: $\mathbf{MSE} = 6.5575e\text{-}05$.

Figure 3 gives a PDF plot of the predicted remaining life at seven different inspection points. The curves gradually shift left and become sharper as data accumulates, which means that the uncertainty of the remaining life prediction is decreasing as more and more data are used to estimate the parameters of the model. According to Fig. 2 and Fig. 3, it can be seen that the model proposed in this paper fits very well with the real model.

5.2 *Determination of sequential inspection intervals*

The calculation process of sequential inspection interval is given as follows: Firstly, R_S is set to be

Table 1. The calculation results of the sequential inspection interval ($R_S = 0.9$).

The serial number	The initial state ($t_0 = \mathbf{0}$)	The new product						Replace as new (t_1)	After one maintenance				Replace a new (t_2)	After two maintenances			
		t01	t02	t03	t04	t05	t06		t11	t12	t13	t14		t21	t22	t23	…
t_{ik}/millions of cycles	0.0000	0.0429	0.0858	0.1171	0.1274	0.1309	0.1322	0.1322	0.2328	0.2575	0.2629	0.2645	0.2645	0.3725	0.3941	0.3960	…
xik/inches	0.9000	1.0647	1.2970	1.4851	1.5541	1.5792	1.5825	0.9000	1.3860	1.5417	1.5783	1.5885	0.9000	1.4294	1.5744	1.5814	…
a_{ik}	6.5000	6.3122	6.2132	6.0897	5.9436	5.8073	5.7091	5.7091	5.6880	5.6158	5.5307	5.5032	5.5032	5.4906	5.4340	5.9370	…
D_{ik}	0.5000	0.4647	0.4403	0.4070	0.3668	0.3302	0.3099	0.3099	0.3025	0.2685	0.2316	0.2211	0.2211	0.2164	0.1867	0.1671	…
Q_{ik}	0.5000	4.2608	2.9779	2.0715	1.5555	3.9689	12.0634	12.0634	1.4950	1.1045	4.4839	9.9541	9.9541	0.8480	1.1483	10.9867	…
$(\hat{\sigma}^2)$ *ik*	0.1000	0.2829	0.1780	0.1211	0.0809	0.0594	0.0575	0.0575	0.1048	0.0659	0.0426	0.0357	0.0357	0.0609	0.0539	0.0386	…
$\Delta\hat{t}_{ik}$ / millions of cycles	0.0429	0.0429	0.0312	0.0103	0.0035	0.0013	—	—	0.10007	0.0246	0.0054	0.0016	—	0.1080	0.0216	0.0019	—	…
Remarks	The degradation data exceeds the preventive maintenance threshold 1.58 inches at the sixth inspection, which needs to be replaced.							The degradation data exceeds the preventive maintenance threshold at the fourth inspection, which needs to be replaced.					The degradation data exceeds the preventive maintenance threshold at the third inspection, which needs to be replaced.				…

$R_S = 0.9$, and $t_{02} = 0.0858$ can be obtained by using the method proposed in Section 4.1, so $t_{01} = t_{02}/2 = 0.0429$; Secondly, when $i = 0$, $k = 1, 2$, $\hat{\theta}_{01} = (a_{01}, D_{01}, Q_{01}, \sigma_{01}^2)^T$ and $\hat{\theta}_{02} = (a_{02}, D_{02}, Q_{02}, \sigma_{02}^2)^T$ are respectively estimated by the adaptive estimation method. Thirdly, the inspection interval $\Delta\hat{t}_{ik}$ is determined according to the requirement of real-time reliability, i.e. $t_{i(k+1)} = t_{ik} + \Delta\hat{t}_{ik}$; when $i = 0, k = 2$, t_{03} is obtained; when $i = 0, k = 3$, t_{04} is obtained. If the crack length exceeds the preventive maintenance threshold, the product will be replaced immediately. In the second operating phase, the last parameter $\hat{\boldsymbol{\theta}}_{06}$ of the first phase is taken as the initial parameter, and the parameters are recursively updated, then the time of each inspection and maintenance can be determined, the following inspection time will be obtained in the same way. The inspection time t_{ik} determined by the proposed sequential method is shown in the second row of Table 1, and the third row shows the degradation data x_{ik} of each inspection. Finally, the following results can be obtained from the numerical example:

1. If the aluminum alloy material is not be inspected, the theoretical service life of the material will be about 0.10837 million cycles when R_S = 0.9. However, if the sequential inspection method is used, the effective service life of the material is about 0.132 million cycles, which is close to the theoretical failure time of 0.13343 million cycles, the service life of aviation products is extended effectively.
2. As can be seen from Table 1, the sequential inspection interval is not equal spacing, the number of inspection is reduced from 6 times to 4 times after one maintenance, and reduced to 3 times after two maintenances. As the data accumulated, the number of inspection can be further reduced. Therefore, the sequential inspection method proposed in this paper, not only can effectively reduce the number of inspection, but also can improve the efficiency of inspection and maintenance while ensuring the reliability of aviation products.
3. It can be seen that the convergence rate of model parameters is very fast in the case of small sample data, and the prediction accuracy also meets the actual requirements.
4. If $R_S = 0.8$, the theoretical service life of the material is about 0.11482 million cycles. When the rest conditions remain unchanged, using the similar calculation procedure above, we can obtain the following inspection times: The initial new product {0.0463, 0.0926, 0.1230, 0.1304, 0.1322}; After one maintenance {0.2401, 0.2605, 0.2656}; After two maintenances {0.3770, 0.3966}. According to the calculation results, the effective service life

of the material is about 0.133 million cycles. Moreover, the number of inspections required for the new product is reduced from 6 to 5 times, and reduced from 4 to 3 times for the product after one maintenance. This shows that sequential inspection time, the number of inspections and effective service life are closely related with the requirement of real-time reliability.

6 CONCLUSIONS

In this paper, a sequential inspection method for aviation products based on Wiener process and real-time reliability requirement has been proposed. It is known that in the actual operation process of aviation products, the mechanism of performance degradation is complex, and the degradation process shows randomness. The sequential inspection method can adaptively update the relevant parameters of degradation model in real time, so as to determine the time of each inspection and maintenance more accurately. The method can not only ensure the reliability of the product, but also avoid the problems of over-inspection or under-inspection which may be caused by the traditional equal-pitch cycle inspection. And the number of inspection data is also required less by the sequential inspection method. Moreover, the convergence rate of relevant parameters become faster by integrating the historical information of similar products, and the model has good robustness, so as to ensure the reliability requirement and the prediction accuracy of degradation information for the aviation products, which is very suitable for the determination of inspection and maintenance intervals of the new small-sample product.

The research of this paper is carried out under the condition of considering the perfect maintenance for the product. In some cases, the performance of the product as a whole is affected by other non-replaceable parts and some environmental factors of the system, the performance cannot recover as new after maintenance. Therefore, the further study will consider the inspection method for the product in the case of imperfect maintenance.

ABSTRACT: For repairable products sold with two-dimensional warranty, although burn-in and Preventive Maintenance (PM) actions result in extra costs, they both can be effective approaches to reduce number of warranty claims and servicing cost by early detecting defects and reliability improvement. Longer burn-in or higher burn-in usage rate can remove more defects, but it accelerates the product degradation and incurs more wear-out failures, which in turn need to be alleviated by PMs in the warranty period. This article aims to propose a new warranty performance-based model to minimize the warranty claims and find out the optimal burn-in and PM decisions for two-dimensional warranted products. More specifically, the proposed model subsumes a special case under one-dimensional warranty, allows different failure modes—i.e. defects and wear-out failures, and takes usage heterogeneity into consideration. We find that, it is always reasonable to carry out a burn-in on products. If wear-out failures are more (less) sensitive to product usage rate than defects, the burn-in duration should be extended (increased with the upper limit of PM degree); The optimal burn-in usage rate should be increased with the upper limit of PM degree (conducted at conditions as harsh as possible) and decrease with the upper limit of detecting degree; the optimal PM should always be set at its upper limit.

1 INTRODUCTION

Burn-in as an important production process, where products are operated under the actual working stress for a period. Those weak items and premature failures (e.g. from manufacturing and assembly errors) can be revealed, and then the general product reliability is improved (Chan and Meeker, 1999; Blischke et al, 2011).

Products are sold with warranties. Currently, most of burn-in models focus on the cases of one-dimensional warranties. Leemis and Beneke (1990) have highlighted in their review paper that some researchers had investigated relations between burn-in and warranty policies. According to Nguyen and Murthy (1982), the optimal burn-in duration is determined by the trade-off between the reduction in the warranty cost and the increase in the cost with burn-in. Sheu and Chien (2005) extended the above models by studying two types of failures. Similarly, Kar and Nachlas (1997), and Wu et al. (2007) also have proposed models to determine the optimal burn-in duration for products sold with warranties. They considered different types of warranty policies.

After burn-in, preventive maintenance (PM) is an effective way to reduce warranty claims. Unlike many warranty policies which require restoring a failed product without any schedules, PM is commonly scheduled, aiming to control the wear-out degradation and reduce likelihood of failures. Shafiee et al. (2011, 2013) have paid attention to the effects of PMs on the failure rate and the optimal burn-in duration.

A warranty can be one-dimensional, meaning that only calendar time is considered in determining the warranty period, or two-dimensional, where usages are often evaluated. However, all the above burn-in models are limited to one-dimensional warranted products. Ye et al. (2013) contribute to deal with burn-in under two-dimensional warranties, but this work does not consider PM in the burn-in decisions.

Therefore, this paper focuses on the burn-in and PM decisions for two-dimensional warranted products. Firstly, since the optimal burn-in

decisions should be made by a trade-off between the increase in wear-out failures and the decrease in defects during warranty, we were wondering whether a burn-in should be applied to two-dimensional warranted products. If the answer is yes, the next question is how to set the burn-in duration and burn-in usage rate. Furthermore, we will explore how PM influence the burn-in decision.

The rest of this paper is organized as follows. The modeling assumptions are listed in Section 2. In Section 3, we investigate how to model failures under PM actions and introduce the warranty performance-based model to minimize the warranty claims and help make optimal decisions. Then numerical examples are presented to illustrate the applicability of the proposed model in Section 4. Conclusions and some extensions are given in Section 5.

2 MODEL ASSUMPTIONS

Firstly, all the item failures during the warranty coverage are statistically independent and minimally repaired. Each item is assumed to be repairable and sold with a non-renewing free repair warranty policy. In addition, each failure will incur a warranty claim, and all warranty claims are valid.

We assume that there are two types of failures, the wear-out failures and the defects. The wear-out failures, also known as normal failures, occur over time, while the defects can be revealed in the early period of lifetime. The two failures are independent.

Effects of usage rate on both types of failures are modeled using Accelerated Failure Time (AFT) model (Baik and Murthy 2008; Shahanaghi et al. 2013). We also assume that the failure rate functions are convex, in order to ensure that the failure rate curve of products is close to the bathtub curve as much as possible.

After burn-in, the product is released to the market with a non-renewing free repair warranty (FRW).

Like most of related papers (Iskandar et al. 2005; Wang et al. 2015), we confine the two-dimensional warranty region to be a rectangle one in which the horizontal axis represents age and the vertical axis represents usage. The warranty region is a rectangle $[0, W_0) \cdot [0, U_0)$. The warranty expires when the item reaches either the age or usage limit.

The time of manufacturer implementing repair or PMs programs is negligible and assumed to be zero. And all the PMs are assumed to be performed with fixed time interval τ. In addition, defects can be detected during PMs.

3 MODELING AND ANALYSIS

In this section, we firstly investigate how to model wear-out failures and defects. Then performance-based model is introduced to minimize the warranty claims and help make optimal decisions.

3.1 *Modeling of failures*

The usage rate over time is constant for one customer, but varies across customers. Let R be the random usage rate, and $G(r)$ and $g(r)$ represent cumulative distribution function (CDF) and probability density function (PDF) of R respectively.

Under a two-dimensional warranty, we model the wear-out with a counting process characterized by an intensity function dependent on both age and usage. We introduce $v^w(t|r)$ as the corresponding virtual age under the condition of usage rate r. Considering the item designed for certain nominal usage rate r_0, according to the AFT model, if the usage time is t and the specific usage rate is r, then $v^w(t|r) = t\left(\frac{r}{r_0}\right)^{\gamma}$, where γ is accelerated coefficient due to the wear-out.

Conditional on a specific customer $R = r$, the wear-out process is a Non-homogeneous Poisson process (NHPP) with a non-decreasing rate of occurrence of failure $\lambda^w(v^w)$. Note that v^w is the function of t, so we can achieve the actual failure rate function of an item due to wear-out failures for any customer with usage rate r as $\lambda^w\left(v^w(t|r)\right)\left(\frac{r}{r_0}\right)^{\gamma}$ according to the AFT model.

The number of defects is modeled by a random variable M with a probability mass function $\pi(\cdot)$. All defects are assumed to be independent and identically distributed. For any specific defect, the virtual age is $v^i(t|r) = t\left(\frac{r}{r_0}\right)^{\eta}$, where η is accelerated coefficients due to the defects. And its first time to failure conforms to a CDF $F^d(\cdot)$. Therefore, the number of defects can be described by a binomial process with M trials, each with success probability given by $F^d(\cdot)$.

3.2 *Failures within burn-in*

It is limited to set the values of burn-in durations and usage rates, since longer duration and higher rates can decrease defect on the one hand, but intensify wear-out on the other hand. We use $\overline{t_b}$ and $\underline{t_b}$ as the upper bound and lower bound of Burn-in duration t_b, and $\overline{r_b}$ and $\underline{r_b}$ as upper bound and lower bound of burn-in usage rate r_b.

For an item arriving at the end of burn-in, we let v_0^w and v_0^i be the virtual age of wear-out failure process and potential defects, respectively. The time lag between the end of burn-in and the beginning

of product's running into operation is ignored. Therefore, after burn-in under the usage rate r_b and duration t_b, we can obtain that $v_0^w = t_b\left(\frac{r_b}{r_0}\right)^\gamma$ and $v_0^i = t_b\left(\frac{r_b}{r_0}\right)^\eta$.

The expected number of failures of wear-out failures within the burn-in can be given by,

$$E^w\left[N_b\left(t_b, r_b\right)\right] = \int_0^{t_b}\left[\lambda^w\left(v^w\left(t|r_b\right)\right)\left(\frac{r_b}{r_0}\right)^\gamma\right]dt \qquad (1)$$

For any specific defect, the probability that it is detected within burn-in is $F^d\left(t\left(\frac{r}{r_0}\right)^\eta\right)$. Conditional on M, the number of defects occurs during burn-in follows a binomial distribution with mean value as follow,

$$E^i\left[N_b\left(t_b, r_b\right)\right] = E\left(M\right)\times F^d\left(t_b\left(\frac{r_b}{r_0}\right)^\eta\right)$$

Therefore, the expected number of failures within burn-in can be given by,

$$E\left[N_b\left(t_b, r_b\right)\right] = E^w\left[N_b\left(t_b, r_b\right)\right] + E^i\left[N_b\left(t_b, r_b\right)\right]$$

3.3 *Failures within warranty period under PM*

Different usage rates mean different usage patterns which lead to different termination of warranties due to its age limits or usage limits. For any specific usage rate, only two cases exist, which is illustrated in Fig. 1.

From the Fig. 1, we know that, for a specific usage rate r, define r_0 as $\frac{U_0}{W_0}$, if $r > r_0$, then warranty will end at the time $\frac{U_0}{r}$. If $r \le r_0$, then warranty will end at the time W_0. Therefore, we need to investigate these two cases.

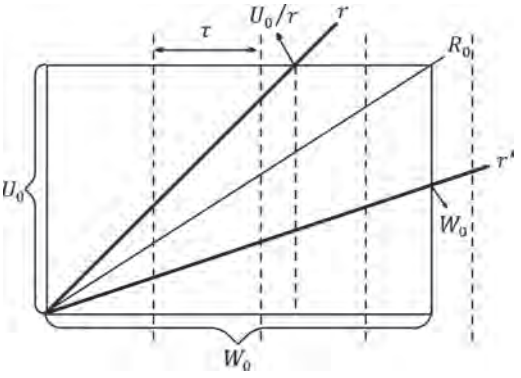

Figure 1. Warranty period under PM.

Within the warranty coverage, though minimal repair is free of charge, the customer has already experienced loss incurred by failures. Besides, the wear-out failure rate of product becomes higher, so that the manufacturer tends to suffer more repair cost. Therefore, PMs are needed, not only to improve product reliability, and reduce repair costs.

We let periodical imperfect PMs are implemented with fixed interval τ, and their effectiveness is depicted by a maintenance degree δ_w for wear-out failures and a detect degree δ_d for potential defects, both of which are between 0 and 1. $\delta_w = 1$ means that wear-out failure rate of the product is back to original level by a perfect PM and then the product is "as good as new", while $\delta_w = 0$ means that no action is carried out. Also, $\delta_d = 1$ means that any defects can be found during PM with probability of 1, while $\delta_d = 0$ means that PM actions cannot find any defects.

3.3.1 *Wear-out failures*

For wear-out failures, there are at least two classes of imperfect PM models in previous literatures. The readers can refer to Doyen and Gaudoin (2004) as a good source of reference. We use the one that PM actions result in a rejuvenation of the product through effectively reducing the virtual age (Doyen and Gaudoin, 2004). We let $\lambda_k^W\left(t|r\right)$ be conditional wear-out failure rate of the item after the kth PM action, and v_k^w be the virtual age of wear-out failure process after the kth PM action. And we already know that $v_0^w = t_b\left(\frac{r_b}{r_0}\right)^\gamma$, then the virtual age of wear-out failure process after the 1st PM action is

$$v_1^w = \left[v_0^w + \tau\cdot\left(\frac{r}{r_0}\right)^\gamma\right]\left(1-\delta_w\right)$$

where r is specific usage rate of a certain customer. Then we have,

$$v_k^w = \left[v_{k-1}^w + \tau\cdot\left(\frac{r}{r_0}\right)^\gamma\right]\left(1-\delta_w\right)$$

When $\delta_w = 1$, v_k^w is always returned to 0. When $\delta_w \ne 1$, divided by $\left(1-\delta_w\right)^k$ on both sides of the equation, so $\frac{v_k^w}{\left(1-\delta_w\right)^k} = \frac{v_{k-1}^w}{\left(1-\delta_w\right)^{k-1}} + \tau\cdot\left(\frac{r}{r_0}\right)^\gamma\left(1-\delta_w\right)^{1-k}$.

Let $S_k = \frac{v_k^w}{\left(1-\delta_w\right)^k}$, then we have $S_k = S_{k-1} + \tau\cdot\left(\frac{r}{r_0}\right)^\gamma\left(1-\delta_w\right)^{1-k}$, add up these equations from S_1 to S_k, so

$$S_k = v_0^w + \tau \cdot \left(\frac{r}{r_0}\right)^{\gamma} \left(1-\delta_w\right) \left(\frac{1-\left(1-\delta_w\right)^k}{\delta_w \left(1-\delta_w\right)^k}\right)$$

Using $S_k = \frac{v_k^w}{(1-\delta)^k}$ to replace it, then we have the general term of v_k^w as follow,

$$v_k^w = \left(1-\delta_w\right)^k v_0^w + \tau \cdot \left(\frac{1-\delta_w}{\delta_w}\right)\left(1-\left(1-\delta_w\right)^k\right)\left(\frac{r}{r_0}\right)^{\gamma}$$

Then we have the wear-out failure rate $\lambda_k^W(t|r)$ of the item after the kth PM action as follow,

$$\lambda_k^W(t|r) = \lambda^w\left(v_k^w + t \cdot \left(\frac{r}{r_0}\right)^{\gamma}\right)\left(\frac{r}{r_0}\right)^{\gamma}$$

Note that v_k^w is still the function of t. Specifically, when $\delta_w = 0$, $\lambda_k^W(t|r)$ is given by,

$$\lambda_k^w(t|r) = \lambda^w\left(v_0^w + k\tau\left(\frac{r}{r_0}\right)^{\gamma} + t\left(\frac{r}{r_0}\right)^{\gamma}\right)\left(\frac{r}{r_0}\right)^{\gamma} \tag{2}$$

For case $r > r_0$, the warranty for the product ceases when the product usage reaches U_0, which corresponds to the age $\frac{U_0}{r}$. And we let the number of PMs within this warranty region be $n_{r>r_0}$, estimated by $\max_j\left\{j \times \tau \le \frac{U_0}{r}\right\}$, where $j \in N$. Therefore, we have the number of PMs performed within warranty when $r > r_0$, namely $n_{r>r_0} = arg\max_j\left\{j \times \tau \le \frac{U_0}{r}\right\}$. Then the expected failures of wear-out failures during this period are given by,

$$E\left[N^w\left(t_b, r_b | r > r_0\right)\right] = \sum_{k=0}^{n_{r>r_0}-1} \int_0^{\tau} \lambda_k^W\left(t|r\right) dt + \int_0^{\frac{U_0}{r}-\tau n_{r>r_0}} \lambda_{n_{r>r_0}}^W\left(t|r\right) dt \tag{3}$$

Here the first term is expected wear-out failures before the last PM within the warranty. The second term is expected wear-out failures between the last PM and the end of warranty. Since the meanings of terms hereafter are similar, we will not repeat.

For the case $r \le r_0$, the warranty for the product terminates when the product age reaches W_0. Similarly, we let the number of PMs within this warranty region be $n_{r\le r_0}$, estimated by $\max\left\{j \times \tau \le W_0\right\}$, where $j \in N$. Therefore, we have the number of PM actions performed within warranty when $r \le r_0$, namely $n_{r\le r_0} = arg\max\left\{j \times \tau \le W_0\right\}$. And then the expected failures during this period are given by,

$$E\left[N^w\left(t_b, r_b | r \le r_0\right)\right] = \sum_{k=0}^{n_{r\le r_0}-1} \int_0^{\tau} \lambda_k^W\left(t|r\right) dt + \int_0^{W_0-\tau n_{r\le r_0}} \lambda_{n_{r\le r_0}}^W\left(t|r\right) dt \tag{4}$$

We use $E\left[N^w\left(t_b, r_b|r\right)\right]$ to denote the expected wear-out failures within warranty period of any specific customer, which means $E\left[N^w\left(t_b, r_b|r\right)\right]$ should be either $E\left[N^w\left(t_b, r_b|r > r_0\right)\right]$ or $E\left[N^w\left(t_b, r_b|r \le r_0\right)\right]$ according to the usage rate r.

Also, we use $E\left(n_{BP}|r\right)$ to denote the number of PMs within this warranty region, which means $E\left(n_{BP}|r\right)$ should be either $n_{r>r_0}$ or $n_{r\le r_0}$ according to the usage rate r. These declarations will be useful for our subsequent modelling analysis.

3.3.2 *Defects*

Consider a specific remaining defect, the virtual age of this defect after burn-in is $t_b\left(\frac{r_b}{r_0}\right)^{\eta}$. After the burn-in, the remaining defects can either be found during operation or detected by PM actions. The distribution for the time to find this remaining defect conditional on specific r before 1st PM action can be given by

$$G_0^d(t|r) = \frac{F^d\left(t_b\left(\frac{r_b}{r_0}\right)^{\eta} + \tau\left(\frac{r}{r_0}\right)^{\eta}\right) - F^d\left(t_b\left(\frac{r_b}{r_0}\right)^{\eta}\right)}{1 - F^d\left(t_b\left(\frac{r_b}{r_0}\right)^{\eta}\right)} \tag{5}$$

Suppose that a total of K defects remains. Given M, K follows a binomial distribution $bi\left(M, 1 - F^d\left(t_b\left(\frac{r_b}{r_0}\right)^{\eta}\right)\right)$.

Conditional on K, the number of remaining defects before the 1st PM actions follows the binomial distribution $bi\left(K, G_0^d(t|r)\right)$. Then we can deduce the probability of remaining defects K that can be found from the end of burn-in to 1st PM action as follow,

$$F_0^d(t|r) = \left(1 - F^d\left(t_b\left(\frac{r_b}{r_0}\right)^{\eta}\right)\right) G_0^d(t|r) = F^d\left(t_b\left(\frac{r_b}{r_0}\right)^{\eta} + \tau\left(\frac{r}{r_0}\right)^{\eta}\right) - F^d\left(t_b\left(\frac{r_b}{r_0}\right)^{\eta}\right) \tag{6}$$

A defect may be detected during the 1st PM. Using the similar deduction of $F_0^d(t|r)$, we can achieve that the probability of remaining defects K that can be detected in the 1st PM with detect degree δ_d is given by,

$$P_1^d(\tau|r)=\left(1-F^d\left(t_b\left(\frac{r_b}{r_0}\right)^{\eta}\right)\right)\left(1-G_0^d(\tau|r)\right)\delta_d$$
$$=\left[1-F^d\left(t_b\left(\frac{r_b}{r_0}\right)^{\eta}+\tau\left(\frac{r}{r_0}\right)^{\eta}\right)\right]\delta_d \quad (7)$$

The rest as follows can be done as the same manner. Then the probability of remaining defects K that can be detected between kst and (k + 1)st PM action, and during the kst PM action respectively can be given by,

$$F_k^d(\tau|r)=\left[F^d\left(t_b\left(\frac{r_b}{r_0}\right)^{\eta}+(k+1)\tau\left(\frac{r}{r_0}\right)^{\eta}\right)-F^d\left(t_b\left(\frac{r_b}{r_0}\right)^{\eta}+k\tau\left(\frac{r}{r_0}\right)^{\eta}\right)\right]\left(1-\delta_d\right)^k \quad (8)$$

$$P_k^d(\tau|r)=\left[1-F^d\left(t_b\left(\frac{r_b}{r_0}\right)^{\eta}+k\tau\left(\frac{r}{r_0}\right)^{\eta}\right)\right]\delta_d\left(1-\delta_d\right)^{k-1} \quad (9)$$

Therefore, considering the cases of warranty region in Fig. 1, taking expectation with respect to remaining defects K, we can find that the expected number of remaining defects found during the operation and during PMs,

$$E\left[N_{op}^d(t_b,r_b|r>r_0)\right]=\sum_{k=0}^{n_{r>r_0}-1}\left[E(M)F_k^d(\tau|r)\right]+E(M)\left[F^d\left(t_b\left(\frac{r_b}{r_0}\right)^{\eta}+W_0\left(\frac{r}{r_0}\right)^{\eta}\right)-F^d\left(t_b\left(\frac{r_b}{r_0}\right)^{\eta}+n_{r\le r_0}\cdot\tau\left(\frac{r}{r_0}\right)^{\eta}\right)\right]\left(1-\delta_d\right)^{n_{r\le r_0}} \quad (10)$$

$$E\left[N_{op}^d(t_b,r_b|r\le r_0)\right]=\sum_{k=0}^{n_{r\le r_0}-1}\left[E(M)F_k^d(\tau|r)\right]+E(M)\left[F^d\left(t_b\left(\frac{r_b}{r_0}\right)^{\eta}+W_0\left(\frac{r}{r_0}\right)^{\eta}\right)-F^d\left(t_b\left(\frac{r_b}{r_0}\right)^{\eta}+n_{r\le r_0}\cdot\tau\left(\frac{r}{r_0}\right)^{\eta}\right)\right]\left(1-\delta_d\right)^{n_{r\le r_0}} \quad (11)$$

$$E\left[N_{pm}^d(t_b,r_b|r>r_0)\right]=\sum_{k=1}^{n_{r>r_0}}\left[E(M)P_k^d(\tau|r)\right] \quad (12)$$

$$E\left[N_{pm}^d(t_b,r_b|r\le r_0)\right]=\sum_{k=1}^{n_{r\le r_0}}\left[E(M)P_k^d(\tau|r)\right] \quad (13)$$

We use $E\left[N_{op}^d(t_b,r_b|r)\right]$ to denote the expected number of defects within warranty period of any specific customer, which means $E\left[N_{op}^d(t_b,r_b|r)\right]$ should be either $E\left[N_{op}^d(t_b,r_b|r>r_0)\right]$ or $E\left[N_{op}^d(t_b,r_b|r\le r_0)\right]$ according to the usage rate r. Also, we use $E\left[N_{pm}^d(t_b,r_b|r)\right]$ to denote the expected number of detects found during PM actions, which means $E\left[N_{pm}^d(t_b,r_b|r)\right]$ should be either $E\left[N_{pm}^d(t_b,r_b|r>r_0)\right]$ or $E\left[N_{pm}^d(t_b,r_b|r\le r_0)\right]$ according to the usage rate r.

3.4 *Performance-based model*

The warranty performance-based model involves simultaneously selecting burn-in duration t_b and usage rate r_b to minimize the expected failures during the warranty period. For a customer with specific usage rate r, we have the expected warranty claims per unit as follows,

$$E\left[N(t_b,r_b|r)\right]=E\left[N^w(t_b,r_b|r)\right]+E\left[N_{op}^d(t_b,r_b|r)\right] \quad (14)$$

As mentioned earlier, we consider that the usage rate is constant for one customer but varies across different customers. Since we let R be its random usage rate, and $G(r)$ and $g(r)$ represent CDF and PDF of R respectively, the final expected number of failures is obtained by un-conditioning, namely by taking the expectation of $E\left[N_W(t_b,r_b|r)\right]$ with respect to the usage rate,

$$E\left[N(t_b,r_b)\right]=\int_0^{\infty}E\left[N(t_b,r_b|r)\right]dG(r) \quad (15)$$

Then the performance-based model can be given by,

$$[t_b^*,r_b^*]=argmin\ E\left[N(t_b,r_b)\right]$$
$$s.t.\quad t_b\in\left[\underline{t_b},\overline{t_b}\right]$$
$$r_b\in\left[\underline{r_b},\overline{r_b}\right]$$

where t_b^* and r_b^* are optimal burn-in duration and burn-in usage rate.

In this performance-based model, obviously the larger the maintenance degree δ_w and the detect degree δ_d are, the smaller the expected number of failures within warranty period is, which means if they were decision variables, they would always be set at the max. In practice, some PM actions are paid by customers, which means manufactures can ignore the maintenance cost and only take into consideration their own possible limitation to implement the PM actions. Therefore, we don't make the mainte-

nance degree δ_w and the detect degree δ_d as the decision variable in this performance-based model.

Proposition 1 Suppose that $[\, t_b^*, r_b^* \,]$ is the optimal burn-in setting for the performance-based model. When the accelerated coefficients of wear-out failures and defects follow the relationship $\gamma \geq \eta$, (i) the optimal burn-in duration t_b^* is always t_b, (ii) the optimal burn-in usage rate r_b^* is increasing with the maintenance degree δ_w, and (iii) decreasing with the detect degree δ_d.

Proof of Proposition 1 Suppose that $[\, t_b^*, r_b^* \,]$ is the optimal burn-in setting for the performance-based model. We use the contradiction to prove $t_b^* = \bar{t}_b$, if $\gamma > \eta$.

Suppose $t_b^* < \bar{t}_b$, because the virtual age $t_b \left(\frac{r_b}{r_0}\right)^{\eta}$ is increasing with t_b and r_b, and also decreasing with t_b and r_b, we can always find r_b' with $r_b' < r_b^*$ such that,

$$t_b^* \left(\frac{r_b^*}{r_0}\right)^{\eta} = \bar{t}_b \left(\frac{r_b'}{r_0}\right)^{\eta} \tag{16}$$

It means that the virtual age of defects is the same under the cases of $[\, t_b^*, r_b^* \,]$ and $[\, \bar{t}_b, r_b' \,]$ Therefore, as $E\left[N_{op}^d(t_b, r_b)\right]$ is the expected number of defects within warranty coverage, we obviously have the same expected numbers under these two cases, namely,

$$E\left[\, N_{op}^d(t_b^*, r_b^*) \,\right] = E\left[\, N_{op}^d(\bar{t}_b, r_b') \,\right]$$

Based on (16), we have,

$$\bar{t}_b \left(\frac{r_b'}{r_0}\right)^{\gamma} = t_b^* \left(\frac{r_b^*}{r_0}\right)^{\eta} \left(\frac{r_b'}{r_0}\right)^{-\eta} \left(\frac{r_b'}{r_0}\right)^{\gamma}$$
$$= t_b^* \left(\frac{r_b^*}{r_0}\right)^{\gamma} \left(\frac{r_b'}{r_b^*}\right)^{\gamma-\eta}$$

Because $\gamma > \eta$ and $r_b' < r_b^* \left(\frac{r_b'}{r_b^*}\right)^{\gamma-\eta} < 1$, then we have,

$$\bar{t}_b \left(\frac{r_b'}{r_0}\right)^{\gamma} < t_b^* \left(\frac{r_b^*}{r_0}\right)^{\gamma}$$

Therefore, the virtual age of wear-out failures of case $[\, t_b^*, r_b^* \,]$ is bigger than that of case $[\bar{t}_b, r_b']$. As $E\left[N^w(t_b, r_b)\right]$ is the expected number of wear-out failures during operations. Since the failure rate is increasing, we have,

$$E\left[N^w(\bar{t}_b, r_b')\right] < E\left[N^w(\, t_b^*, r_b^*)\right]$$

Because $E\left[\, N(t_b, r_b) \,\right] = E\left[\, N^w(t_b, r_b) \,\right] + E\left[\, N_{op}^d(t_b, r_b) \,\right], E\left[\, N(\bar{t}_b, r_b') \,\right] < E\left[\, N(\, t_b^*, r_b^*) \,\right]$

Therefore, the case $[\bar{t}_b, r_b']$ is better than $[\, t_b^*, r_b^* \,]$, which obviously contradicts our assumption. Then we have $t_b^* = \bar{t}_b$. This completes the proof of (i).

Now we set t_b as a constant $\bar{t}_b$, and give the proof of (ii).

When $r_b = r_b^*$, based on principle of optimization, we obviously have,

$$\left.\frac{dE\left[N^w(\bar{t}_b, r_b)\right]}{dr_b}\right|_{r_b = r_b^*} = -\left.\frac{dE\left[N_{op}^d(\bar{t}_b, r_b)\right]}{dr_b}\right|_{r_b = r_b^*}$$

Since δ exists in $\frac{dE\left[N^w(\bar{t}_b, r_b)\right]}{dr_b}$, we let $Z^w(\delta, r_b) = \frac{dE\left[N^w(\bar{t}_b, r_b)\right]}{dr_b}$ and $Z^d(\delta, r_b) = -\frac{dE\left[N_{op}^d(\bar{t}_b, r_b)\right]}{dr_b}$.

Suppose that when $\delta = \delta'$, optimal burn-in usage rate $r_b^* = r_b'$, We use the contradiction to prove (ii). When $\delta' < \delta''$, suppose $r_b' \geq r_b''$.

Lemma 1 If $f(x, y)$ is convex in x for each $y \in A$, and $\omega(y) \geq 0$ for each $y \in A$, then the function ϕ defined as,

$$\phi(x) = \int_A \omega(y) f(x, y)\, dy$$

is convex in x. (Boyd and Vandenberghe 2004).

Based on (3), we can find $\int_0^{\frac{U_0}{r} - \tau \cdot n_{r>\eta_0}} \lambda_{n_{r>\eta_0}}^W(t \mid r)\, dt$ conforms to Lemma 1 since $\lambda_{n_{r>\eta_0}}^W(t|r)$ is a convex function which is our assumption. Therefore, when we set $t_b = \bar{t}_b$ as a constant, we can easily achieve that $\int_0^{\frac{U_0}{r} - \tau \cdot n_{r>\eta_0}} \lambda_{n_{r>\eta_0}}^W(t|r)\, dt$ is convex function in r_b. Then based on (14) and (15), we can find $\int g(r) \left(\int_0^{\frac{U_0}{r} - \tau \cdot n_{r>\eta_0}} \lambda_{n_{r>\eta_0}}^W(t|r)\, dt \right) dr$ also conforms to Lemma 1 since $g(r) \geq 0$ and $\int_0^{\frac{U_0}{r} - \tau \cdot n_{r>\eta_0}} \lambda_{n_{r>\eta_0}}^W(t \mid r)\, dt$ is convex function in r_b. Therefore, we can easily achieve that the whole term is convex in r_b. The other terms can all be deduced in this way.

Therefore, we can find that $\frac{\partial Z^w(\delta, r_b)}{\partial r_b} = \frac{\partial^2 E\left[N^w(\bar{t}_b, r_b)\right]}{\partial r_b^2} \geq 0$. Also, $\frac{\partial Z^d(\delta, r_b)}{\partial r_b} < 0$. It means for specific δ'', $Z^w(\delta'', r_b'') \leq Z^w(\delta'', r_b')$ and $Z^i(\delta'', r_b'') \geq Z^i(\delta'', r_b')$, if $r_b' \geq r_b''$.

Note that δ also exists in $Z^d(\delta, r_b)$, we can easily achieve $\frac{\partial Z^d(\delta, r_b)}{\partial \delta} > 0$, then we have $Z^d(\delta', r_b') < Z^d(\delta'', r_b')$, if $\delta' < \delta''$. In addition, for the expected numbers of wear-out failures $E\left[N^w(t_b, r_b)\right]$ within warranty coverage, when we set $t_b = \bar{t}_b$ as a constant, obviously for achieving the same expected numbers of wear-out failures within warranty coverage, the deeper the mainte-

nance degree δ is, the larger the burn-in usage rate is, which conforms to the property of strictly sub-modular function. Therefore, we can easily find that $\frac{\partial Z^w(\delta,r_b)}{\partial \delta} = \frac{\partial^2 E\left[N^w(t_b,r_b)\right]}{\partial r_b \partial \delta} < 0$. The rigorous mathematical deduction of this term is very similar with the proof of (i), so we omit it.

Then we can find that for specific r_b', $Z^w(\delta',r_b') > Z^w(\delta'',r_b')$ and $Z^d(\delta',r_b') < Z^d(\delta'',r_b')$, if $\delta' < \delta''$. Since r_b' is the optimal value, we have $Z^d(\delta',r_b') = Z^w(\delta',r_b')$, then,

$$Z^d(\delta'',r_b') > Z^d(\delta',r_b') = Z^w(\delta',r_b') > Z^w(\delta'',r_b')$$

Therefore, based on $Z^w(\delta'',r_b'') \le Z^w(\delta'',r_b')$ and $Z^d(\delta'',r_b'') \ge Z^d(\delta'',r_b')$, we have,

$$\begin{aligned} &Z^d(\delta'',r_b'') \ge Z^d(\delta'',r_b') > Z^d(\delta',r_b') \\ &= Z^w(\delta',r_b') > Z^w(\delta'',r_b') \ge Z^w(\delta'',r_b') \end{aligned}$$

It means $Z^d(\delta'',r_b'')$ is strictly bigger than $Z^w(\delta'',r_b'')$, which obviously contradicts the principle that $Z^d(\delta'',r_b'')$ should be equal to $Z^w(\delta'',r_b'')$, if r_b'' is the optimal value. Therefore, r_b'' cannot be the optimal value of r_b, if $r_b' \ge r_b''$. Then we have the conclusion of (ii).

The proof of (iii) can be deduced in the way of proof of (ii).

These complete the proof of Proposition 1.

Proposition 2 Suppose that $[t_b^*, r_b^*]$ is the optimal burn-in setting for the performance-based model. When the accelerated coefficients of wear-out failures and defects follow the relationship $\gamma < \eta$, then(i) the optimal burn-in usage rate r_b^* is always $\underline{r_b}$, (ii) the optimal burn-in duration t_b^* is increasing with the maintenance degree δ_w, and (iii) decreasing with the detect degree δ_d.

Similar with the proof of proposition 1, proposition 2 can be proved. These propositions indicate that if for a certain product of which wear-out failures are more sensitive than defects to the usage rate, the burn-in duration should be conducted at as long as possible. From the proof of proposition, we know that this is because if the burn-in duration increases, for achieving the same virtual age of the failures result from defects under the two burn-in duration settings, the virtual age of the wear-out failures decreases which leads to less failures during warranty. When the burn-in duration is set to be a constant at its upper limit, that the optimal burn-in usage rate is increasing with the maintenance degree, meaning that if manufacturers implement deeper maintenance, they should set burn-in conditions harsher than before. Meanwhile, if they are able to detect more possible defects during PMs, they should set burn-in conditions milder. Conversely, if defects are more sensitive than wear-out failures to the usage rate, the burn-in should be conducted at conditions as harsh as possible, and the optimal burn-in duration increases with the maintenance degree and decreases with the defecting degree. These two converse propositions cover all the possible cases, so that manufacturers can easily select the burn-in decisions according to the features of any specific product or component. In addition, based on these propositions, the proposition 3 below can be easily set up:

Proposition 3 In performance-based model, implementing burn-in is always better than nothing.

4 NUMERICAL EXAMPLES

In this section, numerical examples are presented to illustrate the applicability of the proposed model above.

For the performance-based model, we use an example to show how to reduce the warranty claims by choosing the optimal burn-in duration t_b and usage rate r_b.

Suppose that the product under consideration is certain automobile component covered by a two-dimensional FRW. The following settings are adopted into our performance-based model,

We calculate the expected failures within the warranty region which is a rectangle of 3 years and 100,000 km of usage. Therefore, we let $W_0 = 3, U_0 = 10$.

We assume that the nominal usage rate is $r_0 = 2 \cdot 10^4$ km/y. And the customer usage rate follows uniform (0.4, 4.2), which means the least usage rate is $0.4 \cdot 10^4$ km/y, and the highest usage rate is $4 \cdot 10^4$ km/y.

Wear-out failures follow a Weibull distribution with increasing failure rate, which is $\lambda^w(t) = \frac{\beta_w}{\alpha_w}\left(\frac{t}{\alpha_w}\right)^{\beta_w - 1}$, where $\beta_w > 2$ (as we assume the failure rate functions of two type failures are convex). The number of defects M follows $Poisson(\mu)$. Defect failure them follows $exp(\theta)$.

Other parameters for this model are given in Table 1.

Under different maintenance degrees and detect degrees of PM actions, we perform a grid search for the minimization of numerical examples based on performance model.

Table 1. Parameter settings for performance-based model.

	$[\underline{t_b}, \overline{t_b}]$	$[\underline{r_b}, \overline{r_b}]$	r_0	τ	α_w	β_w	μ	θ
Value	[0,0.5]	[0.2,5]	2	0.5	2.5	3.5	0.5	0.25

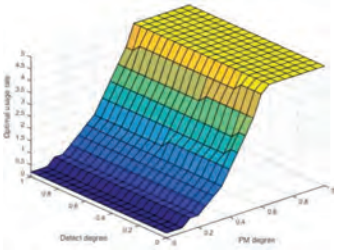

Figure 1a. Optimal usage rate under different PM and detect degree.

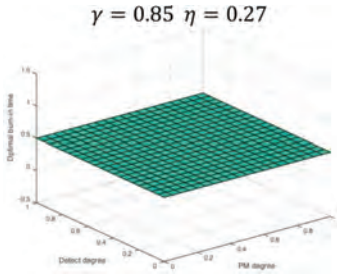

Figure 1b. Optimal burn-in time under different PM and detect degree.

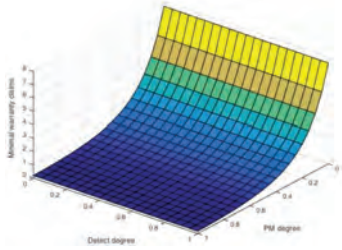

Figure 1c. Minimal warranty claims under different PM and detect degree.

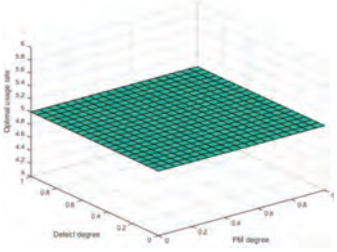

Figure 2a. Optimal usage rate under different PM and detect degree.

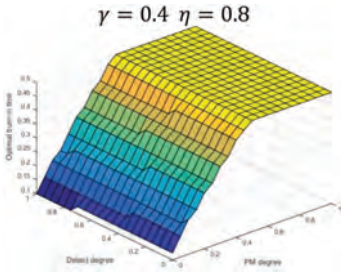

Figure 2b. Optimal burn-in time under different PM and detect degree.

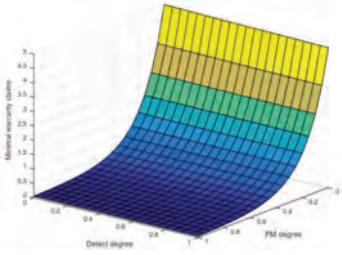

Figure 2c. Minimal warranty claims under different PM and detect degree.

From Fig. 1(a, b, c), we can see that if $\gamma > \eta$, then the optimal burn-in duration is always set to be upper bound $\overline{t_b}$, while optimal burn-in usage rate increases from r_b to $\overline{r_b}$ with the degree of PM actions and decreases with the detecting degree. Conversely, Fig. 2(a, b, c) shows that if $\gamma < \eta$, then the optimal burn-in usage rate stays permanently at the upper bound $\overline{r_b}$, while the optimal burn-in duration increases from t_b to $\overline{t_b}$ with the degree of PMs and decreases with the detecting degree. These curves conform to the proposition 1 and 2. In addition, we also find that as the maintenance or the detecting degree increases, the minimal warranty claims in all examples decrease, verifying that the larger the maintenance degree or the detecting degree increases, the better performance the warranty contract is. Therefore, manufacturers only have to consider their own limited capabilities to implement PM actions.

5 CONCLUSION

In this article, we have studied the optimal strategies of burn-in under PM actions for two-dimensional warranted products.

To help manufacturers to improve the warranty contract performance, we have investigated a performance-based model to help manufacturers to make optimal decisions on burn-in under PMs. In our model, the burn-in duration and burn-in usage rate are set as the decision variables to minimize the expected warranty claims within the warranty coverage. Through computing specific numerical examples, we demonstrate the validity of the model. These findings could help manufacturers to promote the warranty performance in burn-in and warranty management.

Evaluation method of maintenance operation space based on virtual reality

Pengyan Liu, Dong Zhou, Ziyue Guo, Juan Wu & Yuan Li
Beihang University, Beijing, P.R. China

ABSTRACT: In order to ensure the excellent maintainability of the product, it is necessary to give full consideration to the operation space of the maintenance personnel at design time. The traditional evaluation method of the operation space is that gives qualitative evaluation results and puts forward suggestions based on the virtual maintenance simulation animation and the digital prototype while comparing with rules of maintainability design by experts. The evaluation result usually depends on the expert level with subjective tendency. There is still a lack of widely used quantitative evaluation methods. This paper analyzes the main attitude of maintenance personnel in maintenance activities, evaluates their comfort level, and then evaluates the operation space. First of all, through the analysis of the characteristics of maintenance activities, the article draws the main factors of human comfort evaluation. Based on the artificial potential field theory commonly used in robot obstacle avoidance path planning, a reachability potential field that can be used to describe the upper limb posture of maintenance personnel is established and a criterion for evaluating upper limb comfort is proposed. Then, combined with the virtual maintenance technology, using the virtual maintenance simulation platform, together with a comprehensive analysis of tool rotation angle, operation space ratio and the hand swept volume of maintenance posture, the comfort of the maintenance staff's hand gesture is analyzed. After that, the above two parts are combined to comprehensively evaluate the comfort degree of the human body posture and give the evaluation criteria. And a new operation space evaluation method for the key maintenance steps in the maintenance operation process is established. In the end, the maintenance and disassembly process of an engine is taken as an example to verify the validity of this method.

1 INTRODUCTION

With the rapid development of industrial technology and the ever-increasing demands of manufacturers on the machining accuracy, product maintenance activities have become more and more complicated. At present, most design manufacturers have realized that at the same time, ensure the high reliability and maintainability of the products can guarantee in maximum availability throughout the product life cycle and achieve the greatest economic benefits (Sobral & Guedes, 2016). The quality of maintainability determines the procedures and duration of maintenance activities. In addition, excellent maintainability will reduce maintenance errors and avoid safety accidents. Maintenance reachability of the product can directly affect the size of the workload and maintenance posture of maintenance activities. Poor maintenance reachability will lead to fatigue for service personnel, increase the probability of occupational disease and further increase the risk of maintenance errors. Stader, for example, confirmed this by conducting interviews and ergonomics analyzes of general aircraft maintenance tasks (Stader, 2013).

Since the maintenance reachability of a product is an inherent quality characteristic of the product itself, it is important to start with the design phase to improve maintenance reachability. The maintenance reachability of the product means that when the maintenance work is carried out, the degree of difficulty to the system, equipment, and parts of the machine can be seen, touched, inspected, adjusted, disassembled, or other maintenance activities. (Krause & Jager, 1988).The maintenance reachability includes three evaluation indexes, sight line reachability, physical reachability and operation space (Zeng, 2007).

This paper mainly studies the evaluation method of the maintenance operation space, which is the actual operation space for the maintenance personnel to repair the product fault unit. At the design stage, enough maintenance operation space must be reserved to avoid collision in maintenance process and ensure the convenience, safety and comfort of maintenance personnel (Zhou et al, 2011). Designing a suitable maintenance operation space

will enable the maintenance personnel to observe and maintain the equipment more conveniently. Even if it takes a long time to maintain a certain working attitude, the reduction of maintenance personnel fatigue sensation and discomfort can be achieved as much as possible as well as the maintenance staff's safety, health and comfort, so as to improve the overall product maintenance efficiency and reduce maintenance error probability caused by personnel fatigue. At present, the judgement of maintenance operation space in the design stage is mainly based on expert experience and visual effect of virtual maintenance animation presentation (Peng, 2010). Evaluation results usually rely on the level of experts, with strong subjectivity. There is still a lack of a widely used quantitative assessment method. Therefore, this paper presents a calculation method for the quantitative evaluation of maintenance operation space during the design phase.

The rest of this paper is organized as follows: Section 2 proposes the concept of reachability potential field. Section 3 combined with the previous analysis of hand activities, puts forward the evaluation criteria for maintenance space. Section 4 is a case study. Section 5 is conclusion.

2 REACHABILITY POTENTIAL FIELD

2.1 *The proposed process of reachability potential field*

In 1986, Khatib first proposed the artificial potential field method (Weerakoon, 2015), and applied it in the field of robot obstacle avoidance. The basic idea of this method is to construct a repulsive potential field around the obstacle and construct a gravitational potential field around the target point, similar to the electromagnetic field in physics, as shown in Figure 1. The controlled object is under repulsion and gravitation in the composite field composed of forgoing two kinds of potential fields. The combined forces of repulsion and gravitation direct the movement of the controlled object and search for the obstacle avoidance path without collision. In the maintenance process, maintenance personnel in a narrow operation space, bypassing the obstacles, reach the location of the maintenance object. The process is similar to robotic obstacle avoidance, so the concept of artificial potential field is introduced into the evaluation system of maintenance operation space, meanwhile proposes the concept of reachability potential field.

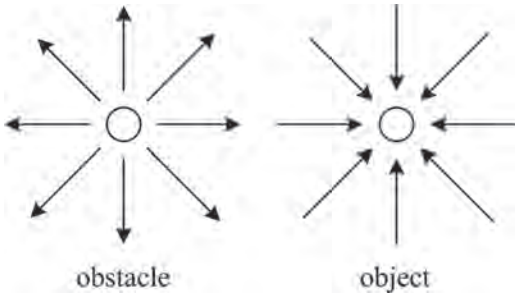

Figure 1.

2.2 *Gravitational potential field*

Since the maintenance staff mainly rely on the upper limb to complete the maintenance action, the following definition is made that the gravitational potential field is mainly related to the distance between the maintenance staff's joint and the object to be repaired. The greater the distance, the greater the potential energy value of the joint; the smaller the distance, the smaller the potential energy value of the joint. The function of the gravitational potential field is:

$$U_g(q)=\begin{cases}\frac{1}{2}\eta\rho^2\left(q,q_g\right), & 0\le\rho\left(q,q_g\right)\le\rho_0\\ 0, & \rho\left(q,q_g\right)\ge\rho_0\end{cases} \tag{1}$$

where η is the proportional gain coefficient, $\rho(q, q_g)$ is a vector representing the Euclidean distance $|q\text{-}q_g|$ between the joint position q and the object position q_g which to be repaired, and the vector direction is from the position of the joint to the position of the object to be repaired. When maintenance personnel are far away from the object to be repaired, it makes no sense to consider the comfort of the operation space during maintenance. Therefore, it can directly consider whether the maintenance object can be reached. To simplify the formula, this paper only considers the situation when the distance between maintenance staff and the object to be repaired is close. As the maintenance action is mainly completed by the human upper limb, define ρ_0 as the maximum length of the serviceman's shoulder joint to the tip of the ipsilateral middle finger, as shown in Figure 2.

Define when the joint of the maintenance personnel is just an arm away from the object to be repaired, the reachability gravitational potential of the joint is 1; and when the joint of maintenance personnel completely wraps the object to be repaired, the reachability gravitational potential of the joint is 0. That is, when $|q\text{-}q_g| = \rho_0$, $U_g(q) = 1$; and when $|q\text{-}q_g| = 0$, $U_g(q) = 0$.

$\eta=\frac{2}{\rho_0^2}$ can be obtained.

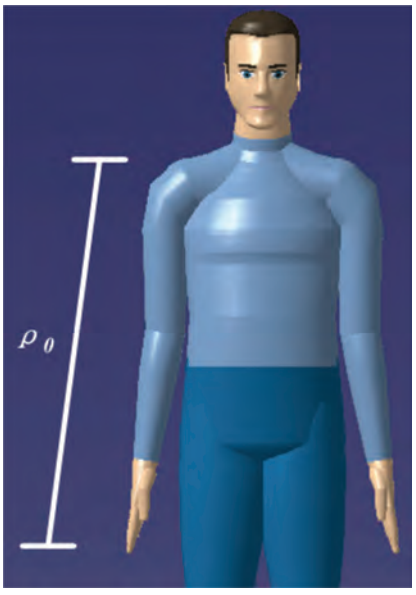

Figure 2. Shoulder joint to the ipsilateral middle finger fingertips maximum length.

2.3 *Repulsion potential field*

Only in the case of limited maintenance operation space, can the analyzation and verification be meaningful. Therefore, the obstructions in the vicinity of the object to be repaired always exist. The factor that determines the repulsion force field of obstacle is the distance between a certain joint of the maintenance staff and the obstacle. When the joint is beyond the influence range of the obstacle, its potential energy value is zero. After the joint enters the influence range of the obstacle, the greater the distance between the two is, the smaller the potential energy value of the joint will be, and the smaller the distance, the greater the potential energy value of the joint will be. The repulsive potential field potential function is:

$$U_r(q) = \begin{cases} \frac{1}{2}k\left(\frac{1}{\rho(q,q_r)} - \frac{1}{\rho_0}\right)^2, & 0 \le \rho(q,q_r) \le \rho_0 \\ 0, & \rho(q,q_r) \ge \rho_0 \end{cases} \quad (2)$$

where k is a positive proportional coefficient. $\rho(q, q_r)$ is a vector whose size is the distance $\rho(q, q_r)$ between the joint and the obstacle, pointing in the direction from the obstacle to the joint. ρ_0 is a constant that represents the maximum distance the obstacle affects the joint. Only when the obstacle is within reach of the upper limbs of the maintenance personnel will the maintenance activities be affected. Therefore, define that the maximum influence distance of the obstacle is the length ρ_0 of maintenance staff shoulder to the ipsilateral middle finger fingertip maximum length.

Define when the maintenance personnel just enter the edge of the obstacle range, the maintenance staff's joint repulsion potential energy is 0. When the maintenance staff completely wrapped obstacles, the maintenance staff's joint repulsion potential energy is 1. That is, when $|q\text{-}q_r| = \rho_0$, $U_r(q) = 0$; and when $|q\text{-}q_r| = 0$, $U_r(q) = 1$.

$k = 2\rho_0^2$ can be obtained.

3 MAINTENANCE POSTURE COMFORT EVALUATION

3.1 *Upper limb comfort evaluation*

Human upper limb mainly includes four parts of hand knuckles, wrist, elbow and shoulder joints. Knuckle and wrist joint comfort will be discussed in Section 3.2. This part mainly analyzes the reachability potential energy and relative comfort of the human elbow and shoulder joints.

Upper limb comfort is mainly determined by two factors, one is the upper limb stretch, and the other is whether there are obstacles around the upper limbs. The upper arm's stretch is mainly determined by the size of the gravitational potential field. The impact of obstacles mainly depends on the size of the repulsive potential field. Since each obstacle in the maintenance process affects the maintenance activities respectively without counteraction, it makes no sense to superimpose repulsion potential fields. In the calculation, engineers only need to examine the distance from the joint of the most obstructions, namely the maximum repulsion potential field.

Define that ω is the evaluation value of upper limb comfort obtained from the theory of reachability potential field.

$$\omega = \omega_g \cdot \omega_r \quad (3)$$

The reachability gravitational potential suffered by the shoulder joint measures the stretch of the human upper limb during maintenance activities. According to ergonomics (Xie & Huang, 2009), people tend to feel tired when they bend over. The optimal range and normal range of human arm activity are respectively 0.59 and 0.78 times of maximum range when the upper body is in the upright position.

When $\rho(q,q_g) \le 0.59\rho_0$, that is, $0 \le U_g(q) \le 0.35$, the upper limbs' stretching posture is the most comfortable, and $\omega_g = 1$.

When $0.59\rho_0 \le \rho(q,q_g) \le 0.78\rho_0$, that is, when $0.35 \le U_g(q) \le 0.61$, the extension posture of the upper limbs is normal, and $\omega_g = 0.61$.

When $0.78\rho_0 \le \rho(q,q_g) \le \rho_0$, that is, when $0.61 \le U_g(q) \le 1$, the posture of the upper extremity is the worst, and $\omega_g = 0.35$.

The reachability gravitational potential energy size of elbow joint and the repulsive potential energy size caused by the recent obstacles are compared to measure the influence of the obstacles around the upper limbs during maintenance activities.

When the maintenance posture is determined, the elbow's reachability gravitational potential energy size is

$$U_g(q) = \left(\frac{\rho(q,q_g)}{\rho_0} \right)^2 \tag{4}$$

Among them, $\rho(q,q_g)$ is the longest distance from the elbow to the fingertip in this maintenance posture.

The elbow reachability repulsive potential energy size is

$$U_r(q) = \left(\frac{\rho_0}{\rho(q,q_r)} - 1 \right)^2 \tag{5}$$

Among them, $\rho(q,q_r)$ is the shortest distance between the elbow joint and the nearest obstacle in this maintenance attitude.

When $U_g(q) > U_r(q)$, it is considered that the elbow joint is subjected to a larger gravitational potential field and a smaller repulsive potential field, and the maintenance posture is comfortable. Define that $\omega_r = 1$.

When $U_g(q) \le U_r(q)$, it is considered that the elbow joint is subjected to a small gravitational potential field and a large repulsion force potential field, which is obstructed by obstacles during the maintenance activities. The maintenance posture is uncomfortable. Define that $\omega_r = 0.5$.

The evaluation index of the comfortableness of the upper limb of the maintenance personnel can be obtained according to the Equation 3.

3.2 *Hand swept comfort index*

Since most of the maintenance operations are completed by the maintenance staff's hands, this part of the measurement method focuses on the hand comfort of the maintenance personnel. Maintenance operations are divided into three basic maintenance activity units (MAUs): screw, twist and translate (Zhou et al, 2011). Specific actions shown in Figure 3, Figure 4, Figure 5. Screw is the hand act of tightening or loosing a screw with a screwdriver. Twist is the hand act when the nut is installed or dismantled by a wrench. Translate is the parallel movement of human hands without any posture change. DELMIA (Digital Enterprise Lean Manufacturing Interaction Application) is a digital manufacturing application made by the French Dassault Systemes company. In the product design stage, designers can make maintenance simulation animation with it, to perform virtual maintenance and verify the maintainability of the product. With DELMIA, we can establish the swept volume for each maintenance activity unit. There are two types of swept volumes: free swept volume (V_{fsv}) and constraint swept volume (V_{csv}).

Figure 3. Screw sweep volume.

Figure 4. Twist sweep volume.

Figure 5. Translate sweep volume.

Under completely freedom circumstance, free swept volume is the maximum swept volume of the hand movement range when taking a comfortable attitude to perform maintenance tasks. The maximum or maximum angle at which the human hand can move comfortably can be obtained by consulting ergonomic data. The constraint swept volume is the swept volume determined by the actual hand movements of the maintenance personnel in the virtual maintenance animation, subject to the constraints of the machine parts, which can be obtained by DELMIA.

The restricted sweep volume is equal to or less than the free-sweep volume. The wrist maximum angle of motion is 180° in the screwed state

through the ergonomics. So define that the sizes of sweep volume of the wrist when screw 180° is the screw free sweep volume. When the person is in a free state, the twist angle is generally 120.

We can see through the body efficacy that the maximum wrist motion range is 180°, so the definition of the wrist swept volume of 180° twisting volume of free sweep. When the person is in a free state, the rotation angle is generally 120°. Define the swept volume at 120° twist as a free-sweep volume.

Define the sweep comfort index P_v, as shown in Equation 6. Based on the ergonomic data to establish a quantitative evaluation standard for P_v -based operation space quantitative evaluation criteria (Zhou et al, 2011). The evaluation criteria of different maintenance activity units are shown in Table 1.

$$P_v = V_{csv} / V_{fsv} \tag{6}$$

3.3 *The total comfort evaluation*

Maintenance staff's hand movements are important in themselves, and comfort in the upper limbs also significantly affects comfort. Furthermore, a complete set of maintenance actions is a combination of a series of operations. Therefore, in order to combine the comfort of the upper limb with the comfort of the hand, total comfort is defined.

$$s = \sum_{i=1}^{n} \omega_i P_{vi} \tag{7}$$

where s is the total maintenance operation space scores. The set of maintenance actions is made up of i maintenance activity units, ω_i is the upper limbs comfort score for an action, and P_{vi} is the hand swept volume ratio for that action. The higher the value of s, the higher the comfort level.

$$0 \le \omega_i \le 1$$

$$0 \le P_{vi} \le 1$$

3.4 *Evaluation criteria*

Suppose a set of maintenance actions have x screwing action, y twisting action, and z translation action. According to the criteria in Table 1, the maintenance operation space involved in the whole set of actions is defined as excellent when the evaluation of each maintenance activity unit is excellent. When the evaluation of each maintenance activity unit is bad, define maintenance operation space involved in the entire operation as bad. When the evaluations of each maintenance activity units consist of all levels of excellent, normal and bad, the maintenance operation space involved in the entire operation is defined as normal. In summary, the maintenance of operation space evaluation criteria as shown in Table 2.

Table 1. The evaluation criteria of hand.

Maintenance activity unit	Evaluation criteria	P_v
Screw	Good	>0.8
	Normal	0.5–0.8
	Bad	<0.5
Twist	Good	>0.75
	Normal	0.25–0.75
	Bad	<0.25
Translate	Good	>0.9
	Normal	0.7–0.9
	Bad	<0.7

Table 2. The evaluation criteria of operation space.

Evaluation criteria	s
Good	$s \ge 0.8x+0.75y+0.9z$
Normal	$0.5x + 0.25y + 0.7z < s < 0.8x + 0.75y + 0.9z$
Bad	$s \le 0.5x + 0.25y + 0.7z$

3.5 *The scope of application*

Operation space determines the maintenance staff's physical posture. By evaluating the comfort of the maintenance personnel posture, the design of the operation space can be obtained and quantitatively evaluated. The evaluation of the operation space is not based on the entire maintenance process, but rather on the key actions in the maintenance process. Throughout the maintenance process, visual inspection and qualitative analysis by engineers shall confirm that most of the operation gestures are comfortable. Quantitative analysis, which can be used to help improve design, is only necessary in the key steps that engineers have questions.

4 APPLICATION EXAMPLES

This case is the quantitative evaluation of the maintenance operation space of the disassemble a certain type of passenger aircraft APU hexagonal nut. The purpose is to use the proposed method to quantitatively evaluate maintenance operation space to demonstrate the flexibility and effectiveness of the method. The APU virtual maintenance operation animation screenshot shown in Figure 6. There are six orange hex nuts on the APU. Take nuts 1, 2, and 3 as typical cases. The positions of the three nuts are shown in Figure 7.

When disassembling the three nuts, remove the No. 1 nut and the right elbow is closest to the No. 4 thick round pipe. When disassembling the No. 2 and No. 3 nuts, the right elbow joint is closest to the No. 5 thin round pipe. A large space around nuts

Figure 6. Virtual maintenance process screenshots.

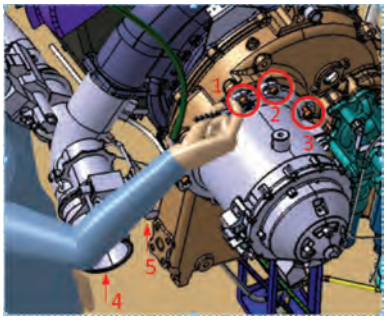

Figure 7. APU nut position diagram.

Table 3. Case study results.

	No. 1 nut	No. 2 nut	No. 3 nut
V_{csv}	1.152	1.152	0.576
V_{fsv}	1.152	1.152	1.152
P_{vi}	1	1	0.5
ρ_0(mm)	733	733	733
$\rho(q, q_g)$ (mm)	569	604	676
$\rho(q, q_r)$ (mm)	280	263	255
$U_g(q)$	0.6025826	0.6789940	0.8505218
$U_r(q)$	2.6174617	3.193627	3.513787
ω_g	0.61	0.35	0.35
ω_r	0.5	0.5	0.5
s	0.305	0.175	0.175
Level	Normal	Bad	Bad

1, 2, and maintenance personnel can reach 120° hand rotation. No. 3 nut is relatively narrow, and maintenance personnel can only reach 60 degrees rotation hand. According to Equation 4, Equation 5, Equation 7 gives the following Table 3.

5 CONCLUSION

When evaluating the comfort of the operation space during the design phase, the traditional method is to use DELMIA, Jack and other simulation software to make the maintenance simulation animation and give the evaluation results and suggestions for improvement through the animation effects. This paper presents a new method of quantitative evaluation of maintenance operation space in Section 2 and Section 3. Maintenance activities are mainly concentrated in the human upper limbs, so the evaluation of the operation space should be taken into account the hand movements and arm movements. Reference to the concept of artificial potential in the research of robot obstacle avoidance, the concept of reachability potential energy is proposed and used to analyze and evaluate the upper limb posture of maintenance personnel in maintenance activities. At the same time, combined with the predecessors' use of swept volume to evaluate the maintenance of hand space, get the overall evaluation of maintenance attitude data. Later, make a comparison with the evaluation criteria proposed in Section 3.4. Finally, the paper concludes whether that operation space is qualified or not by assessing the comfort of the maintenance posture.

In the evaluation of human upper limb comfort, this article considers only the single obstacle nearest. In subsequent studies, the effects of multiple obstacles acting simultaneously on the upper limbs can be considered.

Maintenance resources allocation for the profit maximization of a park of identical systems

W. Zhu
School of Mechanical Engineering, Northwestern Polytechnical University, Xi'an, China

B. Castanier
Laboratoire Angevin de Recherche en Ingénierie des Systèmes (LARIS), Université d' Angers, Angers, France

ABSTRACT: For the park (system of systems) consisting of a set of identical systems, the mission of each time unit is shared by all the survival systems which could be overexploited to achieve the global park objective. This overexploitation is stressful for each individual system and increases its respective degradation. This leads to increase the probability of failure of the system before the next planned maintenance. Otherwise, the system can be subject to operational constraints such as the reduction of exploitation because of an excessive degradation. Such constraint could affect the overall objective. We propose in this study to analyze the problem of the maintenance resource allocation on a park of n identical systems for ensuring a given production goal on a two successive maintenance period. Each system is degrading due to cumulative load and can be totally or partially renewed only during planned maintenance. We propose to construct a simulation-based model for the profit assessment of the whole park on a given time horizon for different maintenance allocation policies given the different assumptions described above.

1 INTRODUCTION

For the park which consists of n identical system, which referred as "system of systems" in this study, the load of each mission is shared by the survival systems. During the mission phase, the random failure of systems keep changing the load charging state of the survival systems (Park 2010, Ye et al. 2014, Zhang et al. 2017). Meanwhile, the maintenance planning and completion of the systems are affected by the random system failures and realistic conditions, such as the maintenance resources, the maintenance windows and production plan (Gundegjerde et al. 2015, Abdollahzadeh et al. 2016). Nowadays, the study of system degradation has extended from two-state to multi-state (Peng et al. 2017), (Dao & Zuo 2017b, Dao & Zuo 2017a). The performance levels of each system are corresponding to different stage of system degradation. For the system of systems, the mission load is usually achieved by redistributing the remaining load on the survival systems, meanwhile the total cost of maintaining the system state and performance is preferable to be as low as possible. Taking offshore wind farm as an example, the electricity production of the whole wind farm should be in accordance with the contract (Hawker & McMillan 2015). The manager of the wind farm has to control and distribute the production demand according to the contract and the actual state of each wind turbine. The maintenance resources, such as the maintenance time, the maintenance team and spare parts of the wind farm are limited due to the economic concerns and the offshore environment, which makes the maintenance policy of offshore farm more complex (Martin et al. 2016). Hence, how to balance the control strategy and the maintenance policy is the common challenge for the system of systems (Irawan et al. 2017, Santos et al. 2015).

Ye et al. (2014) proposed a load-sharing industrial system where the operator allocates load to balance the level of the degradation condition of all parallel components to achieve system performance, where a simple replacement policy is conducted according to the cumulative work load. Zhu et al. (2011) conducted a cost-based selective maintenance decision-making on a machine line for selecting the optimal machine group under limited maintenance duration. Zuo (2017b) addressed a selective maintenance problem for multi-state systems where each component can be in one of multiple working levels and several maintenance actions are optional. The dependency of the system is presented by multiple hierarchical levels and dependence groups. Further Dao and Zuo (2017a) studied the selective maintenance problem on multi-state series systems sharing in variable loading conditions in the next mission with the aim of

maximizing the expected system reliability in the next mission within available resources. Santos et al. (2015) presented a simulation method to study how the variation of failure and repair models, vessels logistic times, weather windows and waiting times affect a wind turbine performance, hence to identify the factors which most influence the turbines performance.

Based on the previous industrial practice of offshore wind farm and maintenance practices of complex system, the main goal of the present paper is to focus on a specific case of system of systems and to propose a simulation-based optimal maintenance resource allocation rules in the context of offshore wind farm. Besides, control rules based on the system condition and remaining production of mission are included in this study. By setting the different assumptions for the elaboration of the assessment model, we will conduct a series numerical simulations based on the degradation model, control and maintenance decision rules with the proposed algorithms. Our study contributes on the follow facts: (1) The study is based on the framework of "system of systems" under random working condition. (2) The control rules which regulate the system degradation and production rate are considered. (3) The maintenance crew transfer time from one-to-one site is introduced, which is the practical issue for offshore wind farm. The remainder of this paper is organized as follows: Section 2 describes the degradation model of single wind turbine based on cumulative load and the performance of the wind farm. The assumptions of maintenance policy is introduced as well. Section 3 describes the production decision rule and integrates the maintenance decision considering both the production and maintenance resource allocation. The simulation algorithm and numerical results are given in section 4. The contributions, limits and future works of this paper are discussed in conclusion.

2 PERFORMANCE MODEL

The objective of this section is to present the performance model of the wind farm with n Wind Turbines (WTs) from period to period. The performance is defined by an average cumulated amount of energy objective P_τ produced over a period τ. Each of the wind turbines will contribute to reach this production objective. A wind turbine is subject to degradation. In the next paragraph, the degradation model for one WT is presented.

2.1 *Performance model for one wind turbine*

We assume that a WT is subject to continuous random cumulative degradation $X(t)$ from 0 to a failure threshold x_F. $X(t)$ is a function of the cumulative load of the WT. The instantaneous load at time t is a function of the rotation speed of the blades given a wind speed, w_t and a WT rotation control parameter, ρ_t. Rotation can be controlled by both the pitch control and a brake. Braking should increase degradation. Finally, the degradation rate is given by:

$$\lim_{dt\to 0}\frac{X(t+dt)-X(t)}{dt} = \frac{\alpha(\rho_t,w_t)}{\beta} = \frac{a_1\cdot\rho\cdot w + a_2\cdot(1-\rho)}{\beta} \quad (1)$$

Let remark that the blades rotation speed is assumed to be directly proportional to the wind speed $\omega = a\rho\cdot w$ and the degradation rate be constant if $w_t = w$ and $\rho_t = \rho$. Another constant can be directly introduced for modeling degradation for idle states, specifically due to the lack of wind.

Under such assumptions, the degradation over a time period $(0,t_k)$ can be modeled by a non-stationary Gamma process where the degradation increments over $(t_i,t_{i+1}), i\in\{1,\ldots,k\}$ are gamma distributed. Some assumptions on a_1 and a_2 can be done to ensure some of empirical degradation properties.

The failure $t_f = \min\{t>0 \mid X_t \geq x_F\}$ leads to an immediate stop of the WT.

We assume a constant production rate of one WT per unit of time given by $f_P(\omega_t) = f_P(\rho_t,w_t)$ where ω_t is the instantaneous rotation speed as a function of ρ_t and the wind w_t. The production rate of a WT has to be evaluated at each changing times, wind transition or change in the ρ-value.

2.2 *Maintenance assumptions*

A periodic maintenance policy is implemented every τ period. No maintenance is allowed out of this maintenance period (block replacement model). This maintenance consists in visiting a certain number of WTs and renew them as much as possible. Other maintenance such as minimal maintenance are not considered in this model. The total maintenance capacity is here assumed to be fixed and not all of the failed or degraded WTs will be maintained in the good state. The maintenance capacity is related to a limited number of maintenance resources and is defined by a given maintenance duration D_M and a given renewal efficiency rate per unit of time e_m. Hence, the maximum allowed degradation reducing is $D_M\cdot e_m$. Moreover, some of maintenance crew transfer time from one-to-one WT is introduced. It is assumed this crew tranfer time is constant and denoted d_{ij}. Finally, if n_i over the n WTs are visited during a maintenance period, the maximum maintenance capacity is $\left(D_M - n_i\cdot d_{ij}\right)\cdot e_m$.

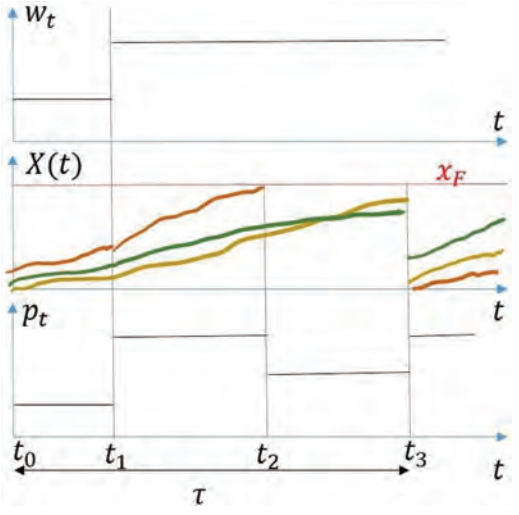

Figure 1. Sketch of the wind farm over a period.

2.3 *Illustration of the performance model*

Figure 1 sketches the evolution of the production rate, p_t, and the WTs degradation, $X_t(t)$, given the wind behavior, w_t, and a constant rotation control parameter ρ on the whole τ period. Here, the wind is modelled by a Continuous Time Markov Chain. Such a discrete model is motivated by, first, the wind speed forecasts are not so precise for a middle-term time horizon and only average values would be necessary. Second, a precise effect of the wind on degradation can be a challenge and should be estimated for average wind levels. Note that the associated transition rates and probabilities can be functions of the seasons. For the sake of simplicity, no variations are considered in this paper. When the wind increases at t_1, both the production rate p_{t_1} which is the sum of the functioning WTs and the WTs degradation rates increase. When a WT fails and stops at t_2, the others continue to produce but the production rate of the farm is decreasing until the next maintenance at t_3. In this example, the 3 WTs are repaired and the sum of the repair level is therefore $\Delta_M = \left(D_M - 3d_{ij}\right)\cdot e_m$. All of the times t_0, t_1, t_2 and t_3 define a change in the wind farm environment.

3 DECISION PROCESS

The decision rules are twofold: production and maintenance which should be combined for ensuring the production objective.

3.1 *Production decision rule*

We propose here to focus on the production decision rules which can be captured in the blade rotation speed control parameter ρ (controlled by the pitch). At time t, these decision rules are a function of the production objective P_τ over the time period τ, the cumulative production at time t, $t < \tau$, $P(t)$, the current wind speed w_t, the wind forecasts over the end of the time period, $Ew(t)$, the current state vector of the WTs, $X(t) = \left(X_1(t), X_2(t), \ldots, X_n(t)\right)$ and finally the forecasts in the production from t to τ, $EP\left(t; X(t), w_t, Ew(t), \rho_t\right)$.

For the sake of simplicity, the decision in ρ at time t will be defined in order to satisfy the production objective given a constant forecast, i.e. without considering the future state of the other WTs on the farm. Because no additional information occurs between two successive changes, the ρ_t decision will be considered as constant. Finally, updates in the decision would only occur at any change. If a WT fails, if it is possible, the production rate of all the remaining WTs has to be increased to ensure the same yield and so ρ_t should be greater.

Let n_F the number of failed WTs. We can approximate the expected energy production for the $n - n_F$ survival WTs given the ρ_t variable, the wind forecasts and the vector $x(t) = \left(x_1(t), \ldots, x_n(t)\right)$ of the known WTs states by:

$$EP\left(t; X(t), w_t, Ew(t), \rho_t\right) = \sum_{i=1}^{n} 1_{\{x_i(t) < x_F\}} \times \cdots$$
$$F(\tau - t \mid x_i(t), Ew(t), \rho_t) \cdot f_P\left(\rho, \frac{Ew(t)}{\tau - t}\right) \cdot (\tau - t) \quad (2)$$

where $F(\cdot \mid x, w, \rho)$ is the conditional survival distribution and $f_P(\cdot,\cdot)$ the WT production rate function per unit of time. Let remark that the ρ_t is the same for all the survivals and is considered unchanged until the end of the period. Then, if the production criterion is P_τ, ρ_t should be chosen to ensure the missing production $P_\tau - P(t)$ and thus ρ_t is the solution of:

$$EP\left(t; X(t), w_t, Ew(t), \rho_t\right) = P_\tau - P(t) \quad (3)$$

If there is no solution, then $\rho_t = 1$ which ensures the maximum of the potential production.

3.2 *The decision variable as a function of the maintenance*

ρ_t should be defined to ensure both the current and the future periods production objectives. If the maintenance resources are limited, then it will not be possible to maintain the whole WTs in a perfect good state. Denote $X_p = D_M \cdot e_m$ the maximum cumulative degradation level the maintenance crew can save in a fixed maintenance period. Some maintenance allocation rules will be discussed later in the paper.

Let define X_{min} that is the minimum amount of degradation of the whole WTs to ensure the P_τ production over a complete period. In this paper, we define the farm state $Y(t) = \sum_{i=1}^{n} x_i(t)$. At time t, ρ_t should be updated to respect:

$$\Pr(Y(\tau) \le X_p + X_{\min} \mid x(t), Ew(t), \rho_t) < \epsilon_1 \quad (4)$$

where ϵ_1 is a decision parameter decision variable which represents the risk aversion of the decision-maker faced the non-respect of the production in a period. Numerical experiments should be conducted to highlight the influence on such a parameter as a function of the X_p maintenance capacity. Note that if there is no solution, it means that the current state farm $Y(t)$ is already greater than $X_p + X_{min}$. A lot of decision alternatives can be designed:

1. Increase the maintenance resources, X_p. Penalty costs should be added. It could be done with extra-time (and so decrease the next production period) or extra-resources.
2. Decrease the next maintenance period to ensure the respect of this maintenance specification next maintenance time
3. This maintenance specification can be evaluated at any time rather only at any operational change.
4. This can motivate the definition of a more flexible control rule for each of the WTs as a function of the individual degradation states. This would be closer to the load repartition problem.

3.3 *Maintenance allocation decision rules*

At the end of the production cycle, the overall farm system is $Y(\tau)$. A maintenance is specified by:

- D_M its duration;
- d_{ij} the time for a crew to move from one WT to another;
- e_m the efficiency of the maintenance per unit of time, i.e. the number of degradation points the maintenance can rehabilitated in one time unit (this degradation point is a function of the production point);
- costs and penalty costs which could be integrated.

If δ_i denotes the indicator of visiting the WT_i, the maintenance problem is then defined as the following optimization problem:

$$\max_{(\delta_i, t_i)} \sum_{i=1}^{n} \delta_i (d_{ij} + t_i) \quad (5)$$

subject to the following constraints:

$$\begin{cases} \sum_{i=1}^{n} \delta_i (d_{ij} + t_i) \le D_M + d_{ij} \\ e_m t_i \le x_i(\tau), \forall i \in \{1, \ldots, n\} \\ \sum_{i=1}^{n} (x_i(\tau) - e_m t_i) \le X_{min} \end{cases} \quad (6)$$

This optimization problem is a mixed-integer linear problem and it will not be treated in this paper. We propose to discuss two different allocation rules in the next section.

4 NUMERICAL EXPERIMENTS

We propose in this section to compare two maintenance resource allocation strategies. The main question here is should the maintenance favor the number of WTs in operation versus a limited number of operating WTs but in a better state. Before presenting and analyzing the different results, we propose to briefly introduce the simulation model with additional assumptions and the data.

4.1 *Simulation model and data*

We propose to analyze the performance of the model based on a Monte Carlo approach for the simulation of the production wind farm over a τ period. For ensuring the steady-state in the simulation process, a long-term time horizon with thousands τ periods will be considered. Average quantities will be then analyzed for conclusions. We will consider that, for the first period of this long-term horizon, all of the $n = 5$ wind turbines are new $x(0) = (0,0,0,0,0)$.

The decision framework requires the definition of P_τ, the production objective for the wind farm over τ. In the wind turbine industry, a WT can be considered available approximatively 70% of its life cycle. We define P_τ as the 0.7 of the maximum of the expected total production of n operating WTs over the whole production cycle given an average wind speed, $Ew(0)$ without any rotation control, $\rho = 1$. We have:

$$P_\tau = 0.7 \cdot n \cdot \left[f_P(1, Ew(0)/\tau) \cdot \tau \right] \quad (7)$$

The evaluation of X_{min}, the minimum farm state at the beginning of the period for ensuring the production with a given probability ϵ_1, is the solution of the following equation:

$$Pr\left(\bar{P}_0(X_{min}) \ge P_\tau\right) > \epsilon_1 \quad (8)$$

where $\bar{P}_0(X_{min})$ is the expected production over τ which is defined as a Gamma-distributed variable. The shape function of this Gamma variable is function of the wind forecast, $\bar{W}$, and an average

rotation control level ρ_0 over the period. In our paper, we have considered that the wind is modeled by a CTMC and the forecast can be directly evaluated. ρ_0 can be optimized from the simulation model. In this paper, we consider ρ_0 as a decision parameter.

The simulation algorithm is iterative from 0 to τ and can be summarized by the following steps, at each changing time $t \in (0, \tau)$:

1. Simulate the current wind condition (speed and next change time) and evaluate the forecast over the remaining time to the end of the period;
2. Find ρ_t, the minimum of the solutions of Equations (3) and (4);
3. Simulate the WTs degradation. For each of the WTs in operation:
   a. Simulate the remaining time as a function of $x_i(t)$ the current degradation level, the wind estimates and ρ_t;
   b. Identify the change time which is the minimum between the wind change, the remaining times and the end of the period
   c. Simulate the corresponding degradations for every WTs in operation.

The data used in our numerical experiments are fixed and presented in Table 1.

Let remind that ρ_0 and ϵ_1 are two decision parameters. Their relevance will be analyzed in the next paragraphs. Given these data, the production objective P_τ equals 14312 units and the Mean Time to Failure, in unit of time, for each WT without any maintenance is:

$$MTTF_i = \int_0^\infty Pr(X_i(t) < x_F)dt = 487 \quad (9)$$

4.2 *Policy 1: Maximization of the degradation rehabilitation levels*

Maximizing the degradation rehabilitation levels is here equivalent to restrict the crew move between WTs. Finally, the allocation rule for Policy 1 is:

Table 1. Data for the numerical experiments.

General	τ		WT yield factor	
	200		$r_p = 10$	
Degradation	a_1	a_2	β	x_F
	0.02	0.006	1.25	20
Maintenance operation	D_M	e_m	d_{ij}	
	10	4	1	
Constraints	Production		Maintenance	
	$\bar{\rho}_p = 0.7$		ρ_0	ϵ_1

Algorithm 1 Policy 1

Require: $x(\tau) = (x_1(\tau), \cdots, x_n(0)); D_M; e_m; d_{ij}$
  Sort the WTs from the most to the less degraded;
  $t_r \leftarrow 0$
  while $t_r < D_M$ **do**
    Renew to the best condition as possible the most degraded WT
    Update the repair time t_r (maintenance + transport)
  end while

Estimations of different performance indicators through 1000 runs are presented in Table 2: $\bar{P}(\tau)$ the energy produced in a cycle, $\bar{Y}_0$ the wind farm level after the maintenance, *rho* the mean of the rotation control on a cycle and $\rho == \rho_m$ the percentage of time ρ is defined by the maintenance constraint in a cycle.

These results are obtained for different values of the decision parameters ρ_0 and ϵ_1. From these experiments, we can measure the low effect of the ρ_0 parameter on the proposed indicators. This can be partially explained because of the choice of different linear functions for $\alpha(\cdot,\cdot)$ and $f_P(\cdot,\cdot)$. The relaxation of the maintenance constraint, ϵ_1, leads to some intuitive results such as more energy production in average because the rotation is mainly controlled by the production objective but the wind farm is more degraded in average. Another is, because the maintenance resource are here very restricted, some of the 5 WTs remain failed after the maintenance.

4.3 *Policy 2: Maximization of the operating WTs number*

We propose to conduct the same experiments when the objective of the maintenance is to ensure a maximum available WTs at the beginning of the production cycle. Policy 2 algorithm is now to find the threshold x_0 which verifies $x_i(0) \geq x_0, \forall i \in \{1, \cdots, n\}$ and $Y(\tau) - Y(0) = (D_M - (n_m - 1) \cdot d_{ij}) \cdot e_m$ where n_m is the number of maintained wind turbines. Table 3 presents the numerical results.

Table 2. Performance indicators for Policy 1.

Parameters		Performance indicators			
ρ_0	ϵ_1	$\bar{P}(\tau)$	$\bar{Y}_0$	$\bar{\rho}$	$\rho == \rho_m$
0.9	0.95	14362	34.2	82%	94%
	0.9	14555	32.9	79%	85%
	0.8	14713	32.5	80%	60%
	0.6	15155	37.5	84%	39%
	0.4	15131	36.9	85%	18%
0.8	0.8	14560	35.8	80%	73%
0.6	0.8	14633	35.0	82%	76%

Table 3. Performance indicators for Policy 2.

Parameters		Performance indicators			
ρ_0	ϵ_1	$\bar{P}(\tau)$	$\bar{Y}_0$	$\bar{\rho}$	$\rho == \rho_m$
0.9	0.95	13545	74.5	96%	99%
	0.9	13394	74.5	96%	99%
	0.8	13422	73.9	96%	99%
	0.6	13590	74.6	96%	98%
	0.4	13470	74.0	96%	99%
0.8	0.8	13438	74.4	96%	99%

In this case, the experiments do not allow to highlight the impact of the decision variables. In fact, the maintenance resource is too low for such a policy and the losses because of the transportation of the maintenance crew from one wind turbine to another are too high. After a maintenance, the wind farm state Y_0 remains very degraded. The mean ρ remains very high for ensuring the production given the fact that a lot of WTs would fail before the end of the cycle. The maintenance constraint cannot minimize these number of failures. Extra maintenance resource is required.

Finally, from these two numerical analysis, we can conclude the dominance of Policy 1 versus Policy 2 according to the proposed assumptions.

5 CONCLUSION AND PERSPECTIVES

In this paper, we have proposed a decision-making framework for the production and maintenance management of a wind farm which is defined as a system of systems. Based on this problem, we have introduced the problem of maintenance allocation when the resource are shared and limited. Two maintenance allocation policies have been presented. We have also proposed a rule for managing the production rate to guarantee both the production objective and the degradation level according to the maintenance resource. This is clearly a contribution in the maintenance optimization topic and especially for the study of imperfect block replacement policies.

This paper should be seen as a preliminary work. We have voluntary chosen some simple assumptions that seem to be realistic to us in an industrial context. Nevertheless, some of them could be seen too restrictive (the linearity of the production rate function or a constant degradation rate for given operating conditions, e.g.) and other more explicit (what means the degradation level for a complex system such as a wind turbine). At this stage, the current problem could be modeled as a Markov Decision Problem. Such a model could allow to identify some structural properties for the optimal control rules. Other perspectives can be drawn for, e.g., the production rate rule (rotation control ρ). In this paper, the updates in the ρ value are driven by stationary states in terms of wind forecasts and in ρ (no change from now to the end of the production cycle). To increase profitability at a minimum of risk, variability and uncertainty should be integrated in the decision framework.

Risk-based maintenance backlog

Harald Rødseth
Norwegian University of Science and Technology (NTNU), Trondheim, Norway

ABSTRACT: A relevant issue in manufacturing and production seems to be "silo"-organisations and "silo"-planning with lack of coordination between departments. Integrated Planning (IPL) is a concept that aims to cope with this "silo"-problem. With the ground-breaking potentials from Industry 4.0 it should be expected that the advancement of IPL will speed up in development and implementation in companies. To manage IPL sound Key Performance Indicators (KPIs) must be implemented and established in the company. A promising indicator for IPL is Maintenance Backlog (MB). A strength of this indicator is the capability to be modelled with Risk OMT (Risk modelling—Integration of Organisational, human and Technical factors). It remains to investigate how MB can be modelled to a Quantitative Risk Analysis (QRA). The main objective of this article is to develop a model of MB in QRA. In particular the article demonstrates a case study of a production system where both Fault Tree Analysis (FTA), and Event Tree Analysis (ETA) is modelled. The article discusses the demonstration results and evaluate how potentials in Industry 4.0 can support QRA.

1 INTRODUCTION

The Oil & Gas (O&G) industry has experienced challenges with the demand of increasing oil production, lowering operating costs and life extension (Ramstad et al., 2010). These challenges have among other efforts resulted in the concept Integrated Operations (IO) and is described to be a new way of doing business (Rosendahl and Hepsø, 2013). This concept has further resulted in the Center for Integrated Operations in the petroleum industry (IO Center) where one important issue is to go from "silo organisations" towards integrated operation of all the relevant organisations (IO Center, 2012). When transferring the IO principle into the planning domain, leads us to the concept *Integrated Planning* (IPL) (Ramstad et al., 2010). In the planning domain the "silo" problem is also present.

The problem with "silo" planning in O&G industry is lack of coordination across domains and organisations (Rosendahl and Hepsø, 2013). In particular, lack of IPL results in limited resources, system failures and unscheduled maintenance (Wahl and Sleire, 2009). It is also argued that other disciplines such as drilling may affect maintenance (Sleire and Wahl, 2008). The maintenance backlog (MB) is according to Øien and Schjølberg (2009) and Meland et al. (2009) to be represented in the ageing phase for O&G facility and should be controlled at that stage. In addition, the Petroleum Safety Authority (PSA) Norway measures MB systematically for Oil companies at the Norwegian Continental Shelf (Petroleumstilsynet, 2012). In fact, according to PSA, maintenance critical backlog is regarded as a potential for major accidents.

A case study of indicators related to IPL that are applied in the O&G industry has been performed (Wahl and Sleire, 2009). Plan attainment was one type of indicator and can be related to maintenance backlog. More research for improving indicators for plan performance is concluded (Wahl and Sleire, 2009). However it is not clear in this case study how these indicators are modelled to a Quantitative Risk Analysis (QRA).

In risk modelling, the Risk OMT (Risk modelling—Integration of Organisational, human and Technical factors) model has been developed by Vinnem et al. (2012) and evaluated though a case study (Gran et al., 2012). In this model, a Bayesian belief network is applied to structure two levels of Risk Influencing Factors (RIFs) connected to the basic events in QRA. Also, the principles for updating the risk picture with a QRA-basis have been demonstrated (Vatn, 2014). The Risk OMT seems to be a promising model for a dynamic risk barometer based on indicators (Paltrinieri et al., 2017, Paltrinieri et al., 2014).

Due to different views of the term "maintenance backlog" and how it is modelled and the relevance for IPL, a novel model for MB of physical assets has been recently developed and structured in a framework for IPL (Rødseth and Schjølberg, 2017). Furthermore, the Risk OMT was tested for MB in a reliability model, demonstrating that the risk aspect is included for MB. In the Risk OMT

model proposed by Rødseth and Schjølberg (2017) the RIF structure adjusted the level of MB after evaluating the RIF of *people* such as the skills to the craft technicians and the RIF of *tools* they use in maintenance planning. It remains however to investigate how MB can be evaluated as a RIF itself and connected to the QRA.

With the potentials within Industry 4.0 it would be expected that enterprises establish Cyber Physical Systems (CPS) where the physical world and the virtual world are converging (Kagermann et al., 2013, Monostori, 2014).

To implement the potentials from Industry 4.0 an architecture for CPS should be established in the organisation (Lee et al., 2015). Nevertheless, more effort is needed to investigate more in detail how Risk OMT can be adapted to such an architecture.

The main objective of this article is to develop a model of MB in QRA. To achieve this main objective following sub-objectives have been outlined:

1. Develop a general model that connects MB with QRA.
2. Test the model with a case example.
3. Propose how the model can be improved with support from the potentials in Industry 4.0.

The remainder of this article is structured as follows: Section 2 presents the CPS as a potential in Industry 4.0, Section 3 presents an example case with a corresponding risk model developed in Section 4. The results from the example case is presented in Section 5. Further, Section 6 provides a discussion of how the results can be related to CPS where concluding remarks are made in Section 7.

2 CPS AS A POTENTIAL IN INDUSTRY 4.0

With the trend of digitalizing manufacturing, Industry 4.0 offers several promising technologies. An essential element in Industry 4.0 is convergence of the physical world and the virtual world represented in CPS (Kagermann et al., 2013). This enables network resources, information, physical assets and people to create Internet of Things (IoT) and Internet of Services.

Maintenance clearly positions in Industry 4.0 where both predictive and remote maintenance provides value creation in enterprises in terms of improved asset utilization and reduced maintenance costs (McKinsey & Company, 2015). For maintenance, the 5C architecture seems to be promising as a CPS architecture (Lee et al., 2015, Lee et al., 2017). This architecture has also been tested for manufacturing (Lee et al., 2017) and process industry (Rødseth et al., 2016). The 5C architecture forms a pyramid with following levels:

- Level 1: *Connection.* Data collection from e.g. sensors connected to machines.
- Level 2: *Conversion.* Data converted into useful information, e.g. calculations of vibration data.
- Level 3: *Cyber.* The information is connected to internet where advanced analytics can take place in terms of e.g. fleet analytics.
- Level 4: *Cognition.* To support a decision, visual interfaces such as dashboards and key performance indicators are necessary.
- Level 5: *Configuration.* Decision-making is supported through e.g. "digital advices" for conducting maintenance activities.

This architecture has also been proposed to be a sound structure for the maintenance model Deep Digital Maintenance (DDM) (Rødseth et al., 2017). DDM comprises the module planning where it remains to elaborate how MB can improve the planning function for DDM.

3 DESCRIPTION OF SYSTEM AND AN EXAMPLE CASE

In this article a heat exchanger with a barrier system is outlined in Figure 1 as an example. The system is a heat exchanger with a barrier system. The heat exchanger receives gas from two processes, process 1 and 2. If there is a leakage from the heat exchanger both valve 1 and valve 2 must close in order to avoid further leakages. Figure 2 further

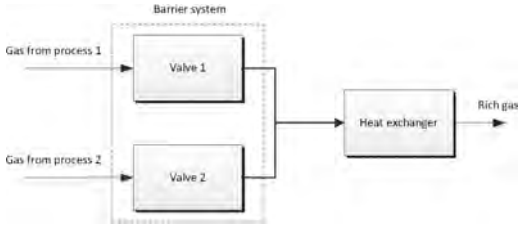

Figure 1. Illustration of a heat exchanger with a barrier system.

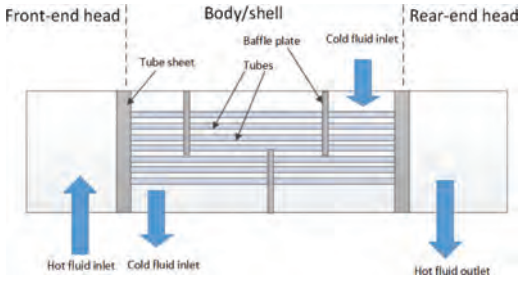

Figure 2. Illustration of a heat exchanger, adapted from (Utne et al., 2012).

describes the heat exchanger system in details (Utne et al., 2012).

This heat exchanger is a single-pass tube, baffled single-pass shell, shell-and-tube heat exchanger designed to provide counter flow conditions. In addition, this type of heat exchanger is one of the most commonly used in offshore oil and gas processing plants. In the case study we will consider an example case of the tubes in the heat exchanger where the model developed is tested with example data. The tubes constitute a bundle, meaning that no single tube can be solely replaced. If there is leakage from a tube it will be plugged. However, this will decrease the efficiency of the heat exchanger and at some point the whole bundle will be changed. This will then set the efficiency back to 100% of the design efficiency.

For the heat exchanger it is assumed that leakage only occurs from tubes and is located in the shell section. For the barrier system, only valve 1 is of interest. For the heat exchanger and the valves there exists a specific maintenance programme coordinated by the maintenance management.

4 RISK MODELLING

The core of the RISK OMT is modelling RIFs and how these affect the operational barriers. In this paper the RIFs are identified in the tasks in the maintenance programme and affect both the barriers (valves) and the production facility (heat exchanger). A RIF is defined by (Øien, 2001) to be *"an aspect (event/condition) of a system or an activity that affects the risk level of this system/activity"*. Further a RIF is a theoretical variable that can be measured.

The risk picture is illustrated in Figure 3. The initiating event in the QRA is leakage from shell and tube heat exchanger. This leakage is due to either leakage from front-end head section, rear-end head section or shell section.

In this article the shell section denoted as basic event 3 is further studied. It is assumed that the frequency of leakage from front-end head section and rear-end head section is negligible. When the initiating event occurs the barrier system shall shut down the gas supply. Both valve 1 and valve 2 must function in order to avoid a safety critical event.

The worst scenario in the QRA occurs with an impact of both a safety critical and economic critical consequence shown with the dotted circle in Figure 3. For this scenario the annual expected frequency is of interest.

Figure 4 presents the FTA for the initiating event with leakage from the shell and tube heat exchanger, while Figure 5 presents the barrier system structured with FTA. The barrier system comprises two shutdown valves where both must fail.

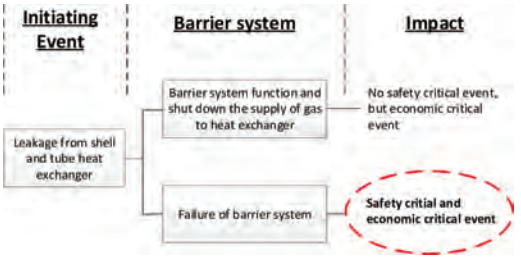

Figure 3. The total risk picture in QRA.

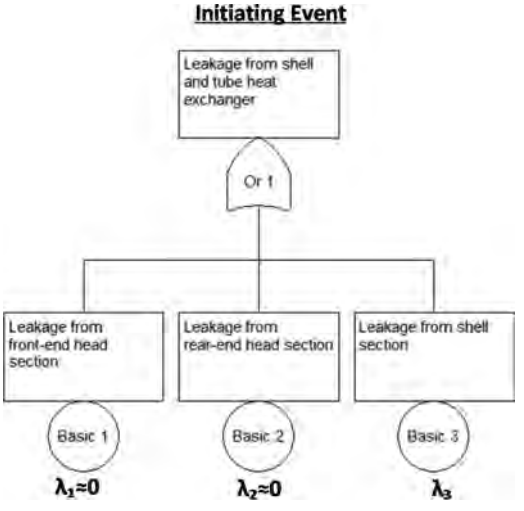

Figure 4. FTA of initialing event.

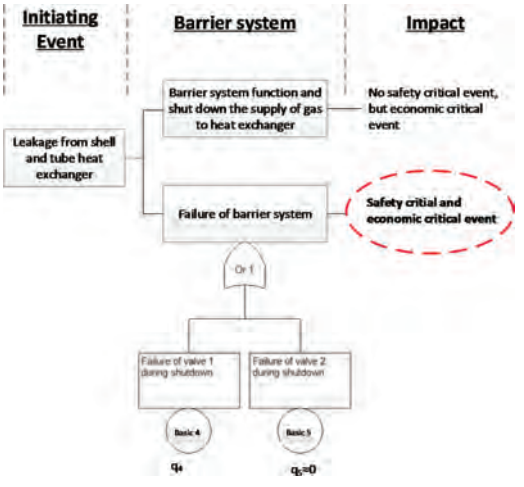

Figure 5. FTA of barrier system.

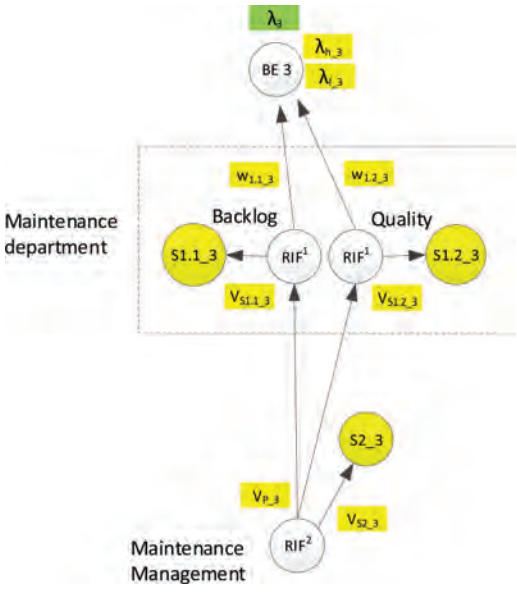

Figure 6. RIF structure that connects to QRA.

Figure 6 presents the RIF structure which is connected to the basic event 3 in the FTA from Figure 4. The same design of the RIF structure is also connected to the basic event 4 in the FTA from Figure 5. For each RIF, a score, S from A-F is observed and a variance, Vs of the score is evaluated.

The variance of the score reflects on how accurate the observation is to the "real" RIF. The RIF structure consists of two levels where there is a structural dependency Vp between level 2 parent RIF and level 1 child RIFs. At level 1 the RIFs are weighted with weight w based on expert judgment. The RIF structure is further described in this section with elaboration of Risk OMT.

4.1 *Level 2 RIF*

Maintenance management is defined as (CEN, 2010) "*all activities of the management that determine the maintenance objectives, strategies and responsibilities, and implementation of them by such means as maintenance planning, maintenance control, and the improvement of maintenance activities and economics*". This level is on the organisational level and affects the operative level 1.

4.2 *Level 1 RIFs*

4.2.1 *Maintenance backlog*

Maintenance backlog is defined as (Rødseth and Schjølberg, 2017) "*the amount of unfulfilled demands at a given point of time in explicit reference to predefined standards to be achieved. The demands comprise both demands for the technical condition itself and demand in meeting the planned due dates in the work orders. Furthermore, maintenance backlog can be expressed in functional (non-monetary) or monetary terms and it refers to single components, sub-assets or to the whole asset*".

Table 1. Score and evaluation criteria.

Score	Evaluation criteria
A	«Best case» score
B	
C	«Normal case» score
D	
E	
F	«Worst case» score

It is proposed by Rødseth and Schjølberg (2017) that maintenance backlog can have a financial perspective that is both based on work orders and the technical condition of the facility based on the understanding of maintenance backlog from petroleum authorities (Petroleumstilsynet, 2016) and road authorities (Weninger-Vycudil et al., 2009) respectively. When providing a score of maintenance backlog, both the deviation of expected wok completed from the work orders and the technical condition should be evaluated.

Table 1 presents the score and evaluation criteria for maintenance backlog.

4.2.2 *Maintenance quality*

Maintenance quality is an aggregation of all factors that affects the quality of the service provided in the maintenance task. A comprehensive list of factors that can be related to maintenance quality has been outlined (Rødseth and Schjølberg, 2017). The list of relevant factors for maintenance quality can also be based on the findings from audits (Øien et al., 2010):

1. Classification
2. Documentation
3. Use of classification
4. Competence
5. Maintenance efficiency evaluation

The evaluation of the score, variance and weight of this RIF is based on questionnaires and interviews for the assessing the "soft" issues like competence and maintenance efficiency evaluation. For the more "hard" issues like classification the observation of the score is based on direct observations in the organisation.

4.3 *Standard calculation of two level 1 RIFs and one level 2 RIF*

When calculating the basic event with the RIF structure presented in Figure 6 a mathematical approach is needed. This approach has also been presented by (Rødseth and Schjølberg, 2017). It is here included for completeness. Further details and foundations for this approach and the formulas are elaborated by (Vatn, 2013). The approach comprises 6 stages for calculating basic event q_i and can be summarized as follows:

1. Perform an expert judgement and evaluate the score of each RIF in the range of A-F, the variances, the weights w_i and values for q.
2. Map the scores into values in the interval [0,1] with following scores:
   A = [1/12], B = [3/12], C = [5/12], D = [7/12], E = [9/12], F = [11/12]. The range in the vector is then: [1/12, 3/12, 5/12, 7/12, 9/12, 11/12].
3. Calculate the posterior distribution of parents RIF based on following formulas where Jeffreys prior is used with the prior parameters $\alpha_0 = \beta_0 = 0.5$:

$$\alpha = \alpha_0 + s^2(1-s) \Big/ V_s \tag{1}$$

$$\beta = \beta_0 + s(1-s)^2 \Big/ V_s \tag{2}$$

4. Calculate the prior distributions α_0 and β_0 of child RIFs based on following equations:

$$\beta_0 = \left(\frac{p(1-p)}{V_p} - 1 \right)(1-p) \tag{3}$$

$$\alpha_0 = \frac{p\beta_0}{(1-p)} \tag{4}$$

5. Calculate the weighted sum for level 1 RIFs and the expected probability for each possible combination, *i*. All the combinations are distributed in a list.
6. Apply the law of total probability and calculate the basic event with following formula of qi:

$$q = \sum_p \left[\sum_r q_L * \left(\frac{q_H}{q_L} \right)^{\sum_j w_j * r_j} * p_{\boldsymbol{R}}(\boldsymbol{r} \mid \boldsymbol{P} = \boldsymbol{p}) \right] * p(\mathrm{p}) \tag{5}$$

4.4 *Modelling the basic events*

For the example case we assume that we have two independent RIF structures that affects the initial event and the barrier system in the QRA. In this case example we have two outsourced maintenance organisations that are specialised in maintenance for heat exchangers and valves. Further it is assumed that these organisations are independent from each other.

When λ_3 for basic event 3 is calculated, the frequency can also be calculated. Since the heat exchanger is regarded as a repairable unit following formula is used:

$$q_i \approx \lambda_i * MTTR_i \tag{6}$$

From basic event 3, the frequency of initiating event, IE, is of interest. Since we have one OR gate and neglect basic event 1 and 2, the frequency of the initial event can be calculated as follows:

$$\lambda_{IE} \approx \frac{q_1}{MTTR_1} + \frac{q_2}{MTTR_2} + \frac{q_3}{MTTR_3} \approx \frac{q_3}{MTTR_3} \tag{7}$$

5 RESULT

5.1 *Input data*

The input data is shown in Table 2 and Table 3, partly based on data from the OREDA handbook (Sintef and Oreda, 2009). The failure rates for the heat exchanger are collected from OREDA data base. The high and low values for λ_3 and q_4 is in accordance with the Risk OMT model.

5.2 *Result data*

The result from the example case is structured in Table 4. For the scenario, the frequency is calculated.

6 ADAPTING RISK OMT WITH CPS

The objective of this article was to develop a model of MB in QRA. With a model from Risk OMT, a structure of RIF with two levels was developed and connected to a case example of a heat exchanger. Improved maintenance quality can to some extent compensate for poor maintenance backlog. Still the organisation should strive to reduce MB in order to improve the overall risk picture of QRA of the plant.

To improve the implementation and application of the model of MB, an essential evaluation would be to what degree could this model be automated. The motivation of this automation is due to the huge amount of technical objects in a plant that is maintenance significant. Obviously some evaluations such as maintenance quality should remain manually performed by experts, but the evaluation of MB should have potential in being conducted more automatically.

Figure 7 proposes how an CPS architecture could be constructed, inspired by the 5C model from (Lee et al., 2015). At level 1 relevant data for maintenance backlog is captured in real-time from both the computerized maintenance management system and condition monitoring systems. At Level 2 the values for MB is calculated both from CMMS and condition monitoring in monetary terms in accordance to (Rødseth and Schjølberg, 2017). At level 3 the score, S is automatically evaluated based on comparing

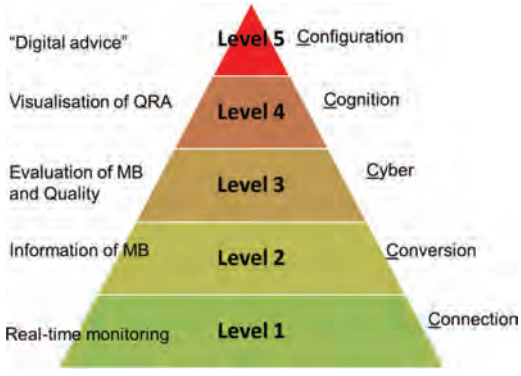

Figure 7. CPS architecture proposed for Risk OMT, inspired by the 5C model from (Lee et al., 2015).

with earlier measurements of MB. In level 4 the QRA will be visualized as a risk picture. Finally in level 5 a digital advice is provided to propose reduction of maintenance backlog if necessary.

7 CONCLUDING REMARKS

It is concluded in this article that the proposed model of MB in QRA should be further developed, in particular with respect to decision criteria for providing the score. In addition, a CPS architecture for industry should be established with respect to Risk OMT modelling and include it in the maintenance model DDM. Further studies of this model should also be performed not only in the O&G industry, but also in industry branches such as the maritime industry, manufacturing, process industry and the railway industry.

Reliability-based maintenance optimization for the leased equipment with deterioration depending on age and usage

Lijun Shang, Shubin Si, Zhiqiang Cai & Xianzhi Wang
School of Mechanical Engineering, Northwestern Polytechnical University, Xi'an, Shaanxi, China

ABSTRACT: In this paper, we first consider a two-dimensional lease region that is composed of age limit and usage limit, and then from the leaser's perspective develop maintenance policies so that the total cost in the lease region can be reduced. Deterioration process of the equipment is simultaneously dependent on age and usage. When reliability drops to a threshold, called reliability threshold, Preventive Maintenance (PM) is carried out to improve reliability. This repeated PM action is ceased until the associated remaining lease limits terminate. Under the situation that the lessee's usage rate is single usage rate class, a unified maintenance policy is used to maintain reliability of the equipment. Under the situation that the lessee's usage rate is classified, customized PM integrating with usage rate class is used to maintain reliability. We derive the leaser's total cost models that are respectively related to a benchmark lease contract with the unified maintenance policy and the proposed lease contract with customized PM. By means of Root Mean Square (RMS), lease contract selection is performed. An example experiment is provided to verify the proposed methodologies. As showed in the example experiment, optimal values can be searched by minimizing the total cost and the proposed lease contract is beneficial for both the leaser and the lessee.

1 INTRODUCTION

Due to the limits of ability to maintain reliability and the lack of capital, some users (called lessees) buy only the right to use and don't buy an equipment from its owner (called leaser). The lessee uses the equipment to accomplish tasks or missions by paying rent for the leaser; and the leaser is often responsible for maintaining reliability of his equipment in a period, called lease period. In the lease period, reliability size of the equipment not only has effect on the leaser' maintenance cost but also influences the lessee's task progress. Specially mentioning, the lessee may incur some loss if the task is not accomplished on time due to a longer time to recover failure of the equipment. In this setting, the lessee usually requires a penalty cost for the leaser so that her loss is compensated. For reducing penalty cost and maintenance cost in the lease period, the leaser usually performs preventive maintenance (PM) in the lease period.

For purpose of maintenance cost saving and penalty cost saving, various PM policies have been proposed by academic researchers and industry practitioners. Jaturonnatee et al. (2006) developed a sequential PM scheme using the reduction in failure rate. Yeh et al. (2009) proposed more effective PM policies than PM policy in Jaturonnatee et al. (2006). Other PM policies related to leased equipment have offered in Pongpech & Murthy (2006), Zhou et al. (2014) Mabrouk et al. (2016), Hajej et al. (2016) and Hung et al. (2017).

Although the mentioned-above literature studied various types of PM policies related to the equipment, their implicit assumption is that aging of the equipment is uniquely characterized by the time (age)-dependent random distribution. In real life, the deterioration of some equipment is affected not just by age, but it is influenced by accumulative usage. For example, accumulative mileage of automobile can increase the probability of a failure. Considering this fact, Iskandar & Husniah (2017) recently developed a PM policy for the equipment with a two-dimensional lease region. However, this literature ignored a fact that all usage rates of individual lessee are not same. According to difference of usage rate, in practice, it is more popular with the lessee for the leaser to perform customized PM integrating with usage rate class in the two-dimensional lease region. Besides, PM in this literature was performed periodically. For the equipment with deterioration depending on age and usage, it is well known that its reliability sharply and nonlinearly declines with respect to age and accumulative usage or its deterioration is accelerated with respect to age and accumulative usage. Obviously, periodic PM actions can't be applied to effectively and in real time improve the sharply and nonlinearly declining reliability since its interval is a constant.

In this paper, we consider a two-dimensional lease region with customized PM, which is used as a lease limit of the equipment with deterioration depending on age and usage. Because the leaser

can't obtain usage rates of all individual lessees when lease contract takes effect, customized PM can't be used to maintain reliability of the equipment. In order to use customized PM in the two-dimensional lease region with the unknown usage rates, we divide the two-dimensional lease region into multiple disjoint regions and then propose a flexible lease contract with customized PM. According to repair records or/and electronic monitoring records in the first two-dimensional lease region, the leaser can obtain usage rates of all individual lessees. This acquisition is convenient to usage of customized PM in the remaining lease limits. Besides, since reliability sharply declines with respect to age and accumulative usage, the customized PM considered in this paper is based on reliability threshold, as a decision variable. That is, PM is performed depending on whether reliability declines to reliability threshold. As well known, lease termination of weighty lessee is decided by usage limit and lease termination of light lessee is decided by age limit. To measure effect of customized PM, some assume that customized PM for each weighty lessee class reduces age and customized PM for each light lessee class reduces usage. For illustrating the performance of the proposed lease contract, moreover, we compare the total cost models under different lease contracts by means of Root Mean Square (RMS) technology.

The structure of this paper is listed as follows. In Section 2, a benchmark lease contract and the lease contract proposed in this paper are defined. In Section 3, we derive the leaser's total cost models respectively related to two lease contracts. Section4 presents a numerical experiment to illustrate the considered lease contracts. Finally, Section 5 concludes this paper.

2 MODEL FORMULATION

2.1 *Assumptions*

The following assumptions are made in this paper.

- The usage rate of individual lessee is fixed through the whole life cycle;
- Usage rates after the first two-dimensional lease region are obtained and they are classified into $\boldsymbol{m}$ ($m>1$) classes.

2.2 *Lease contract definition*

2.2.1 *Benchmark lease contract*

In real life, minimal repair frequently is used to remove failure. In this paper, we call the two-dimensional lease contract where all failures are removed by minimal repair as the benchmark lease contract. Under the benchmark lease contract, since minimal repair is unique method to sustain running, we call minimal repair as the unified maintenance policy. Due to the unknown usage rate in the two-dimensional lease region Ω, age and accumulative usage at the two-dimensional lease region Ω termination are respectively expressed as

$$T_{\Omega}(t)=\begin{cases}\varpi, & if\ \ r\le r^*\\ u/r, & if\ \ r>r^*\end{cases} \text{ and } X_{\Omega}(t)=\begin{cases}r\varpi, & if\ \ r\le r^*\\ u, & if\ \ r>r^*\end{cases}.$$

2.2.2 *The proposed lease contract*

Let ϖ be maximal time limit, u be maximal usage limit and r^* be average usage rate. Then $r^*=u/\varpi$ and the two-dimensional lease region can be defined by the set $\Omega=(\varpi,u)$. For the sake of analytical tractability, we define the first two-dimensional lease region as $\Omega_1=\{(\omega_1,u_1)\,|\,0\le u_1<\varpi r_{\min} \text{ and } 0\le \omega_1<u/r_{\max}\}$ where $r_{\min}$ is minimal usage; $r_{\max}$ is maximal usage; and $u_1=r^*\varpi_1$. Obviously, the first two-dimensional lease region Ω_1 is a part of the two-dimensional lease region Ω, which can be depicted in Figure 1.

As showed in Figure 1, the two-dimensional lease region Ω is classified three regions. According to repair records in the first two-dimensional lease region Ω_1, the leaser can conclude usage rate of individual lessee and further classify usage rate for them. So the leaser can obtain the following information when the equipment with the unknown usage rate class goes through the first two-dimensional lease region Ω_1, as follows: a) the usage rate class can be known; and b) the remaining lease limits, namely, the remaining time limit $\varpi-\varpi_1>0$ and the remaining usage limit $u-u_1>0$, can be known.

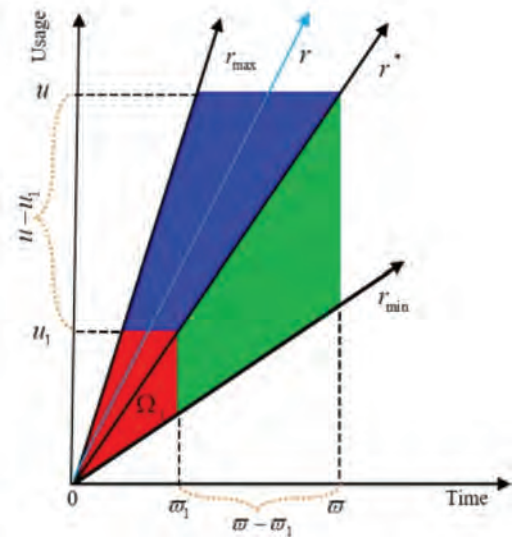

Figure 1. Description of lease region.

Further, age and accumulative usage at the first two-dimensional lease region Ω_1 termination are respectively given by

$$T_{\Omega_1}(t)=\begin{cases}\varpi_1, & if\ r\le r^*\\ u_1/r, & if\ r>r^*\end{cases} \text{ and } X_{\Omega_1}(t)=\begin{cases}r\varpi_1, & if\ r\le r^*\\ u_1, & if\ r>r^*\end{cases}.$$

Reliability-centered (or based) PM policy is a nice maintenance policy, which is frequently applied in reliability maintenance field (see Niu et al., 2010, Zhou et al., 2007, Lin et al., 2015). From the leaser's perspective, here we propose a two-dimensional lease contract with customized PM by integrating reliability-centered PM policy with usage rate classes. For this lease contract, when reliability in the remaining lease limits declines to a threshold, called reliability threshold, then PM is performed to improve reliability. This repeated PM action is ceased until the associated remaining lease limit expires. That is, customized PM is applied to keep reliability no lower than reliability threshold, in the remaining lease limits. For the given remaining lease limits, a smaller reliability threshold must result in a lower number of PMs, and vice versa. Under the proposed lease contract, therefore, both reliability threshold and number of PMs are considered as decision variables.

3 MODEL ANALYSIS

Failure rate (function), as an increasing function, is generally used to characterize aging. In this paper, we assume that aging is modeled by a failure rate given by $\gamma(x|r)$ where r is a random variable following $G(r)$. The total cost under each lease contract is the sum of the expected maintenance cost, the expected penalty cost and the expected depreciation cost, i.e.,

$$\begin{aligned}\textit{The total cost} = {} & \textit{maintenance cost} + \textit{penalty cost}\\ & + \textit{depreciation cost.}\end{aligned} \tag{1}$$

By (1), next, we will derive the associated total cost under the case that c_m is minimal repair cost.

3.1 *Cost model under the unified maintenance*

Under the unified maintenance policy, the equipment is not classified. That is, all equipment have a same usage rate class $r\in[r_{\min},r_{\max}]$. We call this same usage rate class as single usage rate class in this paper.

3.1.1 *The expected maintenance cost*

The expected maintenance cost of single usage rate class can be obtained as

$$MC_b^s = c_m\left(\int_{r^*}^{r_{\max}}\int_0^{u/r}\gamma(x|r)\,\mathrm{d}x\mathrm{d}G(r)+\int_{r_{\min}}^{r^*}\int_0^{w}\gamma(x|r)\,\mathrm{d}x\mathrm{d}G(r)\right), \tag{2}$$

3.1.2 *The expected penalty cost*

From the lessee's perspective, essentially, recovery of the equipment failure can cause revenue loss. Hamidi *et al.* (2016) formulated the revenue rate as the product of an increasing function in r and a decreasing function in t. Similarly, we also use this product to describe the revenue rate of single class, as

$$\mathbb{R}_s(t\,|\,r)=\frac{\mathbb{R}_{\max}}{r_{\max}}r\left(1-\frac{t}{L}\right), \tag{3}$$

where $\mathbb{R}_{\max}$ be the potential revenue rate that can be generated by the new equipment if its capacity is fully used (i.e., $\mathbb{R}_s(0\,|\,r_{\max})$); and L is life cycle of the equipment.

If $r\le r^*$, then the expected revenue rate of single usage rate class in the interval $(0,\varpi]$ is given by $\mathbb{R}_s=\int_{r_{\min}}^{r^*}\int_0^{\varpi}\mathbb{R}_s(t\,|\,r)\mathrm{d}t\mathrm{d}G(r)/\varpi$. If $r>r^*$, then the expected revenue rate of single usage rate class in the interval $(0,u/r]$ is given by $\mathbb{R}_s^u=\int_{r^*}^{r_{\max}}r\int_0^{\varpi}\mathbb{R}_s(t\,|\,r)\mathrm{d}t\mathrm{d}G(r)/u$. Further, the expected penalty cost of single usage rate class in the two-dimensional lease region Ω can be expressed as

$$\begin{aligned}PC_b^s = \bar{H}(\vartheta)\cdot\Big(&\mathbb{R}_s^u\int_{r^*}^{r_{\max}}\int_0^{u/r}\gamma(x|r)\,\mathrm{d}t\mathrm{d}G(r)\\ &+\mathbb{R}_s\int_{r_{\min}}^{r^*}\int_0^{\varpi}\gamma(x|r)\,\mathrm{d}t\mathrm{d}G(r)\Big),\end{aligned} \tag{4}$$

where the function $\bar{H}(\vartheta)$ is the expected excess of recovery time to failure.

3.1.3 *The expected depreciation cost*

The equipment in the two-dimensional lease region Ω faster deteriorates with respect to age and accumulative usage. This process makes the equipment depreciate. In order to measure depreciation value of the equipment at the two-dimensional lease region Ω termination, we offer a measure model by modifying residual value model in Hamidi *et al.* (2016), as

$$DC_s(r,t)=\theta_1X^2(t)+\theta_2T^2(t) \tag{5}$$

where $\theta_1>0;\ \theta_2>0;\ \theta_2=(V_0-V_L)/\varpi^2-\theta_1r_{i+1}^2;$ V_0 is purchase price; and V_L is residual value at the end of the life cycle L when the equipment is used at the maximum usage rate.

If $r\le r^*$, then the expected depreciation cost of single usage rate class at the two-dimensional lease region Ω termination is given by

$DC_b^l = \theta_1 \varpi^2 \int_{r^*}^{r_{\max}} r^2 \mathrm{d}G(r) + \varpi^2$. If $r > r^*$, then the expected depreciation cost of single usage rate class at the two-dimensional lease region Ω termination is given by $DC_b^w = \theta_1 u^2 + \theta_2 \int_{r_{\min}}^{r^*} (u/r)^2 \mathrm{d}G(r)$. Thus, the expected depreciation cost of single usage rate class at the two-dimensional lease region Ω termination is given by

$$\begin{aligned} DC_b^s &= DC_b^w + DC_b^l \\ &= \theta_1 \left(u^2 + \varpi^2 \int_{r^*}^{r_{\max}} r^2 \mathrm{d}G(r) \right) + \\ &\quad \theta_2 \left(\int_{r_{\min}}^{r^*} (u/r)^2 \mathrm{d}G(r) + \varpi^2 \right). \end{aligned} \tag{6}$$

3.1.4 *The total cost model*

By (1), finally, the total cost of single usage rate class in the lease Ω can be obtained as

$$\begin{aligned} TC_b^s &= MC_b^s + PC_b^s + DC_b^s \\ &= \left(c_m + \bar{H}(\vartheta) \mathbb{R}_s^w \right) \int_{r^*}^{r_{\max}} \int_0^{u/r} \gamma(x|r) \mathrm{d}x \mathrm{d}G(r) + \\ &\quad \left(c_m + \bar{H}(\vartheta) \mathbb{R}_s^l \right) \int_{r_{\min}}^{r^*} \int_0^{w} \gamma(x|r) \mathrm{d}x \mathrm{d}G(r) + \\ &\quad \theta_1 \left(u^2 + \varpi^2 \int_{r^*}^{r_{\max}} r^2 \mathrm{d}G(r) \right) + \\ &\quad \theta_2 \left(\int_{r_{\min}}^{r^*} (u/r)^2 \mathrm{d}G(r) + \varpi^2 \right). \end{aligned} \tag{7}$$

3.2 *Cost model under the customized PM*

As indicated in the definition of the proposed lease, customized PM is used to maintain equipment reliability in the remaining lease limits. Next, so we derive the expected total costs in the remaining lease limits. We state that the expected total cost of light lessee is derived in this subsection, and the expected total cost of weighty lessee will be presented in Appendix A.

We use the reduction in age as a PM effect. As well known, the relationship between reliability and failure rate is a one-to-one mapping. Let R_i be reliability threshold corresponding to the i^{th} usage rate class (similarly hereinafter) $r \in (r_i, r_{i+1}]$, then R_i can be expressed as

$$R_i = \exp\left\{ -\int_{r_i}^{r_{i+1}} \left(\int_{W_{k-1}^i}^{W_{k-1}^i + T_k^i} \gamma(\varpi_1 + S_{k-1}^i + x|r) \mathrm{d}x \right) \mathrm{d}G(r) \right\}, \tag{8}$$

where $H_k^i(-\ln R_i)$ is inverse function of $\boldsymbol{H}_k^i(T_k^i) = \int_{r_i}^{r_{i+1}} \left(\int_{\Gamma_{k-1}^i}^{\Gamma_{k-1}^i + T_k^i} \gamma(\varpi_1 + S_{k-1}^i + x|r) \mathrm{d}x \right) \mathrm{d}G(r)$; T_i^k is a time interval between the $(k-1)^{\text{th}}$ PM and the k^{th} PM; $S_{k-1}^i = \sum_{j=0}^{k-1} \alpha_j^i T_j^i$; $\Gamma_{k-1}^i = \sum_{j=0}^{k-1} T_j^i$; $1 \geq \alpha_1^i \geq \alpha_2^i \geq \cdots \geq 0$; and $T_0^i = S_0^i = \Gamma_0^i = 0$.

Since lease of light lessee terminates only when age reaches age limit, customized PM of light lessee is only confined to the remaining time limit $\varpi - \varpi_1$. Next, so we derive the total cost in the remaining time limit $\varpi - \varpi_1$.

3.2.1 *The expected maintenance cost*

Since each failure between two successive PMs is removed by minimal repair, the expected maintenance cost in the k^{th} PM interval $(0, T_k^i]$ is minimal repair cost in the k^{th} PM interval $(0, T_k^i]$. So, it can be calculated as

$$C_k^i(T_k^i) = c_m \int_{r_i}^{r_{i+1}} \left(\int_{\Gamma_{k-1}^i}^{\Gamma_{k-1}^i + T_k^i} \gamma(\varpi_1 + S_{k-1}^i + x|r) \mathrm{d}x \right) \mathrm{d}G(r). \tag{9}$$

After the last PM, i.e., the n_i^{th}, minimal repair cost of the i^{th} rate class is given by

$$C_{n_i}^i = c_m \int_{r_i}^{r_{i+1}} \left(\int_{\Gamma_{n_i}^i}^{\varpi - \varpi_1} \gamma(\varpi_1 + S_{n_i}^i + x|r) \mathrm{d}x \right) \mathrm{d}G(r), \tag{10}$$

where $n_i = \{ n_i > 0 | \Gamma_{n_i}^i \leq \varpi - \varpi_1 \}$.

Let the increasing function $C_{p_i}^k(\beta_k^i T_k^i)$ be PM cost resulted from the reduction $\beta_k^i T_k^i$, where $\beta_k^i = 1 - \alpha_k^i$. The expected maintenance cost in the remaining time limit $\varpi - \varpi_1$ is equal to the sum of minimal repair cost $\sum_{k=1}^{n_i - 1} C_k^i(T_k^i)$ resulted from the first $n_i - 1$ PM intervals, the minimal repair cost $C_{n_i}^i$ after the n_i^{th} PM and the PM cost $\sum_{k=1}^{n_i} C_{p_i}^k(\beta_k^i T_k^i)$ resulted from n_i PMs. And it can be mathematically expressed as

$$\begin{aligned} MC_i(R_i, n_i) &= \sum_{k=1}^{n_i - 1} C_k^i(T_k^i) + C_{n_i}^i + \sum_{k=1}^{n_i} C_{p_i}^k(\beta_k^i T_k^i) \\ &= c_m \left(\sum_{k=1}^{n_i - 1} \int_{r_i}^{r_{i+1}} \left(\int_{\Gamma_{k-1}^i}^{\Gamma_{k-1}^i + T_k^i} \gamma(\varpi_1 + S_{k-1}^i + x|r) \mathrm{d}x \right) \right. \\ &\quad \left. \mathrm{d}G(r) + \int_{r_i}^{r_{i+1}} \left(\int_{\Gamma_{n_i}^i}^{\varpi - \varpi_1} \gamma(\varpi_1 + S_{n_i}^i + x|r) \mathrm{d}x \right) \mathrm{d}G(r) \right) \\ &\quad + \sum_{k=1}^{n_i} C_{p_i}^k(\beta_k^i T_k^i). \end{aligned} \tag{11}$$

3.2.2 *The expected penalty cost*

We modify the revenue rate in (3) as

$$\mathbb{R}_p^i(t|r) = \frac{\mathbb{R}_{i+1}}{r_{i+1}} r \left(1 - \frac{t}{L}\right), \tag{12}$$

where $\mathbb{R}_{i+1}$ be the potential revenue rate that can be generated by the new equipment with the usage rate $r \in (r_i, r_{i+1}]$ if its capacity is fully used (i.e., $\mathbb{R}_p^i(0 | r_{i+1})$).

The expected revenue rate in the k^{th} PM interval $(0, T_k^i]$ is given by $\mathbb{R}_k^i = (\int_{r_i}^{r_{i+1}} \int_{\Gamma_{k-1}^i}^{\Gamma_{k-1}^i + T_k^i} \mathbb{R}_p^i(\varpi_1 + S_{k-1}^i + x \mid r) \mathrm{d}x \mathrm{d}G(r)) / T_k^i$. And the expected revenue rate after the n_i^{th} PM is given by $\mathbb{R}_{n_i}^i = \int_{r_i}^{r_{i+1}} \int_{\Gamma_{n_i}^i}^{\varpi - \varpi_1} \mathbb{R}_p^i(\varpi - \varpi_1 + S_{n_i}^i + x \mid r) \, \mathrm{d}x \mathrm{d}G(r) / (\varpi - \varpi_1 - \Gamma_{n_i}^i)$. Further, the expected penalty cost in the remaining time limit $\varpi - \varpi_1$ can be expressed as

$$\begin{aligned} PC_s(R_i, n_i) = & \bar{H}(\vartheta) \\ & \left(\sum_{k=1}^{n_i - 1} \mathbb{R}_k^i \int_{r_i}^{r_{i+1}} \left(\int_{\Gamma_{k-1}^i}^{\Gamma_{k-1}^i + T_k^i} \gamma(\varpi_1 + S_{k-1}^i + x \mid r) \mathrm{d}x \right) \mathrm{d}G(r) \right. \\ & \left. + \mathbb{R}_{n_i}^i \int_{r_i}^{r_{i+1}} \left(\int_{\Gamma_{n_i}^i}^{\varpi - \varpi_1} \gamma(\varpi_1 + S_{n_i}^i + x \mid r) \mathrm{d}x \right) \mathrm{d}G(r) \right). \end{aligned} \tag{13}$$

3.2.3 *The expected depreciation cost*

When the two-dimensional lease region Ω terminates, accumulative usage and age of the equipment is respectively $X_\Omega(t) = r\varpi$ and $T_\Omega(t) = \varpi - \sum_{k=1}^{n_i} \beta_k^i T_k^i$. In this setting, by (5), the expected depreciation cost is given by

$$DC_i^\Omega(R_i, n_i) = \theta_1 \varpi^2 \int_{r_i}^{r_{i+1}} r^2 \mathrm{d}G(r) + \theta_2 (\varpi - \sum_{k=1}^{n_i} \beta_k^i T_k^i)^2. \tag{14}$$

Similarly, the expected depreciation cost at the first two-dimensional lease region Ω_1 termination is given by

$$DC_i^{\Omega_1} = \theta_1 \omega_1^2 \int_{r_i}^{r_{i+1}} r^2 \mathrm{d}G(r) + \theta_2 \omega_1^2. \tag{15}$$

Thus, the expected depreciation cost at the remaining time limit $\varpi - \varpi_1$ termination is obtained as

$$\begin{aligned} DC_i(R_i, n_i) &= DC_i^\Omega(R_i, n_i) - DC_i^{\Omega_1} \\ &= \theta_1 (\varpi^2 - \omega_1^2) \int_{r_i}^{r_{i+1}} r^2 \mathrm{d}G(r) + \\ & \theta_2 \left((\varpi - \sum_{k=1}^{n_i} \beta_k^i T_k^i)^2 - \omega_1^2 \right). \end{aligned} \tag{16}$$

3.2.4 *The total cost model*

By (1), finally, the total cost in the remaining time limit $\varpi - \varpi_1$ can obtained as

$$\begin{aligned} TC_i(R_i, n_i) &= MC_i(R_i, n_i) + PC_s(R_i, n_i) + DC_i(R_i, n_i) \\ &= \left(c_m + \bar{G}(\vartheta) \mathbb{R}_{n_i}^i \right) \int_{r_i}^{r_{i+1}} \int_{\Gamma_{n_i}^i}^{\varpi - \varpi_1} \gamma(\varpi_1 + S_{n_i}^i + x \mid r) \\ & \mathrm{d}x \mathrm{d}G(r) + \sum_{k=1}^{n_i} C_{p_i}^k (\beta_k^i T_k^i) + \theta_1 (\varpi^2 - \omega_1^2) \\ & \int_{r_i}^{r_{i+1}} r^2 \mathrm{d}G(r) + \theta_2 \left((\varpi - \sum_{k=1}^{n_i} \beta_k^i T_k^i)^2 - \omega_1^2 \right). \end{aligned} \tag{17}$$

Our target is to seek the optimal reliability threshold R_i^* and the optimal number n_i^* of PMs so that the total cost in (17) is minimized. As mentioned earlier, for a given remaining time limit $\varpi - \varpi_1$, if the reliability threshold R_i is smaller, then number n_i of PMs is lower; if the reliability threshold R_i is bigger, then the number n_i of PMs is greater. These monotonous regularities mean that once the optimal reliability threshold R_i^* is determined, then the optimal number n_i^* of PMs can be uniquely determined. Since expressions of $G(r)$ and $\gamma(\varpi_1 + S_{k-1}^i + x \mid r)$ are uncertain, obtaining analytical solution is clearly difficult and so the optimal values (R_i^*, n_i^*) need to be searched numerically by masterly designing reliability in the remaining lease limits.

3.3 *Improvement evaluation and contract selection*

How to select lease contract is an important problem for the leaser. In practice, a key approach of lease contract selection is to compare the total costs under different lease contracts. In this subsection, we consider a qualitative analysis method to select lease contract.

As mentioned in Assumption, usage rates are classified into m classes. In the remaining lease limits (including the remaining time limit and the remaining usage limit), finally, the minimizing total cost of m usage rate classes can be obtained as

$$TC_2^T(\boldsymbol{R}^*, \boldsymbol{N}^*) = \sum_{i=1}^{m} TC_i(R_i^*, n_i^*), \tag{18}$$

where $\boldsymbol{R}^*$ is a vector composed of the optimal reliability thresholds and it is given by $\boldsymbol{R}^* = \{R_1^*, R_2^*, \cdots, R_m^*\}$; and $\boldsymbol{N}^*$ is a vector composed of the optimal number of PMs and it is given by $\boldsymbol{N}^* = \{n_1^*, n_2^*, \cdots, n_m^*\}$.

The total cost in (7) is the total cost of single usage rate class in the two-dimensional lease region Ω, whereas the total cost in (18) is the minimizing total cost of m usage rate classes in the remaining lease limits. This means that they are not equivalent, and so they are not compared directly. In order to compare them, we must transform the minimizing total cost of m usage rate classes into the total cost of single usage rate class. By root mean square (RMS), the total cost of m usage rate classes in the remaining lease limits can be approximately transformed as

$$TC_2^s(\boldsymbol{R}^*, \boldsymbol{N}^*) = \sqrt{\frac{1}{m} \sum_{i=1}^{m} \left(TC_i(R_i^*, n_i^*) \right)^2}. \tag{19}$$

Besides, by (7), the total cost of single usage rate class in the first two-dimensional lease region Ω_1 can be obtained as

$$TC_1^s = \left(c_m + \bar{H}(\vartheta)\Re_s^w\right)\int_{r^*}^{r_{\max}}\int_0^{u_1/r}\gamma(x|r)\,\mathrm{d}x\mathrm{d}G(r) + \left(c_m + \bar{H}(\vartheta)\Re_s^l\right)\int_{r_{\min}}^{r^*}\int_0^{\varpi_1}\gamma(x|r)\,\mathrm{d}x\mathrm{d}G(r) + \theta_1\left(u_1^2 + \varpi_1^2\int_{r^*}^{r_{\max}} r^2\mathrm{d}G(r)\right) + \theta_2\left(\int_{r_{\min}}^{r^*}(u_1/r)^2\mathrm{d}G(r) + \varpi_1\right), \quad (20)$$

where $\Re_s^w(=\int_{r^*}^{r_{\max}} r\int_0^{\varpi_1}\mathbb{R}_s(t\,|\,r)\mathrm{d}t\mathrm{d}G(r)/u_1)$ is the expected revenue rate of single usage rate class in the interval $(0,u_1/r]$; $\Re_s^l(=\int_{r_{\min}}^{r^*}\int_0^{\varpi_1}\mathbb{R}_s(t\,|\,r)\mathrm{d}t\mathrm{d}G(r)/\varpi_1)$ is the expected revenue rate of single usage rate class in $(0,\varpi_1]$.

Under the proposed lease contract, further, the total cost of single usage rate class in the whole two-dimensional lease region Ω can be calculated as

$$TC_p^s(\boldsymbol{R}^*,\boldsymbol{N}^*) = TC_1^s + TC_2^s(\boldsymbol{R}^*,\boldsymbol{N}^*). \quad (21)$$

Clearly, the total cost in (21) is the total cost of single usage rate class in the two-dimensional lease region, and it is equivalent to the total cost in (7). This equivalency is facilitated to select lease contract by comparing the total costs. We neglect the error produced by RMS and consider two performance measures, as follows.

If $TC_b^s > TC_p^s(\boldsymbol{R}^*,\boldsymbol{N}^*)$ or $TC_b^s < W_p^s(\boldsymbol{R}^*,\boldsymbol{N}^*)$, then the leaser should select the proposed lease contract with optimal customized PM or the benchmark lease contract to maintain reliability of the equipment in the two-dimensional lease region Ω. Under this situation, the relative improvement of the total cost can be measured as

$$\xi_p = \left|\frac{TC_p^s(\boldsymbol{R}^*,\boldsymbol{N}^*) - TC_b^s}{TC_p^s(\boldsymbol{R}^*,\boldsymbol{N}^*)}\right|\times 100\% \quad \text{or} \quad \left|\frac{TC_b^s - TC_p^s(\boldsymbol{R}^*,\boldsymbol{N}^*)}{TC_b^s}\right|\times 100\%. \quad (22)$$

4 NUMERICAL EXPERIMENT

The lease region considered by us possesses the time limit and usage limit. This is consistent with vehicle warranty in real life. Huang *et al.* (2017) recently utilized the data collected from a car dealer to demonstrate the effectiveness of the proposed policy. Similarly, the intensity function is used as a failure rate that reflects the interdependence among the age and usage, and it is given by $\gamma(x|r) = 0.1 + 0.4r + (1.5x + 1.5r)x$. Also, we assume that the random usage rate r is subject to the uniform distribution $G(r)$ with the maximum $r_{\max} = 8$ and the minimum $r_{\min} = 0.5$. Shang *et al.* (2016) used a quadratic function to model the PM cost function regarding maintenance degree. We use power function to model PM cost and it is given by $C_{p_k}^k(\bullet) = c(\bullet)^\rho$, where c, $\rho > 0$ and dot • is the reduction in age or usage due to PM.

We specify $\varpi = 2$ (years) and $u = 4$ (10^4 kilometers), then the average usage rate $r^* = 2$ and further the two-dimensional lease region is given by Ω = (2,4). The first two-dimensional lease region includes the following three cases, as $\Omega_1 = (0.3, 0.6)$, (0.4, 0.8) or (0.45,0.9). We classify all lessees into two classes, light lessee and weighty lessee. In practice, revenue rate is increasing with usage rate. Due to this fact, we specify the potential revenue rate as \$12500. Some parameters are constants throughout the whole numerical experiment, which are listed in the Table 1. In order to analyze sensitivity, we present some figures, which are used to describe variation tendency related to parametric variation.

For light lessee, since reliability at the first two-dimensional lease region Ω_1(=(0.45,0.9)) is equal to 0.8875, we take step length as 0.1 and obtain Table 2. As indicated in Table 2, the optimal values (i.e., the optimal reliability threshold and the optimal number of PMs) are existed for light lessee. The existence of the optimal values is visually and vividly displayed in Figure 2. For weighty lessee, besides, reliability at the first two-dimensional lease region Ω_1 is equal to 0.6553. Since it is less than reliability 0.8875 of light lessee, we take a lower step length as 0.05 and obtain Table 3. From the Table 3, we can see that the optimal values are existed for weighty lessee. Similarly, this existence is also visually and vividly displayed in Figure 3. In order to illustrate the performance of the considered two-dimensional lease contracts, we plot Figure 4, where step length is 0.05. From Figure 4, we can obtain the following results.

a. The total cost under the proposed lease (PL) contract are increasing and tends to be equal to total cost under the benchmark lease (BL) contract when the area of the first two-dimensional lease region gets bigger.
b. The relative improvement of the total cost under PL contract is decreasing when the area of the first total region gets bigger.

The bigger area of the first two-dimensional lease region Ω_1 produces the smaller the remaining lease limits. Further, the smaller the remaining lease limits leads to the lower PM count. Furthermore, the

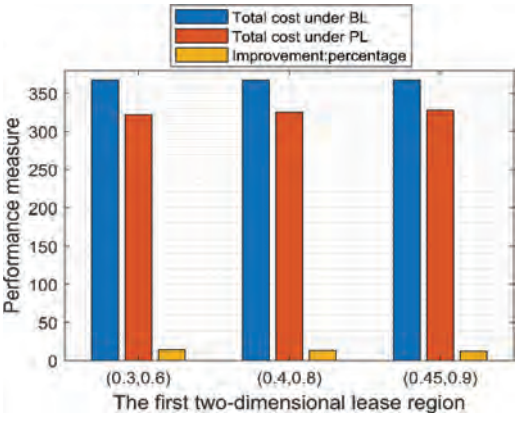

Figure 4. Total cost versus the first two-dimension.

lower PM count leads to the lower minimal repair cost reduction and the greater depreciation cost, thus the results presented in a) is obvious. Since the total costs under the two types of contracts tends to be same when the area of the first region Ω_1 approaches the area of the two-dimensional lease region Ω, the relative improvement of the total cost under PL contract is decreasing. Therefore, the results presented in b) is obtained. These changes illustrate the performance of PL contract is superior to that of BL contract. Compared with BL contract, conclusively, the leaser should use PL contract as a reliability guarantee in the two-dimensional lease region, which is more beneficial since the leaser incurs the lower total cost. Compared with BL contract, additionally, the lessee may be also inclined to PL contract since PMs in the PL contract can keep a higher reliability which can slow down deterioration and indirectly reduce number of failures and increase revenue rate.

5 CONCLUSIONS

In this paper, the two-dimensional lease contract in which all failures in the two-dimensional lease region were removed by minimal repair was taken as a benchmark lease contract. From the leaser's perspective, we proposed a two-dimensional lease contract with customized PM by dividing the two-dimensional lease region. We specified that minimal repair was used to remove failure in the first two-dimensional lease region and customized PM integrating with usage rate class was adopted to improve reliability in the remaining lease limits so that maintenance cost, penalty cost and depreciation cost can be reduced simultaneously. From viewpoint of generality, the proposed two-dimensional lease contract can be translated into benchmark lease contract by adjusting parameters. From viewpoint of management, the proposed lease contract is beneficial for both the leaser and the lessee since the total cost for the leaser and the failure counts for the lessee are less that under the benchmark lease contract. These have been illustrated by the numerical results.

The main contribution of this paper is that the proposed two-dimensional contract with the divided regions is a solution of the leaser how to use customized PM to maintain reliability, under the case that usage rate classes in the two-dimensional lease region can't be known when the lease contract takes effect. This method still can be applied to maintain reliability in the two-dimensional warranty region although it was considered from viewpoint of the two-dimensional lease contract.

APPENDIX A

For weighty lessee, the lease expires only when usage reaches the usage limit u, so we use the reduction in usage to measure effect of customized PM.

The reliability threshold R_i associated with the i^{th} usage rate class $r \in (r_i, r_{i+1}]$ can be expressed as

$$R_i = \exp\{-\int_{r_i}^{r_{i+1}} \left(\int_{U_{k-1}^i/r}^{(U_{k-1}^i+u_k^i)/r} \gamma((u_1+Z_{k-1}^i)/r+x|r)\,\mathrm{d}x \right) \mathrm{d}G(r)\}, \tag{23}$$

where $J_k^i(-\ln R_i)$ is inverse function of $\pi_k^i(u_k^i) = \int_{r_i}^{r_{i+1}} \left(\int_{U_{k-1}^i/r}^{(U_{k-1}^i+u_k^i)/r} \gamma((u_1+Z_{k-1}^i)/r+x|r)\,\mathrm{d}x \right) \mathrm{d}G(r)$; $(u_k^i = J_k^i(-\ln R_i))$ is an usage interval between the $(k-1)^{\text{th}}$ PM and the k^{th} PM; $Z_{k-1}^i = \sum_{l=0}^{k-1} \alpha_l^i u_l^i$; $U_{k-1}^i = \sum_{l=0}^{k-1} u_l^i$; and $u_0^i = U_0^i = Z_0^i = 0$.

The expected maintenance cost

The expected maintenance cost in the k^{th} PM interval $(0,\ u_i^k/r]$ can be calculated as

$$C_i^k(u_i^k/r) = c_m \int_{r_i}^{r_{i+1}} \left(\int_{U_{k-1}^i/r}^{(U_{k-1}^i+u_k^i)/r} \gamma((u_1+Z_{k-1}^i)/r+x|r)\,\mathrm{d}x \right) \mathrm{d}G(r). \tag{24}$$

After the n_i PM, the expected maintenance cost is

$$C_i^{n_i} = c_m \int_{r_i}^{r_{i+1}} \left(\int_{U_{n_i}^i/r}^{(u-u_1)/r} \gamma((u_1+Z_{n_i}^i)/r+x|r)\,\mathrm{d}x \right) \mathrm{d}G(r), \tag{25}$$

where $n_i = \{n_i > 0 | U_{n_i}^i \le u - u_1\}$.

The expected maintenance cost in the remaining usage limit $u-u_1$ is expressed as

$$\begin{aligned} MC_i(R_i,n_i) &= \sum_{k=1}^{n_i-1} C_i^k(u_i^k/r) + C_{n_i}^i + \sum_{k=1}^{n_i} C_{p_i}^k(\beta_k^i u_k^i) \\ &= \sum_{k=1}^{n_i-1} c_m \int_{r_i}^{r_{i+1}} \left(\int_{U_{k-1}^i/r}^{(U_{k-1}^i+u_k^i)/r} \gamma((u_1+Z_{k-1}^i)/r+x|r)\,\mathrm{d}x \right) \mathrm{d}G(r) \\ &\quad + c_m \int_{r_i}^{r_{i+1}} \left(\int_{U_{n_i}^i/r}^{(u-u_1)/r} \gamma((u_1+Z_{n_i}^i)/r+x|r)\,\mathrm{d}x \right) \mathrm{d}G(r) + \sum_{k=1}^{n_i} \left(C_{p_i}^k(\beta_k^i u_k^i) \right). \end{aligned} \tag{26}$$

The expected penalty cost

The expected revenue rate in the k^{th} PM interval $(0,\ u_i^k/r]$ is given by $\mathbb{R}_k^i = \int_{r_i}^{r_{i+1}} r \int_{U_{k-1}^i/r}^{(U_{k-1}^i+u_k^i)/r} \mathbb{R}_p^i((u_1+Z_{k-1}^i)/r+x\,|\,r)\mathrm{d}x\mathrm{d}G(r)/u_k^i$.

And the expected revenue rate after the n_i^{th} PM is given by $\mathbb{R}_{n_i}^i = \int_{r_i}^{r_{i+1}} r \int_{Z_{n_i}^i/r}^{(u-u_1)/r} \mathbb{R}_p^i((u-u_1-Z_{n_i}^i)/r+x\,|\,r)\mathrm{d}x\mathrm{d}G(r)$

Thus, the expected penalty cost in the remaining $/(u-u_1-Z_{n_i}^i)$. usage limit $u-u_1$ can be expressed as

$$\begin{aligned} PC_i(R_i,n_i) &= \bar{H}(\vartheta) \cdot \\ &\left(\sum_{k=1}^{n_i-1} \mathbb{R}_k^i \int_{r_i}^{r_{i+1}} r \int_{U_{k-1}^i/r}^{(U_{k-1}^i+u_k^i)/r} \mathbb{R}_p^i((u_1+Z_{k-1}^i)/r+x\,|\,r)\mathrm{d}x\mathrm{d}G(r) \right. \\ &\left. + \int_{r_i}^{r_{i+1}} r \int_{Z_{n_i}^i/r}^{(u-u_1)/r} \mathbb{R}_p^i((u-u_1-Z_{n_i}^i)/r+x\,|\,r)\mathrm{d}x\mathrm{d}G(r) \right). \end{aligned} \tag{27}$$

The expected depreciation cost

Accumulative usage and age at the lease region Ω termination are respectively $X_\Omega(t) = u - \sum_{k=1}^{n_i} \beta_k^i u_k^i$ and $T_\Omega(t) = u/r$. By (5), so the expected depreciation cost is

$$DC_i^\Omega(R_i,n_i) = \theta_1(u - \sum_{k=1}^{n_i} \beta_k^i u_k^i)^2 + \theta_2 \int_{r_i}^{r_{i+1}} (u/r)^2 \mathrm{d}G(r). \tag{28}$$

Similarly, the expected depreciation cost at the lease region Ω_1 termination is

$$DC_i^{\Omega_1} = \theta_1 u_1^2 + \theta_2 \int_{r_i}^{r_{i+1}} (u_1/r)^2 \mathrm{d}G(r). \tag{29}$$

Thus, the expected depreciation cost at the remaining usage limit $u-u_1$ termination is

$$DC_i(R_i,n_i) = DC_i^\Omega(R_i,n_i) - DC_i^{\Omega_1}. \tag{30}$$

The total cost model

By (1), the total cost in the remaining usage limit $u-u_1$ can be obtained as

$$\begin{aligned} TC_i(R_i,n_i) &= MC_i(R_i,n_i) + PC_s(R_i,n_i) + DC_i(R_i,n_i) = \\ &\sum_{k=1}^{n_i-1} \left(c_m + \bar{H}(\vartheta)\mathbb{R}_k^i \right) \int_{r_i}^{r_{i+1}} \left(\int_{U_{k-1}^i/r}^{(U_{k-1}^i+u_k^i)/r} \gamma((u_1+Z_{k-1}^i)/r+x|r)\,\mathrm{d}x \right) \mathrm{d}G(r) \\ &+ \left(c_m + \bar{H}(\vartheta)\mathbb{R}_{n_i}^i \right) \int_{r_i}^{r_{i+1}} \left(\int_{U_{n_i}^i/r}^{(u-u_1)/r} \gamma((u_1+Z_{n_i}^i)/r+x|r)\,\mathrm{d}x \right) + \mathrm{d}G(r) \\ &\sum_{k=1}^{n_i} \left(C_{p_i}^k(\beta_k^i u_k^i) \right) + \theta_1 \left((u - \sum_{k=1}^{n_i} \beta_k^i u_k^i)^2 - u_1^2 \right) + \\ &\theta_2 \int_{r_i}^{r_{i+1}} \left((u/r)^2 - (u_1/r)^2 \right) \mathrm{d}G(r). \end{aligned} \tag{31}$$

ABSTRACT: This paper takes heavy vehicle systems as case study to propose a fuzzy evaluation method based on fuzzy consistency matrix for evaluation maintenance design program, and formulate its process, which are determining the evaluation index, developing the hierarchical structure model, constructing fuzzy complementary matrix, operating the single hierarchical arrangement, operating the weight total ordering, and evaluating the level of maintenance design program. In order to illustrate the reasonable and feasible of the proposed evaluation method, its weight is compared with the results by other methods: Analytic hierarchy process, Fuzzy analytic hierarchy process based on consistency matrix, Fuzzy analytic hierarchy process based on triangular fuzzy number. Furthermore, the evaluation result is compared with those of the evaluation method based on cloud model. All in all, this paper proposes a new evaluation method for evaluating maintenance design program of repairable systems.

1 INTRODUCTION

The availability of product is the key factor to determine the stability of product performance. The availability of the product is determined by the reliability and maintainability [1]. By carrying out the reliability design of the product, the failure rate of the product can be reduced. Similarly, the maintenance design [2–3] in the product design stage is needed to achieve economic, convenient and effective maintenance. At present, the maintainability design has been paid attention to by the designers. The key factors affecting the maintenance level are as follows: simplification, standardization and interchangeability, detection, repairability, mistake proofing, safety, accessibility, human element engineering, maintenance time. The important part of the maintenance design is the evaluation of the maintenance design scheme with the comprehensive consideration of the above factors [4–5]. At the same time, the evaluation results can provide the basis for the analysis of the maintainability of the product and the improvement of its maintenance level. For this kind of evaluation, analytic hierarchy process, cloud model algorithm and so on are often used. There are two outstanding issues in the evaluation of maintenance design scheme by such evaluation methods: (1) The results obtained by these evaluation techniques can be affected by the subjective factors of experts. Only the influence of the subjective factors turn weak, can the evaluation results become more reasonable, (2) The expert scoring matrix is widely used in this kind of evaluation method, it is necessary to keep the evaluation intention of experts without changing.

Thus, based on the above problems, taking heavy vehicles as the research object, a fuzzy evaluation method based on consistency matrix for evaluating maintenance design program is presented. The main contributions of this paper are as follows:

1. As an appropriate scale [6–7] can soften the impact of subjective factors, the comparisons between the following scales are carried out: 1~9 scale, the deformation scales 9/9~9/1 and 10/10~18/2, and exponential scales $9^{0/9}$~$9^{8/9}$, $2^{0/2}$~$2^{8/2}$, $e^{0/4}$~$e^{8/4}$. The results can reduce the trouble about the selection of scale.
2. A fuzzy evaluation method based on consistency matrix for evaluating maintenance design program is proposed, and the corresponding evaluation process is also developed. Naturally,

the problem of consistency of expert opinions and scoring matrix is solved.

The remainder of the paper is organized as follows. A fuzzy evaluation method based on consistency matrix for evaluating maintenance design program is proposed in section 2. Section 3 illustrates a practical example, which is a heavy vehicle, based on the proposed method. Section 4 conducts result analysis with the method based on the cloud model. Section 5 provides some conclusions on the findings of the research.

2 THE IMPROVED FUZZY EVALUATION METHOD BASED ON CONSISTENCY MATRIX

For the maintainability initiative design, the maintenance evaluation is necessary and an improved evaluation method based on consistency matrix is proposed. The method combines evaluation with the maintainability design content and weaken the subjective influence of expert. At the same time, a simple and reliable maintainability evaluation process is given for design personnel to provide the basis for maintainability design work actively.

2.1 *Scale analysis*

Scale is the tool for expert to evaluate, and the existing scale can be divided into three categories: three scales, five scales and nine scales. The nine scales have the highest accuracy, strong psychological foundation, and the widest application. The nine scales are mainly: 1~9 scale, the deformation scales 9/9~9/1 and 10/10~18/2, and exponential scales $9^{0/9}$~$9^{8/9}$, $2^{0/2}$~$2^{8/2}$, $e^{0/4}$~$e^{8/4}$. In addition, the exponential scales have higher requirements on readability, availability, and normalization. There are so many kinds of nine scales and large differences between them, so the applications are suitable after comparisons.

For convenience, we define the natural language description and the corresponding scale level as shown in Table 1.

The relationship between the scale value and the natural language description can be connected, and the result is shown as in Table 2.

The relative characteristics of different scales are shown in Table 3.

From Table 3, some conclusion can be obtained:

1. All of the scales can keep the rank property under a single criterion, but the rank property under multiple criteria is unclear.
2. From the uniformity, memory, and perception, 1~9 scale is the best, but its consistency is just ordinary. Therefore, 1~9 scale is only applicable in the case of that the requirement about the evaluation accuracy is not high. The consistency of $1\sim9^2$ scale is not qualified and other indexes

Table 1. The corresponding relationship between scale level and natural language description.

Scale level	1	3	5
Natural language description	E—equal	S—slight	O—obvious
Scale level	7	9	2,4,6,8
Natural language description	I—intense	U—ultra	intermediate value

Table 2. The corresponding relationship between scale value and natural language description.

Scale	E	S	O
1~9	1	3	5
$1\sim\sqrt{9}$	1	$\sqrt{3}$	$\sqrt{5}$
$1\sim9^2$	1	9	25
$\frac{9}{9}\sim\frac{9}{1}$	9 / 9 (1)	9 / 7 (1.286)	9 / 5 (1.8)
$\frac{10}{10}\sim\frac{18}{2}$	10 / 10 (1)	12 / 8 (1.5)	14 / 6 (2.33)
$9^{0/9}\sim9^{8/9}$	$9^{(0)}$ (1)	$9^{(1/9)}$ (1.277)	$9^{(3/9)}$ (2.08)
$2^{0/2}\sim2^{8/2}$	$2^{0/2}$ (1)	$2^{2/2}$ (2)	$2^{4/2}$ (4)
$e^{0/4}\sim e^{8/4}$	$e^{0/4}$ (1)	$e^{2/4}$ (1.649)	$e^{4/4}$ (2.718)
Scale	I	U	Formula
1~9	7	9	k
$1\sim\sqrt{9}$	$\sqrt{7}$	3	$\sqrt{k}$
$1\sim9^2$	49	81	k^2
$\frac{9}{9}\sim\frac{9}{1}$	9 / 3 (3)	9 / 1 (9)	$\frac{9}{10-k}$
$\frac{10}{10}\sim\frac{18}{2}$	16 / 4 (4)	18 / 2 (9)	$\frac{9+k}{11-k}$
$9^{0/9}\sim9^{8/9}$	$9^{(6/9)}$ (4.327)	$9^{(9/9)}$ (9)	$9^{(\frac{k-1}{9})}$
$2^{0/2}\sim2^{8/2}$	$2^{6/2}$ (8)	$2^{8/2}$ (16)	$2^{\frac{k-1}{2}}$
$e^{0/4}\sim e^{8/4}$	$e^{6/4}$ (4.482)	$e^{8/4}$ (7.39)	$e^{\frac{k-1}{4}}$

Table 3. The relative properties of different scales.

Characteristics	1~9	$1\sim\sqrt{9}$	$1\sim9^2$	$\frac{9}{9}\sim\frac{9}{1}$
Retentivity (Single criterion) [8]	Correct	Correct	Correct	Correct
Consistency	Ordinary	Ordinary	Nonconformity	Ordinary
Uniformity	Excellent	Excellent	Poor	Ordinary
Memory	Excellent	Ordinary	Ordinary	Poor
Perception	Excellent	Poor	Ordinary	Poor
Weight fitting [8]	Ordinary	Good	Ordinary	Ordinary
Total evaluation	Good	Ordinary	Poor	Good
Characteristics	$\frac{10}{10}\sim\frac{18}{2}$	$9^{0/9}\sim9^{8/9}$	$2^{0/2}\sim2^{8/2}$	$e^{0/4}\sim e^{8/4}$
Retentivity (Single criterion) [8]	Correct	Correct	Correct	Correct
Consistency	Ordinary	Excellent	Excellent	Excellent
Uniformity	Ordinary	Good	Ordinary	Good
Memory	Poor	Poor	Poor	Poor
Perception	Poor	Poor	Poor	Poor
Weight fitting [8]	Good	Excellent	Excellent	Excellent
Total evaluation	Good	Excellent	Good	Excellent

are not good, so it is not recommended. The perception of $1\sim\sqrt{9}$ scale is poor, and the calculation is troublesome, and can be used when calculating conditions permit. The uniformity of 9/9~9/1 scale and 10/10~18/2 scale is poor, and they may be considered as appropriate.

3. Although the memory and perception of exponential scales $9^{0/9}\sim9^{8/9}$, $2^{0/2}\sim2^{8/2}$, $e^{0/4}\sim e^{8/4}$ are poor, their consistency and weight fitting is good. They are suitable for the requirement of high accuracy, and can be complementary with 1~9 scale.

2.2 *Improved evaluation method based on consistency matrix*

1. Determining the indexes of the object in an evaluation

As the evaluation object has multiple attributes, it is necessary to determine the indexes to guide the evaluation direction. The evaluation result must be achieved with these indexes under the same conditions.

2. Establishment of hierarchical model

The evaluation target is difficult to be evaluated directly, so the object is usually decomposed into different parts. These parts can indirectly represent the object, the same as the evaluation result. According to the relationship between the parts, as well as the subordinate relations, a multi-level analysis model can be obtained. The factors with similar character are divided in the same level, i.e. they are the parallel relationship. Naturally, the factors are part of another factor or dominated, they are divided in the lower layer. The hierarchical model can be shown as in Figure 1.

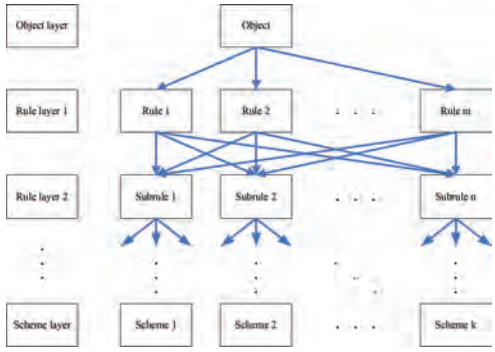

Figure 1. Hierarchical structure diagram.

Although there is no limit on the number of elements per layer in a rule layer, it is generally not more than 9. Psychological research shows that people can have reasonable judgments when the number of object is within nine. When there are more than 9 elements in the same level, the number of elements in the same layer can be reduced by increasing the number of layer.

3. Establishment of consistency matrix

When experts start to give estimation scale for every comparison, it is best to choose the memorable and perceptive scales, for example 1~9 scale. Meanwhile, the effect of scale is that translate the qualitative results of experts into quantitative value and the retentivity and consistency of scale

must meet the requirements to avoid the quantitative result deviate from the expert's intention. Last but not least, taking into account the evaluation habits of experts, the uniform and weight fitting indexes are also important. Above all, experts give estimation scale using 1~9 scale and 1~9 scale will be translated correspondingly into $e^{0/4}$~$e^{8/4}$ scale to form the consistency matrix.

4. Hierarchical ranking

For every layer, the weight value of all elements can be calculated according to the consistency matrix. After the eigenvector corresponding to the eigenvalue of maximum in a consistency matrix is obtained, the weight value of the elements in the same layer can be got by the normalization of eigenvector.

5. Total ranking

By step (4), the weight value of elements in each layer can be obtained. The following assumptions are given: the weight of m elements in k-1_{th} layer relative to the object is $w^{(k-1)}=\left(w_1^{(k-1)},w_2^{(k-1)},\ldots,w_m^{(k-1)}\right)$; the weight of n elements in k layer subject to the j_{th} element in k-1_{th} layer is $p_j^{(k)}=\left(p_{j1}^{(k)},p_{j2}^{(k)},\ \ ,p_{jn}^{(k)}\right)$ and the weight of elements in k layer irrelative to the j_{th} element in k-1_{th} layer is zero; $P^{(k)}=\left(p_1^{(k)},p_2^{(k)},\ \ ,p_m^{(k)}\right)^T$ represents the weight of all elements in k_{th} layer subject to k-1_{th} layer. The calculation formulas are shown as in Eqn. (1) and (2).

$$w^{(k)}=\left(w_1^{(k)},w_2^{(k)},\ldots,w_n^{(k)}\right)^T=w^{(k-1)}\ P^{(k)} \tag{1}$$

$$w_i^{(k)}=\sum_{j=1}^{m}p_{ij}^{(k)}w_j^{(k-1)},\ i=1,2,\ldots,n \tag{2}$$

All the weight values are summarized and unified from top to bottom to get the total weight. The total weight can represent the priority of all the schemes.

6. Set up a set of fuzzy comments

For the evaluation of maintainability design content, a set of fuzzy comments is needed for designers. The set of fuzzy comments is usually divided into five levels, V = {v1, v2, v3, v4, v5} = {excellent, good, ordinary, poor, bad}.

7. Establishment of fuzzy evaluation matrix

Through questionnaire survey of designers, fuzzy evaluation matrix is constructed for calculating the evaluation levels of units. Based on step (6), the fuzzy evaluation matrix E of all factors in the lowest level can be counted as shown in Eqn. (3).

$$TE=\begin{bmatrix}E_1\\ \vdots\\ E_n\end{bmatrix}=\begin{bmatrix}e_{11} & \cdots & e_{15}\\ \vdots & \ddots & \vdots\\ e_{n1} & \cdots & e_{n5}\end{bmatrix} \tag{3}$$

where, e_{ij} represents the fuzzy evaluation of i_{th} factor, which subject to the j_{th} evaluation level, given by designers.

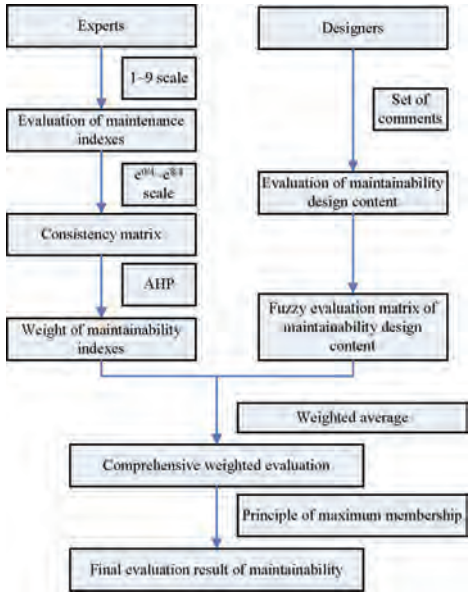

Figure 2. The procedure of proposed fuzzy evaluation method based on consistency matrix.

Combined with the weight values above, comprehensive weighted evaluation [9] can be calculated from bottom to top, i.e. membership matrix. The membership matrix can be calculated as shown in Eqn. (4).

$$B=f\left(w^{(k)}E\right)=\left(w_1^{(k)},w_2^{(k)},\cdots,w_n^{(k)}\right)\begin{bmatrix}e_{11} & e_{12} & \cdots & e_{1m}\\ e_{21} & e_{22} & \cdots & e_{2m}\\ \vdots & \vdots & \ddots & \vdots\\ e_{n1} & e_{n2} & \cdots & e_{nm}\end{bmatrix}=\left(b_1,b_2,\cdots,b_m\right) \tag{4}$$

where, b_i indicates that the membership of evaluated object subject to v_i degree.

8. Final evaluation result

Based on the above analysis results, the final evaluation result of system can be obtained based on the principle of maximum membership. Meanwhile, the weak links can be found and provide basis for the corresponding correction strategies.

The procedure of proposed fuzzy evaluation method based on consistency matrix is shown in Figure 2.

3 CASE STUDY

Taking heavy vehicles as example, the maintenance evaluation based on the proposed evaluation method is conducted. Specific implementation steps are as follows:

1. Selection of evaluation indexes for heavy vehicles

The key factors affecting the maintenance level are as follows: simplification (A), standardization and interchangeability (B), detection (C), repairability (D), mistake proofing (E), safety (F), accessibility (G), human element engineering (H), maintenance time (I). All the above evaluation indexes can be accepted by relevant personnel and departments. The first seven indexes are qualitative properties, and the last two indexes are quantitative properties. The corresponding detailed maintainability design content can be listed simply: A1, A2, A3, B1, B2, B3, B4, C1, C2, C3, D1, D2, D3, E1, E2, E3, F1, F2, F3, G1, G2, G3, H1, H2, H3, I1, I2, I3.

2. Establishment of hierarchical model

The object is the maintainability of heavy vehicle system, and the maintainability indexes are listed in rule layer. The lowest layer is the corresponding detailed maintainability design content. The hierarchical model is conducted as in Figure. 3.

3. Consistency matrix

Several experts provide the evaluations about the elements in rule layer 1 by 1~9 scale. The evaluation of the first expert can be shown as in Table 4.

According to the proposed method and the evaluation results of experts, the corresponding consistency matrix can be obtained, as shown in Table 5.

4. Order ranking

According to the Table 5, the weight of maintainability indexes can be obtained and shown in Table 6.

For every layer, the weight value of all elements can be calculated according to the consistency matrix. For the same elements, different weight can be obtained by different expert. Taking the average of different weight, the final weight of maintainability indexes are shown in Table 7.

5. Total ranking

All the weight values are summarized and unified from top to bottom to get the total weight. The total weight is shown in Table 8.

6. Set up a set of fuzzy comments

For the evaluation of maintainability design content, the set of fuzzy comments V = {v1, v2, v3, v4, v5} = {excellent, good, ordinary, poor, bad} is used.

7. Establishment of fuzzy evaluation matrix

Through questionnaire survey of designers, the fuzzy evaluation matrix *E* is shown as in Table 9.

8. Final evaluation result.

Based on the above analysis results and Eqn. (4), the membership result of all elements in rule layer 1 and system are shown in Table 10. Based on the principle of maximum membership, the final evaluation result is also shown in Table 10.

We can see from Table 10 that the membership of system subject to ordinary evaluation as high as 46.3%. It is indicated that the maintainability of heavy vehicle is still insufficient and need to be improved urgently. At the same time, according to

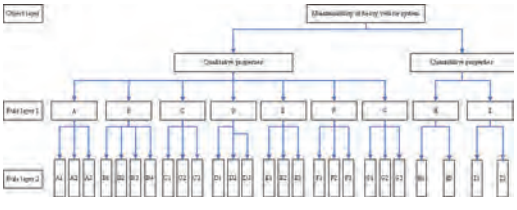

Figure 3. The hierarchical model of maintainability of heavy vehicle system.

4 RESULT ANALYSIS

In order to illustrate the accuracy and applicability of the proposed method, the relative comparisons were carried out.

1. Comparison about weight

The result obtained by proposed method was compared with the results by other methods: Analytic hierarchy process (AHP) [7], Fuzzy analytic hierarchy process based on consistency matrix (FAHP) [10], Fuzzy analytic hierarchy process based on triangular fuzzy number (SFAHP) [11]. All the results are listed in Table 11.

As can be seen from the above table, the weights obtained by AHP and proposed method are very

Table 11. Weight comparison.

	W_A	W_B	W_C	W_D	W_E
AHP	0.1	0.095	0.125	0.136	0.066
Proposed method	0.1	0.095	0.129	0.132	0.065
FAHP	0.112	0.111	0.112	0.112	0.106
SFAHP	0.108	0.106	0.119	0.121	0.085
	W_F	W_G	W_H	W_I	
AHP	0.103	0.088	0.141	0.147	
Proposed method	0.103	0.09	0.141	0.143	
FAHP	0.112	0.111	0.113	0.112	
SFAHP	0.11	0.102	0.124	0.125	

Table 12. Evaluation results between the proposed method and cloud model method.

	Cloud model method	Proposed method
Simplification	Excellent	Excellent
Standardization and interchangeability	Excellent	Excellent
Detection	Good	Ordinary
Repairability	Good	Ordinary
Mistake proofing	Ordinary	Excellent
Safety	Excellent	Excellent
Accessibility	Good	Ordinary
Human element engineering	Good	Ordinary
Maintenance time	Good	Ordinary
System	Good	Ordinary

close, but the range of result obtained by proposed method is slightly smaller than that of AHP. The main reason is that, although the judgment matrix of 1~9 scale is inconsistent, the error is not very large due to its high precision. And the weight obtained by FAHP is close, which is result from the poor precision of 0.1~0.9 scale. The result obtained by SFAHP is not good and the procedure of SFAHP is more complicated than other methods.

2. Comparison of evaluation results

The evaluation results obtained by the proposed method is compared with the cloud model method [12] based on golden partition evaluator and normal similarity [13–14], all the results are listed in Table 12.

According to Table 12, the qualitative evaluation results obtained by the proposed method are more conservative than that of cloud model method. As the using of golden partition evaluator and normal similarity is complex, and the proposed method is more suitable for the engineering application of maintenance evaluation.

5 CONCLUSION

Maintainability initiative design is an important way to improve the maintainability of equipment. And the maintenance evaluation can effectively grasp the maintenance design content and the maintenance level. From the purpose of the engineering application of maintenance evaluation, the appropriate scale can be selected which can weaken the influence of subjective factors after the comparisons between different scales are conducted. According to the grade that experts give, the consistency matrix is constructed to solve the problem about the consistency of expert opinion, and the related method and procedure are optimized. By using the AHP method, the expert experience can be translated into weight values. In addition, the fuzzy comprehensive evaluation method also can translate the designer's understanding about maintainability design content into values. Combined both, the fuzzy evaluation about the system can be obtained. Finally, a reasonable and simple evaluation process is given to make practical application more convenient.

Simultaneously, the proposed method is applied on heavy vehicles to study the maintenance evaluation. To verify the accuracy of the proposed method, two comparisons are conducted. The first comparison is the weight values between different methods: the proposed method, AHP, the FAHP based on fuzzy consistency matrix using 0.1~0.9 scale, and the FAHP based on triangular fuzzy number. The result proves that the proposed method has higher accuracy. The second comparison is that the evaluation result of the proposed method is compared with that of cloud model algorithm. The result of second comparison verifies the applicability and accuracy of the proposed method applied on heavy vehicles. The efficiency of the evaluation also can be improved. The proposed method effectively combine expert experience and maintainability design content to provide a basis for the follow-up maintenance initiative design and improvement.

Towards a model based asset deterioration framework represented by probabilistic relational models

Haoyuan Zhang & D. William R. Marsh
Risk and Information Management Research Group, School of Electronic Engineering and Computer Science, Queen Mary University of London, UK

ABSTRACT: Most asset deterioration tools are designed for a specific application, as a consequence, a small change of the specification may result in a complete change of the tool. Inspired by the model-based approach of separating problem specification from analysis technique, we propose a model-based asset deterioration assessment framework using probabilistic relational models. The probabilistic relational models express abstract probabilistic dependency covers a range of deterioration modelling assumptions. An expert in the domain of asset deterioration can then use his knowledge of the factors that affect deterioration to customise the abstract models to a specific application, without requiring a detailed understanding the underlying computational framework. We illustrate the use of the framework with multiple variants of deterioration models.

1 INTRODUCTION

Traditionally, inspection and maintenance of infrastructure has followed a fixed time interval. One idea to make inspection more cost-effective is to use a statistical model to predict the rate of asset deterioration and use the predictions to plan detailed inspections or maintenance. A range of deterioration models has been developed in different field, from railway track (Guler et al., 2011) to bridge (Sobanjo, 2011). Despite having common objectives such as condition prediction and using the prediction to leverage maintenance planning, the models differ in many ways. For example, the deterioration distribution and the grading system for asset condition may differs depending on the asset type or the standards set by inspection agencies. Our aim is to build a unified framework that is general enough to encode a wide variety of deterioration models.

The approach of providing unified tools, so called model-based system engineering, has been advocated in both industry and academia. It aims to provide descriptive modelling of systems, common to different system analysis techniques. Importantly, this approach aims to enable decision makers to use analyses without a detailed knowledge of the underlying mathematical models. We review previous work in Section 2 and consider how it applies to deterioration models.

In Section 3, we describe a framework for maintenance domain experts, which does not require a detailed understanding of the underlying deterioration models. Our framework extends standard hierarchical Bayesian models with relational schema, allowing model variants to be expressed using domain concepts. In Section 4, we illustrate the use of the framework with a variety of deterioration model.

2 MODEL-BASED APPROACH

The emerging field of model-based system engineering focuses on bridging the gap between problem specification and modelling (Estefan, 2007), with an agile modelling formalism to meet different modelling requirements without changing the entire tool (Prosvirnova et al., 2013). The model-based approach formalises the system development process using a unified language (e.g. SysML language) to provide a platform integrating different modelling approaches and system analysis methods. This formalism has been extended to the safety and reliability domain, so called model-based safety assessment (MBSA) (see Lisagor et al. (2011)). MBSA aims to unify classical safety and reliability modelling methods (e.g. fault tree and stochastic process), and to generate an integrated structure for a range of safety and reliability analysis (e.g. fault tree analysis and system diagnosis). For example, the AltaRica modelling language (Arnold et al., 1999), separates system specification from analysis with a range of reusable techniques.

The MBSA concept has been applied in deterioration assessment in recent years, with the modelling of stochastic process and Markov chain for complex system developed in project AltaRica 3.0 (Prosvirnova et al., 2013). However, to our knowledge, the current practice of MBSA does not yet encompass learning from data, which is a component of deterioration modelling when since we wish to learn deterioration rates from inspection data. Fortunately, advances in machine learning provide a promising perspective for tackling these problems.

Previous studies have shown the power of a hierarchical Bayesian network (BN) based approach to learn asset deterioration rates from data and how it can be adapted when there is insufficient data, both with expert knowledge (Frangopol et al., 2004, Zhang and Marsh, 2018), or by learning from similar groups (Memarzadeh et al., 2016, Zhang and Marsh, 2018). In the work of Zhang and Marsh (2018), six generic BN models for asset deterioration were developed, which both provides us the possibility of adopt different deterioration models, but also enables us to include alternative data and unused expert knowledge. These model variants cannot yet be presented to an asset deterioration domain expert in a unified framework: adapting the underlying concepts to a particular context requires a deep understanding of their implementation as BNs.

In model-based machine learning (MBML) (see Bishop (2013) and Ghahramani (2015)), models and problem specifications are defined in a compact language, while inference or machine learning algorithm codes are generated automatically. Bayesian networks are such a language, though they lack structure. More recently, probabilistic programming languages such as Figaro (Pfeffer, 2009), has been developed which could also be used in our framework.

Model-based approaches, both in MBML and MBSA, often use the object-oriented paradigm to provide a library of generalized models for reuse. This is not provided by traditional BNs, with a fixed set of variables and relationships. This issue has been widely researched for BNs, with proposals including idioms in Neil et al. (2000) and fragments in Laskey and Mahoney (2000). Probabilistic relational models (PRM), developed by Koller (1999) combines relational structure with probabilistic graphical models (i.e. BNs). A PRM combines probabilistic dependencies with a relational schema that describes the entities in the problem domain. This representation provides a separation between model library and structure relationships.

Therefore, we propose to develop a model-based framework for asset deterioration assessment in the spirit of MBSA. The framework separates reusable low-level models from modelling choices and asset descriptions. The framework is encoded with a PRM representation of a hierarchical Bayesian network, with a range of generalised models for asset deterioration each represented by its probabilistic dependencies, and the problem specification of the target domain is represented as the relational schema.

3 MODEL-BASED ASSET DETERIORATION ASSESSMENT FRAMEWORK

3.1 *Asset deterioration model using hierarchical BNs*

3.1.1 *A simple deterioration model*

For a system that is either working or failed, given historical data on the times that it remained in working condition, we can estimate the distribution of time for its transition to the failed state and so predict its likelihood of failing. A basic deterioration BN model, from Zhang and Marsh (2016), is shown in Figure 1. This is a hierarchical BN model that both learns from data and can be used for decision support.

However, this specific model can only be used to describe a type of asset with two-state and deterioration that follows a one-parameter distribution. This is not usually the case in asset deterioration, for example a 4 point grading system is used to describe bridge condition, and a two-parameter Weibull distribution is used to fit the bridge transition distribution in Sobanjo (2011). So instead, the model has to be adapted: the variables are similar but the number of them and links between them must change.

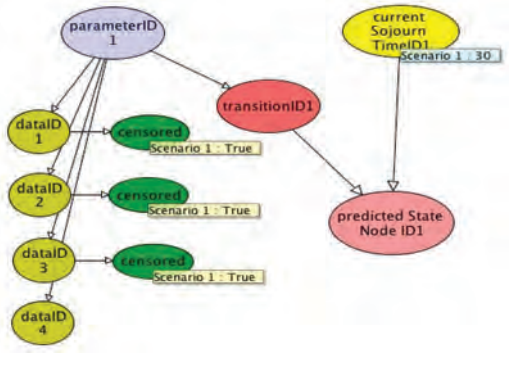

Figure 1. A simple deterioration model.

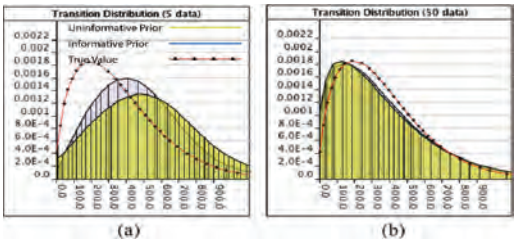

Figure 2. Effects of prior knowledge and data quantity in distribution training.

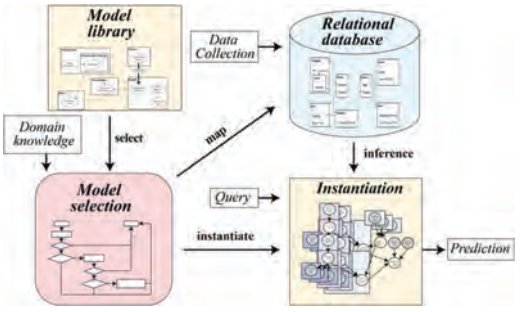

Figure 3. Stages of model-based asset deterioration assessment framework.

The structure of the model may also need to change when we have limited domain data. Although the parameters of the transition distribution are learnt from the historical transition data, some prior knowledge of the transition distribution is also required. In Figure 2, two different prior probability distributions have been used: i) an uninformative prior and ii) an informative prior, available when there is good knowledge representation of the deterioration. Figure 2(a) shows that with good prior, we can provide a good estimate of the true distribution with only a little data, while Figure 2(b) shows a larger dataset will give a correct estimate of the parameter even the prior is weak.

However, when failure data is scarce (which is the usual case in slow deteriorating asset, for example, bridges) or knowledge is poor for a particular asset class (which is also usual for new assets), we can combine data from asset types that, though not identical, are similar and so are believed to have the similar deterioration rate (Morcous, 2011). This kind of approximation is necessary, especially for assets types that are inspected infrequently so that the deterioration dataset is not large enough for each asset types. Two techniques are proposed in Zhang and Marsh (2016): one is to add another layer of parameter (hyper-parameter) to form a hierarchical BN that can group or pool data from different asset types sufficiently to overcome an uninformative prior; the other technique is to use influencing factors to adjust the transition distribution of a specific asset from distribution learned from a pool of similar assets (i.e. assets of the same type). Both methods may change the BN's structure depending on how assets are assigned to groups and what other factors influence the transition times. We refer to these (and related) issues as 'modelling assumptions'.

3.1.2 *A framework for expressing modelling assumptions*

To address the problem of many variants of the deterioration models, we provide a framework to help domain experts express modelling assumptions. The stages of model-based asset deterioration assessment framework can be illustrated in Figure 3:

- The model library encodes the possible dependencies of probabilistic models in the problem domain.
- Model selection uses modelling assumptions to determines what models, knowledge and data are included in the problem model.
- The relational database includes the configuration and failure data; its schema is derived from the modelling assumptions.
- Instantiation and inference, performed automatically, are used to evaluate queries on the model for domain decision support.

The following sections describe each aspects of the framework.

3.2 *Model library: Abstract PRM*

The generic models in the model library are represented as abstract probabilistic relational models (PRMs). Figure 4 shows an example developed from Zhang and Marsh (2018).

In Figure 4, a square (called a class) defines a group of identical objects that share the same set of variables or probabilistic models. An oval defines a variable, and directed edge defines the dependency of variables. Aggregation is defined by a bold arrow. *N* represents a fixed multiple relationship, and * represents a multiple relationship of uncertain degree. The classes are as follows:

Class	Purpose
Asset	We wish to predict the state of a specific asset, conditioned on its previous inspection and the deterioration data of similar assets. This prediction will inform decisions about maintenance and inspection.
Transition	Objects of this class represent transitions in a Markov chain, where the conditional probability of moving into future state S_t+_1 at time $t+1$ given the present state S_t at time t follows a distribution with parameters learnt from data.
Data	Data is gathered from inspections, each giving information about the current state of an asset. Different types of data are used: for example, it is common to have only censored data giving a time after which a transition occurred. This is modelled as constraints on the transition time.
Group	Assets of the same type form a group. A group is represented by the model by parameters of the distribution (for each transition) learnt from historical data for this type of assets. Since the parameters are learnt, their values are uncertain and the model include them as probabilistic variables.
Parameter	The population as a whole also has distribution parameters. The similarity of each group of assets to the population as a whole is judged and this establishes a way to learn a group's distribution parameters from data of other closely related groups.
Factor	The idea of assets of the 'same type' is defined in relation to properties of the asset that influence deterioration rate. However, if all relevant factors are used to distinguish groups then there is likely to be insufficient historical data to estimate the transition distribution parameters. Therefore, groups need to be defined by the factors that are most important (and are known for all assets). Other factors—for example, loading and environment condition—can be used to estimate a target asset's distribution.

We describe this model as 'abstract' as it represents number of different structures. In particular, the following issues need to be resolved to give a specific model:

- The distribution (Weibull or exponential) used for the transition and the number of parameters needed.
- The population priors.
- The number of state of deterioration and therefore the number of transitions between states.

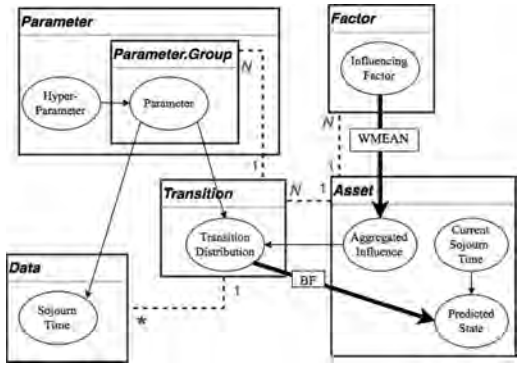

Figure 4. Probabilistic dependencies represented as an abstract PRM.

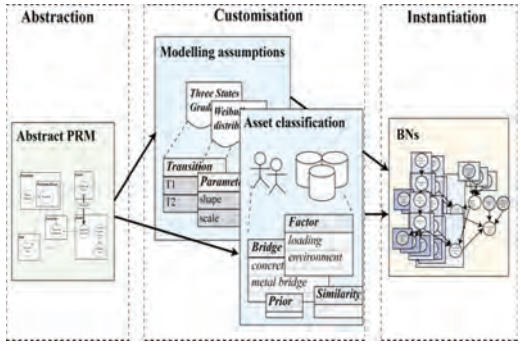

Figure 5. Process to customise the abstract PRM.

- The number of asset groups (or types) and the factors (e.g. material used in construction) used to define membership of a group.
- The similarity of each group to the population as a whole.
- The remaining factors that adjust the transition distribution, possibly varying by group, and the weighting used to aggregate the effect of these factors.
- The types of data available.

Although these factors are uncertain they are not part of the probabilistic reasoning. Instead, these are the decisions made by domain experts to apply the generic models to a specific situation. The next two subsections describe how this is done: the first covers 'modelling assumption' and the second asset classification. Together, as shown in Figure 5, these processes turn the abstract probabilistic model into a model that can be run.

3.3 *Customising the abstract PRM with modelling assumptions*

This aspect of the customisation covers four issues: a) the choice of transition distribution; b) the number of deterioration states; c) prior distributions and d) available inspection data.

3.3.1 *Transition distribution and parameters*

Different distributions can be used to estimate transition times, based on their goodness of fit. The goodness of fit of the distribution is usually done by visual observation and hypothesis test, such as coefficient of determination (R^2) and Anderson Darling (AD) test (Mendenhall et al., 2012). A range of study has been developed to find the best fit distribution of asset state sojourn times. For example, the exponential distribution has been used for railway track (Guler et al., 2011) and the Weibull distribution for bridges (Sobanjo, 2011). The number of parameter in the distribution's survival function fixes the number of instances of the Parameter class for each Transition. An example is showed in the left side of Figure 6: there are two instances of class of Parameter if the guideline shows a Weibull distribution is normally adopted in practice.

3.3.2 *Deterioration states used for grading*

Each asset is usually rated with a state representing its functionality. For example, a 4 point grading system is used in Sobanjo (2011). Grading systems are normally adopted from industry standards and are often used to identify and priorities maintenance actions. They vary for different infrastructure type, countries, and sometimes, inspection agencies. An *n*-states grading system results in *n–1* transitions represented in the instantiation of class Transition. An example is showed in Figure 6's right side: there are two instances of class Transition since it is rated by a three-state grading system.

3.3.3 *Asset deterioration characteristics: Prior*

Classical statistical methods, such as maximum likelihood estimators or least square method can be used to estimate priors if the data are sufficient. An alternative source is the expertise from experienced engineers (Welte and Eggen, 2008) from whom a prior range can be elicited. In addition, each group of assets is also characterised by its degree of similarity to the overall population. These group parameters are modelled used a truncated error distribution, with a mean inherited from the value of the learnt hyper-parameters, and the elicited degree of similarity defining the variance.

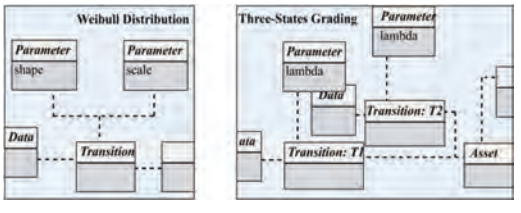

Figure 6. Example customisations of transition distribution and grading system.

3.3.4 *Inspection data: Inferring state sojourn time*

Continuous monitoring can provide exact transition times but periodic inspection is more common. In periodic inspection, the state of asset is only known at the inspection times. Therefore, the time an asset stayed in a state before deteriorating to another state is only constrained by the inspection result. Fortunately, this type of censored data can be modelled by different variants of the Data class. For example, periodic inspection requires three types: left, interval and right censored representing the state transition happening before, between and after the inspection respectively.

3.4 *Asset classification*

Asset deterioration rate may be influenced by many contributing factors, such as age, loading and environment (Fu and Devaraj, 2008, Wellalage et al., 2014). By classify assets into groups with the same factor levels, we can expect groups to have similar patterns of deterioration (Veshosky et al., 1994). Our framework provides two ways to adjust deterioration based on such factors:

1. **Grouping**: some factors are chosen to define groups of assets so that historical data can be pooled and used to learn assets deterioration parameters. The number of groups fixed the number of instances of the Group class in the abstract probabilistic model.
2. **Adjusting**: other factors are used to adjust the deterioration rates learnt from data. A range of studies has been developed to identify these impact factors, for example, closeness to the coast, galvanic response level and structure type are identified in Yianni et al. (2016) as the key contributing factors for railway bridge deterioration. The number of these factors fixes the number of instances of the class *Factor*. The importance of each factor in the aggregated effect is modelled by a weight and this is used to shift effect of the learnt parameters.

3.5 *Model instantiation*

The final stage of the process shown in Figure 5 is the instantiation of the BN. This set is provided by

the framework as the domain expert has expressed all the information needed in the steps described in sections 3.3 and 3.4.

As Figure 3 shows, the customisation process also defines the schema of the database that holds both configuration parameters and the records of assets and inspections results. The class of each asset is defined either directly or inferred from the values of factors held in the database.

Suppose that investigated asset is x, where x belongs to group g, which is similar to group h. We suppose that some time has elapsed since x was last inspected and we wish to estimate its current state. The following steps are involved to instantiate the BN:

1. Creating transition variables for each deterioration stage of asset classes g and h.
2. Creating hyper-parameters for each transition of group and at the population level. The group parameters approximate the population ones, using the similarity degree defined for the group.
3. Create the variables for the state of x and its adjustment by the factors (the ones that do not define the grouping). The values of the factor variables are extracted from the database and used as observations in the probabilistic calculation, but note that the model still operates if any of the values are missing (provided that priors have been provided).
4. Create variables for the all the inspection data—taken from the database—for both groups g and h. Starting from the current state, the inspection reports show either that one transition has occurred since the previous inspection or that no transition has occurred. By selecting the appropriate variant of data object both of these observations can constrain the transition time. It is even possible for more than one transition to have occurred between inspections.

For illustration, we assumed that it was known that group h needed to be include alongside data for assets in group g, the group to which x belongs. Two steps are involved in automating this. Firstly, we need to determine whether the number of observations in group g is sufficient to give a good estimate of the deterioration rate. We could evaluate this either from the variance of the learnt parameters or from a threshold value on the absolute number. The second step is to find the group that is closest in characteristics to g, perhaps by the proportion of the values of the factors that define the groups shared between the two groups.

3.6 *Inference and refinement*

Inference of the ground BN is performed automatically in the model-based machine learning framework. As suggested previously, probabilistic programming languages with an extensive list of inference algorithms can be adopted. For example, when dealing with hybrid Bayesian network that contains both discrete and continuous variables, Gibbs sampling can be used.

The query – to predict the unknown state of asset x – has to be expressed in domain terms and translated to a query on a BN variable. The result is a probability distribution over the possible states and further 'decision rules' or guidelines are needed to determine an action. For example, a small probability of the worst state of deterioration may determine that an urgent inspection is required.

Model evaluation can be made by comparison of different variants of the model, with the metrics such as predictive accuracy or computational speed. Further refinement of data sources (e.g. from other source domain), expert knowledge (e.g. different experts or different types of expertise), and variations in the models (e.g. different groupings of assets) are possible. This process repeats until a level of acceptable performance is accepted or it exhausts all the resource. As a future study, with the success of automatic inference software (Bishop, 2013), the refinement process can be made automatically with a defined threshold in a model-based machine learning framework.

4 REPRESENTING ASSET DETERIORATION MODEL WITH DIFFERENT STRUCTURE

Customised instantiation of this framework for practical uses have been developed, for example, general maintenance problems in Zhang and Marsh (2016), and rail bridge deterioration in Zhang and Marsh (2018). Since the focus of this paper is to show how the model-based asset deterioration framework to deal with different modelling assumptions that may happen in practice, we present a series of instantiation variants of a basic deterioration model, which is sufficient to convey the idea.

4.1 *The simple deterioration model*

The basic deterioration model is showed in Figure 1, and Table 1 shows its customisation setting. Notes that since the focus of this section is the model structure, we only show the setting that have influence on the shape of the model structure.

From the practice guideline, we decide there is only one transition (because it only has a binary state: working or failed), one group (representing the entire group has only one subgroup, the prior of

Table 1. The setting of the model in Figure 1.

	Transition distribution	Grading system	Prior	Sojourn time
Customisation	Exponential (λ)	Binary states	λ ~ Uniform (0, 0.05)	15 < sojourn < 35 12 < sojourn < 24 12 < sojourn < 36 sojourn = 24

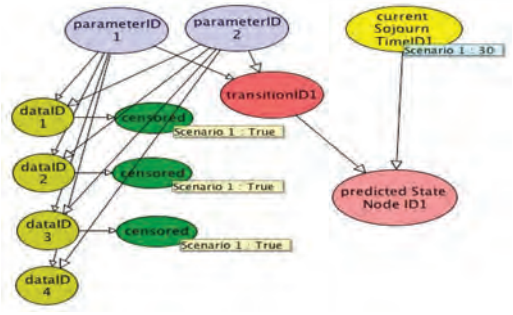

Figure 7. Deterioration follows a two-parameter distribution.

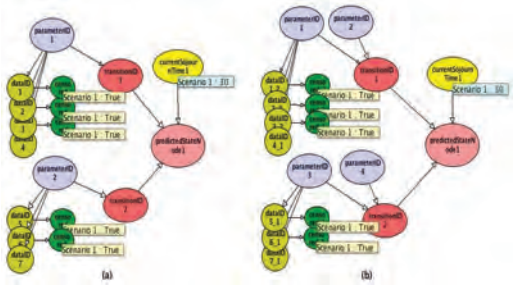

Figure 8. Deterioration under multi-states: (a) Markov chain based; (b) semi-Markov chain based.

the hyper-parameter becomes the prior of parameter), and one parameter (because its distribution is exponential). The expression of transition follows the distribution parameter in Parameter class, while the parameter's prior is given by experts, here is a uniform distribution between 0 and 0.05. Four sojourn time data are inferred from the inspection data, and three of them have censorships.

Based on this model, a range of variants can be extended to represent different assets, whose underlying modelling assumptions vary.

4.2 *Variant 1: Deterioration that follows a two-parameter distribution*

Extended from the basic model, Figure 7 presents a deterioration model of asset that follows a two-parameter distribution. Studies have found that transition probabilities between states of some assets are better fitted with distributions with two or even more parameters. For example, the two-parameter Weibull distributions for bridge deterioration are suggested in Ng and Moses (1998) and Sobanjo (2011).

This is achieved by the one-to-many relationship encoded in the relational database. Each instance of Transition class is linked to two identical instances of Parameter class.

4.3 *Variant 2: Deterioration under multi-states*

Asset may degrade with several stages representing the decrease of its functionality. For safety and reliability reasons, they can be rated from perfectly working to completely failure accompanied with several intermediate states. Extended from the last two subsections, Figure 8 shows two deterioration models for multiple states asset.

Degradation of asset with multi-states is modelled in the form of a Markov chain (Figure 8 (a)) by a sequence of states (represented by the transition nodes) representing the condition of an asset over time. Markov chain deterioration models are widely accepted in modelling most asset's life-cycle performance (Frangopol et al., 2004), but they also bear with the assumption that the transition probabilities between states follow the same stationary transition rate, which do not change over time. This property implies the sojourn time follows an exponential distribution regardless how long it has been in the current state (Ng and Moses, 1998). This is modelling is performed by the one-to-many relationship in the relational database: one instance of Asset class with two instances of transition class.

This restriction can be relaxed by semi-Markov model (Figure 8 (b)), which allows the modelling of transition probabilities to follow non-stationary distributions depending on current state and its next state. This extension enables the modelling of multi-state deterioration that follows multi-parameters based distributions. This modelling is performed by the many-to-many relationship: one instance of Asset class with two instances of transition class, and each instance of transition class links to two instances of parameter class.

4.4 *Variant 3: Learning from similar assets*

Assets classified into different groups may share similar deterioration rate, which gives a potential to learn from others. Two types of learnings from similar assets are presented:

1. Figure 9 shows an example of pooling all the available data to learn a universal distribution in the domain, and distinguish a specific asset by defining the influence of aggregated external factors on deterioration rates. A suggestion use of this form is in the situation when the entire population has little data. This is achieved by the instantiation of Factor class.
2. Figure 10 shows an example of pooling available data within its associated group to learn their own distribution but governed by their shared hyper-parameter introduced by hierarchical BN. This hyper-parameter helps the transfer learning of the weekly learnt group (typically target group with little data) from strongly learnt group (source groups with lots of data). A suggestion use of this form is in the situation when the groups are highly correlated. This is achieved by the introduction of the class hierarchy by adopting layer 3 data sources.

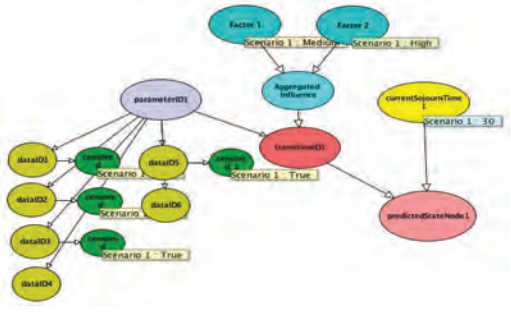

Figure 9. Distinguish an asset's deterioration from factors.

Figure 10. Learning from other groups hierarchically.

5 CONCLUSION AND FUTURE STUDY

We have argued the need to provide a generalised asset deterioration framework encoded by probabilistic relational models, which can be adapted to model assets with different modelling assumptions. The emerging field of model-based approach gives us a suitable formalism for separating specifications from analysis techniques, and we have applied this to asset deterioration.

We also used several variants of the deterioration model to demonstrate how it can be adapted to a variety of applications with different modelling assumptions. In the future, we hope to extend the amounts of models in the model library, and extend the applications to more safety and reliability related problems.

Industry 4.0 and real-time synchronization of operation and maintenance

J. Vatn
Department of Mechanical and Industrial Engineering, NTNU—Norwegian University of Science and Technology, Trondheim, Norway

ABSTRACT: Industry 4.0 represents a trend in manufacturing which includes cyber-physical systems, the Internet of things, cloud computing and cognitive computing. Cyber-Physical Systems (CPS) refers to smart systems that include engineered interacting networks of physical and computational components. The term digital twin refers to a digital replica of physical assets, processes and systems that can be used in real time for control and decision purposes. The digital twin representation is seen as a prerequisite for effective synchronization of operation and maintenance within the manufacturing industry as well as in other industries. The relation between production plans and activities and actual production can to some extent be described by deterministic. The relation between maintenance plans and activities and the production system availability on the other and requires probabilistic representation. The term stochastic digital twin is therefore introduced. An ambition of Industry 4.0 is to support real-time processing whenever possible. This paper discusses elements of Industry 4.0. A case study is provided to demonstrate these terms and challenges to the mathematical modelling required for optimal synchronization of operation and maintenance.

1 INTRODUCTION

1.1 *Background*

Nowadays Industry 4.0 and digitalization are frequently used terms for the changes that are taking place in industry, civil engineering, transportation, public services and so on. The "4.0" refers to the forth industrial revolution and points to the opportunities communication over the internet gives with respect to real-time control of processes at almost every level. Industry 4.0 and related concepts as cyber-physical systems, internet of things, cloud computing and digital twins give new opportunities for both production and maintenance, but even more important the synchronization and coordination of the two.

1.2 *Objective*

The objective of this paper is to clarify basic terms and elaborate on basic elements of Industry 4.0 in relation to real-time synchronization of operation and maintenance. A case study from the railway sector is used to exemplify the concepts.

2 DEFINITIONS AND CONCEPTS

Industry 4.0 is a collective term particularly used in manufacturing to emphasize technologies and concepts of value chain organizations. Further the terms Cyber-Physical Systems, the Internet of Things, Cloud computing and the Digital Twin are often used in relation to Industry 4.0. Although the term originates from the manufacturing industry, the elements of Industry 4.0 are relevant for most businesses.

The current usage of the term Industry 4.0 has been criticized as essentially meaningless. The 4.0 points to the forth industrial revolution under a premise that digitalization is the really new thing. But why digitalization and not Nano technology? Further, the content of Industry 4.0 also seems to vary from industry to industry, and from author to author. From a scientific point of view it might therefore be better to avoid a precise definition but rather focus on Industry 4.0 *elements*.

The aim of this paper is to shed light on Industry 4.0 elements that are relevant for the interaction between production and maintenance. Here production has a very broad meaning, it could cover manufacturing, logistics, transportation systems, hospitals, power supply and so on.

The *Internet of Things* (IoT) is the network of physical devices, production facilities, cars, airplanes and in general items embedded with electronics, software, sensors, actuators, and network connectivity which enable these objects to connect and exchange data. Each "thing" is able to interoperate within the existing Internet infrastructure.

The IoT allows objects to be sensed or controlled remotely across existing network infrastructure, creating opportunities for more direct integration of the physical world into computer-based systems. When IoT is augmented with sensors and actuators, the technology becomes an instance of the more general class of *Cyber-Physical Systems* (CPS).

Cyber-physical systems (CPS) refers to smart systems that include engineered interacting networks of physical and computational components.

Cloud computing is an information technology paradigm that enables access to shared pools of configurable system resources. The companies can focus on their core businesses instead of expending resources on computer infrastructure and maintenance. Downsides of such a strategy could be unexpected operating expenses if administrators are not familiarized with cloud-pricing models and vulnerabilities and security issues. In some presentations the term Internet of Services (IoS) are used rather than cloud computing.

The term *digital twin* refers to a digital replica of physical assets, processes and systems that can be used in real-time for control and decision purposes. The digital twin representation is seen as a prerequisite for effective synchronization of operation and maintenance within the manufacturing industry as well as in other industries. The relation between production plans and activities and actual production can to some extent be described by deterministic models. The relations between maintenance plans and activities and the production system availability on the other and require probabilistic representations.

A *stochastic digital twin* is a computerized model of the stochastic behaviour of a system where the model is updated in real time based on sensor information and other information accessed via the internet and the use of cloud computing resources.

To be useful a digital twin needs "what-if" capabilities. This means that the decision makers, i.e., humans or computers, shall be able to "ask" the digital twin what will be the consequences of various decisions. For a stochastic digital twin this means that the "answer" is given as a set of probability statements.

A *real-time model* is a model where it is possible to obtain values of system performance and system states in real-time. With real-time we mean that data referring to a system is analysed and updated at the rate at which it is received. As for the digital twin a real-time model typically connects to the "real world" via the IoT, although other means of communication is also possible. A real-time model is also referred to as an on-line model.

A *test model* is a mathematical model describing relations between future and current values of the variables of interest, but where we are not able to monitor system performance and system sates in real-time. Such a model is often referred to as an off-line model. A test model is still valid in order to establish decision rules to be used in real-time.

Most methods and models used in production planning and optimization as well as in maintenance planning and optimization are off-line models. These models can be used for establishing optimal strategies, but they can not give real-time decision support. Areal-time model is often used to describe a limited part of a system, whereas a digital twin aims at giving a complete digitalized representation of the system and decision processes.

A *real-time decision support systems* is a system where relevant data is collected and processed into relevant information in real time. This means that the raw data stream is automatically collected and processed into information. Information is further interpreted in such a way that it gives meaningful decision support.

A *real-time execution system* is a system which implement algorithms to determine optimal decisions at time, and then execute these decisions. An example of a real-time execution system is an Automated Replenishment Program (ARP). The aim is to provide automated replenishment of products based on real-time demand information to the production, warehouses and distribution processes in the supply chain. This corresponds to real-time control in control theory. Similarly for maintenance a real-time execution system will automatically issue a work order with task descriptions and due date.

Predictive maintenance builds on the idea to utilize the condition of a component and the future expected loads in order to judge the correct time for "hard" maintenance such as overhaul, replacement of worn parts, calibration and so on. Sensor technology is usually used to capture the condition of components or a system, and the term 'condition monitoring' is often used to describe the collection and analysis of state data relevant for predictive maintenance. It should be noted that manual inspection and use of "human sensors" to capture noise, smell, vibration could also be treated as condition monitoring.

3 THE DIGITAL TWINS

This section presents principal elements of the digital twins for maintenance and production.

3.1 *Maintenance*

To a large extent the Computerized Maintenance Management System (CMMS) could be seen as a digital twin for maintenance. Principal content found in the CMMS are the asset register covering all components, the Preventive Maintenance (PM) program covering the type of maintenance and the

plan for maintenance. The CMMS will also contain required spare parts, resources and tools for conducting maintenance and so on. But there is relevant information not found in the CMMS which is essential for the stochastic digital twin to be developed. First of all the CMMS has no inherent mathematical models to be used for degradation development and time to failure. Further information regarding component condition is often not part of the CMMS, and needs to be obtained from stand alone systems operated in parallel to the CMMS. Further the CMMS is not connected to the supervisory control and data acquisition (SCADA) system and other systems giving information regarding process parameters and future loads from production and the environment.

It is beyond the scope of this presentation to write out the details regarding the content of a stochastic digital twin for maintenance. For illustrative purposes and for use in the case study presented later a very simple digital twin is presented in the following. Although we in many situations can do much better, the classical failure rate function is used as a basis. The situation relates to so-called delay time models (Christer 1987), often referred to as PF-interval models. The situation is as follows: A component is put into service at time $t = 0$. Then after a random time the component enters a degraded state. This state is often referred to as a potential failure. It is assumed that a condition monitoring activity can reveal such a potential failure with some detection probability, say $1 - q$. If no action is taken the component will fail after another random time T_{PF}. A Cox proportional hazard rate function (Cox 1972) is used as a basis for formulating the failure rate function, $z(t) = f(t)/R(t)$ for T_{PF} (t is running time after the potential failure has occurred). T_{PF} is often referred to as the PF-interval, and the corresponding failure rate function is:

$$z(t \mid \mathbf{y}, \overline{\mathbf{x}(t)}) = z_0(t) e^{\beta_1 \mathbf{y}} e^{\beta_2 \overline{\mathbf{x}(t)}} \quad (1)$$

where $z_0(t)$ is a baseline failure rate function, typically on the form $z_0(t) = \alpha\lambda^{\alpha} t^{\alpha-1}$ in the Weibull case. $\mathbf{y}$ is a vector of state variables at the point of time of the potential failure is observed, $\overline{\mathbf{x}(t)}$ and is the average load profile t time units ahead. β_x and β_y and are regression coefficient vectors established by for example statistical analysis of data.

The failure rate function in eq. (1) is a classical model and it could be questioned whether this model represent at digital twin. A prerequisite for being at least a part of a digital twin is that $\mathbf{y}$ could be accessed from sensor readings and communicated via the internet. Further $\overline{\mathbf{x}(t)}$ needs to be accessed in real time from enterprise resource planning (ERP) systems and other system for future production plans.

If eq. (1) is part of the stochastic digital twin we may now "ask" for the probability of failure if we wait for example t time units before the potential failure is fixed:

$$F(t \mid \mathbf{y}, \overline{\mathbf{x}(t)}) = 1 - e - \int_0^t z(u \mid \mathbf{y}, \overline{\mathbf{x}(u)}) du \quad (2)$$

Only a few aspect of the "maintenance twin" are elaborated here. For real applications it will be an enormous amount of work to structure the raw data, information, knowledge, models and so on to have a digitalized stochastic maintenance twin.

3.2 *Production*

There are so many aspects to deal with when it comes to production and logistic optimization that we will not even make an attempt to cover these in this presentation. However, with respect to maintenance there are some important aspects that we will emphasize when setting up the digital twin for production.

3.2.1 *Objective function*

Operations Research (OR) is the systematic approach to optimize production under various constraints (Phillips, Ravindran, & Solberg 1976). The objective function, Z, is typically the quantity to maximize or minimize with respect to some vector of decision variables, say $\mathbf{x}$, i.e., $Z = Z(\mathbf{x})$.

3.3 *Constraints and conditions*

Usually there are constraints to take into account in the optimization, for example a set of functions, say $g_j(\mathbf{x})$ should all be positive. In addition to these constraints we also have to optimize $Z = Z(\mathbf{x})$ subject to $\mathbf{S}$, where $\mathbf{S} = [s_1, s_2, \ldots, s_n]$ is the state vector of the components in the system. For example $s_i = 1$ could represent that component i is functioning, and $s_i = 1$ represents a fault state.

It should be emphasized that both the objective function and the constraints and conditions are changing all the time. It is therefore required to have real-time access via the internet to the "physical" plant, existing orders, inventory levels and so on.

3.4 *Maintenance interaction*

The digital twin for production will also be a *stochastic* twin due to the probabilistic nature of production optimization. From classical OR examples variability in supply and demand are the main sources for uncertainty. However, we will focus on the relation to maintenance. Important aspects that need to be structured as part of the digital twin for production are:

- Slots for maintenance, i.e., possible opportunities for doing maintenance

- Specifications of how utilizing possible slots will affect the objective function $Z = Z(\mathbf{x})$ and the constraints $g_j(\mathbf{x})$
- Specification of possible "relaxes" in production, for example avoid running a component with full load if a "potential failure" has been revealed
- Specifications of how such "relaxes" will affect the objective function $Z = Z(\mathbf{x})$ and the constraints $g_j(\mathbf{x})$.

Note that the objective function $Z = Z(\mathbf{x})$ in traditional OR does not include maintenance. Since the objective of this paper is to investigate synchronization and coordination of activities in the production and maintenance departments, the objective function should cover both departments.

4 CASE STUDY

4.1 *Introduction*

A railway example is used to demonstrate challenges in synchronization and coordination of activities in the production and maintenance departments. Only few aspects are dealt with, and issues related to really establish the stochastic digital twins and have them to play together is not addressed in this presentation. One aspect of "digitalization" within maintenance is related to increased used of predictive maintenance. Turnouts (switches) are important components in the railway infrastructure, and failure of a turnout will usually give large problems with the circulation, and delays are expected. Although various condition monitoring techniques exist for turnarounds, they have not been implemented on the Norwegian railway network due to high cost. In Norway Bane NOR is a state-owned company responsible for the Norwegian national railway infrastructure. In recent years Bane NOR has been running a test project on a simplified predictive maintenance strategy for turnouts based on measuring only power as function of time when the traction motor is activated to change the position of the turnout. The time required for changing the position of the turnout varies from one to up to 20 seconds. The idea is that the power as function of time for each individual turnout is a "signature" for that turnout, and deviation from that signature could be seen as a potential failure as discussed in Section 3.1. The main advantage of this system is that the information is available more or less "free of charge". The challenge is to use it in an efficient way.

The system has been piloted over a period of almost 3 years. As part of the pilot project data have been analysed for one of the turnouts. In a follow up project it is planned to conduct more comprehensive analyses. During the test period 11 failures were observed. For 3 of these failures a potential failure was not observed at all. Thus the reliability of the condition monitoring system is only some 70%. The analysis was conducted by visual analysis of the power/time curve for all movements of the turnout for a period of 10 days prior to the failure. More comprehensive analysis could obvious give a higher reliability.

4.2 *The PF-interval model*

The average PF-interval, i.e., the estimate of $E(T_{PF})$ were found to be 80 hours. However, 2 failures had an observed PF-interval of less than 3 hours. To estimate the parameters in the failure rate function in eq. (1) assuming a Weibull distribution and ignoring covariates $\mathbf{y}$ and $\mathbf{x}(t)$ we may use the following procedure:

1. Let x be such that $F_T(x) = p_x$ where both x and p_x are known. It can be shown that the following iterative scheme may be used to estimate α: $\alpha_{i+1} = \frac{\ln(-\ln(1-p_x))}{\ln(x\Gamma(1+1/\alpha_i)/E(T_{PF}))}$
2. For the location parameter we use set: $\lambda = \Gamma(1 + 1/\alpha)/E(T_{PF})$.

In the example we had $p_x = 2/(11 - 3)$ and $x = 3$ hours, and $E(T_{PF}) = 80$ hours. Applying the procedure this will give $\hat{\alpha} \approx 0.49$ and $\hat{\lambda} = 0.026$. It should be noted that $\alpha < 1$ means that the PF-interval is not very consistent. The reason for the low value of α is that we are mixing several failure mechanisms. There are three main failure mechanisms with quite different characteristics here, i.e., snow and ice with short PF-interval, lack of lubrication with a medium PF-interval, and mechanical failure with a rather long PF-interval. This means that we need to apply the procedure above for each separate failure mechanisms. From the failure statistics obtained from the pilot project we do not have sufficient number of observations to apply the procedure above. For the case study we will proceed with assuming that the failure mechanism is related to lack of lubrication and without any statistical support we set $\hat{\alpha} = 2$ and $\hat{\lambda} = 0.0246$ corresponding to $E(T_{PF}) = 36$ hours.

4.3 *The initial cost model*

The operational hindrance cost of executing a "hard maintenance" task, and the cost of a failure depends on the position of the turnout, the time of the day, the traffic and so on. Therefore an example situation is presented in the following.

The location of the turnout is assumed to be on a part of the line where access only can be made by means of a work train. We assume a single track line where access by the work train will disturb the circulation. Investigating the time table for today four opportunity windows have been identified. They are shown in column 1 in Table 1. The first

Table 1. Optimization results.

t (hours)	Delay (min)	c_{PM}	c_F	c_{Tot}
3	30	18 500	441	18 941
5	15	11 750	1 218	12 968
7	10	9 500	2 370	11 870
9	0	5 000	3 880	8 880

Table 2. Optimization results—with covariates.

t (hours)	Delay (min)	c_{PM}	c_F	c_{Tot}
3	30	18 500	822	19 322
5	15	11 750	3 422	15 172
7	10	9 500	9 812	19 312
9	0	5 000	22 562	27 562

three of these will, however, cause delays in circulation. The expected delay minutes for each window is shown in column 2 in Table 1. In average there are 150 passengers per train and a minute delay cost per passenger of 3 NOKs is used by Bane NOR. In addition to the delay cost there is a fixed cost of NOK 5 000 for ordering the work train and associated personnel cost. If the failure can not be "caught" in due time, the expected total delay is 3 hours. The cost equation to minimize is:

$$C(t) = c_{PM}(t) + c_U F(t) \tag{3}$$

where $c_U = 3 \cdot 150 \cdot 60 \cdot 3 = 81\,000$ NOKs, $F(t)$ is given by eq. (2). Table 1 shows that in this situation one should utilize the last maintenance window since the circulation is not affected, and the probability of failure is still rather low. It can be shown that if the failure mechanism is ice and snow, and assuming $E(T_{PF}) = 10$ hours and $\hat{\alpha} = 2$ the risk is much higher, and one should rather use the first opportunity. Note that the optimization here is seen from the maintenance department, i.e., the only "production" related cost is the increased c_{PM}-cost by rushing the maintenance.

4.4 *The refined cost model*

So far the covariates $\mathbf{y}$ and $\overline{\mathbf{x}(t)}$ have been ignored. We now introduce two variables, y which is a measure of degradation at the point of detection of the potential failure, and x as the number of times per hour the turnout will be operated. The proposed Cox proportional hazard model reads:

$$z(t \mid y, x(t)) = z_0(t) e^{\beta_y y + \beta_x x t} \tag{4}$$

For simplicity we have assumed that the number of train passages per hour is constant over the day. From the case study we do not have sufficient data to estimate β_y and β_x. We will therefore proceed with illustrative values for these parameters. That is, for the example we proceed with $\beta_y = \ln 2 \approx 0.69$ and $\beta_x = 0.1 \ln 2 = 0.069$.

Now, assume that at the time of the potential failure we assess $y = 0.15$ by analysing the power vs time curve from the condition monitoring system, and further from the time table we wind $x = 2$. Table 2 shows the result when the covariates are taken into account. Compared to the original situation we have to advance the point of time for doing hard maintenance, i.e., lubrication and required adjustments. The number of times per hour we operate the turnout, x, is a decision variable seen from operation. Since the failure rate function is increasing with increasing value of x, we should investigate whether it pays off to reduce x. Now, assume that wecan completely remove the need for operating the turnout by changing the station where trains are crossing. This corresponds to set $x = 0$ in the model. Rerunning the model shows that the optimal value of t is $t = 9$. The cost has been reduced from 15 172 to 12 249, i.e., a total saving of ≈ NOK 3 000. However, if this causes total delays of more than 7 minutes the delay cost will be higher than the savings. For the railway case it seams unrealistic that changing the crossings for the actual station for an entire day will not cause more than 7 minutes of total delay.

A first attempt to formalize such a "relax" strategy is to add an extra cost term in the objective function, $c_R(x)$:

$$C(t,x) = c_{PM}(t) + c_U F(t \mid y, x) + c_R(x) \tag{5}$$

The joint optimization of t and x is not pursued further in this presentation.

5 DISCUSSION

The objective of this paper has been to investigate "Industry 4.0 solutions" to facilitate synchronization and coordination of operation and maintenance. By a "paper exercise" it is rather easy to demonstrate how this can be done, and potential savings. This section discusses challenges when such ideas are to be implemented for real systems.

5.1 *Slots for maintenance and consequences for the production model*

In order to synchronize and coordinate production and maintenance it is essential that the digital twin on request can provide time slots for maintenance and evaluate the production consequences for each possible slots. In the example we assumed that "some" could establish the time slots at 3,5,7 and 9 hours. Here, "some" could be a train manager

at the Train Control Centre (TCC). But this is not really a part of the "digital twin" for production. To develop a digital twin all production plans, cost optimization functions etc. need to be implemented in a computerized system supported with algorithms to both find possible slots, and do calculations to evaluate the consequences. For the railway example we are far from realizing such systems. To the author's knowledge the situation is the same in most Norwegian industries.

The way forward is therefore to develop simplified production models. For example in Norway a simplified circulation model for use by the TCC-personnel upon traffic deviations to assist planning has been developed. The model acts like a "what-if" tool that can simulate the consequences if crossing is moved to station A rather than on the scheduled station B. It is hard to spot significant achievements here unless modelling competence within the companies is significantly increased. A vision behind "cloud computing" is that ready to use models could just be plugged in whenever needed. But still this is a vision.

5.2 *Specification of possible "relaxes" in production*

In the example, and in many real case situations a mitigating measure upon a component degradation is to reduce the load on that component to increase residual life. An even more realistic example than the railway example is maintenance and operations of wind farms. A wind farm can be difficult to access in periods of the year due to harsh weather conditions. Upon a potential failure of for example the main bearing of the turbine it may be better to close down the turbine in situations with high wind loads. Although this will reduce the power produced for some hours, it might prevent a failure which would have made the turbine unavailable for weeks and even months.

The digital twin for production therefore need to respond upon request on what are the possible "relaxes" that could be made in production that will have a positive impact on residual life of a component. In addition to respond on *what* can be done, the digital twin also needs to specify the consequences, for example by quantifying the reduced production.

5.3 *Maintenance models*

The literature in the field of maintenance optimisation produces every year a huge number of models. Very few of these models are used in practice. One reason for this is that it is hard to get access to statistical data for estimation of model parameters. In our example we need to estimate α, λ, β_Y and β_X. Further this have to be done for all failure mechanisms. We can easily imagine an enormous workload. Next, comes the question whether the Cox-proportional hazard model is the appropriate model to use. It is rather simple, but it does not really take into account the physical aspects of the phenomenon causing a failure.

The prospects for the maintenance twin is therefore also not that promising. Again, starting with a set of rather simplified models seems a natural first step.

5.4 *Machine-learning*

Machine learning is a field of computer science that gives computers the ability to learn without being explicitly programmed. Machine-learning is quite different from the model based approach advocated here. A strength of machine-learning is it's efficiency to produce huge amount of results without the explicit need to do all the "hard work". From a model based approach perspective most of us are reluctant to just "let the computer work out the answers". However, for sub-problems like establishing a failure model, looking into machine learning approaches are more acceptable.

5.5 *Real-time execution models*

An objective of Industry 4.0 solutions is to have automated decision processes. For simple situations such as replenishment in retail we see automated replenishment policies. However for mixed problems as discussed here it is a long way to go to get trust in real-time execution models.

6 CONCLUSIONS

This paper has discussed steps in synchronization of operation and maintenance. An example was provided to illustrate some of the challenges and opportunities this will give. With idealized examples and simplified assumptions we are able to carry out relevant modelling. Still, these models are test (off-line) models and integration into real-time (on-line) models require significant effort. To succeed it is recommanded to start with a relative small set of standardized models for critical processes in the value chain of the company.

ABSTRACT: Many papers are dedicated to maintenance strategies of deteriorating systems and almost all of them share a common assumption that the parameters of the degradation process are known. In this paper, we deal with a dynamic and aperiodic condition-based maintenance of single-unit systems with unknown parameters of deterioration. It has been considered that the deterioration is governed by an Inverse Gaussian (IG) process. The time interval between two successive inspections is scheduled based on the Remaining Useful Life (RUL) of the system. The Bayes method is employed to use the available information of degradation paths and update the information about parameters during the time. The proposed maintenance decision rule aims to avoid too frequent and costly inspections by implementing an aperiodic planning. The decision process is dynamically improved with the successive Bayesian update of the degradation parameters. The ability of the proposed modeling framework to drive the Bayesian update while controlling the number of inspection is analyzed through numerical experiments. The global maintenance cost is considered over a finite time horizon.

1 INTRODUCTION

Maintenance decision making is of prime importance to improve the global performance of industrial systems and structures during their useful life. Different strategies for maintenance can be considered, see Wang (2002). Their choice depends mainly on the system failure process and on the associated monitoring system. This paper is related to systems or structures which gradually deteriorates from initial "new" state to failure and whose degradation level can be perfectly observed through inspections. In this general context, predictive and Condition-Based Maintenance (CBM) strategies are understandably relevant candidates. Actually, they allow to adapt decisions about maintenance actions and the inspection scheduling to the current system state and possibly to remaining lifetime estimation including prospective usage. The global design of a predictive or condition-based maintenance policy requires mathematical modeling which brings together deterioration model, maintenance decision-rule and cost function for policy assessment and optimization.

Stochastic processes are natural choices to model deterioration over time. The Wiener process, the gamma process, and the Inverse Gaussian (IG) process are commonly used, Alaswad and Xiang (2017). The last two processes have the particularity to exhibit monotone evolutions of degradation indicator. The most popular stochastic process employed in maintenance literature is the gamma process; see van Noortwijk (2009) for a review in this subject. The IG process is an alternative stochastic process introduced by Wang and Xu (2010) to the reliability literature. Ye and Chen (2014) precisely investigated the IG process properties and mentioned its advantages. Having a clear physical interpretation, flexibility in incorporating random effects and covariates or even prior information, and the existence of explicit formulas for important related functions are some of such advantages. Although the IG process is employed progressively (see e.g. Pan et al. (2016), Peng et al. (2014), Peng (2015), and Ye et al. (2014)), the literature on CBM policies are scarce. Chen et al. (2015) investigated the optimal CBM policy with periodic inspections when the system degradation follows an IG process with random-drift model.

In this paper, we discuss the condition-based maintenance of a single unit system whose degradation follows an IG process. The considered system has degradation parameters that can be different from one unit to the other among a population. Hence it is considered that parameters of the model are unknown but a prior information like expert judgment is available. As an illustrative example, one can consider the degradation of roads subject to longitudinal cracking. For a road section, the degradation level corresponds to the ratio of the fissured length on the total length of the section. A maintenance action is a complete resurfacing of the road section. The dynamics of crack propagation depends on several parameters which may represent features of the road foundation and are unknown. As a consequence, there are some differences from a section to the others and the specific parameters for a given section are unreachable. An adaptive Bayesian method is employed to update the information about parameters after inspections as the degradation state of the system is measured. In order to reduce unnecessary inspections and to control maintenance actions, an aperiodic maintenance policy is considered. The time interval between two successive inspections depends on the system current degradation level and on degradation prediction. The knowledge about the degradation process can be improved on-line through the adaptive Bayesian method, simultaneously. The aim is to introduce this on-line improvement structure within the maintenance decision rule: the next inspection is planned based on the remaining useful life (RUL) of the system. At each inspection, the RUL is estimated according to the last update of degradation parameters.

The aim of the paper is twofold. First, the performance of the Bayesian update process has to be checked especially because of the inspection schedule which is driven by the aperiodic maintenance decision rule. Hence the times for updates are nonperiodic and scarce. Secondly, the effect of on-line updates of RUL prediction on the global maintenance cost is assessed and analyzed for different alternatives.

The remainder of the paper is organized as follows. The next section is devoted to the description of the stochastic process for degradation modeling and RUL prediction. Section 3 is related to the proposed maintenance policy including the procedure for on-line adaptation of the decision based on Bayesian update and the cost considered for assessment. Some numerical simulations are proposed in Section 4 to illustrate the behavior of the considered policy. Section 5 concludes and shows further possible extensions of this paper.

2 MODEL DESCRIPTION FOR RUL CALCULATION

Consider a single component system which is subjected to degradation. Let X_t denote the degradation state of the system at time t. In the absence of repair or replacement actions, the evolution of the system degradation is assumed to be strictly increasing. Then X_t can be modeled by an increasing stochastic process. Moreover, other assumptions are considered:

- The initial state X_0 is 0.
- The system is failed if its degradation crosses a critical threshold level L.
- The system failure is not self-announcing and if it fails, it remains failed until the next inspection. This down time imposes some extra cost.

2.1 *Stochastic degradation process*

The IG process is a stochastic process with independent, non-negative increments such that for each $t > s \geq 0$, the increment $Y = X_t - X_s \sim IG(\mu(t - s), \lambda(t - s)^2)$ with following probability density function (pdf):

$$f(y) = \sqrt{\frac{\lambda(t-s)^2}{2\pi y^3}} \exp\left\{\frac{-\lambda(y-\mu(t-s))^2}{2\mu^2 y}\right\}, \qquad (1)$$

where $\mu, \lambda > 0$. Then, the mean and the variance of X_t are μt and $\mu^3 t/\lambda$, respectively.

Known parameters are common assumptions in the maintenance literature. However, in practice, the model parameters are unknown and must be estimated. Here, we use the Bayesian approach to overcome this difficulty, also we consider that all information in hand like expert opinions are reflected in prior information. The assumption of the conjugate priors can be a good option to reduce the complexity of finding the posterior distribution. To this end, let λ have the gamma density function,

$$f(\lambda) = \frac{\lambda^{\alpha-1}}{\Gamma(\alpha)\beta^{\alpha}} \exp\{-\lambda/\beta\}, \qquad (2)$$

and let $\delta = 1/\mu$ have the conditional normal density function with mean ξ and variance σ^2/λ,

$$f(\delta \mid \lambda) = \sqrt{\frac{\lambda}{2\pi\sigma^2}} \exp\left\{-\frac{\lambda(\delta-\xi)^2}{2\sigma^2}\right\}. \qquad (3)$$

Then, the joint prior distribution of (δ, λ) is given by $f(\delta, \lambda) = f(\delta|\lambda)f(\lambda)$. Furthermore, to avoid the probability of getting non-feasible degradation slopes, it is supposed that $P(\delta \leq 0)$ is negligible.

In other words, the degradation model can be rewritten as:

$$\begin{aligned} &X_t \mid \mu,\lambda \sim IG(\mu t,\lambda t^2),\\ &\delta \mid \lambda \sim N(\xi,\sigma^2/\lambda),\\ &\lambda \sim \Gamma(\alpha,\beta). \end{aligned} \tag{4}$$

2.2 *Degradation model update*

Assuming the priors mentioned above, the posterior distribution of (δ, λ) can be obtained as soon as the new observations are available. Let $X_{t_1}, X_{t_2}, \ldots, X_{t_n}$ be new observations of the system's degradation state at times t_1, t_2,…,t_n. It can be shown that the joint posterior distribution of (δ, λ) is:

$f(\delta, \lambda|\text{Data}) = f(\delta|\lambda, \text{Data}) f(\lambda|\text{Data})$,

where

$$f(\delta \mid \lambda,\text{Data}) = \sqrt{\frac{\lambda}{2\pi\sigma^{2*}}}\exp\left\{-\frac{\lambda(\delta-\xi^*)^2}{2\sigma^{2*}}\right\},$$
$$f(\lambda \mid \text{Data}) = \frac{\lambda^{\alpha^*-1}}{\Gamma(\alpha^*)\beta^{*\alpha^*}}\exp\{-\lambda/\beta^*\}.$$

The updated hyperparameters are:

$$\alpha^* = \alpha + n/2, \qquad \beta^* = (1/\beta + 1/D)^{-1},$$
$$\xi^* = B/A \quad \text{and} \qquad \sigma^{2*} = A^{-1};$$

where

$$A = \sum_{i=1}^{n}\Delta x_i + \frac{1}{\sigma^2}, \qquad B = \sum_{i=1}^{n}\Delta t_i + \frac{\xi}{\sigma^2},$$
$$C = \sum_{i=1}^{n}\frac{(\Delta t_i)^2}{\Delta x_i} + \frac{\xi^2}{\sigma^2}, \quad D = \frac{1}{2}\left(C - \frac{B^2}{A}\right),$$

and $\Delta x_i = X_{t_i} - X_{t_{i-1}}$, $\Delta t_i = t_i - t_{i-1}$ when X_{t_0} is considered as the degradation level of the current time t_0. Then, new observations can be employed to update the information about δ and λ through the Bayesian method. It can happen at each inspection ($n = 1$) or at the end of each cycle (n would be the number of inspection in the cycle).

2.3 *Remaining useful life*

Herein, the objective is to determine the distribution of the remaining useful life (RUL) of the system. At a given time t and with knowing the current state, the RUL of the system can simply be computed as a first passage time when the degradation X_t crosses the threshold L. Hence, we define the RUL, R, of a system at time t as:

$$R = \inf\{r > 0 : X_{t+r} \geq L \mid X_t\},$$

where X_t is the observed degradation at time t. Assuming the parameters of the IG process are known, the cumulative distribution function (CDF) of R given the parameters can be expressed as:

$$\begin{aligned} F_{R|\delta,\lambda}(r \mid \delta,\lambda,X_t) = &\Phi\left(\frac{\sqrt{\lambda}\left(r-\delta\left(L-X_t\right)\right)}{\sqrt{L-X_t}}\right)\\ &-\exp(2r\lambda\delta)\Phi\left(-\frac{\sqrt{\lambda}\left(r+\delta\left(L-X_t\right)\right)}{\sqrt{L-X_t}}\right), \end{aligned} \tag{5}$$

where Φ is the CDF of the standard normal distribution. Then, in case of unknown degradation parameters and knowing the joint distribution of (δ, λ), the CDF of R can be obtained by:

$$F_R(r \mid X_t) = \int_0^{\infty}\int_{-\infty}^{\infty} F_{R|\delta,\lambda}(r \mid \delta,\lambda,X_t) f(\delta \mid \lambda) f(\lambda)\,\mathrm{d}\delta\,\mathrm{d}\lambda,$$

where $F_{R|\delta,\lambda}(r \mid \delta,\lambda,X(t))$ is given in (5). With some similar calculation given in Peng (2015), we have:

$$F_R(r \mid X_t) = \sqrt{\frac{\beta}{2\pi}}\frac{\Gamma\left(\alpha+1/2\right)r}{\Gamma\left(\alpha\right)}\int_{L-X_t}^{\infty} g\left(z\right)\mathrm{d}z, \tag{6}$$

where,

$$g\left(z\right) = z^{-\frac{3}{2}}(\sigma^2 z+1)^{-\frac{1}{2}}\left(1+\frac{\beta(\xi z-r)^2}{2z\left(\sigma^2 z+1\right)}\right)^{-\left(\alpha+\frac{1}{2}\right)}.$$

3 MAINTENANCE POLICY

3.1 *Maintenance policy structure*

Let $\{T_n\}_{n\in\mathbb{N}}$ be the aperiodic inspection times ($T_0 = 0$). At each inspection, one must decide about the required maintenance action. This decision is driven based on the knowledge of the system condition after the inspection. Here, we assume that the maintenance actions are performed in a negligible time and T_n^- refers to the time just before the maintenance date. To control the system failure occurrence, a preventive threshold $M < L$ is chosen. The possible scenarios which can arise are:

- If $X_{T_n^-} \geq L$, the system is failed and it is correctively replaced with the cost of C_c.
- If $M \leq X_{T_n^-} < L$, the system is not failed but it is too deteriorated and cannot function appropriately. Hence, a preventive replacement with the cost of C_p is performed.

- If $X_{T_n^-} < M$, the system is still properly functioning. Then, there is no need for replacement and the system is left as it is.

Both preventive and corrective replacements are perfect and reset the system to "as good as new" condition. Then, the system condition after the inspection X_{T_n} would be:

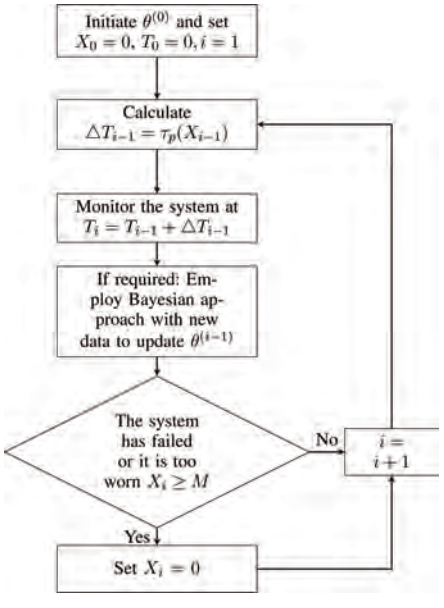
$$X_{T_n} = \begin{cases} 0 & \text{if } X_{T_n^-} \geq L \\ 0 & \text{if } M \leq X_{T_n^-} < L \\ X_{T_n^-} & \text{if } X_{T_n^-} < M \end{cases}$$

In all the above cases, the RUL based inspection is carried out. Therefore, the time for the next inspection T_{n+1} is determined from time T_n by:

$$T_{n+1} = T_n + \Delta T_n \text{ with } \Delta T_n = \tau_p\left(X_{T_n}\right),$$

where $\tau_p\left(X_{T_n}\right)$ is the p-quantile of the RUL distribution given in Equation (6).

The maintenance decision rule is dynamically updated through the Bayesian method. The time between two successive inspections is derived from the RUL assessment which depends on the stochastic degradation process hence on the hyperparameters. Different strategies can be considered for the update frequency. Typically it can be at each inspection time or at each replacement time. The general flowchart describing the evolution of the maintained system state submitted to the proposed aperiodic maintenance policy with the Bayesian update is given hereafter.



$\theta^{(i-1)}$ is the vector of hyperparameters at iteration i and $\tau_p\left(X_{i-1}\right)$ is the p-quantile of the RUL distribution obtained with $\theta^{(i-1)}$.

3.2 *Maintenance cost*

The inspections are planned discretely and each of them incurs a cost C_i. At each inspection, the decision of replacement is checked and a preventive or corrective action is performed, if needed, with costs C_p and C_c respectively. As the maintenance performed on a more deteriorated system is more complex and hence more costly, $C_c > C_p$. Moreover, since the failure can only be detected through inspections, there is a system downtime after failure and the additional cost is incurred from the failure time until the next replacement time at a cost rate C_d. The cumulative maintenance cost is:

$$C(t) = C_i N_i(t) + C_p N_p(t) + C_c N_c(t) + C_d d(t)$$

where $N_i(t)$, $N_p(t)$, and $N_c(t)$ are respectively the number of inspections, the number of preventive replacement, and the number of corrective replacement in $[0,t]$. Also, $d(t)$ is total time passed in a failed state in $[0,t]$.

Here, we use the expected cost function over a finite time horizon T_{end}, as the objective function to assess and optimize the maintenance policy.

4 SIMULATION STUDY

In order to illustrate the behavior of the aperiodic maintenance policy, let consider the case of a system which deteriorates according to an IG process with fixed parameters $\mu_{\text{real}} = 1$ and $\lambda_{\text{real}} = 1$. The prior information about the system is given by the values of hyperparameters such that $\alpha = 1.5$, $\beta = \frac{2}{3}$, $\xi = 1$ and $\sigma = \frac{1}{\sqrt{3}}$. The limit threshold is $L = 9$. The Bayesian update introduced before helps us to get better information about the model parameters (δ, λ) in comparison to the initial information which may be wrong or partly wrong in some cases. Figure 1 shows the mean and variance

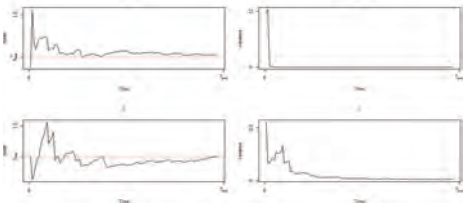


Figure 1. The mean (on the left) and the variance (on the right) of the distribution of δ (top) and λ (down) over the time.

of the evolving distribution of (δ, λ) over time with the update at each inspection. It is clear that after a while the means tend to their correct values, μ_{real}^{-1} and λ_{real}, while their variances vanish to zero.

The maintenance cost is the expected cumulative maintenance cost over a finite horizon with $T_{\text{end}} = 100$, where $C_i = 0.2$, $C_p = 4$, $C_c = 10$ and $C_d = 4$. It is estimated by a Monte Carlo simulation with 5000 samples over the considered finite horizon. Four different versions of the proposed maintenance policy are considered corresponding to four configurations of the model used for RUL prediction. The p-quantile of the RUL hence the time for the next inspection is successively obtained from Equation (6) or as the first passage time of the IG process used for degradation simulation. This last case is hereafter referred as "perfect" case because it assumes that the model used for prognosis is exactly the model used to describe the degradation of the system. Equation (6) describes the case of unknown degradation parameters. Three considered options depend on hyperparameters. In the first one, the values of hyperparameters are fixed to the ones given by experts. This case is called "no update" case. The second and third cases consider updates of α, β, ξ and σ respectively at each inspection time (case "inspection") and at each replacement time (case "cycle").

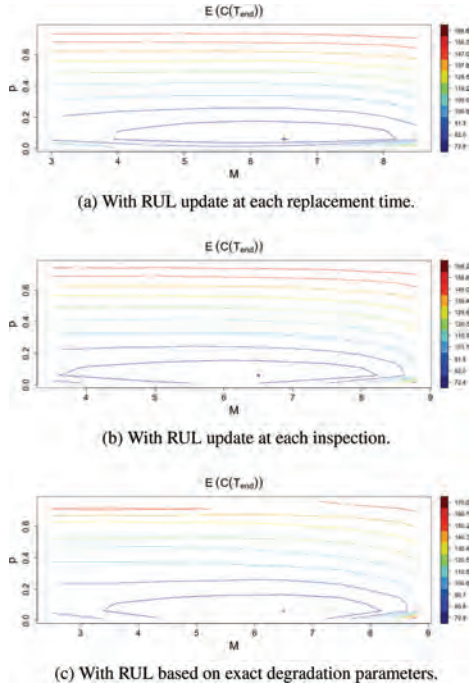
As an example, specific values of the decision parameters p and M are chosen, which are the optimal decision parameters obtained under the assumption of known degradation parameters (case "perfect"). The values obtained by Monte Carlo simulation are $p^*_{\text{known}} = 0.03$ and $M^*_{\text{known}} = 6.5$. Table 1 gives different results obtained with these values of decision parameters for the four different configurations of maintenance decision rule over the finite time horizon $[0; T_{\text{end}}]$. The given quantities are the cumulated expected maintenance cost, its variance, the mean numbers of maintenance actions (inspections, corrective and preventive replacements), the mean unavailability duration and the mean number of renewal cycles.

Table 1. Mean values for comparison of different maintenance decision rule options applied on degradation data generated from IG process with fixed parameters $\mu_{\text{real}} = 1$ and $\lambda_{\text{real}} = 1$.

Case	Perfect	Insp.	Cycle	No update
Cost mean	69.26	72.20	74.78	97.416
Cost Var.	11.41	11.86	12.25	7.62
Inspections	32.8	44.7	62.3	193.3
Prev. actions	11.5	11.4	11.7	12.8
Corr. actions	1.3	1.38	1.23	0.7
Unav. dur.	0.85	0.91	0.76	0.12
Nb of cycles	13.8	13.8	13.9	14.5

The variations of the cost for the considered policies are in line with logical thinking. The considered decision parameters correspond to the minimal cost for the highest possible level of information i.e. for known real deterioration parameters. The optimal cost is used as a reference. For the lowest level of information i.e. for RUL assessment based on initial hyperparameters values without any update, the cost increase with respect to the reference is about 40%. The introduction of the Bayesian update leads to maintenance costs which are close to the best case. The increase is close to 4.2% and 7.5% if the RUL prediction for inspections scheduling is respectively updated at each inspection time (i.e. around 44 times on $[0; T_{\text{end}}]$) or at each replacement (i.e. around 14 times). The main differences between the costs of the four considered options are due to the number of inspections. In the absence of updates, the probability law of the RUL is spread out and the p-quantile causes small inter-inspection times. With updates, the pdf becomes sharper and it leads to increasing periods of time between successive inspections.

Table 1 contains results for one specific value of $(p; M) = (p^*_{\text{known}}; M^*_{\text{known}})$. In order to illustrate the performance of the proposed maintenance policy for different settings, the expected cumulative maintenance cost as a function of the two decision parameters is depicted in Fig. 2. The two



(a) With RUL update at each replacement time.

(b) With RUL update at each inspection.

(c) With RUL based on exact degradation parameters.

Figure 2. Cost as a function of the maintenance decision parameters p and M for 3 different decision rules with $C_i = 0.2$, $C_p = 4$, $C_c = 10$ and $C_u = 4$ and $T_{\text{end}} = 100$.

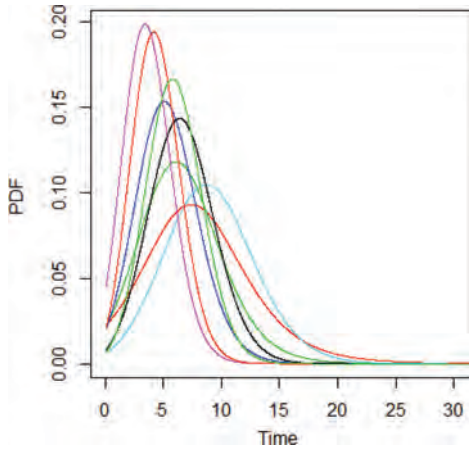


Figure 3. The pdf of the RUL updated at each inspection.

cases with the Bayesian update are investigated as well as the case with fixed and known parameters. It can be seen that the shapes of the different cost surfaces are close to each other. It means that the performance evolves in the same way when the decision parameters are modified. For example, one can see that the sensitivity to the parameter M is low and that too small values of p can produce a sudden cost increase due to the increase of the number of cycles. In order to show how the RUL pdf becomes peakier in each update, the RUL pdf are depicted with successive update at each inspection in Figure 3.

The obtained numerical results show that the efficiency of the Bayesian update procedure as a way to adapt the decision rule of the aperiodic maintenance policy. It allows implementing an auto-adaptive maintenance policy with a small number of decision parameters.

5 CONCLUSIONS

A predictive maintenance policy for deteriorating systems with unknown parameters is proposed in this paper. It includes a 2-parameter maintenance decision rule based on the Bayesian update which allows to jointly decide when to inspect the system and what to do about possible replacement at inspection time. The whole modeling framework based on IG process for degradation modeling and cumulative maintenance cost on a finite horizon is described. Some numerical results are given to illustrate the behavior of the maintenance policy. The inspection times are driven by the maintenance decision rule and used for hyperparameters updates. Two different versions are considered: with the update at each inspection time and with the update at each system replacement time. Whatever the version is, the shape of the cost function is shown to be close to the case of known deterioration parameters. It allows considering possible choices of decision parameters without unexpected behaviors on cost value. According to the Bayesian update procedure, the fast evolution of the means degradation parameters to their exact values make the proposed maintenance policy promising. The problem related to the optimal choice of the decision parameters will be considered in a future work.

An opportunistic maintenance policy for heterogeneous components

P.A. Scarf
University of Salford, Manchester, UK

C.A.V. Cavalcante & R.S. Lopes
Federal University of Pernambuco, Recife, Brazil

ABSTRACT: A hybrid maintenance policy that combines inspection in early life with opportunistic replacement in later life is developed for a one-component system with a heterogeneous lifetime. Inspections and replacements use opportunities that arise periodically, for example due to visits of a maintenance vessel to a turbine in an offshore windfarm. Components may be weak or strong, and the inspection phase of the policy operates like a burn-in period. Inspections are modelled using the delay time concept. The policy mimics reality whereby new systems are carefully maintained and older systems are replaced at events determined by operational constraints. We determine the cost-rate and reliability of the hybrid policy. Using a numerical example we show that the inspection phase offers benefits when the delay time is sufficiently large and/or early failure is a significant possibility. The policy would be relatively easy to implement in practice.

1 INTRODUCTION

Maintenance management of technical systems uses preventive and corrective replacement, inspection, repair and such like (De Almeida et al. 2015; Lee & Cha, 2016) to increase system reliability and availability and to reduce total cost of ownership of industrial assets (Berrade et al. 2013; Xia et al. 2015; Zheng, et al. 2016). For some systems, stoppages may provide opportunities for the execution of preventive maintenance with less disruption and at a lower cost than scheduled preventive maintenance. An example is the loss of the cold water supply to a soft-drinks production line caused by pump failure (Wang et al. 2000), whereby preventive maintenance of bottling and packing sub-systems may be carried out ahead of schedule. The models of opportunistic maintenance policies develop this idea in theory (e.g. Dekker & Smeitink, 1991, Zheng, 1995; Tan & Kramer, 1996; Mohamed-Salah et al. 1999; Budai et al. 2006; Laggoune et al. 2010; Xia et al, 2017b, c; Zhang & Zeng, 2017) and for practice (e.g Ding and Tian, 2011; Shafiee et al., 2015; Yildirim et al. 2017; Hu & Zhang, 2014; Nilsson et al. 2009; Cavalcante & Lopes, 2015; Xia et al. 2017a; Garambaki et al. 2016). Typically, opportunities arise from economic and structural interdependencies among components or parts (Dekker & Smeitink, 1991). Grouped maintenance policies (Wildeman et al. 1997) also exploit such dependencies to maintain groups of parts (Vu et al. 2015; Peng & Zhu, 2017), but opportunistic maintenance is different because it aims to maintain a part or parts when another part of the system causes a stop.

In this paper, we consider opportunities in different way. We suppose that the opportunities arise deterministically and periodically, as they might arise when shutdowns of a plant of which the system of interest is a part are seasonal or when maintenance resources are available only occasionally, as in the case of visits of a maintenance vessel to a turbine in an offshore windfarm.

We further suppose that the system is subject to a two-stage failure process according to the delay time model (Christer, 1999), whereby a defective but operational state precedes the failed state. Then, opportunities may be utilized for inspection, and for replacement if required. Additionally, we model component heterogeneity that may arise, for example, in the context of variable maintenance quality (Scarf & Cavalcante, 2012), supplier selection (Berrade et al. 2012), reliability (Castet and Saleh, 2010), and analysis of failure warranty data (Attardi et al., 2005; Lee et al., 2016). This heterogeneity means inspection in early life has an important role that is similar to operational "burn-in" (Zhang et al. 2014).

Few papers consider this connection between opportunistic maintenance and inspection (Wang & Christer, 2003; Berrade et al. 2017). Cavalcante et al. (2018) exploit this gap in the literature. In particular, they develop a model that generalizes hybrid inspection and replacement (Scarf et al. 2009, Scarf & Cavalcante, 2010) and opportunistic maintenance,

and in which a system is periodically inspected in the first phase of its life and replaced at opportunities during the second phase. In the policy they consider, opportunities arise at random, due to system stoppages that are caused by the failure of other structurally connected systems. In our paper here, we take a different approach and suppose that opportunities are deterministic and periodic. This makes the policy simpler to study (fewer decision variables) and easier to implement in practice (akin to block replacement rather than age replacement, Barlow & Proschan, 1966), but nonetheless applicable to maintenance of windfarms (e.g. Shafiee, 2015), transportation systems (e.g. Corman et al. 2017), and manufacturing systems (e.g. Zahedi et al. 2017).

The structure of the paper is as follows. We begin next with the description of the system and the policy. Then in section 3 we develop the cost rate. Section 4 briefly develops the system reliability. This is followed by a numerical example to illustrate the policy. We conclude with a discussion.

2 THE POLICY

2.1 *Description of the system*

We consider a single component which when in its socket performs an operational function (Ascher and Feingold, 1984). The component is in one of three states, good, defective or failed. The time in the good state, X, the time to defect arrival, has a mixture distribution $F_X(t) = pF_1(t) + (1-p)F_2(t)$, with mixing parameter p. Thus components arise from a mixed population of "weak" and "strong" sub-populations. F_1 and F_2 are in general increasing failure rate distributions, and in our particular example they are Weibull distributions with characteristic lives η_1, η_2 and shape parameters $\beta_1, \beta_2 > 1$. The corresponding density and reliability (survival) functions are denoted by f_X and $\bar{F}_X$ respectively.

The component in its socket constitutes a one-component system. This system is a non-critical system so that, on failure, the system stoppage is revealed only at a subsequent opportunity, whereat the component is replaced and the system returns to operation. Inspection determines whether the system is good or defective. When the system is defective it continues to operate albeit with a degraded function (e.g. a noisy bearing). Inspections are perfect in that an inspection reveals the true system state. At a positive inspection (system is defective), the component is replaced. Component replacement corresponds to system renewal.

Opportunities arise deterministically every S time units, as a result of, for example, seasonal shutdowns or periodic availability of maintenance resources.

The sojourn in the defective state, H, the delay time, has density $f_H(h)$, distribution function $f_H(h)$, and reliability (survival) function $\bar{F}_H(h)$. X and H and opportunities are mutually, statistically independent.

2.2 *Description of the policy*

Opportunities arise every S time units. Inspections are scheduled at each of the first K opportunities from when the system is new and replacement is scheduled at the Mth opportunity $(M \geq K)$. On failure, the system is replaced at the first opportunity that follows the failure. Maintenance interventions (inspections and replacements) cannot occur at instants other than opportunities. In this way, replacements are always synchronized with opportunities, and so renewal occurs only at an opportunity. The policy has two decision variables: K and M. The cost parameters are as follows:

- the cost of an inspection is C_I;
- the cost of a replacement of a defective component is C_O;
- the cost of a preventive replacement of a component at age MS is also C_O;
- the cost of a replacement of a failed component is C_F $(C_I < C_O < C_F)$.

The innovation of this policy is the early-life inspection phase [0, KS], whereby a component is replaced if it is found to be defective. In this way, great care is taken of the system during early life.

We might study a more general policy in which inspections are scheduled every N-th opportunity, that is, at times NS, $2NS$, …, KNS (from new). This policy may be appropriate when opportunities arise very frequently (e.g. at shutdowns or under reduced timetables of transportation systems that occur on a weekly basis). However, in this paper, we focus on the simpler two-variable policy.

We might also study a policy in which the cost of failure is not fixed, but instead related to the unavailability of the system (from the point of failure until the replacement at the subsequent opportunity). This is perhaps a more realistic policy for the case in which the unavailability cost is large relative to the cost of remedial work on a failed system. For a turbine in a windfarm, however, unavailability cost is not large (relatively), because the cost of lost power generation will be small relative to the cost of damage to the turbine as a result of failure. Furthermore, unavailability costs across a large installation are typically factored into the wind power capacity model, so that operators should focus on direct maintenance costs (Shafiee and Sorensen, 2017).

3 CALCULATION OF THE COST-RATE

The cost-rate is determined by calculating the probabilities of the three types of renewal scenario that arise: related to failure; related to preventive replacement; and related to replacement of a defective component at inspection.

A failure can arise as a result of a defect that itself arises either in early-life during the inspection phase or in later-life during the replacement phase. The costs are different in each case, so we develop the calculations separately.

In the first case, a defect arises in the interval $[(i-1)S, iS)$ and fails before time (age) iS. This occurs with probability

$$P_{1,\mathrm{F}_i} = \int_{(i-1)S}^{iS} F_H(iS-x) f_X(x)\,\mathrm{d}x,$$

for $i = 1,\ldots,K$. The cost associated with this event is $C_\mathrm{F} + (i-1)C_\mathrm{I}$ and the length of the renewal cycle is iS, noting that replacement has to wait until the next opportunity and that the cost of unavailability is ignored.

In the second case, a defect arises after KS and fails in the interval $((i-1)S, iS)$, for $i = K+1,\ldots,M$. For $i = K+2,\ldots,M\,(M > K+1)$, this occurs with probability

$$P_{2,\mathrm{F}_i} = \int_{(i-1)S}^{iS} F_H(iS-x) f_X(x)\,\mathrm{d}x + \sum_{j=K+1}^{i-1} \int_{(j-1)S}^{jS} \{F_H(iS-x) - F_H((i-1)S-x)\} f_X(x)\,\mathrm{d}x,$$

and for $i = K+1$ we have

$$P_{2,\mathrm{F}_{K+1}} = \int_{KS}^{(K+1)S} F_H((K+1)S-x) f_X(x)\,\mathrm{d}x.$$

The cost associated with this event is $C_\mathrm{F} + KC_\mathrm{I}$ and the length of the renewal cycle length is iS.

For renewal related to preventive replacement at MS, this can occur only if either no defect arises before MS or a defect arises before MS but after KS and it survives to MS. In either case the cost of K inspections and the cost of the preventive replacement are incurred. Thus the probability of preventive replacement at MS is

$$P_M = \int_{KS}^{MS} \bar{F}_H(MS-x) f_X(x)\,\mathrm{d}x + \bar{F}_X(MS),$$

and the associated cost of the renewal cycle is $C_\mathrm{O} + KC_\mathrm{I}$ and the length of the renewal cycle is MS.

The final renewal scenario is replacement of a defective component at inspection. This can only occur in the early-life phase, and the defect must arise in an interval between opportunities and survive (not fail) by the end of the interval. The probability of renewal at the i-th inspection, for $i = 1,\ldots,K$, is

$$P_{\mathrm{D}_i} = \int_{(i-1)S}^{iS} \bar{F}_H(iS-x) f_X(x)\,\mathrm{d}x,$$

and the associated cost of the renewal cycle is $C_\mathrm{O} + iC_\mathrm{I}$ and the length of the renewal cycle is iS.

Thus, associated with each type of renewal event is a cost, and the expected cost of a renewal cycle is the sum of the products of the cost of each renewal event and the respective probability of each renewal event. Therefore

$$E\{U(K,M)\} = (C_\mathrm{O} + KC_\mathrm{I})P_M + \sum_{i=1}^{K} \left\{(C_\mathrm{F} + (i-1)C_\mathrm{I})P_{1,\mathrm{F}_i} + (C_\mathrm{O} + iC_\mathrm{I})P_{\mathrm{D}_i}\right\} + (C_\mathrm{F} + KC_\mathrm{I}) \sum_{i=K+1}^{M} P_{2,\mathrm{F}_i}.$$

The expected cycle length is found similarly:

$$E\{V(K,M)\} = MSP_M + \sum_{i=1}^{K} iS(P_{1,\mathrm{F}_i} + P_{\mathrm{D}_i}) + iS \sum_{i=K+1}^{M} P_{2,\mathrm{F}_i}.$$

Then we use the renewal-reward theorem to define the cost-rate (the long run average cost per unit time) $C_\infty(K,M) = E(U)/E(V)$. This is the objective function we use to determine the optimum values of the decision variables K and M.

4 RELIABILITY

We can also quantify the reliability of the maintained system (Lewis, 1987; Scarf et al. 2005) using the "long-run time between failures":

$$\frac{\text{expected cycle length}}{\Pr(\text{renewal on failure})} = \frac{E\{V(K,M)\}}{\sum_{i=1}^{K} P_{1,\mathrm{F}_i} + \sum_{i=K+1}^{M} P_{2,\mathrm{F}_i}}.$$

We denote this by $\mu_\infty(K,M)$. We might also describe its inverse as the "failure rate", a term often used in reliability engineering but commonly misunderstood (Ascher & Feingold, 1984; Gaens, 2017). The system availability might also be calculated, but we omit this for brevity.

5 NUMERICAL EXAMPLE

We set the time unit is one year and an arbitrary cost unit, so that all costs are multiples of C_O. The values of parameters (defined in sections 2.1 and 2.2) are typical of wind turbines (e.g. Faulstich

et al. 2011). In the base case (grey fill in row 2 of Table 1), we set $\eta_1 = 2$, $\beta_1 = 2$, and $\eta_2 = 10$, $\beta_2 = 5$ so that the populations of weak and strong components are reasonably well separated. The value of the mixing parameter ($p = 0.1$) is not untypical of mechanical systems (e.g. Gales, 2015). The mean delay time and the time between opportunities are both chosen to be the same (one year), so that we might expect interesting effects to be observed. Some results are shown in Table 1 and Figure 1.

Figure 1 suggests that the cost-rate is sensitive to both M, which determines the age at replacement, and K, which determines the length of the inspection phase. We can further see that the cost-rate increases sharply as inspection reduces ($K = 2$ vs $K = 3$), so the benefit of the inspection phase is clear. This benefit is absent when there are no weak components ($p = 0$ in Table 1). Final point to make about this figure is that it is apparent that if one is unsure about how much inspection to carry out, more ($K > 3$) is better than less.

The effect of heterogeneity (through p) is large, and as p increases we see in Table 1 that the inspection phase extends. Furthermore, there is a three-fold increase in the failure rate between $p = 0$ and $p = 0.2$. Presumably the increase would be greater without inspection, and this is responsible for the high cost-rate of the pure inspection policy in row 3 of Table 2. This is confirmed by the very high failure rate for the pure inspection policy in row 3 of Table 3.

The mean delay time $1/\lambda$ also has a large influence on the policy. As the mean delay time decreases, the usual response in an inspection policy is to carry out more frequent inspection. However, in the policy here, this frequency is fixed and only the length of the inspection phase can be increased. Thus, the opportunity to prevent failures through

inspection and consequently the replacement of defective components is limited by the frequency of opportunities ($1/S$). Nonetheless, inspection at these opportunities is still beneficial.

Although S is not a decision variable in our formulation of the model, we should study its effect. And its effect on the cost-rate and the failure rate is quite large. There is a 40% increase in the failure rate between $S = 0.5$ and $S = 2$. Notice however that the length of the inspection phase (KS) changes little and the age at replacement (MS) does not change at all. The increased cost-rate when $S = 0.5$ is explained by the increased cost of inspection. Thus, the statistical properties of the weak subpopulation determine broadly the length of the inspection phase and then the inspection regime follows from this and the frequency of opportunities. Obviously the frequency of opportunities limits how often inspections can be carried out.

The effect of η_1 is curious (when the life of the weak components is shortest, the cost rate is not the largest) and we have no explanation for this.

Focusing more broadly on Tables 2 and 3 and the policy comparisons (noting that each policy reported is the respective optimum policy in its class), we can see the use of an inappropriate policy has a more profound effect on cost and reliability than do the failure characteristics of the system. Pure replacement is always a high-cost and low-reliability. Whole life inspection gives the highest reliability and this is to be expected; in the circumstances, additional inspections only have a cost-disadvantage. Pure replacement and whole life inspection are the extremes of the K, M policy, and again Tables 2 and 3 suggest that if a maintainer is unsure about the appropriate frequency of inspection then more is better than less.

6 DISCUSSION

We study a hybrid inspection and replacement policy in which the opportunities to carry out inspections and replacement are periodic but limited and somewhat out of the control of the maintenance decision-maker. We consider in particular the effect of heterogeneity of component quality, so that early-life defects are possible. The model is related to the hybrid inspection and replacement policy proposed by Scarf et al. (2009) and to the general hybrid opportunistic policy of Cavalcante et al. (2017) in which opportunities are also limited but occurring at random. The policy proposed in the paper here is natural in the context of the maintenance of an offshore wind-farm.

The calculation of the long-run average cost per unit time (cost-rate) for the policy is presented. We also calculate a measure of the operational reliability of the system. We illustrate the policies with a numerical example. We compare, in terms of cost-rate, the proposed policy with a number of policies that are special cases including pure inspection and pure replacement.

Our results indicate a number of points. Component heterogeneity drives the length of the inspection phase, and then the frequency of inspect-ion during this phase is determined not by the decision-maker but by the frequency of opportunities. Similarly the age limit for replacement is driven by the system failure characteristics and the costs rather than the frequency of opportunities. When the quality of replacements is most poor then the inspection phase of the hybrid policy is most beneficial. Finally, if the maintainer is in doubt about the length of the inspection phase, then more inspection is better than less, provided that inspections do not induce defects (Scarf and Cavalcante, 2012).

The fixed frequency of opportunities for maintenance can simplify maintenance planning, and the policy we propose provides a simple framework in which to mitigate for the effects of variable quality in the execution of maintenance interventions. An interesting question relates to the effectiveness of continuous condition monitoring in the circumstances when the maintenance frequency is fixed. In a simple, single component system, alarms are not useful if the system cannot be accessed. Nonetheless, if failure can be prevented through remote shutdown, then we would expect continuous monitoring to be beneficial.

Influence of selected external factors on satellite navigation signal quality

K. Krzykowska, M. Siergiejczyk & A. Rosiński
Warsaw University of Technology, Warsaw, Poland

ABSTRACT: Signal monitoring is one of the basic tasks, which are included in the satellite system maintenance. Currently, the civil aviation, in terms of navigation, above all, develops solutions based on satellites, indicating them as future-orientated. This activity is coordinated by the ICAO (International Civil Aviation Organization), which oversees the operations of the Global Navigation Satellite System (GNSS). The analysis of satellite system errors is a major aspect limiting the operational functioning of such systems in air transport. From the point of view of this study, the tropospheric and ionospheric errors deserve special attention. It turns out that the time of year and even time of day can have a significant impact on the quality of the satellite signal and, therefore, on the operational safety of aircraft. Relationships occurring between selected external factors (temperature, pressure, cloudiness, precipitation, air humidity) and their very effect on the signal interferences—will be tested using fuzzy reasoning.

1 INTRODUCTION

The high safety level in aviation is placed on top of the pyramid of industrial challenges for modern operators and service providers'. The rationale for the selection of the research problem is the fact that the satellite systems are considered to be the future of navigation and surveillance in aviation. Failure to meet the requirements set out for satellite signals prevents their operational use (Siergiejczyk & Krzykowska 2014). The satellite systems play a significant role in programmes relating to the development of the aviation technology, including the SESAR programme (Single European Sky ATM Research), which is a technological component of the SES (Single European Sky) project implemented in the EU (Kierzkowski & Kisiel 2016). The conditions set out for the use of satellite systems in, for example, air traffic operations are, therefore, associated with four defined, main signal parameters: accuracy, availability, continuity and integrity.

2 SATELLITE SIGNAL PARAMETERS

The satellite signal used in aviation is subject to particularly stringent functional requirements (Siergiejczyk et al. 2015). Therefore, it is crucial to satisfy them. The aforementioned requirements are determined with navigational parameters (International Civil Aviation Organization 2006). They include:

- **accuracy** – defined by an error in determined position; in GNSS it is the difference between the determined and actual position; the probability for a determined position should be at least 95% – the measurement error is then within the specified accuracy;
- **integrity** – is characterized as a measure of confidence in the validity of information provided by a system; it covers the capability of a system to deliver appropriate warnings (alarms) to a user within a predetermined time, which include information on when not to use the system;
- **continuity** – is the ability of a system to utilize the assumed function without unplanned interruptions during an executed flight operation;
- **availability** – can be defined as a percentage of time, during which a satellite system can be used for navigation, and during which reliable information is passed on to the crew, a control system or other aircraft flight management systems.

The requirements in relation to accuracy indicate that in a large set of independent samples, at least 95% should meet specified conditions (stated in metres, per each satellite system type). Such accuracy must be satisfied in relation to the worst geometry of a satellite constellation, for which the system is to be available. It should be noted that position errors, in the case of, e.g. a GPS system, consist of satellite clock and ephemeris errors. They do not include ionospheric and tropospheric delays, multipath errors or self-receiver noise. The latter are in each case included in the standards regarding receivers (International Civil Aviation Organization 2006).

In the context of integrity, in order to determine whether a location error is acceptable—an alarm limit is specified, which allows to reflect the maximum, permissible position error that will not

undermined the executed flight operation. It should be noted that satellite system navigation, thus, a satellite signal, is simultaneously transmitted to many objects (aircraft) over a large area—often one or more continents. Therefore, the impact of losing integrity of a satellite system on an air traffic management system will be much more significant than in the case of conventional navigation methods. Hence, the stringent requirements regarding the parameters. An information about the loss of signal integrity (or exceeding the permissible values of other parameters) delivered sufficiently early, should result in an abandonment of using satellite navigation or discontinuation of the operation (in case of a take-off or landing). Furthermore, an individual, as well as a unique GNSS navigation feature is adapting the navigation capabilities over time, depending on the changing satellite constellation. The impact of changes in the space segment may be increased with an additional fault in the ground segment, e.g., damage to one of the components (International Civil Aviation Organization 2006).

In the case of en-route, approach and landing operations—the continuity of the service is associated with the capability of a navigation system to deliver output data with a specified integrity and accuracy over the course of the operation, assuming that the data were available at the beginning of the operation. Due to the fact that the length of individual operations is variable, the requirement regarding the continuity is defined as a range of signal discontinuity probability values per hour. The bottom range value is the minimum continuity value, at which a system may be used in areas with low traffic and a complex airspace structure (these are areas with a low number of navigation system failure per the number of aircraft). The top value enables the application in area with heavy traffic and a complex airspace structure (these are areas with a higher number of navigation system failures per the number of aircraft). It is worth noting that flight planning may not be approved if it is based solely on GNSS navigation, in which a signal is burdened with a high risk of a continuity loss at the time of planning the executed operation (International Civil Aviation Organization 2006).

Defining the requirements concerning GNSS availability should be considered in terms of the expected level of the provided service. Certain requirements will be set out for a system, which is to replace the existing navigation infrastructure, and different ones for a system supporting the current infrastructure (International Civil Aviation Organization 2006). Basically, the determination of a GNSS signal availability criterion for given operations or areas, should be based on:

a. traffic intensity and complexity;
b. the presence of back-up navigation aids;
c. covering an area with primary and secondary surveillance;
d. guidance procedures to another airport;
e. navigation system used at a back-up airport;
f. duration of interruptions in signal availability;
g. geographical range of interruptions.

In addition, according to the International Civil Aviation Organization, GNSS availability should be determined through engineering, analysing and modelling processes, and not only by measuring them. The signal availability model should take into account, among others, ionospheric and tropospheric errors, as well as receiver faults, which it utilizes to determine integrity via calculated HPL (Horizontal Protection Level) and VPL (Vertical Protection Level) indicators (Januszewski 2012) (Januszewski 2013).

3 LITERATURE STATE OF THE ART

The research problem in the presented paper is not only the analysis of satellite signal parameters, but also a search for external factors causing interference of that signal. Weather conditions will be certainly among those observed. The matter and its essence are already known in the domestic subject literature. R. Zieliński sets forth the issue of thermal noise and their presences in Earth—satellite and satellite—Earth links (Zieliński 2009). Ground receiving antenna receives noises through sky luminance temperature (sky radiation), whereas for a satellite antenna—the noises are the Earth's surface with a defined thermodynamic temperature. Attention was also paid to additional losses arising as a result of precipitation. Signal attenuation they cause, depends on the extent of the precipitation itself, most often expressed in mm/h. The European Broadcasting Union elaborated on measurement results, which present the phenomenon of signal attenuation, depending on the magnitude of precipitation, for the frequency of 11.5 GHz. This statistic provides attenuation distribution function values expressed in dB for 99% and 99.9% of the time for the worst month in Europe. The dependency of meteorological conditions and GNSS in the context of the position determination accuracy can be also found in elaboration of renowned scientific journals (Wilgan et al. 2015). However, in most cases, the impact of weather on satellite signal propagation has been described in the literature in light of tropospheric errors. The following factors are determined: dry-air density, pressure and temperature, and humid-air humidity caused by clouds, rain, fog.

It should be noted that the analysis of external factors, including meteorological, is of large significance also in the case of other fields of air traffic. The elaborations include studies on, inter alia, the impact of meteorological conditions on the

execution of aircraft landing operations or modelling external factors in the context of air traffic. These publications evidence the great importance of different factors present in air traffic. The fact that meteorological factors should not be underestimated in any of the air traffic fields seems crucial (Rychlicki & Miszkiewicz 2013).

In light of the received satellite signal, one should adopt a relevant correction, taking into account its passage through different layers of the atmosphere. For example, in order to determine a correction taking into account the passage of the signal through the ionosphere, a vertical component of electron density TEC [el/m^2] is adopted. TEC (Total Electron Content) is the total number of electrons concentrated between two points, along a column with a cross-section of 1 m^2. The studying of the TEC variable, its modelling and forecasting became a popular issue for contemporary science in the context of the satellite technology development (Rius et al 1994). Due to the demonstrated significant impact of the TEC value on the quality of the received satellite signal, a lot of attention was focused on TEC predictions, also via artificial neural networks (Paul & Sur 2013).

4 RESEARCH METHODOLOGY

The use of fuzzy sets for controlling and modelling processes has a long history. Originally, the creators of fuzzy logic saw their theory in fields such as economics or psychology, where human perception plays a crucial role, and the phenomena can be described in an unclear manner, thus, a fuzzy one. However, already in the 1970s, the possibility to control processes through this tool was observed. Nowadays, the greater part of its application concerns controlling, quite often, technical systems (Żurek & Grzesik 2015) (Robinson et al. 2005) (Skorupski & Uchroński 2016) (Stańczyk & Stelmach 2014) (Losurdo et al. 2017).

In principle, the literature sources define two approaches towards fuzzy control-descriptive and prescriptive (Zadeh 2008). The first one is based on the expertise of an operator who, based on his experience, knows how to control a process. It is a traditional approach, not based on a model. The second approach assumes the existence of a stochastic or deterministic model, and defines how, in an optimal manner, to control it. The traditional approach is closer to the studies in this paper. This is due to the fact that a model of a process defining the output (satellite signal interference) as an input function (weather condition) is not known. This means that the process is a, so-called, black box. However, knowledge on how to correctly control a process, i.e., which control to choose for a current output, is available (Kacprzyk 2001).

The construction of a model and conducting the aforementioned tests is subject to having a sufficient number of data (Siergiejczyk & Krzykowska 2017). The satellite signal analysis was based on EGNOS system data. A total of 181 measurements for a PRN120 satellite, conducted in the 1st half of 2014 at a station in Warsaw for an APV-1 vertical guidance approach operation shall be used for constructing the model. The selection of this period, area and satellite is justified by the completeness of data, which is compulsory in such studies—conditioning high reliability of the results. By agreement with the Institute of Meteorology and Water Management in Warsaw, a list of weather condition measurements (cloud cover, humidity, precipitation, pressure and temperature) was received, for the same period of time and area. The Space Research Centre of the Polish Academy of Sciences publicizes the data on solar activity, including the number of sunspots, number of observations, standard deviations. That data was also used in the research.

The article presents a model regarding the satellite signal accuracy. Therefore, input data was identified. It included:

- cloud cover;
- air humidity;
- precipitation;
- average air temperature;
- atmospheric pressure;
- solar activity expressed as the number of sunspots (daily sunspot number).

At the same time, it can be concluded that cloud cover, humidity and precipitation form a first group of input data, which determines the humid tropospheric part, associated with water vapour content. Two other factors-temperature and pressure constitute a fragment of the dry part of the troposphere and form a second data group. According to the literature (Wołoszyn 2009), the dry factor causes almost 90% of the tropospheric error (delay). The last, but not least, factor-solar activity, forms a third group of input data associated with the ionosphere and ionospheric delay (Siergiejczyk & Krzykowska 2017).

Nonetheless, the determination of an output variable remains important. It was an accuracy error, determined by the average value of HNSE and VNSE.

The next table shows a summary of linguistic values for all variables and their assigned numerical values, representing the total membership to a fuzzy set. This classification, for input variables, was based on known literature of the subject (Wołoszyn 2009) (Moszkowicz & Tuszyńska 2006). The definition of output variable ranges

Table 1. Linguistic values of input and output variables.

I/O data	Linguistic variable	Linguistic value				
I_1	Cloud cover	–	small	average	big	–
I_2	Humidity	v. low	low	average	high	v. high
I_3	Precipitation	–	small	average	big	–
I_4	Temperature	–	low	average	high	–
I_5	Pressure	–	low	average	high	–
I_6	Solar activity	v. low	low	moderate	high	v. high
O	Accuracy error	–	small	average	big	–

Table 2. The function of linguistic variable membership.

I/O data	Measure	Measurement value range	Numerical value
I_1	cloud cover (in octane scale)	0–8	0 4 8
I_2	%	42–100	42 57 72 86 100
I_3	mm water head	0–25	0 12.5 25
I_4	average air temperature in °C	(-15) – 24	-15 4.5 24
I_5	hPa	985–1024	985 1005 1024
I_6	sunspot number	40–222	40 87 110 150 222
O	average HNSE and VNSE value in metres	5–8	5 6.5 8 9.5

was solved otherwise. It applied the expertise and applicable requirements regarding the use of a satellite signal in civil aviation imposed by ICAO (International Civil Aviation Organization 2006).

The input and output variables were assigned the Gaussian membership function according to the ranges given in Table 2. 126 rules were set out.

5 RESEARCH RESULTS

The following visualizations present selected configurations of atmospheric factors with the most significant impact on the accuracy of a satellite signal.

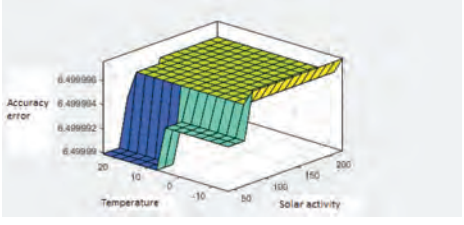

Figure 1. Graphic representation of the impact of temperature and solar activity on the accuracy error.

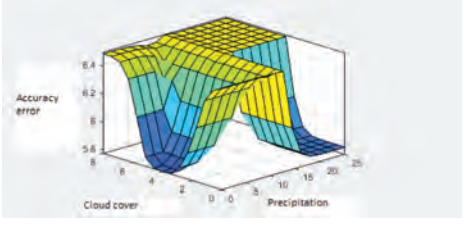

Figure 2. Graphic representation of the impact of cloud cover and precipitation on the accuracy error.

In the presented model, solar activity (I_6) was more important than temperature (I_4), nonetheless, the impact of low temperature on the increase of the accuracy error is noticeable. The configuration of precipitation (I_3) with cloud cover (I_1) and their impact on the satellite signal is interesting. Figure 2 shows an increase of the accuracy error in conditions of big and small cloud cover and rather low precipitation. This leads to a very important conclusion—I are able to indicate the day, during which it was not the weather factor, which impacted the increased signal accuracy error, because pressure changes (I_5) remained insignificant, whereas humidity (I_2) contributed to the error to a small extent. Such was the situation, for example, on 14 March 2014, when the applied principle (no. 78) had the following form:

If the cloud cover is average *and* humidity is very low *and* precipitation is low *and* temperature is average *and* pressure is average *and* solar activity is moderate *then* the accuracy error is high.

In most other cases, when the accuracy error reached a linguistic value of "high", solar activity would assume a linguistic value of "high" or "very high". The presented example, in some ways, confirms the effectiveness of the model and the tool.

6 SUMMARY

The described cases are undoubtedly a big advantage of the model. In many cases, the knowledge that the error source should not be sought among weather conditions is more important. Especially, if the factors are not accompanied by explicitness regarding the impact on signal interference. However, it can be concluded that the tool and the model implemented for it, constitute a clear base for the evaluation of the signal quality, depending on the tropospheric and ionospheric factors.

Bayesian approaches to lifetime prediction

F. Marsili & J. Bödefeld
Federal Waterways Engineering and Research Institute, Karlsruhe, Germany

P. Croce & F. Landi
Department of Civil and Industrial Engineering, University of Pisa, Italy

ABSTRACT: In this paper a framework to predict the remaining lifetime for existing waterways infrastructures based on stochastic modeling of deterioration processes and Bayesian analysis is presented. The application of the Bayes' theorem is motivated by the availability of expert knowledge as well as the collection of both qualitative and quantitative data from the structure. An original method is proposed to derive the prior statistical parameters of the gamma distribution describing the stochastic deterioration process, based on the assumption that the lifetime distribution can be approximated by the Birnbaum-Saunders statistical model. An appropriate Bayesian Network is finally implemented to improve the classification of the structure with respect to its proneness to damage. The outcome of the research work is to assist the owners of large infrastructural network in planning and prioritizing maintenance interventions.

1 INTRODUCTION

In the last decade the management of assets of infrastructures is becoming an increasingly important engineering task. As it is also stated in ISO 55000 (2014), accurate prediction of lifetime distributions are required to develop strategic asset management plan, and the use of a life-cycle management approach is fundamental to realize value from the asset. The German Federal Waterways Engineering and Research Institute (BAW) has developed a management system based on fixed inspection intervals, allowing, in principle, to optimize the repair or strengthening interventions, which are planned and carried out according to the outcomes of the inspections themselves. Although plenty of data regarding structures' condition are available in BAW, further steps should be undertaken in order to extract information regarding asset's lifetime (Haider 2012). The transformation of data into useful information is not always straightforward, and several approaches could be found in literature: for example, Trappey (2012) evaluates the asset lifetime using logistic regression; Lim & Mba (2013) estimate the remaining useful life implementing Kalman filter, while Tse & Shen (2013) pursue the same scope using support vector machines.

Another way to reach this goal is through a more accurate lifetime prediction, which could be obtained by modelling degradation phenomena through stochastic processes (Riascos-Ochoa 2016); the parameters of the process can be also updated applying the Bayes' Theorem, given any new information about the state of damage (Ang & Tang 2007). However this approach, which has already been adopted by Bousquet (2014) and Haowei (2015), has the disadvantage that only quantitative data can be considered for the updating, and only the uncertainty directly affecting model parameters can be reduced.

This paper thus proposes a new procedure, which allows updating prior knowledge considering both quantitative data and qualitative information through the definition and the implementation of a Bayesian Network. Besides, using the Bayesian Network allows also identifying the stochastic process better describing the degradation phenomena affecting the structures; the Bayes' Theorem is thus applied in order to reduce the uncertainty affecting the parameters of the identified stochastic process.

The paper is subdivided in the following way: in Chapter 2 the current approach to the asset management implemented by the BAW is presented, focusing the attention on its advantages and drawbacks; in Chapter 3 the available information for lifetime prediction is examined; in Chapter 4 the new approach to lifetime evaluation is presented, also briefly reviewing the theoretical background to gamma processes, Bayesian Analysis and Bayesian Network; in Chapter 5 the new approach is applied to a real case study, paying particular attention to the elicitation of the prior distribution and the Bayesian Network; in Chapter 6 conclusion and outlook are drawn.

2 CURRENT APPROACH TO ASSET MANAGEMENT

The BAW has developed tools for the management of a huge number of waterways infrastructures. The entire portfolio comprises several types of construction such as locks, weirs, culverts, canal bridges and lighthouses, also having different ages. A huge part of the asset is represented by massive structures older than 100 years and designed according to empirical methods with limited and simplified static calculations. These structures are characterized by sections with a large thickness, in which a multi-axial stress state takes place. Therefore they exhibit significant "reliability reserves" and relevant plastic resources, as demonstrated by the low number of recorded collapses which were mainly characterized by ductile failure modes. Despite their satisfactory performance at the ultimate limit states, these structures often fail to meet serviceability requirements such as crack width limitations or deformations (BAW 2015). Furthermore, several other time-dependent factors may affect their service life, also depending on climate change (Orcesi 2016) and obsolescence (Langston 2011). But, above all, main degradation phenomena affecting such kind of structures are spalling and corrosion. In order to manage maintenance intervention, the BAW developed an *ad hoc* maintenance management system called EMS-WSV (Bödefeld & Kloè 2012), shortly summarized in the following.

A database software, called WSVPruf, is used to store data collected on each structure during execution, inspection and maintenance. All damages are rated on an increasing scale from level 1 to level 4 (1: good condition; 4: critical condition) and they are recorded in a standard format by the program. Another program called 'Zustandsprognose' forecasts future deterioration stages of the structure for the next 20–30 years. Here, different approaches have been considered:

- Survival functions are applied to describe the deterioration of components where no evident damage is detected at the actual inspection time;
- A method based on discrete-time Markov processes is implemented in order to forecast the deterioration of detected damages. The parameters of the transition matrix are also determined according to survival functions;
- In some cases, physical equations have been used in order to validate Markov Chains.

Once the survival functions and Markov Chains have been defined, the evolution of the damage scale in time can be determined in an almost deterministic way, as a unique process. The remaining lifetime is also expressed in a deterministic way, and it represents the time lapse interval required to the damage scale in order to reach the critical condition, corresponding to level 4.

Obviously, the above mentioned methods present some advantages and drawbacks. On one hand, physical equations are usually considered as deterministic; they model only some deterioration processes and they require a huge amount of data to determine the main parameters of the physical laws. On the other hand, survival functions and Markov chains are powerful and flexible methods and they can be easily adapted to different deterioration processes. But, in both cases, it is difficult to take into account the influence of different factors on future degradation stages. In case of Markov Chains, the state of the structure is described through a unique variable, and there are no consolidated methods according which the parameters of the transition matrix can be defined. It must be also underlined that degradation phenomena largely depend on other factors such as the environmental condition and the quality of the materials, which is mainly the quality of concrete. Anyhow, despite they are crucial to determine the proneness to damage of the structure and to predict the remaining lifetime, these factors are almost completely disregarded by the current approach.

3 AVAILABLE INFORMATION FOR LIFETIME PREDICTION

Whether survival functions of Markov Chains are implemented, the parameters of the models should be determined from real data obtained from inspections, surveillance or *ad hoc* investigations. Obviously, provided that enough data exist, the parameters can be obtained through some sort of regression analysis or statistical investigation; but, since inspections are usually carried out every six years, surveillance is executed not later than three years after each principal inspection, and *ad hoc* inspections are only required after accidental shocking events such as ship impacts or flooding, available data are often not sufficient.

As underlined also by Haider (2012), asset lifecycle management is an information intensive task that requires generating, processing and analyzing huge amount of information. Data usually consist in both qualitative and quantitative information, able to describe the static, constructional and hydromechanical condition of the structure; however quantitative data collected during the inspections, being mainly obtained through simple measuring instruments, are quite rough, and for this reason they are affected by great uncertainties.

Another source of information is represented by expert knowledge. In the present case, this information was previously collected through a Delphi Interview submitted to a total amount of 28 experts (BAW 2009). In the Delphi Interview it was asked to answer the following question: "When does a special damage appear for the first time in your opinion?", or in other words, it was asked to elicit the survival functions given a certain degradation process and a specified degradation level. Three degradation levels were especially considered, notionally corresponding to damage levels 2, 3 and 4, subdividing the asset into three categories: fragile, normal and robust constructions, and a choice sheet with several different predefined time intervals (decades) was provided to the experts to facilitate the comparison of the answers.

Other relevant information can be also extracted by unstructured data and secondary database of tests results by conducting data analysis with suitably developed algorithms and software, as shown by Gao & Koronios (2012) and Croce (2018). This information can be supplemented by the results of *ad hoc* investigation such as material or chemical tests carried out on the considered structure or on similar constructions, built in in the same time period in a given geographical area, adopting comparable construction techniques.

Finally, data need to be acquired about relevant climatic actions influencing some degradation processes, like temperature or moisture, as well as about effects of climate change on them.

Aleatoric and epistemic uncertainties are inevitably associated to the above mentioned information, the second one representing a lack of knowledge, which can be reduced as soon as further data become available.

4 A NEW APPROACH TO LIFETIME PREDICTION

4.1 *Description of the new procedure*

In order to obtain more realistic lifetime prediction, an innovative method is proposed in the paper, where the deterioration phenomenon is modelled by an appropriate stochastic process, a gamma process, while epistemic uncertainties are suitably reduced resorting to the Bayesian Theorem.

Although updating the parameters of a stochastic process through data collected during inspection was already suggested (Bousquet 2014, Haowei 2015), the issue here presented involves some complications that have not been yet considered. One complication is due to the fact that different levels of epistemic uncertainties affect the lifetime prediction. A first level is connected to the proneness of the structure to damage: in fact, even if three categories of constructions can be defined (fragile, normal and robust) according to Chapter 3, the "category" to which the structure belongs is not known *a priori*. A second level is represented by the uncertainty affecting the parameters of the gamma process describing the degradation phenomenon within each category.

Moreover, as information derived from the structure is both qualitative and quantitative, but the degradation phenomenon is mainly described in quantitative terms, the problem becomes more and more complex. Nevertheless, qualitative data are important in order to figure out the sensitivity of the structure to damage, and the variables better describing the degradation process. Thus the question becomes: *how could qualitative and quantitative data be considered in order to reduce the two levels of epistemic uncertainties previously identified*?

A possible answer to this question is to resort to a Bayesian Network (BN) and to use it as a Naïve Bayesian Classifier in order to identify the "Proneness to damage" category of the structure and to remove the first level of epistemic uncertainty. Once the category has been identified, the parameters of the gamma process describing the degradation phenomenon within that class could be further updated considering the data about the damage progression collected during the inspection on the structure.

In the following, the theoretical background to the proposed approach is briefly introduced.

4.2 *Gamma process*

Gamma process is always applicable to model positive and strictly increasing degradation data, as suggested by Nicolai (2007) and van Noortwijk (2009).

A non-stationary gamma process $Y(t)$ with shape function $\Lambda(t) > 0$ and scale parameter β has the following properties:

1. $Y(0) = 0$ with probability one;
2. $Y(\tau) - Y(t) \sim \Gamma\left(\Lambda(\tau) - \Lambda(t), \beta\right), t \in [0, \tau)$;
3. $Y(t)$ has independent increments;

where $\Gamma(.)$ is the gamma function. Conditions (1) and (2) provide the probability density function of a gamma process:

$$f\left(Y, \Lambda(t), \beta\right) = \frac{\beta^{-\Lambda(t)}}{\Gamma\left(\Lambda(t)\right)} Y^{\Lambda(t)-1} \exp\left(\frac{-Y}{\beta}\right). \quad (1)$$

Thus the expected deterioration at time t can be expressed by a power law:

$$E\left(Y(t)\right) = \frac{\Lambda(t)}{\beta} = \frac{\alpha t^c}{\beta}, \quad (2)$$

where $\alpha/\beta > 0$ and $c > 0$ is a parameter describing the shape of the expected deterioration. Values of the parameter c for some relevant deterioration processes are given by van Noortwijk (2009).

Suppose now that the lifetime ξ is defined as the time when $Y(t)$ reaches a suitable failure threshold D (first passage). Then the cumulative distribution function (CDF) of ξ can be obtained as:

$$F(t) = \frac{\Gamma\left(\Lambda(t), D_\beta\right)}{\Gamma\left(\Lambda(t)\right)} \tag{3}$$

where $D_\beta = D/\beta$. Park & Pedgett (2005) showed that the exact probability distribution function (*pdf*) of ξ for a gamma process can be extrapolated from Equation (3). However, since the resulting expression is too complex for practical application, they proposed to approximate the CDF of ξ with the Birnbaum-Saunders (BS) distribution (Birnbaum & Saunders 1969), so that the mean lifetime $\bar{\xi}_{BS}$ simply results:

$$\bar{\xi}_{BS} = \left[D\frac{1}{\alpha\beta} + \frac{1}{2\alpha} \right]^c. \tag{4}$$

4.3 *Bayesian updating*

As known, Bayes' theorem represents an actualization principle and it allows the calculation of conditional probabilities or conditional densities.

In the discrete case, it describes the updating of $p(A_i)$ to $p(A_i \mid B)$ once observed the event B.

In the continuous case, given two random variables X and Z, with conditional distribution of X given Z $f(x \mid z)$ and marginal distribution $g(z)$, it describes the conditional distribution of Z given X:

$$f(z \mid x) = \frac{f(x|z)\, g(z)}{\int f(x|z)\, g(z)\, dz} \tag{5}$$

Depending on the interpretation of probability, the meaning of Bayes' theorem differs significantly. If probability (or density) is interpreted in a frequentistic manner, the theorem expresses the proportion of an event given the occurrence of another event. Conversely, if probability reflects the relative plausibility or degree of belief attributed to a certain event, Bayes' theorem forms the mathematical basis for adjusting or updating the probability as soon as more evidence becomes available.

Also the uncertainty on the parameters θ of a model could be described by a probability distribution, which has to be interpreted in most of the cases as a degree of belief. If the model is represented by a density function, a two-levels hierarchical model can be obtained, in which the second level is represented by the *pdf* on the statistical parameters of the probability model at the first level. The statistical parameters of the second level distribution are usually called 'hyperparameters', and the *pdf* 'hyperdistribution'. Anyhow, the degree of belief can be updated when new data are available, so that, once defined the posterior distribution, statements about the parameter can be made.

The computation of the posterior distribution involves the calculation of several integrals and for this reason is not straightforward. Simplified approaches have been sought in order to facilitate the updating of the prior distribution. The most popular approach is to resort to the so called conjugate prior distributions, which have the appealing features that prior and posterior distributions have the same functional form, and the updated parameters can be computed in an analytical way. In case of the gamma distribution, the conjugate prior distribution is characterized by rate parameter $\theta = 1/\beta$ following a gamma distribution, denoted as $\theta' \sim \Gamma(a', \nu')$ where $\nu' = 1/b'$ is the rate parameter and b' is the scale. Let $\boldsymbol{x} = \left[x_0, x_1, \quad, x_n \right]$ the observed degradation data, $t = \left[t_0, t_1, \quad, t_n \right]$ the corresponding times; denoting with $\Delta x_i = x_i - x_{i-1}$ and $\Delta t_i = t_i - t_{i-1}$ the degradation and the time increments, respectively, the posterior shape and rate parameter for θ can be computed in the following way (Ang & Tang 2007):

$$a'' = a' + \alpha\left(t_n - t_0\right) \tag{6}$$

$$\nu'' = \nu' + x_n - x_0 \tag{7}$$

and the posterior mean of θ can be written as:

$$E(\theta|\Delta\boldsymbol{x}) = \frac{\varepsilon''}{\nu''}. \tag{8}$$

from which the scale parameter β is easily obtained.

4.4 *Bayesian Network*

A Bayesian Network (BN) is a flexible tool that allows a rigorous processing of both quantitative and qualitative information (Kjærulff & Madsen 2008). It is defined as a directed acyclic graph (DAG) which determines a factorization of a joint probability distribution, as the nodes of the DAG represent the variables and the directed links describe the factorization. For each direct link from a node X to a node Y (where X is here the 'parent' and Y the so-called 'child'), a conditional probability $p(Y \mid X) = z$ is attached to Y. The conditional probability expresses a rule that assumes the following form: if $X = x$ then $Y = y$ with probability z, where y and x denote the state of Y and

X, respectively. Usually Y represents the effect of X, typically not observable by itself, but whose state is inferable via prior *pdf* $p(X)$, conditional *pdf* $p(Y \mid X)$ and Bayes' theorem:

$$p(X = x|Y = y) = \frac{P(Y = y, X = x)}{\sum_X P(Y = y, X = x)} \quad (9)$$

Observation may have the form of hard evidence if zero probability is assigned to all but one state; otherwise it is said to provide soft evidence. So far it is implied that the nodes of the BN represent discrete variables, at which probability tables expressing conditional probabilities are attached. However it is also possible to have continuous variables: in this case it is necessary to specify a density function for each combination of states for the parent variables. Whether discrete or continuous variables, BN can be applied to solve a wide range of problems, and, *inter alia* for classification purposes. In this specific case, they are especially called Naïve Bayesian Classifier, because of the strong (naïve) independence assumptions assumed among the features that determine the class label drawn.

5 CASE STUDY

In order to clarify the proposed approach, a case study is here developed. The attention is mainly focused on the elicitation of the prior gamma distribution describing the stochastic process; this task is carried out exploiting the approximation of the lifetime distribution with the BS distribution. The case study aims to illustrate a practical application of the proposed method referring to a unique damage detected on an existing lock. Extensions to cases involving several damages and different deterioration processes will be discussed in future works.

5.1 *Elicit the prior distribution*

A prior distribution for the model parameters is elicited according to the expert knowledge collected through the Delphi interview described in Chapter 3. It would be easier if experts could have been asked to represent their opinion in statistical terms, for example: "*Given the degradation phenomena modelled through a gamma process, what would be the shape and the scale parameters of the gamma distribution?*". However it is unlikely that experts could give an accurate answer. Except in case of symmetric distribution, when mean value and standard deviation can be easily elicited, they usually think in terms of percentile. Moreover, expert knowledge actually concerns expected lifetimes rather than damage increments; for this reason, the prior information should be transformed in a form leading to an easy identification of the prior gamma distribution. One way to do this is by using Equation (4) which links the parameters of the gamma distribution with the expected lifetime. Given the expected lifetime required to reach certain degradation levels, and the speed of the process, represented in some way by the value of c, the parameters of the gamma distribution can be easily obtained by solving the system of equations. In this case, two equations are required to determine the two parameters: those related to damage levels 2 and 3 are considered, as expert knowledge about events that happened earlier should be more reliable compared to that related to future events. The uncertainty on the parameter is similarly defined, considering the uncertainty affecting the expected lifetimes and assuming a confidence interval. The procedure, which is very general, can be applied to elicit prior distribution for any degradation process.

In the specific case, in Table 1 the average of the expert predictions are summarized in terms of time lapses required by the crack width to reach the levels corresponding to different degradation class, while in Table 2 the confidence intervals of the predicted time lapses, corresponding to probability of exceedance of 75% and 25%, respectively are reported. Given the progress in time of the degradation process, it is also possible to conclude that the degradation speed can be assumed constant, at which $c = 1$ corresponds. For example, in case of fragile construction, the system of equations results:

$$\begin{cases} 10 = \dfrac{0.3}{\alpha\beta} + \dfrac{1}{2\alpha} \\ 20 = \dfrac{0.7}{\alpha\beta} + \dfrac{1}{2\alpha} \end{cases}. \quad (10)$$

The values of parameters α and β obtained by solving all the systems of equations are shown in

Table 1. Expert knowledge results—Delphi Interview – (DR: damage level, CW: crack width, $\bar{\xi}$: expected lifetime, F: fragile, N: normal, R: robust).

		$\bar{\xi}$ (years)		
DL	CW	F	N	R
2	0.3	10	25	50
3	0.7	20	50	100
4	1	30	75	150

Table 3, while the simulation of the gamma process for fragile, normal and robust structures with these values are shown in Figures 1, 2 and 3, respectively.

For analytical and mathematical tractability, it is then assumed that only β is random and it also follows a gamma distribution, so that the prior distribution is then conjugate through the likelihood function to the posterior, simplifying the updating calculation. The prior distribution can be defined by considering the uncertainty affecting the expected lifetime: each time lapse interval corresponds to an interval for the parameter β. Assuming the same probabilities of exceedance, it will be possible to elicit the shape a' and scale b′ (or the rate v') parameters of the prior distribution (Table 3).

5.2 *Elicit the Bayesian Network*

The Bayesian Network is elicited according to prior information and the previously defined gamma process. In the remainder of the paper, only the most fundamental variables will be considered; anyhow, as soon as that further analysis will be carried out, it will be possible not only to consider the relationships among a greater number of variables, but also to elicit the structure of the network and the conditional probabilities from data itself rather than from expert knowledge. The variables that will be considered are: the proneness to damage of the structure (also called damage category (DC), characterized by three possible states: Fragile (F), Normal (N) and Robust (R)), the concrete quality (CQ, characterized by three possible states: Bad (B), Normal (N), Good (G)), the damage quantity (DQ, characterized by three possible states: extended (E), limited (L), sporadic (S)) and

the crack width referred to different time steps (CW), characterized by 10 possible states.

The states of each variable, the dependency relationships and the associated probability tables are shown in Figure 4. For the sake of simplicity only the probability table referred to t = 10 years is here showed.

The concrete quality, the damage quantity and the crack width can be observed, while the updating of the probability of the damage categories, that cannot be observed, is a key objective. It is assumed that the observable variables are independent, given the variable that it should be classified. Although this assumption facilitates calculation of posterior probabilities, it is actually inaccurate, as it is often the case with Naïve Bayesian Classifier. Nonetheless it has been demonstrated that the crude independence model could perform surprisingly better than more complicated alternatives (Hand 2001); furthermore precise estimation for the posterior class probabilities are here not required, since they will be used for comparison purposes, as better clarified in Chapter 5.3. By collecting evidence regarding the observable variables, it will be possible to infer the proneness to damage of the structure. It is important to underline that assuming a parametric deterioration process simplifies the relationships among the variables; in effect, the deterioration at instant t can be considered independent from the deterioration at the previous instant, preventing us to resorting to a much complicated dynamic Bayesian Network (Straub 2009, Ramìrez & Utne 2015). Furthermore, the probability table associated to the variable 'crack width' can be easily obtained simulating the gamma process. The variable is actually continuous, and the degradation at each time step t is represented by a gamma distribution with shape αt and scale β (see Chapter 4.2). However BNs that involve continuous random variables imply some complications, which are outside the purposes of the present paper and will be discussed later in further studies. Moreover, as it can be seen later from Table 4, data about crack widths are actually given in terms of intervals rather than single values, since, as already stressed, the measuring devices are rough and measures are inevitably affected by great uncertainty. Also for this reason, the continuous variables are then discretized so that each state corresponds to collectable measures.

5.3 *Implementation of the Bayesian Network and updating of the gamma process*

Data referring to three different structures (A, B and C) and related to a damage event having a single cause are considered in the case study (Table 4).

First of all the data are used in order to classify the structure by using the previously defined BN. If all the data point out that one category has very high updated probability (for example higher than 0.70), then it is possible to directly consider the Gamma distribution corresponding to that category and the related uncertainty of the statistical parameters for a further Bayesian updating. However, in several cases, the results could not point out clearly at a certain category, because two adjacent categories have similar updated probabilities; in this case, it is possible to conservatively consider only the lowest category, or to collect further data.

Once that the prior model will be chosen, it is possible to update it resorting to the analytical formula expressed by Equations (6) and (7).

Table 4. Inspection results on three structures, A, B, C, (CQ: concrete quality, DQ: damage quantity, CW: crack width).

			1st inspection			2° inspection		
Str.	Year	CQ	Year	DQ	CW	Year	DQ	CW
A	1995	1	2005	1	0.5	2017	1	0.8
B	1975	2	2005	2	0.5	2017	2	0.7
C	1955	3	2005	3	0.3	2017	3	0.4

Table 5. Updated probabilities for damage category (DC) derived from the Bayesian Network, updated statistical parameters for gamma process, prior and updated lifetime prediction $\bar{\xi}$ in years, obtained simulating the gamma process.

	F	N	R	ε''	v''	$\bar{\beta}''$	$\bar{\xi}'$	$\bar{\xi}''$
1	0.96	0.03	0.01	9.67	1.62	0.16	28	33
2	0.07	0.72	0.21	8.23	1.52	0.184	65	70
3	0.01	0.09	0.90	7.75	1.42	0.183	135	140

Finally β'' can be used to improve the prediction of the structure lifetime when the limit damage level will be reached; the prediction can be obtained by simulating the gamma process considering the updated parameter.

The results are listed in Table 5.

6 CONCLUSION

An innovative procedure to lifetime prediction exploiting the potentialities of the Bayes' Theorem has been proposed, as depicted in the flowchart shown in Figure 5, based on the following points:

- The degradation phenomenon is modelled as a stochastic process in which degradation increments are gamma-distributed.
- Considering background information and qualitative and quantitative data collected during inspections, a Bayesian Network is adopted to classify the proneness to damage of the structure.
- Uncertainties affecting the parameters of the stochastic process are updated considering quantitative data about the degradation level reached by the structure by applying the Bayes Theorem.

Advantages of the proposed method are:

- Qualitative and quantitative data can be used at the same time, to refine lifetime predictions.
- Adoption of gamma processes to model degradation phenomena simplifies the structure of the Bayesian Network and the computation of the conditional probabilities.

A case study has been finally developed in order to show a practical application of the proposed method. Attention has been largely devoted to the elicitation of the prior distribution for the gamma process, and real data collected during inspection on real structures have been considered. In authors' opinion, this approach is very promising although some aspects need further studies. In effect, the value of the constant c, that regulates the speed of degradation, should be determined more precisely, also considering different degradation phenomena. An improved Bayesian Network including continuous variables, representing the state of damage at different time steps and whose parameters are directly derived from measurements, should be suitably developed. Uncertainties in the collected data, as well as uncertainties in the degradation limits should be duly considered too. At the final stage, once the proposed procedure is improved and suitably validated, its efficiency should be also verified by comparing theoretical time lapse predictions with empirical data on a sufficiently large number of existing structures. The approach can be implemented in order to plan in a more precise and realistic way asset life-cycle, and to identify on which structures maintenance interventions should be firstly performed.

A methodology for selecting and defining maintenance tasks for critical equipment

M. Sousa
Department of Production and Systems, University of Minho, Guimarães, Portugal

I.S. Lopes
Department of Production and Systems, Algoritmi Research Centre, University of Minho, Guimarães, Portugal

ABSTRACT: This paper presents a methodology, developed through a case study, to support preventive maintenance tasks selection based on Reliability Centered Maintenance (RCM) methodology. The case study was carried out in an electronic goods company that follows the Total Productive Maintenance (TPM) philosophy. The methodology has six steps and it is intended to be applied in every mechanical and electromechanically equipment of the plant and it is applicable in equipment with some historical data of interventions. To validate the methodology, one system of the plant was selected and all the steps of the methodology were followed. With this application, a reduction of 33% in failures number and production losses was achieved, as well as a MTBF improvement of about 15% and therefore an increase in machine yield.

1 INTRODUCTION

1.1 *Background*

Companies have sought to improve their operational efficiency with the aim of offering high value added products (Ahuja & Khamba 2008; Eti et al. 2004; Konecny & Thun 2011). The growth of mechanization and automation of plants created a need to improve production equipment reliability, availability and productivity. This way, consumer needs can be pleased and at the same time competitiveness is improved (Bakri et al. 2012; Muchiri et al. 2011; Soni 2013).

The maintenance management area gives the means to deal with this challenge because it allows to improve systems performance (Kutucuoglu & Hamali 2001), instead of the traditional vision that maintenance actions are only applicable in repairing "broken items" (Ahuja & Khamba 2008).

Indeed, Moubray (1997) considers that modern management challenges are: to select the most appropriated techniques, to deal with all failure modes, to have cost effective processes and to satisfy customer expectations and of all the society.

1.2 *Objectives*

The main goal of this paper is to present a maintenance planning methodology. The methodology is based on Reliability Centered Maintenance (RCM) process and aims to be applicable in all mechanical and electromechanical equipment. By using failure data, it will define the most appropriated maintenance tasks, as well their periodicity. In addition, with the development of the methodology the following objectives are intended to be achieved:

- Balancing corrective and preventive maintenance tasks;
- Improving key performance indicators of the machines;
- Reducing total maintenance cost;
- Linking the maintenance planning methodology and Total Productive Maintenance (TPM) philosophy;
- Matching qualitative and quantitative maintenance management approaches.

1.3 *Paper outline*

This paper is structured in six sections. In the first one is presented the background, the goals and the structure of the paper. In the second one, a short literature review is produced to frame the subject of the paper. The third section is on the development of the critical equipment maintenance planning methodology and explains all its steps. In section four, one machine of the case study company´s plant is used to exemplify the methodology. The last section presents the paper conclusions.

2 LITERATURE REVIEW

Maintenance management has evolved in last decades and it can be divided in three main generations The first one is related to period before the

second world war (Moubray 1997). In this period, machines were simple and very reliable. Hence, maintenance was based on corrective actions to repair the equipment when some failure occurs (Ahuja & Khamba 2008; Garg & Deshmukh 2006; Soni 2013). After the second world war, equipment became more complex which triggered the first preventive maintenance tasks (Alsyouf, 2007; Moubray, 1997).

More recently, the research made in maintenance management field allowed to innovate these concepts and new techniques emerged, such as condition monitoring and failure mode and effects analysis (FMEA) (Moubray 1997). At the same time, TPM and RCM philosophies were developed (Garg & Deshmukh 2006; Soni 2013).

According to NP EN 13306 (2007) standard, maintenance is defined as a "combination of all technical, administrative and managerial actions during the life cycle of an item intended to retain it in, or restore it to, a state in which it can perform the required function". The same standard also defines the maintenance interventions types or strategies. In a first level, the maintenance concept can be divided into preventive or corrective. Performing preventive maintenance tasks reduces the number of failures. As the cost of preventive maintenance increases with increasing frequency of interventions, the cost of corrective maintenance reduces. Thus, a replacement periodicity which minimizes maintenance costs should be found out (Figure 1).

Until the 60th decade, maintenance was based on the premise that every part has a defined life time at which it is necessary to do a general review, so it was applied the scheduled maintenance approach (Siddiqui & Ben-Daya 2009). However, in 1960, airline companies started to realize that this mindset was not cost-effective. The found solution was to study the failure pattern of every component.

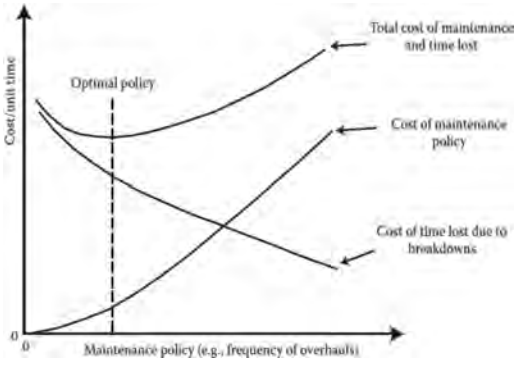

Figure 1. Maintenance total cost (source: Jardine & Tsang, 2013).

Hence, it was proposed the Maintenance Steering Group publications, that gives rise to RCM methodology named by Stanley Nowlan & Howard Heap (Siddiqui & Ben-Daya 2009). The Maintenance Steering Group is a coordination group that defines maintenance plans to new aeronautics projects. The main goal of RCM methodology is to keep system functions during its operational time. To achieve this intention, RCM uses some maintenance strategies such as time-based maintenance (TBM), condition-based maintenance (CBM), run-to-failure (RTF), hidden failures and design modification (Siddiqui & Ben-Daya 2009). This methodology is also supported by FMEA, Failure Tree Analysis and other decision making tools (Backlund & Akersten 2003; Eti et al. 2004; Siddiqui & Ben-Daya 2009; Waeyenbergh & Pintelon 2002). One definition of the RCM process given by Ahuja & Khamba (2008) is: "structured, logical process for developing or optimizing the maintenance requirements of a physical resource in its operating context".

RCM methodology is based on system functions, failure modes and effects study and its aim is to define the system maintenance requirements (Ahuja & Khamba 2008; Carretero et al. 2003; Mokashi et al. 2002; Siddiqui & Ben-Daya 2009). The selected maintenance tasks should be effective in reducing the possibility of occurrence of failure modes as well as applicable (Mokashi et al. 2002; Siddiqui & Ben-Daya 2009; Smith 1993). In this scope, "applicable" means that the task should avoid or detect the failure, while "effective" is related to costs (Siddiqui & Ben-Daya 2009).

In terms of application, Smith (1993) shows that RCM implementation should follow seven steps:

1. System selection and information collection;
2. System barriers definition;
3. System description and functional block diagram;
4. System functions and functional failures;
5. FMEA;
6. Decision tree analysis;
7. Task selection.

Eisinger & Rakowsky (2001) developed a new version of the decision tree because they believe that the questions should not be answered with total assurance. Thereby, the authors developed a tree in which the path is decided in terms of probabilities. A set of eight questions are answered according to the probability of the answer be "YES". After that, a value r_i is calculated using the traditional method of decision trees, where i is the index of each option. At the end, the option with bigger r_i is selected. This procedure was applied to a fire detection and extinction system.

Waeyenbergh & Pintelon (2002) developed a framework that combines TPM and RCM philosophies with an economic concern, once they claim that maintenance is now an economic concern. Hence, to each question of the decision tree, one is requested to answer first with a technical point of view and then with an economic criteria. Finally, the decision is the use of one the five possibilities of maintenance tasks or the search for additional data.

Rastegari & Mobin (2016) studied the case of a gearbox Swedish company. These authors settled up two flowcharts with two different points of view: technical and output-based. The types of questions are different to each flowcharts, however the result is the selection of one of the following tasks: Time-Based Maintenance (TBM), Breakdown Maintenance (BM), CBM or Improvement and Restoration.

Dehghanian, Fotuhi-Firuzabad, Aminifar, & Billinton (2013) recognized the RCM importance but also the barriers in the implementation of this methodology in energy industry. To improve the current situation, they developed a RCM version with a cost benefit analysis, as well as an output evaluation to help to improve maintenance plans. Following a set of steps similar to Smith (1993) approach, the authors have proposed a prioritization of maintenance tasks through Benefit-to-Cost Ratio (BCR) index.

The main benefits of RCM cited in the literature are:

- Maintenance plans quality improvement (Deshpande & Modak 2002);
- Increase of equipment reliability and availability (Backlund & Akersten 2003);
- Ensure safety (Backlund & Akersten 2003);
- Increase of equipment lifetime (Carretero et al. 2003);
- Maintenance costs reduction (Carretero et al. 2003; Waeyenbergh & Pintelon 2002);
- Unplanned downtime reduction (Backlund & Akersten 2003; Carretero et al. 2003).

On the other hand, the most cited disadvantage is the fact that RCM process is based in a qualitative base and focused only on system reliability and do not quantify the maintenance costs (Braglia et al. 2013; Waeyenbergh & Pintelon 2002).

3 METHODOLOGY

The proposed methodology aims to define a cost-benefit maintenance plan based on machine's failure modes. The process follows the RCM principles and uses some TPM concepts once the TPM philosophy is currently adopted by the case study company. Thus, the methodology has six steps and starts with the selection of the critical system, the team building and collection of some data about the system selected. The second step consists in system description and identification of analysis boundaries. Afterwards, the system functions and functional failures are defined. The fourth step uses a matrix to find the relationship between components and functional failures as base to apply the machinery FMEA technique. In the next step, a decision tree is proposed to help to find out which maintenance tasks can be used to mitigate the critical failure modes defined by FMEA. By the end, it is proposed a cost analysis step that allows choosing a cost-benefit plan for the machine.

3.1 *System selection, team building and data collection*

This step starts with a prioritization of equipment based on three criteria: Mean Time Between Failures (MTBF), spare parts cost (C) and preventive maintenance total time (T). Using Analytic Hierarchy Process (AHP) method, it was assigned weights to the mentioned criteria with the support of the case study company. This procedure was done with help of Saaty's relative importance scale (Table 1).

The result matrix is shown in Table 2 that was validated by a consistency test.

Table 1. Saaty's relative importance scale.

Intensity	Meaning	Explanation
1	Equal importance	Two activities contribute equally to the objective
3	Weak importance of one over another	Experience and judgment slightly favor one activity over another
5	Essential or strong importance	Experience and judgment strongly favor one activity over another
7	Demonstrated importance	An activity is strongly favored and its dominance demonstrated in practice
9	Absolute importance	The evidence favoring one activity over another is of the highest possible order of affirmation
2, 4, 6, 8	Intermediate values	When compromise is needed between two definitions

Table 2. Matrix of comparison of criteria.

	MTBF	C	T	Weight
MTBF	1	0,2	0,3333	0,1096
C	5	1	2	0,5813
T	3	0,5	1	0,3092
Sum	9	1,7	3,3333	1

Table 3. Criteria's scale.

Level	MTBF (min)	C (€)	T (min)
1	MTBF > 4897	C < 390	T < 333
2	4897 ≥ MTBF > 1825	390 ≤ C < 703	333 ≤ T < 442
3	1825 ≥ MTBF > 976	703 ≤ C < 1483	442 ≤ T < 664
4	976 ≥ MTBF > 766	1483 ≤ C < 5456	664 ≤ T < 976
5	MTBF ≤ 766	C ≥ 5456	T ≥ 976

At this point, it is necessary to solve another concern. Each criterion has its own measure, thus, a quantitative scale with five levels was defined, where 1 is assigned to the best scenario and 5 is assigned to the worst. Table 3 presents an example that was obtained with data of the case study company.

The levels shown in Table 3 were obtained by analyzing a random sample of the plant machines. For each type of machine the MTBF, spare parts cost and preventive maintenance time was collected from a period of 18 months. The levels were chosen using the percentiles 20, 40, 60 and 80 of the sample.

After the collection of the values, the machine ranking (R) is obtained by equation (1) considering the previously defined weights.

$$R = 0{,}1096*MTBF + 0{,}5813*C + 0{,}3092*T \quad (1)$$

The critical equipment is the one that has the lowest R value.

After the selection of the more critical equipment, the team is built according to the equipment type. It is also necessary to collect some information about the equipment, such as: supplier specifications manual, defined process rules for production and events data. The latter is composed by corrective, preventive and improvement actions.

3.2 *System description and limits*

The second step comprises the steps 2 and 3 of original RCM procedure. The procedure is simplified because this methodology will analyze machines with known operation behavior. Hence, this step consists in drawing the functional diagram of the equipment and lists the analysis limits, i.e. the system parts that will not be considered.

In this scope, a standard structure for all machines was considered, as shown in Figure 2.

Following the Figure 2 concepts, a "system" is a complex structure that has several functions. Each function is associated to a "subsystem" to facilitate the organization. In the next level appears the "parts" at which failure modes are associated. Lastly, the "causal elements", i.e., the reasons of failure modes (causes), are connected to the failure modes.

3.3 *Function analysis and functional failures*

In the third step, the subsystems functions are listed and each function should be described on basis of quantitative requirements, if possible. This way, it will be easier to understand the functions that make the machine useful.

Afterwards, the functional failures to each function, i.e., the conditions in which some function is not achieved, are listed. Only some of these functional failures will progress in the analysis. Hence, the team should choose the critical functional failures in terms of department objectives, costs, maintenance time required or breakdown frequency.

3.4 *Failure Mode and Effects Analysis (FMEA)*

In this step, the authors added a preparation phase before FMEA. Using a matrix with parts in line and functional failures in column, the team will identify what parts have relationship with what functional failures. This way, only critical parts will be analyzed in FMEA.

To each of these parts, the team will deliberate what failure modes can occur based on experience. To each failure mode is associated an effect at system level. This effect should be described in two ways: machine condition and error message. One example is "Machine stop with error 'NOK'", so after the failure mode has occurred, the machine has stopped and the message error was displayed on the monitor.

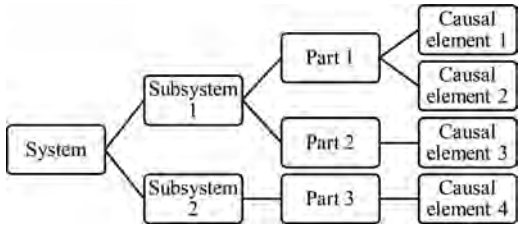

Figure 2. Standard structure of a system.

Afterwards, the team needs to find the causes. In this methodology three types of causes are considered: causal element, operation error or raw material issue. These three groups are adopted because the plant has the experience that an operation error or a raw material issue causes a breakdown of the equipment, so these problems should be considered to mitigate them since they affect machine and plant performance.

Detection and prevention actions should be filled in FMEA form. Examples of detection actions are: error messages, parameter changes and sensorial detection of an irregular behavior. It needs to be highlighted that not only detection before failure should be considered but also the detection modes after failure occurrence.

Regarding prevention actions, redundancies, tests or other methods that prevent the failure mode are considered. This field should not be confused with preventive maintenance actions.

Lastly, the Risk Priority Number (RPN) is calculated. In this methodology, a critical failure mode is characterized by a RPN > 100.

3.5 *Decision tree*

The proposed decision tree (Figure 3) is based on RCM original concepts but also in the autonomous maintenance and the planned maintenance TPM pillars. Thus, the alternative maintenance policies considered are: CBM, TBM, Design-Out Maintenance (DOM) and RTF.

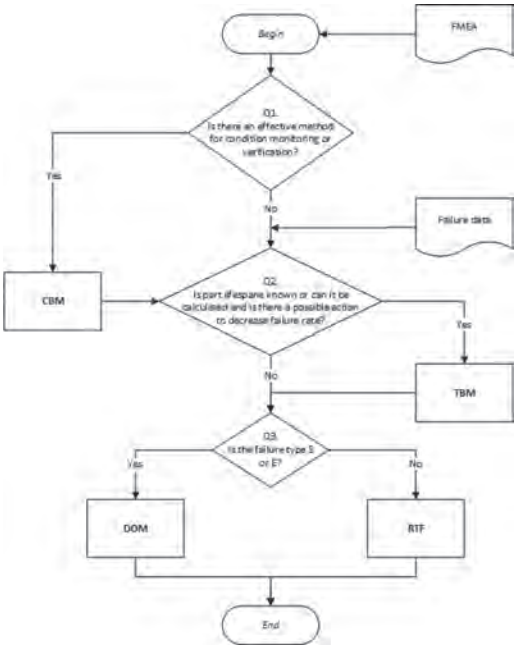

Figure 3. Decision tree.

The application of the decision tree is simple and intuitive. To each failure mode, the first question that is done is: "Is there an effective method of monitoring or checking the condition?" This question is related to CBM policy. If the answer is positive, the policy is taken as an option. However, the analysis continues once the goal is to find out all the applicable maintenance tasks. If the question is "No", the analyst goes directly to the second question.

Retaking the analysis, the second question is: "Is the component life span known or can it be calculated and is there an effective action that can decrease the failure rate?" In other words, to apply a time-based maintenance action it is needed to have some available historical failure data to calculate the life span of the part and an action that reduces the failure rate. Going down, the third question is: "Is the failure type S or E?" The failure modes can be classified in one of four types: safety (S), environment (E), operational (O) or none (N). According to RCM, a failure with impact on safety or environment should not occur, so for these types the option is a design modification (DOM). A RTF task can be considered to the other two types of failures.

For CBM, TBM and RTF policies there is the possibility to involve the operator in the maintenance action. So, after the selection of the applicable policies, it should be asked "Can the task be performed by the operator?" This shows the TPM influence in this methodology and it was considered because an autonomous maintenance task is more cost-effective, it makes maintenance planning easier and improves the operator skills and motivation.

3.6 *Economic evaluation and maintenance task selection*

The last step of this methodology has three main goals: to characterize the failure data distribution, to define the preventive intervention periodicity and to select the more cost-effective maintenance task.

The failure pattern of the component can be estimated by adjusting the failure data to a Weibull distribution. This distribution was chosen for the reason that it is adaptable because of its three parameters: form (β), scale (η) and position (γ) (Jardine & Tsang 2013).

In the end, it is possible to estimate average and standard deviation by equations (2) and (3).

$$\mu = A * \eta + \gamma \tag{2}$$

$$\sigma = B * \eta \tag{3}$$

The next goal is to calculate the optimal periodicity of preventive intervention, tp, if TBM was one of the selected policies. To obtain this value, maintenance costs should be balanced to minimize total cost (Jardine & Tsang 2013). Hence, the aged based policy is considered and involves two types of costs: failure cost (Cf) and preventive cost (Cp) (Jardine & Tsang 2013).

To obtain Cf spare part cost, workforce cost (MDO) and production loss (PL) cost are accounted for, as equation (4).

$$C_f = C_{spare\ parts} + C_{MDO} + C_{PL} \tag{4}$$

On the other hand, Cp is calculated by spare part cost and workforce cost – equation (5).

$$C_p = C_{spare\ parts} + C_{MDO} \tag{5}$$

This effort to obtain the cost values allows the use of the Glasser graph to find out the tp value (Fig. 4).

The Glasser graph allows reading z and ρ values. The variable z is used to obtain tp through equation (6) (Jardine & Tsang 2013).

$$tp = \mu + z * \sigma \tag{6}$$

The value ρ means the cost of optimal policy as a percentage of RTF policy cost (Jardine & Tsang 2013).

Finally, the annual cost of the different options is estimated. The authors have defined this period of time to make easier the cost comparison.

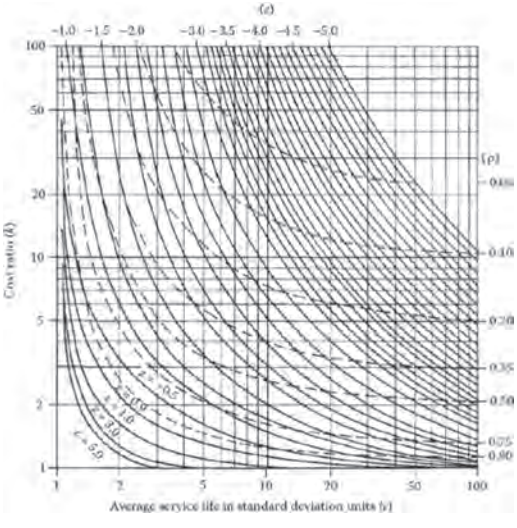

Figure 4. Glasser method for age-replacement policy.

The first one is CBM and its cost involves the preventive maintenance cost C_p, an inspection cost ($C_{inspection}$) and the investment value (Inv), if required.

$$C_{CBM} = f_1 * C_p + f_2 * C_{inspection} + (Inv/n) \tag{7}$$

Equation (7) assumes that failure is always predictable and f1 is the number of preventive intervention in a year and f_2 the number of inspection actions also in a year. The f_1 value can be calculated using a reliability study or estimated based in team experience. The f_2 value should be estimated the same way. The value of Inv is divided by n that indicates the expected number of years in which the condition monitoring equipment is expected to function well.

For TBM two distinct calculation formulas were considered.

$$C_{TBM} = \rho * f_3 * C_f \tag{8}$$

Equation (8) considers an optimal scenario where data is available and in which f_3 is the inverse of MTTF. About ρ, this variable allows to obtain TBM cost based on RTF cost. Hence, equation (8) represents the optimal TBM policy cost (with periodicity tp).

$$C_{TBM} = f_4 * C_p \tag{9}$$

On the other hand, equation (9) will be used when there is no available data to use Weibull distribution to estimate tp. Here, f_4 is an annual frequency defined by the team based on its experience.

For the RTF policy, the cost is obtained by equation (10).

$$C_{RTF} = f_3 * C_f \tag{10}$$

In case of equation (10), f_3 should be in an annual base.

After the calculation of cost through the previous equations, the maintenance task to apply the critical failure mode should be chosen. Between TBM, CBM and RTF policies, the cheaper one will be chosen. However, if DOM is an option, the team needs to analyze its benefits comparing to the cheapest task. In case of S or E effect of failures, it shall be analyzed if the probability of failure is reduced to a level considered adequate. Therefore, for each policy the associated probability of failure (or reliability) must be calculated and it should be made an analysis of costs together with an analysis of this probability.

4 APPLICATION

The described methodology was applied to electronic goods of the company plant.

The critical equipment was chosen between 10 types of machines. Table 4 shows the result of the prioritization (step 1).

In Table 4, it can be seen that GP is the machine with biggest rating value. This machine is a dispensing equipment whose process consists in dispensing a mixture with thermal conductivity properties.

After the selection of the critical equipment, a team of five members with multidisciplinary knowledge was formed. One of the members was the moderator.

Related to historical failure data, the interventions done during year 2016 were collected.

The first task of the team was to draw a functional diagram of the system GP. The result was a set of eight subsystems and it is shown in Figure 5.

The team has deliberated that subsystems 6 and 7 should be excluded from analysis because of their lower failure rate.

The third step is functions and functional failure study. In Table 5 it is possible to see an application example for dispensing subsystem.

In this case, the two functional failures go to next step. Following this thought, the team found out 22 functional failures and chose 13 ones, since some of them do not have great importance in terms of preventive or corrective interventions.

Through the relationship matrix the team crossed functional failure data with machine parts.

Table 4. Application of prioritization method.

Machine	MTBF	C	T	R
GP	5	5	4	4,6908
BUR	3	4	5	4,1996
LB	1	4	2	3,0529
ICT	3	3	3	3,0000
AOI	2	3	1	2,2721
RH	4	2	2	2,2192
AMF	5	1	3	2,0566
FCT	2	1	4	2,0370
MMC	1	1	1	1,0000
PR	1	1	1	1,0000

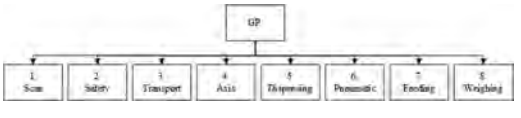

Figure 5. System structure.

The result was 12 parts with a strong relationship with system failures. Table 6 presents an example for 2 machine parts.

So, FMEA technique was applied to study the failure modes of these 12 parts and find out their causes. Using RPN rule, 25 critical failure modes was discovered. However, 3 of them are related to operation errors and raw material issues and, therefore, only 22 failure modes go to next step—the decision tree.

After running the decision tree 22 times, the team selected all the effective and possible tasks to each critical failure modes. Table 7 presents an excerpt of this step.

Calculating the costs of each task, Table 8 was obtained.

As example, for failure mode with code 1.1.1.1.1 TBM task was selected with a frequency of 7 hours and for 1.1.1.1.3 RTF was the only available option.

Table 5. Functions and functional failures analysis.

Subsystem	Function	Functional failures	Y/N
5. Dispensing	5.3 Mix materials A and B by 1:1	5.3.1 Do not mix materials A and B by 1:1	Y
		5.3.2 Do not mix materials A and B at all	Y

Table 6. Relationship between parts and functional failures.

	Functional failures				
Parts	1.1.1	1.1.2	1.1.3	2.1.1	2.1.2
Pump A	X	X	X		
Axis X				X	X

Table 7. Decision tree results.

Failure mode	Q1	Q2	Q3	Possible tasks
1.1.1.1.1	N	Y	N	TBM, RTF
1.1.1.1.3	N	N	N	RTF

Table 8. Economic evaluation of tasks.

Failure mode	Options	Annual cost	Frequency
1.1.1.1.1	TBM	8 526 €	7 hours
	RTF	11 392 €	
1.1.1.1.3	RTF	401 987 €	–

5 CONCLUSION

This paper presents a methodology for selecting and defining maintenance tasks for critical equipment. This procedure is based on RCM methodology and uses the AHP method to machine prioritization, the FMEA technique to study parts failure modes and an economical evaluation of maintenance tasks, the Weibull distribution and the Glasser Graph to define the most appropriate maintenance policy. In addition, some TPM concepts are taken into account by the methodology.

In short, the main differentiating factors regarding RCM are: the consideration of autonomous maintenance as a possible maintenance task to be selected and the economical evaluation of the tasks for this selection.

As results of application in the GP equipment of the case study company, the plant has achieved a 33% reduction in the number of failures, a 33% reduction in production losses, a MTBF improvement of 15% and an increase of machine yield of 1,8%. It is also expected to reduce total maintenance cost in mid-term.

Therefore, the application of the methodology makes the work of maintenance technicians more effective, since only appropriate and cost-effective preventive maintenance tasks are performed. It allows also the involvement of the operators in simple maintenance tasks as recommended by TPM. Since, the selection of maintenance tasks are oriented by costs, whenever adequate, the application of the methodology leads to a reduction in the overall maintenance cost.

A study of the relationship between sample size and the confidence level of MTTF for products with exponential failure distribution

Y. Wang, H. Cheng & D. Xu
NAA, Beijing, China

ABSTRACT: It is common in applications to ignore the influence of sample size and population size when evaluating confidence lower limit of Mean Time to Failure (MTTF) for products with exponential failure distribution. The conventional method assumes that failure times or lives of different samples are independent identically distributed random variables. This assumption holds reasonably when the population size is much larger than the sample size. However, it will induce substantial inaccuracies when the sample size is not negligible to the population. To this problem, the influence from the sample size to the confidence limit of MTTF is analyzed when the population is determined. First, the conventional method is reviewed. Then, the formulae based on hypergeometric distribution are derived to reflect the relationships among sample size, population size, confidence level and confidence limit. Finally, an example is presented to illustrate the suitability of the proposed method and to show the computation errors from the conventional method.

1 INTRODUCTION

Normally, the confidence lower limit of Mean Time to Failure (MTTF) for products with exponential failure distribution are verified by reliability verification test where some samples are picked up randomly (Jiang et al. 2012, Modarres et al. 1999) to conduct the test. Under most conditions, the number of samples is very small compared to the population. Then it is reasonable to assume that the failure times of different samples are independent and identically distributed (i.i.d.) random variables.

However, for complex system or product, the population size is not very large, usually. Hence, the sample size is not ignorable to the population in the reliability verification test plan (Li & Jiang 2006, Yan et al. 2014). The conventional method without considering the influence from sample size will result in computation error.

In this study, the conventional method ignoring the influence of sample size is reviewed. Then, a method considering the number of samples based on hypergeometric distribution (Ronald et al. 2009, Zhao & Mi 2015) is presented. Finally, the example is used to show the suitability of the proposed method. And the conventional method is used as well to show the computation error.

2 THE CONVENTIONAL METHOD

For a product that the failure time following exponential distribution, its failure rate (Tan et al. 2005) is λ. For mission time t, the reliability $R(t)$ is,

$$R(t) = \exp(-\lambda t) \tag{1}$$

where exp() denotes getting natural logarithm.

Meanwhile the expression for failure probability $F(t)$ is,

$$F(t) = 1 - \exp(-\lambda t) \tag{2}$$

Assume the number of population is infinity, and the sample size is n in the reliability verification test. For time t, the probability for r failures observed is,

$$P(X = r) = C_n^r F(t)^r R(t)^{n-r} \tag{3}$$

when n, t, r is specified in the reliability test plan, the formula to compute the confidence lower limit of $R(t)$ is,

$$1\text{-}\gamma = P(X \le r) = \sum_{i=0}^{r} C_n^i F(t)^i R(t)^{n-i} \tag{4}$$

where γ is confidence level.

The confidence lower limit of $R(t)$ can be derived from Eq. (4) through numerical method. Then we can use Eq. (1), where $\lambda = 1/\text{MTTF}$, to get the confidence lower limit of MTTF.

3 METHOD CONSIDERING POPULATION SIZE

Assume that the population size is N, the sample size for reliability test is n, the number of failures for acceptance is r in the test plan. Then, the probability for failure number r is,

$$\begin{aligned} P(X=r) &= \frac{C_M^r C_{N-M}^{n-r}}{C_N^n} \\ &= \frac{n!}{r!(n-r)!}\frac{M!}{(M-r)!}\frac{(N-M)!}{(N-M-n+r)!}\frac{(N-n)!}{N!} \\ &= C_n^r \frac{M(M-1)...(M-r+1)}{N^r} \times \\ &\quad \frac{(N-M)(N-M-1)...(N-M-n+r+1)}{N^{n-r}} \times \\ &\quad \frac{N^n}{N(N-1)...(N-n+1)} \end{aligned} \tag{5}$$

where M is the number of products that cannot pass the test in the population although it is unknown.

The probability for the failure number is equal to or less than r is,

$$P(X \le r) = \sum_{i=0}^{r} \frac{C_M^i C_{N-M}^{n-i}}{C_N^n} \tag{6}$$

By substituting Eq. (5) into Eq. (6) and denoting M/N with F, the confidence upper limit of failure probability, $F = 1 - R$ (R is the confidence lower limit of reliability), we can get,

$$\begin{aligned} 1-\gamma &= P(X \le r) \\ &= \sum_{i=0}^{r} C_n^r \left[F\left(F-\frac{1}{N}\right)...\left(F-\frac{r-1}{N}\right)\right] \times \\ &\quad \left[(1-F)\left(1-F-\frac{1}{N}\right)...\left(1-F-\frac{n-r-1}{N}\right)\right] \times \\ &\quad \frac{N^n}{N(N-1)...(N-n+1)} \end{aligned} \tag{7}$$

Base on the derivation of Eq. (7), the factor in the first bracket is senseless when r is zero. And a step further, when $n = 1$, $r = 0$, in the reliability test plan, Eq. (4) and Eq. (7) can be both rewritten as,

$$1-\gamma = P(X \le 0) = 1-F = R \tag{8}$$

4 EXAMPLE

For a product or system whose failure time follows exponential distribution, the population size N is 28. Assume that we need to perform reliability test to assess the confidence lower limit of MTTF. And the confidence level is 80%. To show the differences of the results of the conventional method and of the proposed method clearly, a series of test plans are presented and analyzed.

4.1 *Test plan 1*

In this reliability test, we set the parameters of the test plan as follows:

Population size $N = 28$.
Sample size of the test $n = 1$.
Acceptance number $r = 0$.
Accumulated test time $T = 4000$ h.
Confidence level $\gamma = 80\%$.

1. Conventional method

For conventional method, substitute the parameters above into Eq. (4), we could get the following equation,

$$\begin{aligned} &1-\gamma = P(X \le r) = \sum_{i=0}^{r} C_n^i F(t)^i R(t)^{n-i} \\ &\Rightarrow R(4000) = 1-0.8 = 0.2 \end{aligned} \tag{9}$$

That is,

$$R(4000) = \exp\left(-\frac{4000}{MTTF}\right) = 0.2 \tag{10}$$

From Eq. (10), we can derive the 80% confidence lower limit of MTTF,

$$\text{MTTF} = 2485.34 \text{ h} \tag{11}$$

2. Proposed method

For the proposed method considering the population size, substitute the parameters above into Eq. (7) or Eq. (8), we could get the following equation,

$$\begin{aligned} &1-\gamma = P(X \le 0) = 1\text{-}F = R \\ &\Rightarrow R(4000) = 0.2 \end{aligned} \tag{12}$$

As shown in Eq. (9) and in Eq. (12), for this test plan where sample size n is 1 and acceptance number r is zero, the proposed method is equivalent to the conventional method. This is because that there is statistical independence for the only one sample no matter what the population size is.

Hence, for the proposed method considering the population size, the assessed result of MTTF is 2485.34 as well.

4.2 *Test plan 2*

In this reliability test, we set the parameters of the test plan as follows:

Population size $N = 28$.
Sample size of the test $n = 2$.
Acceptance number $r = 0$.
Accumulated test time $T = 4000$ h (2000 h for each sample).
Confidence level $\gamma = 80\%$.

1. Conventional method
For conventional method, substitute the parameters above into Eq. (4), we could get the following equation,

$$\begin{aligned} &1-\gamma = P(X \le r) = \sum_{i=0}^{r} \mathrm{C}_n^i F(t)^i R(t)^{n-i} \\ &\Rightarrow R^2(2000) = 1-0.8 = 0.2 \end{aligned} \tag{13}$$

That is,

$$R^2(2000) = \left[\exp\left(-\frac{2000}{MTTF}\right)\right]^2 = 0.2 \tag{14}$$

From Eq. (14), we can derive the 80% confidence lower limit of MTTF,

$$\text{MTTF} = 2485.34 \text{ h} \tag{15}$$

The result is the same as the one from test plan 1.
2. Proposed method
For the proposed method considering the population size, substitute the parameters above into Eq. (7), we could get the following equation,

$$\begin{aligned} &1-\gamma = P(X \le r) \\ &= \left[(1-F)\left(1-F-\frac{1}{N}\right)\right]\left[\frac{N^2}{N(N-1)}\right] \\ &\Rightarrow \left[(1-F)\left(1-F-\frac{1}{28}\right)\right]\left[\frac{28^2}{28(28-1)}\right] = 0.2 \end{aligned} \tag{16}$$

That is,

$$\begin{aligned} &R(2000)\left[R(2000)-\frac{1}{28}\right]\frac{28}{27} = 0.2 \\ &\Rightarrow \exp\left(-\frac{2000}{MTTF}\right)\left[\exp\left(-\frac{2000}{MTTF}\right)-\frac{1}{28}\right]\frac{28}{27} = 0.2 \end{aligned} \tag{17}$$

From Eq. (17), we can derive the 80% confidence lower limit of MTTF,

$$\text{MTTF} = 2556.72 \text{ h} \tag{18}$$

The result is different from the one assessed from the conventional method. This is because that the proposed method has considered the interdependency of the two samples, but the conventional method has not.

And the computation relative error of the conventional method by take the result of the proposed method as standard is,

$$\varepsilon = \frac{2485.34-2556.72}{2556.72} = -2.8\% \tag{19}$$

4.3 *Test plan 3*

In this reliability test, we set the parameters of the test plan as follows:
Population size $N = 28$.
Sample size of the test $n = 10$.
Acceptance number $r = 0$.
Accumulated test time $T = 4000$ h (400 h for each sample).
Confidence level $\gamma = 80\%$.

1. Conventional method
For conventional method, substitute the parameters above into Eq. (4), we could get the following equation,

$$\begin{aligned} &1-\gamma = P(X \le r) = \sum_{i=0}^{r} \mathrm{C}_n^i F(t)^i R(t)^{n-i} \\ &\Rightarrow R^{10}(400) = 1-0.8 = 0.2 \end{aligned} \tag{20}$$

That is,

$$R^{10}(400) = \left[\exp\left(-\frac{400}{MTTF}\right)\right]^{10} = 0.2 \tag{21}$$

From Eq. (21), we can get the 80% confidence lower limit of MTTF,

$$\text{MTTF} = 2485.34 \text{ h} \tag{22}$$

The result is the same as the ones from test plan 1 and test plan 2.

2. Proposed method

For the proposed method considering the population size, substitute the parameters above into Eq. (7), we could get the following equation,

$$\begin{aligned} 1-\gamma &= P(X \le r) \\ &= \left[R\left(R-\frac{1}{N} \right) ... \left(R-\frac{9}{N} \right) \right] \\ &\left[\frac{N^{10}}{N(N-1)...(N-9)} \right] \\ &\Rightarrow \left[R\left(R-\frac{1}{28} \right) ... \left(R-\frac{9}{28} \right) \right] \times \\ &\frac{28^{10}}{28(28-1)...(28-9)} = 0.2 \end{aligned} \tag{23}$$

That is,

$$\begin{aligned} &R\left(R-\frac{1}{28} \right) ... \left(R-\frac{9}{28} \right) \times \\ &\frac{28^{10}}{28(28-1)...(28-9)} = 0.2 \\ &\Rightarrow \exp\left(-\frac{400}{MTTF} \right) \left[\exp\left(-\frac{400}{MTTF} \right) - \frac{1}{28} \right] ... \\ &\left[\exp\left(-\frac{400}{MTTF} \right) - \frac{9}{28} \right] \times \\ &\frac{28^{10}}{28(28-1)...(28-9)} = 0.2 \end{aligned} \tag{24}$$

From Eq. (24), we can derive the 80% confidence lower limit of MTTF,

$$\text{MTTF} = 3055.20 \text{ h} \tag{25}$$

And the computation relative error of the conventional method by take the result of the proposed method as standard is,

$$\varepsilon = \frac{2485.34 - 3055.20}{3055.20} = -18.7\% \tag{26}$$

From all the results of test plan 1, test plan 2 and test plan 3, we can see that for the conventional method the results always keep the same regardless of the sample size when the accumulated test time and acceptance failure number is determined. This is because that the conventional method has ignored the interdependency of different samples from the same population. And it could be verified easily that all the test plans in this example is equivalent to the conventional method, we will not present the verification process here.

5 CONCLUSIONS

In this study, we analyze the influence of population size to the computation accuracy of confidence lower limit of MTTF for products with exponential failure distribution in reliability verification test, and get the following conclusions:

1. A method considering the interdependency of different samples is proposed to compute the confidence lower limit of MTTF mainly based on hypergeometric distribution.
2. The conventional method will give out the same result regardless of how many samples are used in the reliability test when the accumulated test time and acceptance failure number are determined. This is because that the conventional method has ignored the interdependency of different samples from the one population.
3. According to the proposed method considering the interdependency of different samples and the results in the example, the confidence lower limit of MTTF will become greater with the increase of sample size when population size, accumulated test time, acceptance failure number are determined in the reliability test plan.

Failure Mode Effects & Criticality Analysis (FMECA) using Bayesian Dirichlet-multinomial conjugate pair

W. Baun
Pratt & Whitney, East Hartford, CT, USA

ABSTRACT: Failure Mode, Effects & Criticality Analysis (FMECA) is a widely-used tool for system safety and reliability evaluations; one popular approach is outlined by MIL-STD-1629A. MIL-STD-1629A Criticality Analysis requires estimates of the Failure Mode Ratio (α_i) and the Failure Effect Probabilities (β_i) for each failure mode. To maximize impact on the design, FMECAs are initiated early in the Product Development Process (PDP), before reliability data is available for the new product. Typically, initial criticality estimates are derived via a combination of failure mode/effect data from similar legacy products and from engineering judgment. Later in the PDP, actual data on the new product becomes available. Such a situation is ideal for employing Bayesian methods. The data from which the Criticality parameters are estimated is Multinomial. The Dirichlet distribution is chosen to represent prior uncertainty in the Criticality parameters, thus taking advantage of the Bayesian conjugacy property for the Dirichlet-Multinomial pairing. This paper describes the application of Bayesian techniques to FMECA Criticality analysis, the structure of a Bayes-enabled FMECA, briefly outlines some expert elicitation approaches for developing prior distributions for α_i and β_i, and demonstrates the use of evidence in the form of field data to update those prior estimates.

1 CRITICALITY ANALYSIS INTRODUCTION

Failure Mode, Effects and Criticality Analysis (FMECA) is an inductive tool used to analyze the effects, and quantify the risks of failure modes within a larger system. FMECA is an extension of Failure Modes and Effects Analysis (FMEA), which adds a quantitative Criticality assessment to the basic FMEA process. The outputs of the criticality analysis enable risk mitigation activities to be undertaken in a systematic, prioritized fashion.

There are different approaches to conducting criticality analysis. This paper focuses on the FMECA approach outlined in MIL-STD-1629A (MIL 1980), which is also covered in EN 60812:2006. (EN 2006) It is worth noting that the methods outlined in this paper are not applicable to the SAE J1739 (SAE 2009) FMEA approach; SAE FMEA focuses on a very different aspect of design risk, and uses a qualitative risk ranking technique. Criticality analysis as performed in MIL-STD-1629 requires estimation of the following factors for every component-failure mode combination in the system being analyzed:

α: Failure mode ratio
β_i: Failure effects probability factors
λ: Component base failure rate

The failure mode ratio, α, is the probability that a particular component will fail by a certain failure mode. The sum of all failure mode ratios for any specific component must sum to 100%. Where a component has only one failure mode, the failure mode ratio would equal 100%. If a component has three equally-likely failure modes, then each failure mode would have a failure mode ratio equal to 33.3%. If one failure mode is more prevalent than others, then that failure mode would have the largest share of the 100% total. The number of failure modes is not limited, being a function of the various ways in which the particular component can fail.

The failure effects probability factors, β_i, are the probability that a particular component-failure mode will result in effects of a certain severity level. In the case of the MIL-STD-1629A FMECA approach as applied to the aerospace industry, the effects severity level is broken into four distinct categories (CAT):

In this categorization system, there would thus be four different β factors for each failure mode, β_1, β_2, β_3 and β_4, representing the probabilities that a failure by that component-failure mode combination results in CAT I, II, III, or IV effects, respectively. The sum of the β factors for a given component-failure mode combination must equal 100%. If a particular failure mode can only result in effects of one category, then the failure mode

Table 1. MIL-STD-1629A severity categorizations for aerospace application.

Category	Description	Details
I	Catastrophic	A failure which can cause death or loss of aircraft
II	Critical	A failure which can cause major system damage, mission abort
III	Marginal	A failure which can cause minor system damage, mission delay, loss of availability
IV	Negligible	A failure which will not cause system damage, mission delay or loss of availability

effect probability for that category would be 100%; all other categories would be 0%. Generally, a failure mode will have a most likely set of effects; this category would thus have the highest proportion of the 100% total for the four categories. If it is possible for other effect levels to occur, those categories should be given a non-zero rating which corresponds to the best estimate of their probability of occurrence.

While other effects severity rating systems having fewer or more categories are possible, the remainder of this paper will assume that four severity categories exist, as given above. The methods outlined in this paper are equally applicable to any number of severity effects categories.

The component base failure rate, λ, is the overall failure rate for a particular component, for all failure modes, and all outcomes (effects). Typically in FMECA (and other reliability analysis techniques), λ is assumed to be constant, with failure times exponentially-distributed. Under that assumption, the base failure rate would be calculated as the total number of failures of that component observed in the fleet (for all failure modes and effects) divided by the total operating hours for that component across the entire fleet. Failure rate in the aerospace application consistent with Table 1 has units of failures per engine flight hour.

In the MIL-STD-1629A approach to FMECA, Criticality is calculated as the product of the three factors above, and a fourth factor, time, t:

$$C_i = \lambda \alpha \beta_i t \quad (1)$$

For the remainder of this paper, the time factor will be omitted, under the assumption that the Criticality factors are calculated on a per-hour basis. Because there are four severity categories, there exist four criticality numbers for each component-failure mode, one for each category of effect severity.

The units of criticality are also in failures per hour, and represent the failure rate per hour for a given component-failure mode combination producing effects of a particular severity category.

Ideally, estimation of the factors used in criticality analysis will come from an extensive data set of actual field experience. The failure rate estimate for a given component comes from the total number of failures divided by total operating time, as discussed above. The failure mode ratio for a component-failure mode combination would be the number of times a component has failed by that particular failure mode divided by the total number of failures for that component for all failure modes. For a given failure mode, the failure effect probabilities would come from the number of times that failure mode has produced effects of that severity level divided by the total number of failures by that mode.

In practice, some or all of these factors will need to be estimated from other sources. FMECA is most effective as a risk prioritization and mitigation tool when applied early in the product design process. However, this is typically long before any actual field failure data from which to calculate the criticality factors would be available for the new system being designed. In this situation, the FMECA analyst must turn to similar legacy products as a source of such data. However, there may be components in the FMECA which have never experienced a particular failure mode in the legacy fleet. Furthermore, for high severity failure modes (CAT I), it is typically the case (fortunately) that they are rare events, thus there are few to no CAT I failures in the legacy data set from which to calculate a probability. Regardless, estimates must be made, in order to utilize the FMECA process to its full potential. In these situations, where limited / no field experience is available, estimates of criticality factors must be made by expert opinion.

The use of Expert opinion to estimate unknown quantities of interest is widely-used in reliability engineering applications. (Bedford et al. 2006, Hodge et al. 2001, Yadov et al. 2003) Bayes Rule provides a framework for starting with such subjective estimates of parameter(s) of interest, and then updating those estimates with actual data as it becomes available. The remainder of this paper will discuss a method for the application of Bayes Rule to the estimation of FMECA Criticality parameters α and β. Section 2 will provide a brief overview of Bayes Rule. Section 3 will outline the specific choice of distributions for modeling the unknown quantities of interest, α and β for the FMECA application. Section 4 will discuss the process of expert elicitation as it applies in this situation. Section 5 will discuss specific concerns related to prior distribution strength. Section 6 will provide

examples of the Bayesian FMECA updating process, showing how evidence can be combined with the prior estimates via Bayes Rule. Section 7 will discuss conclusions and future work.

2 OVERVIEW OF BAYES RULE

Bayes Rule is a formal mathematical method for updating one's state of belief about unknown parameter(s) of interest (POI) as new evidence is obtained. It enables initial, often subjective, estimates about those POI to be combined with actual data to produce those updated estimates. A classical formula for Bayes rule is:

$$P_f(A|E) = \frac{L(E|A) * P_0(A)}{\int_A L(E|A) * P_0(A) dA} \quad (2)$$

where A is the parameter of interest (POI), the unknown parameter or factor being modeled; $P_0(A)$ is the prior distribution of A (the "Prior"), which is the uncertain estimate of the value of A developed before any actual evidence is obtained, modeled as a distribution to represent the initial state of uncertainty regarding the value of A; E is the evidence; $P_f(A|E)$ is the posterior distribution of A (the "Posterior"), which is the updated estimate of A, after gaining new information in the form of evidence; $L(E|A)$ is the likelihood of the evidence, given parameter A. The denominator is a normalizing factor, sometimes referred to as the "total probability of the evidence", and is the summation of the likelihood of the evidence over all possible values of the parameter, A.

The prior distribution is the mathematical representation of the initial state of knowledge about the POI. Depending upon that state of knowledge, the prior can be diffuse, or concentrated. The prior distribution can be modeled using a wide variety of mathematical distributions to represent uncertainty. Where the POI can take on any value in a range, the initial state of knowledge is represented by a continuous Prior distribution, and the summation term in the denominator is an integral. Typical distributions employed to model continuous Priors include the uniform distribution, lognormal, gamma, beta, as well as many others. The integral is evaluated over the full set of unknown POI, A, which are the parameters of the distribution used to model the prior. If there is more than one parameter, then the integral becomes a double (or higher) integral. As such, the Bayes equation can quickly become difficult to solve. In many cases, a closed-form solution cannot be found, and numerical methods are required.

Fortunately, there are a special set of Prior Distributions and Likelihood Functions which make the calculation process relatively easy. These sets are called Conjugate Pairs. For a certain form of evidence expected, a specific likelihood function is required. Given a particular type of evidence (and thus likelihood function), the choice of a certain form of Prior distribution will make the calculation of the Posterior Distribution via Bayes Rule simple, and obviate the need to evaluate any integrals.

For example, if one is interested in estimating the failure rate, λ, from a constant failure rate process, then the evidence by which failure rate will be estimated will be of the form n failures in observation time T, also known as Poisson data. Given evidence of this form (Poisson) and the resultant likelihood function, the choice of a Gamma distribution with parameters α and β to model the Prior distribution of failure rate (the initial estimate of the unknown POI, λ) results in a Posterior distribution which is also Gamma, and which has parameters α+n, β+T. Other conjugate pairs exist for widely-modeled situations (Fink 2017), including the Beta-Binomial conjugate pair for modeling situations such as "Probability of Failure on Demand" where the value can range between 0 and 1, and the evidence will be in the form of k failures in n trials (Bernoulli process).

3 DIRICHLET-MULTINOMIAL CONJUGATE PAIR

Another Bayesian conjugate pair is the Dirichlet-Multinomial pair (Fink 2017). This pairing is used in situations where the evidence will be multinomial in nature; the prior distribution of the unknown POI will be modeled as a Dirichlet distribution. Multinomial data is applicable in situations where the data can fall into one of n categories (with binomial being the specific case where n = 2). It is easy to see that failure mode and failure effects data are both cases of multinomial datasets—failure modes can fall into one of n categories for a given component, where n = the number of failure modes for that component. Similarly, under the MIL-STD-1629A approach to FMECA, failure effects data can fall into one of four severity categories. Therefore, because the data for estimating FMECA Criticality factors will be of Multinomial form, the Dirichlet distribution will be employed as the choice of priors for the FMECA criticality analysis POI in order to take advantage of the mathematical benefits of the conjugate pairing.

As discussed previously, the criticality calculation for the MIL-STD-1629A FMECA has two parameter sets (POI) which must be estimated—the failure

mode ratio, α, and the failure effects probabilities, $\beta_1 - \beta_4$. For a given component, the failure mode ratio is the probability that the component fails by that failure mode (versus other possible failure modes) when that component fails. Thus, the evidence which will be used to update the prior estimates of failure mode ratios using Bayes rule will be multinomial in nature. Table 2 below shows an example of multinomial data for failure mode ratio for one component.

Similarly, the failure effects probabilities for a given component-failure mode combination are the probabilities that a particular failure mode will result in effects in each of the four different categories of severity from Table 1. Taking the data for failure mode C from Table 2, the failure effects probability data is also multinomial, as shown in Table 3.

The multinomial probability density function for the failure mode ratios, α_i, is as follows:

$$f\left(x_1, x_2, \ldots, x_k \middle| n, \alpha_1, \alpha_2, \ldots, \alpha_k\right) = \frac{n!}{x_1! \mathrm{K} x_k!} \alpha_1^{x_1} \ldots \alpha_k^{x_k} \tag{3}$$

where k is the number of failure modes for that component, x_i are the number of failures by each of the modes $x_1 - x_k$, n is the total number of failures observed for that component.

Similarly, the multinomial probability density function for the failure effect probabilities, $\beta_1 - \beta_4$ is:

$$f\left(x_1, x_2, \ldots, x_4 \middle| n, \beta_1, \beta_2, \beta_3, \beta_4\right) = \frac{n!}{x_1! \ldots x_4!} \beta_1^{x_1} \ldots \beta_4^{x_4} \tag{4}$$

Table 2. Example failure mode data and calculated failure mode ratios.

Failure mode	# Failures	Failure mode ratio
A	2	20%
B	1	10%
C	7	70%
All	10	100%

Table 3. Example failure effect data and calculated failure effect probability factors for failure mode C from Table 2.

Category	# Failures	Failure effect probability
I	1	14.3%
II	1	14.3%
III	2	28.6%
IV	3	42.9%
All	7	100%

where x_i are the number of failures for that mode that resulted in effects of severity level i, n is the total number of failures for that component-failure mode.

Because it is the conjugate prior for this form of evidence, the Dirichlet distribution is used to model the Prior state of knowledge of the criticality parameters α and β.

The Dirichlet distribution for the failure mode ratio parameters $\alpha_1 - \alpha_k$ for a given failure mode is written as follows:

$$f\left(\alpha_1, \alpha_2, \ldots, \alpha_k \middle| \rho_1, \rho_2, \mathrm{K}, \rho_k\right) = \left[\frac{\Gamma\left(\sum_{i=1}^{k} \rho_i\right)}{\prod_{i=1}^{k} \Gamma\left(\rho_i\right)}\right] \prod_{i=1}^{k} \alpha_i^{\rho_i - 1} \tag{5}$$

where $\alpha_1 - \alpha_k$ are the POI – the failure mode ratios for the k failure modes of that component, $\rho_1 - \rho_k$ are the parameters of the Dirichlet distribution.

The values $\alpha_1 - \alpha_k$ are not known exactly, but rather are uncertain quantities, with uncertainty represented by the Dirichlet distribution. The expected value of each of the failure mode ratios, α_i, for the prior distribution are simply the ratio of the parameter ρ_i for failure mode i to the sum of all parameters $\rho_1 - \rho_k$ (Agresti 2017):

$$E\left(\alpha_i\right) = \frac{\rho_i}{\sum_{i=1}^{k} \rho_i} \tag{6}$$

As discussed previously, evidence about the failure mode ratios will come in the form of the number of failures which were caused by a particular failure mode out of a total number of failures for all failure modes—Multinomial data. Because of the conjugacy property of the Multinomial data with the Dirichlet prior distribution, the Posterior distribution of the failure mode ratios $\alpha_1 - \alpha_k$ is also a Dirichlet distrbution, with the following characteristics:

$$\rho_{i_f} = \rho_i + x_i \tag{7}$$

where ρ_i are the initial Dirichlet parameters; x_i are the number of failures which occurred by that failure mode; and ρ_{if} are the final Dirichlet parameters.

The expected value of each of the failure mode ratios, α_{if}, for the posterior distribution are simply the ratio of the parameter ρ_{if} for failure mode i to the sum of all parameters $\rho_{1f} - \rho_{kf}$ (Agresti 2017):

$$E\left(\alpha_{i_f}\right) = \frac{\rho_{i_f}}{\sum_{i=1}^{k} \rho_{i_f}} \tag{8}$$

Unlike the failure mode ratio which can have any number of parameters, one for each failure mode, the failure effects probability can have only four in the MIL-STD-1629A approach to FMECA, since there are four categories of failure effect severity. The Dirichlet distribution for the failure effect probability parameters $\beta_1 - \beta_4$ for a given component-failure mode is written as follows:

$$f\left(\beta_1,\beta_2,\beta_3,\beta_4\middle|\delta_1,\delta_2,\delta_3,\delta_4\right)=\left[\frac{\Gamma\left(\sum_{i=1}^{4}\delta_i\right)}{\prod_{i=1}^{4}\Gamma\left(\delta_i\right)}\right]\prod_{i=1}^{4}\beta_i^{\delta_i-1} \tag{9}$$

where $\beta_1 - \beta_4$ are the POI – the failure effect probability factors for that failure mode; and $\delta_1 - \delta_4$ are the parameters of the Dirichlet distribution.

As with failure mode ratio parameters, the expected values of the prior failure effect probability factors are (Agresti 2017):

$$E\left(\beta_i\right)=\frac{\delta_i}{\sum_{i=1}^{4}\delta_i} \tag{10}$$

Similarly, the parameters of the Posterior Dirichlet distribution are the initial parameters, δ_i plus the number of failures which occurred by that failure mode resulting in effects having severity of that category, x_i.

$$\delta_{i_f}=\delta_i+x_i \tag{11}$$

The expected value of each of the failure effect probability factors, β_{if}, for the posterior distribution are simply the ratio of the parameter δ_{if} for failure effect i to the sum of all four parameters $\delta_{1f} - \delta_{4f}$ (Agresti 2017):

$$E\left(\beta_{i_f}\right)=\frac{\delta_{i_f}}{\sum_{i=1}^{4}\delta_{i_f}} \tag{12}$$

4 EXPERT ELICITATION OF PRIOR CRITICALITY PARAMETERS

For a Criticality analysis of a new product which is in the development process, where no testing (or failures) have yet occurred, the Dirichlet Prior distributions of α_i and β_i are the initial estimates of those parameters. By setting up the FMECA structure with a Bayesian framework, as multinomial data are gathered later in the design and verification/validation processes, the criticality estimates may be updated. This allows for updated FMECA-based risk assessments to be made as additional evidence is accrued over time.

Because of the stage of the process where the prior estimates will be needed, development of the Dirichlet prior distribution may require the elicitation of information from experts. A detailed review of the topic of expert elicitation is beyond the scope of this paper. Some basics as they apply to this situation will be briefly discussed in this section, but the remainder of the paper will assume any expert-elicited estimates utilized sound methods in the elicitation process.

In order to develop the Priors for α_i and β_i, experts must provide their estimates of each of the values, $\alpha_1 - \alpha_k$ and $\beta_I - \beta_{IV}$. Once values are obtained from experts, assuming more than one expert, their answers (which may differ) must be aggregated into a single set of estimates. There are a couple of different approaches which can be taken to this aggregation process, often categorized as either mathematical or behavioral approaches (Clemen et al. 1999). At a high level, the mathematical approach allows each expert to independently provide their assessments, and then the analyst combines them via some form of averaging. Weighted averages can be used to reflect differing degrees of expertise. The advantage of this approach can be that it requires less time in formal joint meetings with experts, whose time may be of limited availability. The alternative behavioral approach requires the experts to develop to a jointly-agreed upon estimate through discussion. This method has the advantage of allowing all of the experts to share their viewpoints and reasoning for their initial positions. As the experts share their unique knowledge and perspectives with each other, they may collectively arrive at an estimate which is more comprehensive and representative than if they had each provided independent assessments. The drawback to this method is the time it may take the experts to reach that consensus, and the difficulty in getting all experts together for the necessary consensus-reaching discussions.

One particular nuance in developing expert estimates of FMECA Criticality parameters is that the parameters being estimated are dependent. For example, when estimating the failure mode ratios for a component with k distinct failure modes, only k – 1 estimates can be provided; the last estimate is derived by subtracting the sum of the other estimates from 1, since the sum of the failure mode ratios must equal 100%. This dependency can produce some challenges to the elicitation process. Some techniques for eliciting estimates

for dependent parameters include overfitting as described in (Zapata-Vazquez et al. 2012).

5 PRIOR DISTRIBUTION STRENGTH

Once a set of criticality factor estimates have been developed, the experts must determine whether to apply those estimates as strong or weak data. The prior estimates of the Dirichlet parameters, ρ_i and δ_i, can be assigned any nominal value, as long as their relative values are consistent with the experts' opinions. For instance, assuming three failure modes, the following two sets of failure mode ratio prior distribution parameter estimates are all the same from a relative perspective. Both sets of prior distribution parameters imply the assumption that the expected value of Mode 1's failure mode ratio, α_1, is 10%, Mode 2's expected value is 65% and Mode 3's expected value is 25%. However, in the first case, the parameters are set as decimal values representing the percentage, whereas in the second case, the parameters are set as the integer values representing the percentage.

These two sets of prior parameters, both representing the same expected values for the failure mode ratios produce prior distributions with very different strengths. The sum of the ρ_i values in each case can be thought of as a quasi-number of failures previously observed. The stronger prior in this case is approximately the same as having observed 100 past failure events from which initial estimates of failure mode ratio have been made, whereas the weak prior is approximately equivalent to having observed only 1 failure. As actual field data is gathered and combined with these prior estimates to update predictions of failure mode ratios, the stronger prior will require significantly more data to overcome the initial estimates, if those initial estimates are proven to be incorrect by the field data.

For example, assume that actual field data is gathered on the failure modes in Table 4. Assume ten failures have occurred, and all 10 were due to Mode 1. This is not at all what was expected based on the prior estimates above (in both cases, the prior parameters would have predicted only 1 out of 10 failure would be via Mode 1). Table 5 below compares the Posterior estimates of the expected value for the failure mode ratios, using Bayes rule to combine the prior parameters with the field data. Note that the results obtained using the weak prior shifted significantly, and "feel" more correct in light of the field data. Conversely, the posterior estimates obtained using the strong prior have only marginally changed from their prior values, despite the significant disagreement between the prior estimates and the field results.

Table 4. Examples of two Dirichlet parameter sets with differing strengths for a given component.

Failure Mode	ρ_i – weak	ρ_i – strong
1	0.10	10
2	0.65	65
3	0.25	25

Table 5. Posterior estimates of failure mode ratio expected values as a function of prior strength.

Failure mode	α_i – weak	α_i – strong
1	92%	18%
2	6%	59%
3	2%	23%

The key takeaway here is to be cognizant of the fact that the choice of absolute values for the Dirichlet parameters, ρ_i, determines the strength of the prior distribution. The absolute values should be determined based upon the strength of the prior information from which those parameter estimates were developed. Pre-fitting of hypothetical field data can help the analysis team to see how such data would affect posterior estimates, and help the team to select a set of prior values which best represent the team's true state of prior knowledge.

Note that this same behavior is true for the prior parameters for the failure effect probability factors, β_1 – β_4, too—the prior distribution strength is positively correlated with the sum of the failure effect probability estimates for that failure mode.

6 APPLICATION OF EVIDENCE TO UPDATE PRIOR CRITICALITY FACTOR ESTIMATES

Data to enable Bayesian update of the prior FMECA criticality parameters will be in the form of a number of failure events categorized by failure modes and their resultant failure effects. The utility of the proposed FMECA with Bayesian structure will be shown via an example.

Assume experts have provided prior estimates of the Failure Mode Ratios and Failure Effect Probabilities for a particular component. Those prior estimates have been provided in the form of Dirichlet distribution parameters, ρ_i and δ_i, and their associated expected values, α_i and β_i, calculated from those parameters in Tables 6–8. Note that in this example, the expert-estimated parameters result in weak prior distributions for both Failure Mode Ratios and Failure Effects Probabilities, presumably reflecting their lack of certainty about those prior estimates. Such weak priors will be quickly influenced by any new evidence which is gathered.

Assume that later in the development process for the component/system in question, the following failure information is obtained:

Combining the prior Dirichlet distribution information with the new evidence following Bayes Rule as outlined in Section 3 results in the updated (Posterior) estimates of the Failure Mode Ratio and Failure Effect Probability Dirichlet parameters and expected values for this component in Tables 10–12.

Table 6. Example prior failure mode ratio estimates.

	Prior failure mode ratio	Estimates
Failure mode	Dirichlet parameters, ρ_i	Expected values, α_i
1	0.05	5%
2	0.30	30%
3	0.65	65%

Table 7. Example prior failure effect probability factor dirichlet parameter estimates.

	Prior failure effect probability factor			
	Dirichlet parameter estimates, δ_i			
Failure mode	CAT I	CAT II	CAT III	CAT IV
1	0.00	0.20	0.50	0.30
2	0.00	0.00	0.80	0.20
3	0.01	0.01	0.75	0.23

Table 8. Example prior failure effect probability factor expected value estimates.

	Prior failure effect probability factor			
	Expected value estimates, β_i			
Failure mode	CAT I	CAT II	CAT III	CAT IV
1	0%	20%	50%	30%
2	0%	0%	80%	20%
3	1%	1%	75%	23%

Table 9. Example failure mode and effects data.

		# Failures by failure mode/effect category			
Failure mode	#Failures by mode	I	II	III	IV
1	0	0	0	0	0
2	2	0	0	2	2
3	1	0	1	0	0

Table 10. Posterior failure mode ratio estimates.

	Posterior failure mode ratio estimates	
Failure mode	Dirichlet parameters, ρ_{if}	Expected values, α_{if}
1	0.05	1.3%
2	2.30	57.5%
3	1.65	41.3%

Table 11. Posterior failure effect probability factor dirichlet parameter estimates.

	Posterior failure effect probability factor			
	Dirichlet parameter estimates, δ_{if}			
Failure mode	CAT I	CAT II	CAT III	CAT IV
1	0.00	0.20	0.50	0.30
2	0.00	0.00	2.80	0.20
3	0.01	1.01	0.75	0.23

Table 12. Posterior failure effect probability factor expected value estimates.

	Posterior failure effect probability factor			
	Expected value estimates, β_{if}			
Failure mode	CAT I	CAT II	CAT III	CAT IV
1	0%	20%	50%	30%
2	0%	0%	93.3%	6.7%
3	0.5%	50.5%	37.5%	11.5%

The changes for the Failure Mode Ratio expected values are shown graphically in Figure 1. Based on the new evidence, one would conclude that the probability of occurrence of failure modes 1 and 3 are less than originally estimated (despite having observed one failure via failure mode 3), and the probability of occurrence of failure mode 2 has nearly doubled.

The changes for the Failure Effect Probability Factor expected values for Failure Mode 3 are shown graphically in Figure 2. Based on the new evidence, one would conclude that the probability of failure mode 3 producing CAT II severity effects is significantly higher than was originally estimated.

A key item to note in both examples above is that all categories' predictions change in response to new evidence, even if that new evidence didn't explicitly include events in that particular category.

This is one of the key benefits of the Bayesian approach to FMECA updating—new evidence showing that a failure occurred in one of the categories updated all of the other categories' predictions, too. For example, in the failure effects probability example, the single piece of new evidence (occurrence of a single event with CAT II failure effects) also informed the other three categories; it was a failure that did NOT result in effects from those other severity categories, and thus their predicted values shifted downwards by varying degrees.

A final benefit of approaching FMECAs in a Bayesian fashion is that it enables sensitivity and uncertainty analysis techniques to be applied to the results. Because the criticality factors are modeled in a Bayesian framework as uncertain parameters of interest, one can report FMECA criticality factors calculated based on the expected value of those parameters, or one can report criticality factors calculated based on worst-case values, such as upper confidence limit values. The confidence limits for any Dirichlet-distributed parameter are found by calculating the marginal Beta distribution for that parameter. (Farrow 2017) In the case of the uncertain estimate of the failure mode ratio for failure mode 3, α_3, from the previous examples,

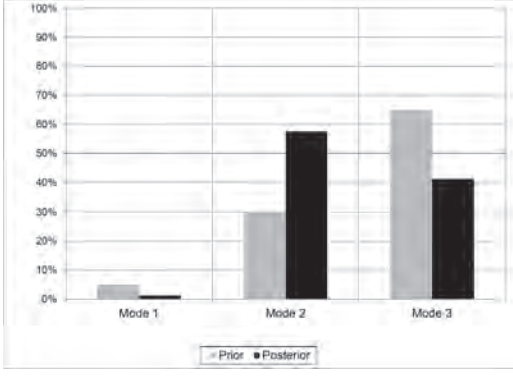

Figure 1. Comparison of prior and posterior failure mode ratio expected values.

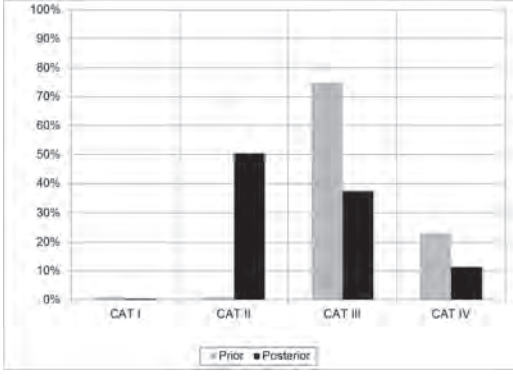

Figure 2. Comparison of prior and posterior failure effect probability factor estimates.

Table 13. Comparison of criticality estimates based on use of expected values versus 90% UCL values for failure mode ratio and failure effect probability estimates for failure mode 3, failure effect CAT II.

Parameter	Expected Value	90% UCL
Failure Mode Ratio, Mode 3, α3	41.3%	94.1%
Cat II Failure Effect Probability, β3	50.5%	97.7%
Component Base Failure Rate, λ	6.2E-8	6.2E-8
Cat II Criticality (failures per hour)	1.3E-8	5.7E-8

$$\alpha_3 \sim Beta\left(\rho_3, \sum_i \rho_i - \rho_3\right) \tag{13}$$

The same holds true for the failure effect probability Dirichlet parameters. Table 13 shows a comparison of the criticality values calculated for Failure Mode 3, Failure Effect Category II based on the data used in the examples above. Note that the table assumes no uncertainty in the base failure rate, λ, and thus the same failure rate is used for both the nominal criticality value calculation and the upper confidence limit criticality value calculation. (In practice, the base failure rate could also be treated as an uncertain POI, and modeled in a Bayesian framework). The upper confidence bound estimate of the criticality value for this failure mode effect combination is more than 4X higher than the nominal estimate. The Bayesian structure of the FMECA enables such uncertainty analysis, which can serve as a means of prioritizing future data-gathering efforts, or can allow for uncertainty-based risk evaluations. For failure modes with the highest severity effects, risk prioritization efforts can be based upon upper confidence limit values of the Criticality estimates.

7 CONCLUSIONS AND FUTURE WORK

FMECA is a widely-used tool in a broad range of industries for evaluating and quantifying the risks associated with a design. Because FMECA is most effective when applied early in the product design process, it is frequently the case that the criticality analysis must proceed before any actual data from

which to conduct that analysis is available on the system in question. The methods outlined herein provide a framework for allowing the synthesis of expert-elicited prior estimates of criticality factors with later-arriving direct evidence via Bayes Rule to produce updated estimates of those factors. This approach imparts a broad range of analytical benefits, including allowing uncertainty and sensitivity analyses to be conducted on the quantitative outputs of the FMECA.

Future work in this area will focus on the development of FMECA-specific techniques for eliciting expert estimates of criticality factors α and β, notably in dealing with the dependency of those factors, and in addressing the difficulties in estimating rare event probabilities.

Bringing formal methods on the rail: On automatic verifying railroad interlockings from railML models

Tim Gonschorek, Ludwig Bedau & Frank Ortmeier
Chair of Software Engineering, Faculty of Computer Science, Otto-von-Guericke-University Magdeburg, Magdeburg, Germany

ABSTRACT: The theoretic foundations for formally verifying railway interlocking systems have already been studied extensively. There exist a lot of work covering the application of methodologies like model checking in this context. However, some design faults still remain undetected until final on-track evaluation of the system. This is strongly related to missing automation solutions for real-world models and standards as well as the high theoretical expertise required. There exist many well-developed tools each requiring different modeling formalisms and focusing on a different question/scenario. Without specific experience in formal system modeling, it is extremely complicated to model such complex systems. In this paper, we present a methodology for the automatic model generation and verification of railway interlockings in a tool-independent(!) way. Therefore, we define a generic template set of atomic track elements and safety properties in a formal modeling language applicable with precise semantics. This generic template enables us to verify the structure of any given track layout. The already existing tool support of VECS allows to automatically translate these specifications into various model checkers for verification. More important, we present a robust transformation of the upcoming data exchange format for railway interlocking systems railML into the presented specification template. As a consequence, this approach really may help to bridge the gap between formal methods and system design in railway interlockings. We evaluate this approach on a real-world case studies train station of Brain l'Alleud. We also show the tool-independent modeling by automatically translating the specification to different verification engines and compare their performance.

1 MODEL-BASED VERIFICATION AND INTERLOCKING SYSTEMS

Designing interlocking systems for large railway stations is a very complex task. Lots of different routes, not only for passengers but also for logistics and freight traffic, must be combined with a vast traffic network. Moreover, such railway components, e.g., the interlocking system structure and corresponding route network, are safety critical infrastructures. This means, errors in the network plan, as an unconnected or a dead-end track, an incorrect working switch or wrong scheduled and therefore crossing routes can lead to costly and dangerous hazards. Verifying such railroad interlocking systems by applying formal verification techniques (e.g., model checking (Clarke et al. 1999)) increases the quality a lot.

Even though there exists a vast amount of work on the formal verification of railway interlocking systems, techniques as model checking or deductive verification are not commonly used in practice. We think that one major problem is that there exists no off-the-shelve implementation that can be applied as a simple addon to a given interlocking design tool.

In particular, there exist several tools providing their domain specific language or an interface to a particular modeling tool that can do the verification task. However, either you need to find the one tool that applies to your specific modeling environment, or you must transform your model into the input language of your verification tool. The first approach can lead to the conclusion that there does not already exist such tool and the second is very erroneous and due to the time consumption and required skill level of the engineer.

To overcome this problem, we want to define a structural transformation from an accepted interlocking modeling standard into a formal representation of a railway interlocking system and its routing tables. Over the last ten years, a data scheme standard enabling the interchangeability of railroad design data has been developed by a consortium of leading companies from the interlocking and signaling domain. It is called Railway Markup Language (railML) (Nash et al. 2004) and defines a data scheme based on XML. By using this standard, it becomes possible to define a standardized verification approach for general interlocking system designs and logical routing tables. Since we think that this standard will be used through industrial application by the next years, a verification tool based on this can help to lower the hurdle of using formal verification techniques for

interlocking systems in practice. For example, it is imaginable that a an algorithm for the automatic processing of paper-written interlocking schemes generates railML output, as presented in Klockman et al. (2018), which is later on verified by the algorithm defined in this paper.

In this paper, we define a transformation from a given railML description into a formal model representation which can be used for model-based verification, i.e., for verifying safety properties and additional measures as probabilistic analysis or failure injection techniques. Therefore, we defined a set of template automata for essential interlocking elements and their instantiation with the information derived from the railML representation. Further, we present a realworld case study of the Belgian railway station Braine l'Alleud and a representation of the German train station of the city of Leipzig. This is, to provide an idea of the capabilities enabled by the automatic transformation and corresponding model checking tools.

We think that the fully automatic transformation from an accepted railway data scheme will lower the hurdle for the application of formal verification techniques within the development of interlocking systems and even increases the acceptance of the assessment. This is especially the case since we try to provide a 1:1 transformation be keeping as much information of the original data, which also ensure a full, and easy to understand, traceability from the design to the formal model.

Related Work Of course, the verification of railway interlocking systems has already been researched during the last years by several publications as Cimatti et al. (1998a) or Haxthausen et al. (2011), Cappart and Schaus (2016), Cimatti et al. (1998b), Bonacchi (2013), or Limbrée et al. (2016). These authors showed the overall applicability of formal verification, in particular, model checking, in the context of the analysis of railway interlocking systems. However, Banci et al. (2004) presented a first general representation of interlocking components using statemate and Harel state charts (Harel 1987). Further, the first transformation of a railway interlocking system from a specific Domain Specific Language into a formal modeling language, Event-B Abrial (2010), was presented by Iliasov and Romanovsky (2012) in the context of the SafeCap project (Iliasov et al. 2013) intending to improve the time-effectiveness of route plans without violating the safety properties of the systems. Therefore, the B verification engine ProB (Leuschel and Butler 2003) was used. However, the main focus of this project was not on the formal verification but the optimization of the system.

The remainder of the paper is the following: In section two we present preliminary background information about the implemented interlocking components and railML. Further, we show the generation algorithm for the formal model by presenting abstractions for the minimal set of required elements (switches, tracks, etc.) and the corresponding safety properties to be verified (derailment, collision, etc.). Section four presents the real-world case study and experimental results of the verification using different model checking tools. The conclusion and further work are given in section five.

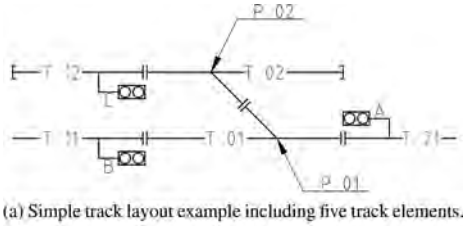
2 THE BASIC ELEMENTS OF AN INTERLOCKING SYSTEM AND RAILML

Before we introduce the mentioned approach, we need to clear the atomic elements of an interlocking system which must be implemented for a correct abstraction of an interlocking system.

Figure 1 presents a simple example of a railway interlocking system's track layout (Fig. 1a) as well as the corresponding interlocking table (Fig. 1b) representing the available routes.

The track layout is divided into connected track elements like T01, T02, T11, etc. Track T12, for example, is a dead-end track ending with a bumper. Openended track elements T11 and T21 can connect the system to other interlockings. Tracks T01 and T02 are connected by switches (the points P01 and P02) for branching between several track elements.

Points (P01 and P02) can be in normal position so that trains will drive straight on, or in reverse position so that trains will branch off the current track element. Further, the given interlocking table supports flank protection, i.e., Switch P02 is also



(a) Simple track layout example including five track elements.

Route	Direction	Tracks	P01	P02
A11	$A \rightarrow T11$	T01, T11	N	N^F
A12	$A \rightarrow T12$	T01, T02, T12	R	R
B21	$B \rightarrow T21$	T01, T21	N	N^F
C21	$C \rightarrow T21$	T02, T01, T21	R	R

(b) Interlocking table of the example track layout containing four simple routes.

Figure 1. A simple interlocking system example with track layout (a) and the route definitions given by an interlocking table with the corresponding direction, track elements, and position of the switches (P01, P02) as nominal (N) or reverse (R).

switched as a safety function. In normal position, it will disconnect track T12 from the main track T11↔T01↔T21 to prevent wagons from rolling back into main track. Of course, an industrial real-world interlocking system plan contains more elements than the presented ones. However, this is sufficient to verify the basic system topology and on top of that the logical route planning and scheduling of the system.

Railway Markup Language If we want to process the data of a given representation in different steps and tools, we are required to base our transformation on some standard scheme. As mentioned before, we, therefore, focus on the infrastructure definition of railML. The definition of railML in general contains schemes for *Timetable Rostering, Infrastructure* definitions, *Rollingstock,* and *Interlocking* tables and signal plans. It would have also been interesting to use the Interlocking scheme which is meant to support the definition of interlocking and route tables. Unfortunately, this scheme is under development at the moment and therefore not available. Instead, we use a simple csv representation of the route table as given in Fig. 1.

In the following, we present an excerpt of the infrastructure railML representation of the example in Fig. 1. In particular, these are elements covered by route *C21* (cf. Fig. 1b), i.e., *T12*, *T02*, *T01*, and correlated elements like switches and signals. In the following, we give a short explanation of the listing in Fig. 2, without providing a complete description of railML. The basic elements of the infrastructure are ① tracks with an *id*. For each *track* element we define its *trackBegin*, its *trackEnd*, and the connections to other track elements or a *bufferStop* if it is a blind end ②. Each *trackBegin* and *trackEnd* has, in addition, a position that is used to define the direction on the track. From the position with the lower value to the higher value the position is *up*wards, otherwise *down*wards. The connections are realized by references to other *trackBegin* or *trackEnd* elements via their unique *id*. Further, we find ③ *switch* elements within a *track*, which can be connected to corresponding switch elements on other tracks, also via *id* of the elements. Signals ④ can be modeled, too, by using *signal* elements with a specific position and a direction in which they work, e. g., *down* if they work in the downwards direction of the track.

Using this representation, we get an applicable standard for exchanging interlocking data between different modeling and verification tools. The original stand contains, of course, more than only these elements, but they are sufficient for proofing the applicability of the presented approach.

3 A TEMPLATE SYSTEM FOR INTERLOCKING SYSTEMS

The basic idea of our transformation system is to provide a set of accepted templates in a formal language, e.g., SAML in our prototype, for single track elements and to derive the instantiations and the links between elements from the railML representations.

The class diagram in Fig. 3 shows the templates and their relations. All infrastructure elements

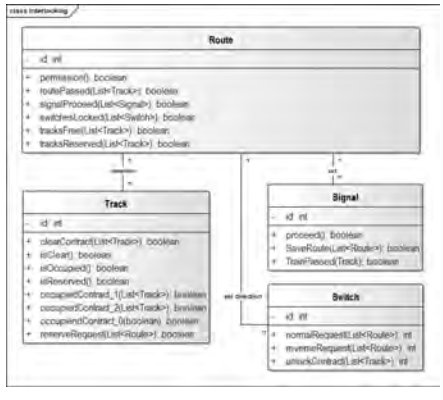

Figure 3. Class model of the templates.

(tracks, signals, switches) are controlled via route automata. Each route holds information about the track segments it contains and the corresponding signal states and switch positions. Therefore, all activities are correlated to the currently active routes, i.e., which tracks must be blocked, which signal must be set, or which switch must be set to a particular position.

Route Scheduling The route scheduling itself is implemented indeterministic, i.e., each nonactive route can request to get active at each time if all required track segments are not blocked by another route. If more than one route tries to get active, we solve this race condition by choosing the route with the lower id (e.g., route 1 before route 2). Overall, more than one route can be active at the same time, but only one additional route can get active at each time step.

Logical Trains At the moment, the train movement is modeled in an indeterministic, logical, way. This means a train can leave a specific track segment or not, without taking into account physical parameters like train velocity and length of the track segment. Each train consists of one to n adjacent track elements to model the movement from one to another track element and trains of different size. If required the formal model can easily extend with physical behavior. Further, we define two trains per route for modeling collisions, flank protection, and other safety properties.

In the following, we present the internal automata of the templates and their basic instantiation idea.

3.1 *Track*

In general, a track can be *clear, reserved*, or *occupied*. Since we are verifying the system with two trains, the track can be occupied by train No. 1 or train No. 2 (*occupiedBy1* or *occupiedBy2*). Model checking, in combination with non-deterministic behavior, covers all possible combination of train positions and routes and therefore two trains are sufficient for analyzing all possible train to train situations.

railML relation In the following, we need information on adjacent tracks. This information is derived from the railML element track (cf. Fig. 2 ①) and underlying connection information (cf. Fig. 2 ②). To identify, which tracks are before and behind a track element, we use the railML direction conventions, where the direction is from the lower *pos* value to the higher. From this, tracks that are referenced *track-Begin* are precedent tracks and those references at *trackEnd* are subsequent. The assignment of tracks to routes and their required direction (*normal* or *reverse*) is extracted from the route table.

Behavior A track can be requested by a route. This is done indirectly by checking the current state of all routes containing the track.

$$reserve\ Request\ := \bigvee_{r \in requireingRoutes} r.state = commanded$$

Tracks will be occupied in addiction to their neighbor tracks.

$$\begin{aligned} occupiedContract1 :&= trackLeft.occupiedBy1 \\ &\vee\ trackRight : occupiedBy1 \\ occupiedContract2 :&= trackLeft.occupiedBy2 \\ &\vee\ trackRight.occupiedBy2 \end{aligned}$$

The initial state of the model is with empty tracks, so there has to be a possibility to place some trains on the tracks. Therefore, all possible starting tracks have a non-contradictional formula *occupiedContract*0 with

$$occupiedContract0 := \bigvee_{r \in requireingRoutes} r.commanded$$

The transition from occupied to clear is enabled when the next track is occupied, and the previous track is clear. This assures that a train will not be split or removed.

Further a train is not forced to enter or leave a track in every step modeling trains with different length.

$$clearContract := (trackLeft.occupied \wedge trackRight.state = clear) \vee (trackLeft.state = clear \wedge trackRight.occupied)$$

3.2 *Signals*

Signals can be in one of two states – *stop* (red) or *proceed* (green). States which allow the trains to proceed with low speed are not modeled.

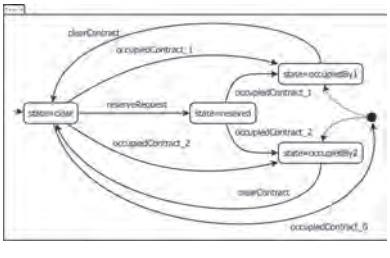

Figure 4. Automat model of tracks.

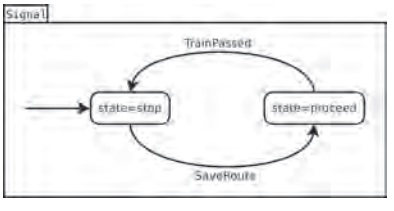

Figure 5. Internal automaton for signals.

railML relation For the signals, we need to know on which track the signal is placed and the direction of the signal, as well as the next track behind the signal to define when the train entered a route and set the signal respectively. These information can be derived from the signal element of the railML description (cf. Fig. 2 ③) and the parent track element.

Behavior The complete automaton of the signal template is given in Fig. 5. Its initial state is *stop*. It changes to *proceed* if the following route (behind this signal) is ready, i. e., the route is accessible. *Save Route* gets true one of the routes starting at the signal is accessible and the signal state changes to *proceed*.

$$saveRoute := \bigvee_{r \in requireingRoutes} r.proved$$

If a train passed the signal, it falls back to *stop*. Therefore, formula *TrainPassed* is connected to the track behind the signal to detect when a train passed it. This is detected by a subsequently occupied track.

$$trainPassed := trackBehind.isOccupied$$

3.3 *Switch*

A switch can be in two states according to its position: *normal* (straight on) and *reverse* (branching).

railML relation Besides the *id*, we must derive the information of the connection relations from the switch, i.e., which tracks are connected via *normal* and reverse position. This is done by utilizing the switch tag information (cf. Fig. 2 ④) and the references to the adjacent track or switch in combination with the parent track element.

Behavior A switch automaton has four states, two for each position *normal* or *reverse*, and two according to its possibility to change its position. This means a switch can be *locked* (no change possible), or *unlocked* (changing the position is possible) for preventing switches from changing while occupied by a train. The transitions *normalRequest* and *reverse Request* will cause the switch to change its position corresponding to the one required by the active route and lock the switch against any other requests.

$$normalRequest := \bigvee_{r \in requireingRoutesNormal} r.reserved$$

$$reverseRequest := \bigvee_{r \in requireingRoutesReserve} r.reserved$$

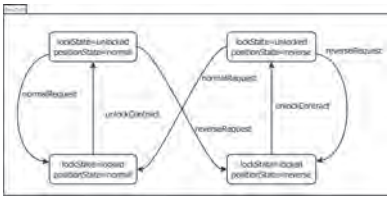

Figure 6. Internal automaton for switches.

The transition *unlockContract* will open the switch for new commands if both connected tracks are clear.

$$unlockContract := Track1.isClear \wedge Track2.isClear$$

3.4 *Route scheduling*

railML relation As mentioned before, the railML *Interlocking* scheme is not finished, i.e., not available, and therefore we have to process simple csv data. This has the same structure as given in the route table in Fig 1b.

Behavior A route controls and observes all track side elements necessary for a save train movement. It can be in one of three states (*idle*, *commanded*, or *occupied*). A route is initialized as *idle*. As previously mentioned, the routes are commanded nondeterministic.

If a route can get active, i.e., is in the state *commanded*, it causes the corresponding tracks to be reserved for this route and the switches to change their position as required. The route will check the state of the elements (*tracksReserved* and *switchesLocked*).

$$tracksReserved := \bigwedge_{t \in includedTracks} t.reserved$$

$$switchesLocked := \bigwedge_{s \in includedSignals} s.locked$$

If everything is correct the start signal is changed to *proceed*.

$$signalProceed := \bigwedge_{s \in includedSignals} s.proceed$$

After that, the route will be *occupied*. When the train passed the complete route, the route will change its state back to idle.

$$routePassed := \bigwedge_{t \in includedTracks} t.isClear$$

3.5 *Safety specifications*

In the following, we want to present the safety properties we provide for our method. Since the defined model is built after a given mechanism, we

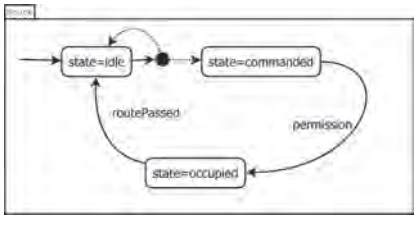

Figure 7. Internal automaton for routes.

think it can be easily extended with other safety specifications as the presented ones.

3.5.1 *Collision detection*

Two trains collide if they are at the same time at the same place. As described in 3.1 there are two or more track objects for one track element in the track layout to save additional information about the direction of the trains. Therefore, a collision occurs if a track is occupied by more than one train. With this definition, you can detect collisions on switches and head-to-head collisions.

To detect rear-end collisions, tracks have to recognize if a collision can occur in the next step. This is done by observing the reserved and occupied state of the track elements. If a track should get occupied in the next step, *occupiedContract_a* gets true. If it is also already occupied by another train (*track.state = occupied By_b*) we found a possible collision in the next step.

$$collision(Trackt) :=$$
$$(t.occupiedContract\_1 \,\&\, t.state = occupiedBy2)$$
$$|\,(t.occupiedContract\_2 \,\&\, t.state = occupiedBy1)$$

3.5.2 *Derailment detection*

In this model derailment due to wrong switch positions is checked. The two cases which can happen are i) derailment because a train is moving over a switch while it is changing its position and ii) derailment because a train is passing a switch which is in a wrong position.

The specification will ensure that the position of a switch correlates with the track object which is occupied. So it will check if the switch is in the correct position according to the direction of the train. In the transformation, we derive the correct position for a switch from the route table and encode this within the model. For readability, we refer here to *inRightPos* that evaluate to *true* if the switch has the required position. As a second aspect, the specification will check if the switch is locked every time a train is on a track linked to this switch.

$$isDerailed :=$$
$$\bigvee_{t \in Tracks} (t.isOccupied$$
$$\bigwedge_{s \in switch(t)} s.inRigthPos \wedge s.isLocked)$$

3.5.3 *Flank protection check*

Especially on sidings, some parked wagons can start rolling unadvisedly. To prevent accidents between those wagons and trains specific switches which are not on the route of the train can be commanded to a position so that they route the wagons to the other track than used by the train. Nearly the same problem is caused by trains which miss stopping at red signals.

(a) Train flank protected. (b) Train flank not protected. (c) Flank protection not available.

Figure 8. Verification of flank protection.

For checking this safety guideline every time a train is on a switch a backward search is performed. This backward search will start at the not used branch of the switch and will progress hand over hand along the tracks. If it reaches a switch which is in the position to guide wagons away from the train, it will stop (8a). If the switch is in the other position, the search will proceed (8b). If the search reaches a uniting switch, it will continue on both branches (8c). The specification ensures that the backward search will never reach a station or main track.

This formula is also derived automatically from the track layout for each route, i.e., for each route that is active, all adjacent tracks, which are not directly on a function *isFlankProtected(r)* is defined. It returns true if the switch in in the correct position.

$$isFlankProtected(Router) :=$$
$$\bigwedge_{s \in Switch} s.sFlankProtected(r)$$

4 CASE STUDY BRAINE L'ALLUDE

The validation of the presented modeling methods was executed on a real-world case study of the Belgian train station Braine l'Alleud, taken from (Cappart and Schaus 2016). Braine l'Alleud station consists of four platforms, twelve switches, twelve signals, and 18 track segments. From the given layout, 32 different routes are available.

From this layout, we generated a model with about 100 state machines. This contains representations of the track elements, switches, routes, etc. In the following, we present the verification times of different model checking engines for the defined specifications from sec. 3.5. For providing information about the computation times and capabilities of different verification methods, different tools implementing divers qualitative model checking techniques were chosen. Further, we checked these specifications on a correct model, i.e., the specifications hold for the system. On the other hand, we injected faulty behavior to provoke erroneous behavior. The failures can be categorized as follows:

- a route does not reserve a needed track
- a route requests a wrong position of a switch
- a route does not request any position of a needed switch

To check the verification time for the erroneous models, we also model checked the specifications and calculated the mean time for each specification, not separating for the found error (i.e., whether a switch or a track was not commanded correctly). We hope that the evaluation of different tools may help users, which are not familiar with model checking, in choosing a proper tool for their purpose.

4.1 *Experiments with the model checking tools*

To check the modeled interlocking system the model checking tools iimc, nuXmv, and aigbmc were used. The tests were performed on a computer with Intel i7 core (3.2 GHz). The target language of our prototype is the System Analysis and Modeling Language (SAML) (Güdemann and Ortmeier 2010). Using SAML, we can verify the imported qualitative model with several states of the art model checking tools (nuXmv, iimc, UUPAAL), for which the SAML IDE VECS (Verification Environment for Critical Systems) provides implemented connectors. We used this connectors for the experiments with the different model checking tools.

aigbmc This tool is a bounded model checker built on top of the AIGER distribution provided by Biere (2007). Being a bounded model-checker makes it necessarily incomplete (if the system diameter is unknown), but allows for very efficient counter-example search, as only the base case is checked and the induction step is not encoded.

iimc This tool, described by Hassan et al. (2012), is the evolution of the original IC3 method. It uses different proof engines (BMC, IC3, FAIR), depending on the type of property to verify. The tool is one of the most efficient model-checkers for sequential circuits and allows for multi-threaded verification.

nuXmv This tool is the evolution of NuSMV, described by Cavada et al. (2014). It supports infinite state spaces via real-valued variables with an analysis based on the SMT solver MathSAT5 and also PDR-style verification using SMT solvers (Cimatti and Griggio 2012).

4.2 *Evaluation of the results*

In the following, we present the results of the verification experiments. Table 1 presents the verification run time for the different tools and specifications. In this diagram, the BMC-based algorithms are missing since BMC is not capable of proving the correctness of a system rather than falsifying specifications. One most important fact is that all tools that terminated for a given specification also produced correct verification results for both, the correct and the incorrect model. For the verification of the correct model iimc performed best for all specifications. It took between 120 s for the collision specification and 608 s for the flank protection, which is a quite acceptable computation time. In comparison, the nuXmv model checker had quite more difficulties with about 2400s for the derailment specification (iimc: 120 s).

Table 1. Verification results of the evaluation. The star * marks the specifications of the defect model.

Spec	iimcIC3	iimcBMC	nuXmv	AIGBMC
collision	120*s*	—	1419*s*	—
collision*	45*s*	2*s*	52*s*	51*s*
derailment	120*s*	—	2402*s*	—
derailment*	38*s*	3*s*	33*s*	29*s*
flank protect	608*s*	—	—	—
flank protect*	223*s*	—	437*s*	—

For the verification of the incorrect model we also used the BMC-based tools. The results show that for medium complex formulae, as the derailment or the flank protection specification, BMC-based algorithms outperformed the inductive ones. However, they were not able to complete their analysis for the flank protection (2 s iimc BMC compared to 45 s iimc IC3 for the derailments specification). This behavior is not a surprise. The reason is that the BMC algorithm is very fast for simple specifications and short counterexample paths (10 to 11 steps for derailment and collision). However, the algorithm is not very applicable for complex specifications and, moreover, with high bounds, it was not able to compute the results for the flank protection specification within 24 h. This is connected to the algorithm itself since for each step towards the bound, new formulas are added increasing the complexity of the underlying SAT problem. In contrast to that, it is quite fast for the short counter examples since the computation of the invariants is quite complex, without a direct correlation to the number of steps.

Summarizing, BMC has shown up to be a suitable method for finding bugs in a system, especially if the error bound is small. Nevertheless an IC3 implementation is needed for proving the correctness of the system and, moreover, even for the discovery of errors in a deep bound, e.g., the presented flank protection faults. This means iimc would be the best tool out of our small collection for the verification of the interlocking systems since it contains both, a fast BMC and a fast IC3 engine.

5 CONCLUSION

In this paper, we presented an approach for reducing the complexity of the formal verification of

railroad interlocking systems. Therefore, we presented an approach for automatically generating a formal model from a given track layout and the corresponding route definitions. Moreover, the declaration rules for basic safety specifications, i.e., derailment, collision avoidance, and flank protection were presented.

To validate our method we generated a model of a real-world case study of the Belgian train station Braine l'Allude. For giving an insight view into available verification algorithms and tools, we verified the specifications with four state-of-the-art verification tools implementing the currently most effective algorithms, IC3 and Bounded Model Checking. In addition to the experiments where the specifications hold, we also examined the behavior of the verification for the error case and injected failures into the model.

The results show, in our point of view, the applicability of the transformation and the computability of the verification. This opens new perspectives for the analysis of interlocking systems since the presented target modeling language SAML supports both, qualitative as well as quantitative verification methods.

Mathematical modelling of critical infrastructure reliability

D. Vališ, K. Hasilová & Z. Vintr
University of Defence in Brno, Brno, Czech Republic

M. Forbelská
Mendel University in Brno, Brno, Czech Republic

ABSTRACT: Safety and dependability of technical systems are key aspects when it comes to a system quality. Critical infrastructure covers many parts such as mains, transportation system, networks and buildings. In our paper, we put an emphasis on a water distribution network where high availability, reliability and safety are very much demanded. Such network usually consists of more lines with different hierarchical importance and age. Moreover, various materials are usually used to manufacture water pipes. The in-field operation of a water distribution system is not very well recorded since it usually does not contain all details about failure occurrences. We have interesting water distribution system recordings covering a wide time span, but, unfortunately, they provide only the numbers of failures during respective months. In this paper, we apply a selected form of dynamic linear models—a modified Kalman filter with the implementation of a structural break point.

1 INTRODUCTION

Critical Infrastructure (CI) is a vital part of each country. It includes important elements such as energy supply networks and distribution systems of, e.g. gas, water, etc. Availability, safety and security of CI elements are key aspects for a country to function smoothly. Some CI elements and nodes are continuously monitored to watch their condition. Failures, which might occur time and again, are also recorded. Unfortunately, not all the records provide every detail about undesirable event occurrence such as failure.

Our paper includes an approach to analyse water distribution system field data related to failure occurrence. Our intention is to introduce the way of modelling some dependability measures despite having only limited records. During our research, we have noticed that there is a certain break point in the displayed data course. It might be explained by the gradual improvement of the water distribution network when old lines are being replaced by new ones. This results in improving some reliability measures. We would like to describe this process analytically and predict how it is going to be developed in the future. For this purpose, we use a dynamic linear model—the Kalman filter with a structural break point.

1.1 *State of the art*

CI is studied from several perspectives—from the conceptual ones to specific applications. A detailed review can be found, for example, in Wilt et al. (2016). Here, we mention only a few articles concerning failures of the critical infrastructure.

Zio (2007) initiated a change in a point of view to frameworks capturing properties emerging from a complex system of critical infrastructure such as water supply, transportation, information and other networks. Eusgeld et al. (2009) proposed a methodological framework for the analysis of critical infrastructures using topology-driven analysis of vulnerabilities. The authors applied the proposed methodology on the Swiss high-voltage grid. Jaskolka and Villasenor (2017) focused on interactions in a distribution system and analysed dependencies in the system. Their approach is based on concurrent Kleene algebra, which offers sequential and concurrent compositions. Korkali et al. (2017) pointed out that mechanism of failures in models provided so far differs from reality where interconnections can be present. They compared several models to understand the impact of network topology. They concluded that understanding both benefits and risks of interconnections is crucial to designing robust and resilient systems.

We would like to focus on water distribution systems. These systems are studied with respect to several factors such as plans for maintenance, rehabilitation and replacement (M/R/R); application to a specific water network; methods and models for water mains failures.

Failures in water networks were studied by Cemagref group. They presented methods to support maintenance of the network based on a survival

analysis model (Le Gat & Eisenbeis 2000). Reliability of the water distribution system was studied in (Jung et al. 2016). The authors investigated sixteen study networks to develop linear reliability models using linear regression. Failures caused by external influences are studied, e.g., in Otřísal et al. (2017). Classification of a water distribution system was given in (Hwang & Lansey 2017). The authors used a graph theory combined with classification to determine adequate parameters for describing the water distribution system.

Evaluation of the efficiency of urban water infrastructure and determination of the optimal time of rehabilitation is given in (Karamouz et al. 2017). The study is completed by examination of the model in a real water distribution network.

Failures are a common keyword of all above mentioned sources. Hazard function (or failure/intensity has been studied by many authors, beginning with Ascher (1970), unified approach for both repairable and non-repairable items by Hokstad (1997), and its modifications by Woch & Vališ (2017). For more complex (non-reconfigurable) flow networks, one can use a topological or algebraic approach (Todinov 2012, Hošková-Mayerová et al. 2013, Ameri et al. 2016).

However, having a limited though interesting data set, we turn our attention to statistical methods. Regarding repairable systems, the non-homogeneous Poisson process is taken into account and its properties were studied by MacLean (1974) or Krivtsov (2007). The data set is in the form of the time series; therefore, Kalman filter is a suitable tool to study the series. Kalman filter was introduced by Kalman (1960) and has been used since then, e.g. in the latest study by Arthur et al. (2018).

2 ANALYSED DATA DESCRIPTION

We have a data set which contains the failures of water lines in three different structures—a magistral/main line, a local line and a branch line to a house. However, the failure records cover the number of failures during single months only, and, unfortunately, there is no more information available. In practice it is rather common to keep records this way. The data set, however, is quite rich when we consider how long it took to record the information—it was a period of fifteen years.

For the purpose of our further analysis, we convert the failure records into an event occurrence rate during the period we are interested in. It is common to use the occurrence rate per one day or a month. However, if we wanted to assess how the seasons affected the process for example, the data would be sorted by quarters, but this is not our case since we are working with the number of failures per month.

Table 1. Example of water distribution system field failures records.

Sample nr.	Month/ year	Nr. of failures	Failure frequency
1	01/2000	6	0.193 548
2	02/2000	12	0.413 793
3	03/2000	27	0.870 968
4	04/2000	23	0.766 666
5	05/2000	18	0.580 645
6	06/2000	8	0.266 667
…	…	…	…

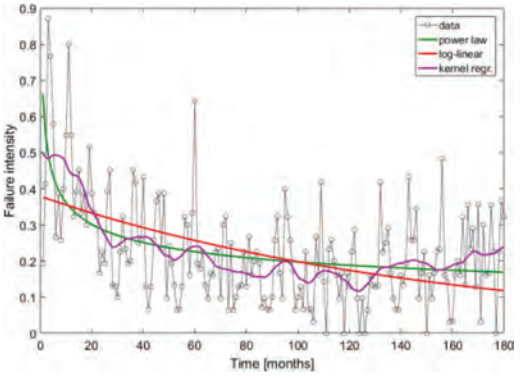

Figure 1. Water distribution system field failures—in the form of failure frequency time series with typical courses applied for non-homogeneous Poisson processes.

In Table 1 there is an example of the way to record the failures and convert them into event frequency which we develop further. The data converted into failure frequency are illustrated in Figure 1. Since this is the Non-Homogeneous Poisson Process (NHPP), a common way to assess this kind of data is modelling with the use of a power-law model and a log-normal model (Rausand & Høyland 2004, NIST/SEMATECH 2017) as we can see in Figure 1. These parametric courses are complemented by a non-parametric kernel regression estimate.

3 THEORETICAL FORM OF MATHEMATICAL MODEL

In order to analyse the data described above, we use in this case time series modelling. If we are to comply with some assumptions for the time series (e.g. an equidistant time increment), it will be necessary to work with a pseudo measurement, failure frequency, where this principle is observed. Another

assumption is a correlation rate in data which will be proved by performing further tests.

For data assessment, we apply generalized dynamic time series model based on linear Kalman filter (LKF) (Bhar 2010, Bain & Crisan 2009). Let the dynamic process X_t follow a transition equation

$$x_t = f(x_{t-1}, w_t) \tag{1}$$

and we also assume that we have a measurement Y_t such that

$$y_t = h(x_t, u_t). \tag{2}$$

In the above equations (1) and (2), w_t and u_t are two mutually uncorrelated sequences of temporally uncorrelated sequence of normal random variables with zero mean and covariance matrices Q_t and R_t, respectively. Additionally, w_t is uncorrelated with x_{t-1} and u_t is uncorrelated with x_t. The prior process estimate is defined as

$$x_{t|t-1} = E[x_t]. \tag{3}$$

which is the estimate of x_t at time t–1 just to making the measurement at time t. Similarly, we define the posterior estimate as

$$x_{t|t} = E[x_t \mid y_t]. \tag{4}$$

which is the estimate at time t after the measurement at t has taken place. We also have the corresponding estimation errors $e_{t|t-1} = x_t - x_{t|t-1}$ and $e_t = x_t - x_t|y_t$. These give us the estimate of the error covariates as

$$P_{t|t-1} = E[e_{t|t-1} \cdot e'_{t|t-1}], P_{t|t} = E[e_t \cdot e'_t]. \tag{5}$$

In order to compute the above mean and covariance, we need the corresponding conditional densities $p(x_t|y_{t-1})$ and $p(x_t|y_t)$. These are determined iteratively via transition and measurement updates. The basic idea is to define the probability density function corresponding to the hidden state x_t given all the measurements made up to that time i.e. $y_{1:t}$. The transition step is based on Chapman-Kolmogorov equation

$$\begin{aligned} p(x_t \mid y_{1:t-1}) &= \int p(x_t \mid x_{t-1}, y_{1:t-1}) p(x_{t-1} \mid y_{1:t-1}) dx_{t-1} \\ &= \int p(x_t \mid x_{t-1}) p(x_{t-1} \mid y_{1:t-1}) dx_{t-1} \end{aligned} \tag{6}$$

following the Markov property. The measurement update step is based on Bayes rule

$$p(x_t \mid y_{1:t-1}) = \frac{p(y_t \mid x_t) p(x_t \mid y_{1:t-1})}{p(y_t \mid y_{1:t-1})} \tag{7}$$

and $p(y_t|y_{1:t-1}) = \int p(y_t|x_t)p(x_t|y_{1:t-1})\mathrm{d}x_t$. At this point it is instructive to specialize the transition and the measurement equations (1) and (2) for a linear system and state the updating equation in a form amenable for easier implementation.

Let us focus on a linear state space system with transition equation of the form

$$x_t = T_t x_{t-1} + c_t + w_t \tag{8}$$

and the measurement equation

$$y_t = Z_t x_t + d_t + u_t \tag{9}$$

where c_t and d_t are possible time dependent vectors of compatible dimensions. Similarly, the matrices T_t and Z_t are of dimensions compatible with the length of the state vector x_t and the measurement vector y_t, respectively.

For our purposes, however, we apply two forms of dynamic local linear models.

3.1 *Dynamic linear local level model*

First form of model—called dynamic Local Level Model (LLM) has the following form:

$$\text{observed series: } y_t = \mu_t + \varepsilon_t \qquad \varepsilon_t \sim NID(0, \sigma_\varepsilon^2)$$

$$\text{latent level: } \mu_t = \mu_{t-1} + \eta_t \qquad \eta_t \sim NID(0, \sigma_\eta^2).$$

Looking at the data plot (see Figure 1), we can notice a negative spike around year 2002 (after approx. 24 months). Recall that the model we just fit the data to (local level plus noise) assume that the variance matrices σ_ε^2 and σ_η^2 are constant over time. Therefore, one way to improve the accuracy of this model and take the jump in failure level (around March 2002) into account is to assume that the variance did change in this year. The new model LLM therefore becomes:

$$\text{observed series: } y_t = \mu_t + \varepsilon_t \qquad \varepsilon_t \sim NID(0, \sigma_\varepsilon^2)$$

$$\text{latent level: } \mu_t = \mu_{t-1} + \eta_t \qquad \eta_t \sim NID(0, \sigma_\eta^2(t))$$

$$\text{where } \sigma_\eta^2(t) = \begin{cases} w & t \neq t_{break} \\ w* & t = t_{break} \end{cases}$$

3.2 *Dynamic linear local level model—seasonal*

The other type of the applied dynamic linear local model is the one which takes into account seasonality. The dynamic Local Level Model (LLM) described in the previous sub-paragraph is extended by seasonality here and has the following form:
observed series:

$$y_t = \mu_t + \gamma_{1,t} + \varepsilon_t \qquad \varepsilon_t \sim NID(0, \sigma_\varepsilon^2)$$

latent level with jump:

$$\mu_t = \mu_{t-1} + \eta_t \qquad \eta_t \sim NID(0, \sigma_\eta^2(t))$$
$$where\ \sigma_\eta^2(t) = \begin{cases} w & t \neq t_{break} \\ w^* & t = t_{break} \end{cases}$$

latent seasonality:

$$\gamma_{1,t} = -\sum_{j=1}^{s-1} \gamma_{j,t-1} + \omega_t \qquad \omega_t \sim NID(0, \sigma_\omega^2)$$
$$\gamma_{2,t} = \gamma_{1,t-1}$$
$$\vdots$$
$$\gamma_{s-1,t} = \gamma_{s-2,t-1}$$

By applying this type of model, we intend to trace potential influence the seasons could have on the course of the observed measure of time series failure intensity.

Before we actually start the modelling of both types of defined dynamic models, we have to apply the Show test sequential algorithm (Bai et al., 1997a, 1997b, 1998, 2003) in order to find the structural break points.

3.3 *Optimal break-points estimation*

The foundation for estimating breaks in time series regression models was given by Bai (1994) and was extended to multiple breaks by Bai (1997a) and Bai & Perron (1998). We implement the algorithm described in (Bai & Perron, 2003) for simultaneous estimation of multiple breakpoints. The distribution function used for the confidence intervals for the breakpoints is given in (Bai 1997b). The ideas behind this implementation are described in Zeileis et al. (2003).

In order to determine the optimal number of *m* break-points we use sequential tests and compare the criteria based on Bayes Information Criterion (BIC) and Residual Sum of Squares (RSS). The principle is based on the RSS calculation and it shows that the bigger the number of regression coefficients which are supposed to be another break-point, the higher the penalization which affects the result of the BIC criterion. The results for the optimal numbers of *m* break-points are put in Table 2.

The selection of the number of break-points *m* might be shown the following way, see Figure 2. Based on the results, we then select one break-point in our further research.

Table 2. Reference criteria for break-points *m* choice.

m	0	1	2	3	4	5
RSS	3.964	2.284	2.719	2.658	2.622	2.636
BIC	–164.6	–216.3	–212.7	–206.4	–198.5	–187.1

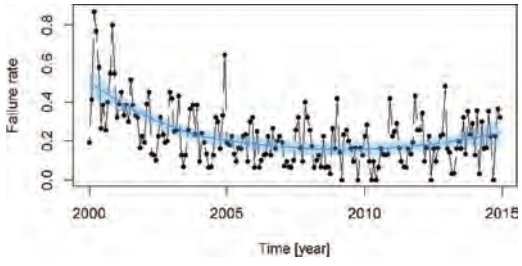

Figure 3. Water distribution system field failures – failure frequency/intensity time series with loess course and its confidence intervals.

4 RESULTS OF SELECTED MODELLING

In this part, we are gradually introducing the results achieved by using the mathematical tools mentioned in paragraphs 3.1 and 3.2. For modelling and simulating, we use the product R-Studio (R Core Team 2005).

First we introduce the approximation of the basic data course, failure intensity, using non-parametric kernel estimation—loess function, see Figure 3.

Before we start the actual modelling, we first construct a static model which is later used for determining initial parameters of the dynamic linear models. Although during the modelling and simulation the software system would be able to estimate the initial parameters of the dynamic models, our own input is by all means better and therefore the static model is made first. This static model is put in Figure 4.

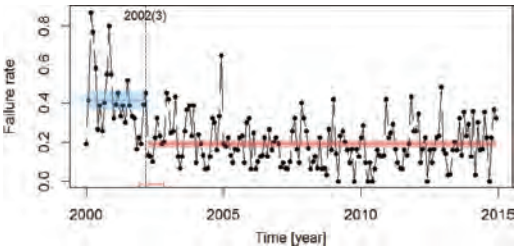

Figure 4. Construction of static linear model with confidence intervals for observed series—failure intensity.

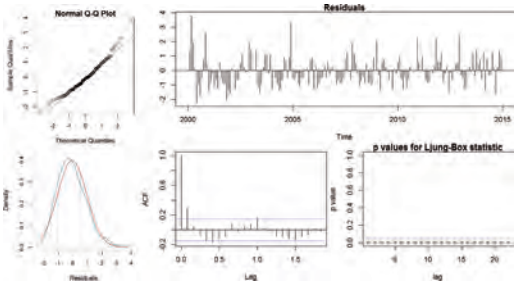

Figure 5. Analysis of residuals of LLM based on Q-Q plot, Auto Correlation Function (ACF) and *p*-value of Box-Ljung.

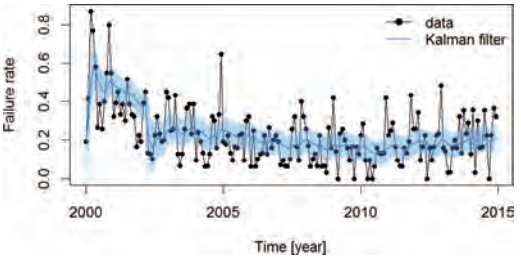

Figure 6. Kalman filter of LLM with confidence intervals for observed series—failure intensity.

4.1 *Results of pure LLM*

In the following steps, we deal with the results of pure LLM. First we analyse and test residuals to find required normality. It is useful to put the results in a graph, see Figure 5. They show clearly that in the normality test (here Q-Q plot) there is a decent compliance. However, the ACF and *p*-value Box-Ljung analyses show that there might be a certain correlation among the data (events-failures).

In our next step, we make the Kalman filter for the LLM model. The result is put in Figure 6 and it clearly shows a few potential break-points. The only break-point we have selected is illustrated in Figure 6 by a dashed vertical line.

For illustration, we also introduce the decomposition of single components of this applied LLM type Kalman filter and the observed series, see Figure 7.

Next, we construct the Kalman smoother for our analysed data and the LLM model. This is shown in Figure 8, where we can also clearly see the break-point illustrated by a vertical dashed line.

There are also the decompositions of the Kalman smoother for our LLM model and the observed series, see Figure 9.

After, we set the course for the Kalman predictor of LLM and the observed series—failure intensity. The predictor is predicted 10% steps ahead which is about 18 months. The result is shown in Figure 10.

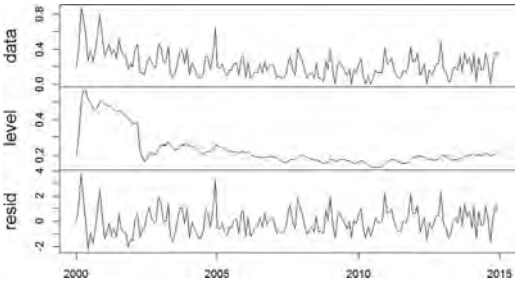

Figure 7. Kalman filter of LLM for observed series—decomposed.

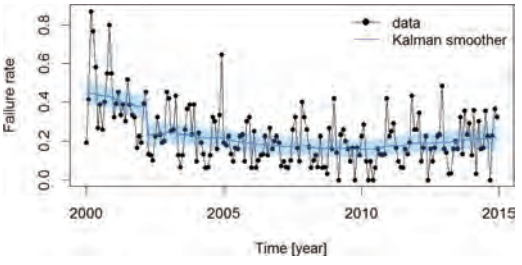

Figure 8. Kalman smoother with confidence intervals of LLM for observed series—failure intensity.

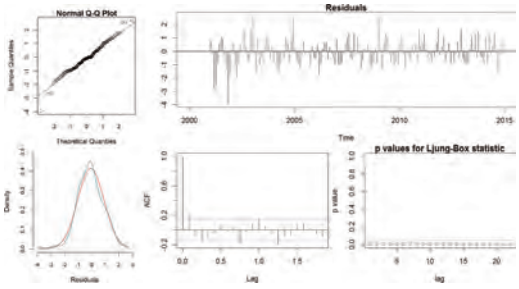

Figure 11. Analysis of residuals of LLM—seasonal based on Q-Q plot, Auto Correlation Function (ACF) and *p*-value of Box-Ljung.

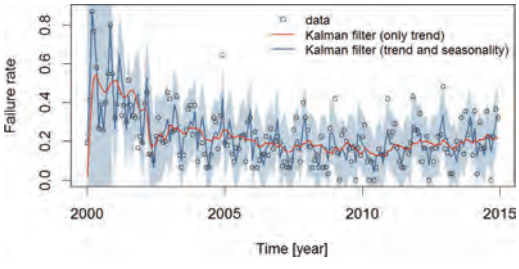

Figure 12. Kalman filter with confidence intervals of LLM—seasonal for observed series—failure intensity.

4.2 *Results of extended LLM—seasonal*

Next, we deal with the results of the LLM model extended of seasonality. First, we analyse test residuals to find required normality. Again it is useful to put the results in a graph, see Figure 11. Again they show clearly that in the normality test (here Q-Q plot) there is a decent compliance which might be even higher than in the previous model. However, the ACF and *p*-value Box-Ljung analyses show that there must be a certain correlation among data (events-failures).

After, we construct the Kalman filter for the introduced seasonal LLM model. The result is put in Figure 12 and it clearly shows a few potential break-points. The only break-point we have selected is illustrated in Figure 12 by a dashed vertical line.

The effect of seasonality is also nicely remarkable in the figure.

For illustration, we also decomposed single components of this applied Kalman filter of seasonal LLM for the observed series, see Figure 13.

In the subsequent stage, we construct the Kalman smoother for our analysed data and the seasonal LLM model. This is shown in Figure 14, where also a break-point in the form of a vertical dashed line along with the effect of seasonality are clearly seen.

For illustration purposes, we also introduce the decomposition of the Kalman smoother for our seasonal LLM model for the observed series, see Figure 15.

After that we set the course for the Kalman predictor of the seasonal LLM for the observed series, failure intensity. The predictor is predicted again 10% steps ahead which is approximately 18 months. The result is put in Figure 16.

5 DISCUSSION

All the numerical values representing single mean value courses of the Kalman filter (KF), the Kalman smoother (KS) and the Kalman predictor (KP) from the applied normal and seasonal LLM models are put in Tables 3 and 4. For comparison purposes, we also included a basic data set for the failure intensity observed series. The results clearly show that each model has a specific estimation power for the observed time series; therefore, the course results slightly vary. The great advantage of the applied models is their ability to estimate the course and predict a few steps ahead. However, when predicting future development, a constant trend is seen for the LLM.

The above estimations show us that if we follow the Kalman predictor, we can spot about four to nine failures on the observed mains during the next few months. We could also provide an accurate calculation for each separate month. Since this information has not been available yet (NA), we compare our results after it is available.

5.1 *Conclusion*

The aim of our article is to show possible ways of appropriate modelling even if there are only short and insufficient records of device failures available. We wanted to introduce the modelling of a pseudo-measure and also show that we are able to estimate possible development of the assessed system behaviour, similarly as Woch & Zieliński (2015).

The observed and later transformed data record is interesting because it shows that the course of the observed failure intensity decreases in time. It might indicate a change in the system properties which are manifested by reliability change. In

this case, it would be advisable to replace-revitalize gradually all water pipe, thereby restoring its original properties.

Moreover, the results of prediction estimations enable us to expect a certain amount of failures on the observed main pipeline section. This can help with planning an operation system and a technical maintenance system.

In our future work, we are going to apply different approaches, different forms of dynamic models based on the observation of the structural changes of the observed pipeline. Some inspiring results, however, which we are going to use for that, have been already introduced in Hasilová & Vališ (2018), Pietrucha-Urbanik et al. (2017 a, b), Pilch et al. (2014), Rojek & Studzinski (2014), Romaniuk (2016), Vališ et al. (2015, 2017 a, b), Vališ & Pokora (2015) and Woch et al. (2015).

Self-healing networks: A theoretical approach to smart grids' resilience

A. Scala

F. Morone & H. Makse
City College of New York, New York, USA

ABSTRACT: To ensure a high quality of service to the users in the next generation of smart grids, self-healing capabilities are a crucial feature to be introduced. We show how distributed communication protocols can enrich complex networks with self-healing capabilities; an obvious field of applications are infrastructural networks distributing a commodity via a flow, like gas, water or electric power. We consider the case where the presence of redundant links allows to recover the connectivity of the system. We then introduce a theoretical framework to calculate the fraction of nodes still served for increasing levels of network damages. Such framework allows to analyse the interplay between redundancies and topology, a key point in improving the resilience of networked infrastructures to multiple failures.

1 INTRODUCTION

The functioning of any advanced society relies on networks that distribute commodities like water, gas, energy. The increasing urbanization and the accelerated growth of the size and the numbers of mega-cities (Facchini et al. 2017, Kennedy et al. 2015) requires such networks to be not only robust—i.e. able to sustain natural hazards, random failures or intentional attacks—but also to be resilient, i.e. to quickly recover from such hazards. Thus, the key feature to be implemented in network systems is *resilience* (Francis and Bekera 2014, Ganin et al. 2016), i.e. the ability of recovering an acceptable level of service in the face of faults, failures, accidents and attacks. In this paper, we described a simplified model for networks who are able to increase their resilience through self-healing capabilities while considering the effects both of the topology and of the redundancy on the capability of network recovery. After introducing the concept of resilience in sec.2, we will introduce in sec.3 a percolative model of self-healing reconnection. In sec.4 we will describe the analytic approaches needed to solve the problem at the mean-field level; we will compare the results of the model prediction with numerical simulation in 5.

2 RESILIENCE

Resilience is a complex property and is best expressed via the function describing the recovery history of a system (see Fig. 1, upper panel). Loosely speaking, there are three main factors characterizing resilience: the initial after-event state s^*, the recovery time τ and the recovery level s_C. In the usual resilience cycle, an accident happens at time t^* and the quality of service s drops quickly to value s^* that depends on the robustness (Cohen and Havlin 2010) and on the reliability (Chaturvedi 2016) of the network; after a recovery time τ that will depend on the restoration plan, service would have been restored up to a level s_C that in some cases can be equal or even higher than the initial one. In this paper we will concentrate on the restored quality of service s_C and we will introduce a self-healing percolation model for characterizing such quantity.

Self-healing is a crucial feature for implementing resilience in the smart networks of the future (Quattrociocchi et al. 2014). An example of already existing self-healing infrastructures are telecommunication networks, which rely on self-healing procedures based on routing protocols to restore traffic using redundant links (Bhandari 1998). This is a typical example of a strategy based on the redundancy in the interconnectivity of its components to ensure the continuity of a system; for example, when a hole is punched in a leaf, the remaining vessels are capable to sustain the extra flow necessary to keep the tissues alive (Katifori, Szöllősi, & Magnasco 2010). On the other hand, self-healing in infrastructural networks should be instead though as a constrained mechanism in which only a limited amount of resources is available.

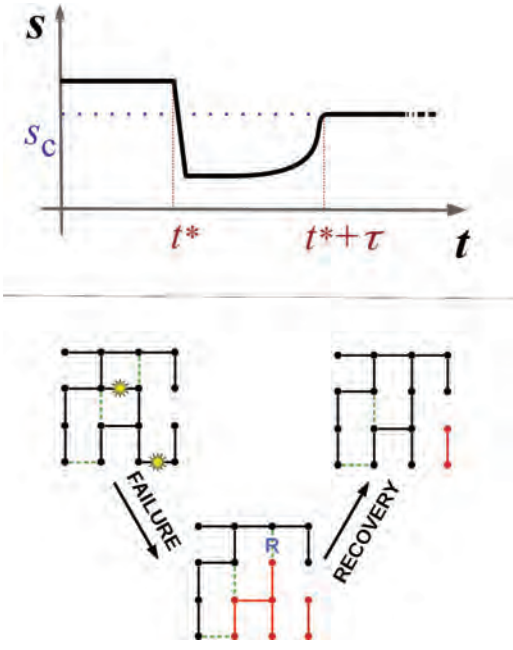

Figure 1. Relations among self healing and Resilience. Upper panel: Cartoon of a recovery function describing the resilience of a system; in this case we are plotting a metric s measuring the quality of service versus the time t. In the picture, an accident happens at time t^* and the s drops to a low value that depends on the robustness and on the reliability of the network; after a time τ, recovery plans will have restored the service s up to a level s_C that in some cases can be equal or even higher than the initial one. While the order of the restoration events determines the recovery time τ, any optimal restoration plan will achieve the same level of service s_C given the same resources. In this paper we will concentrate on the magnitude of s_C and not on the recovery time. Lower panel: Cartoon of a self-healing process in a distribution network.

Such a strategy is also common to material science where new polymeric compounds are capable of self healing due to the presence of small amounts of healing agents that gets released and activated upon cracking (White et al. 2001, Toohey et al. 2007).

While the security of large-scale infrastructural networks—like long range, high-voltage electric power networks—is based on redundancy, most of local (regional, rural and city level) networks due to economic constrains are tree-like objects with few redundant links (Quattrociocchi et al. 2014). To describe and characterize a core feature of the resilience of such local networks, we introduce a new percolation problem that models their capability of recovering connectivity upon random failures. Hence, our model for self-healing networks is inspired by local distribution networks like gas, water and medium/low voltage electric power networks. In real networks, cables and pipes—especially in urban areas—will likely follow the topology of the street networks. Also, tree-like networks allow operators to minimize costs (building physical links in the network requires huge investments) and to have an easy accountability of the consumptions. However, few redundant links must be present in order to recover the connectivity of the networks in case of accidents. Thus, after a link failure, some redundant links can be activated to recover (at least partially) the functionality of the network. In real infrastructures, such a procedure is often implemented manually, while in the smart networks of the future it should function automatically, possibly by embedding distributed algorithms automating the network recovery (Quattrociocchi et al. 2014). In the lower panel Fig. 1 we present a cartoon of the self-healing process in real networks.

3 MODEL

In our scenario we consider network systems distributing some utility; for sake of simplicity, we will consider a single node to be the source of the quantity to be distributed on the network. Examples of such network utilities are water, power, gas or oil pipelines or electric power distribution. At each instant of time, the topology of the network distributing the utility (the *active tree*) is assumed to be a tree; this assumption is partially verified in the above mentioned system; in particular, it is mostly verified in the case of electric power distribution (Pagani and Aiello 2011). In fact, such a structure meets the infrastructures' managers needs—i.e., to measure (for billing purposes) in an easy and precise way how much of a given quantity is served to any single node of the network. Finally, as a further simplification we will not take into account the magnitudes of flows—i.e., all links and sources are assumed to have infinite capacity—but we will focus on maximizing the connectedness of the system in order to serve as many nodes as possible. Notice that in the case of real flows, such assumption can be unrealistic since links and nodes in real networks have limits beyond which they become unoperational.

In order to implement our strategy and its self-healing capabilities, we consider the presence of *dormant* backup links—i.e., a set of links that can be switched on. Nodes are assumed to be able to communicate with their neighbors by means of a suitable distributed interaction protocol with a limited amount of knowledge: in particular, nodes are supposed to possess information only about the state of neighboring nodes connected either via active or via dormant links.

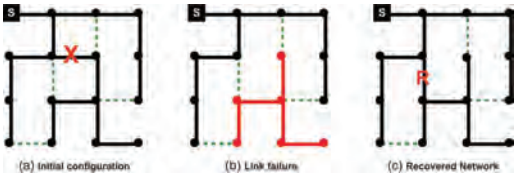

Figure 2. Example of the healing procedure: (Left Panel) In the initial state, the source node (filled square, upper left corner) is able to serve all 16 nodes through the links of the active tree. The 4 dashed lines (green online) represent dormant backup links that can be activated upon failure. The redundancy of the system is $p = 4/9$ as only 4 of the 9 possible backup links are present. The link marked with an X is the one that is going to fail. (Central panel) A single link failure disconnects all the nodes of a sub-tree; in the example, a sub-tree of 6 nodes (red online) is left isolated from the source—i.e., the system has a damage $\Delta = 6$). (Right Panel) By activating a single dormant backup link, the self-healing protocol has been able to recover connectivity for the whole system, in this case bringing back the number of served nodes at its maximum value 16. The link that has recovered the connectivity is marked with an R. Notice that in real networks, due to the physics of the flows and to the constraints on links and nodes capacities, not all the possible reconnection could be viable and on the contrary could lead to cascading behavior.

When either a node or a link failure occurs, all the nodes below the failure will disconnect from the active tree and become unserved. Such unserved nodes can now try to reconnect the active tree by waking up through the protocol some dormant backup links. Such a process will reconstruct a new active-tree that can restore totally or partially the flow, i.e. heal the system. Fig. 2 presents a graphical sketch of the healing procedure.

In the following, we will indicate with $T_s(G)$ a tree on the graph G routed in the node s; we indicate with $R \subseteq G - T$ the set of redundant links and with N the number of nodes. The set of redundant links will be also described by its adjacency matrix R_{ij} that takes the value 1 if a redundant link is present among nodes i and j, 0 otherwise. Moreover, we will describe the damages inflicted to the distribution tree by the matrix $q_{ij} = 0$ if link ij is removed, $q_{ij} = 1$ otherwise. The relevant metric for the effectiveness of a redundancy pattern R given an attack q is the fraction of served nodes FoS, i.e. the number of nodes connected to the root normalized by N.

4 METHODS

Let us first notice that a node i is connected to a node j if and only if a message from node i can reach node j. To solve such a problem, we use a cavity based approach for message passing (Mezard and Montanari 2009).

First of all let us define the set $S(i)$ as the set on nodes which are sons of node i on the original tree T (i.e. not considering the redundant edges): $S(i) \equiv \{k : k \text{ is a son of } i\}$. Moreover we will call $F(i)$ the unique father of node i. Finally, we define $R(i) = \{j : R_{ij} = 1\}$ the set of nodes connected to i via redundant links; obviously, we have $F(i) \notin R(i)$ and $S(i) \cap R(i) = \varnothing$. Then, let us consider a node i and a node $j \in S(i)$ which is one of the sons of node i on the original tree.

We introduce the following quantities:

- $d_{i\to j}$ is probability that node i is connected to the root s, when the son-node $j \in S(i)$ is absent from the tree.
- $u_{i\to j}$ is the probability that node i is connected to the root s, when the father-node $j = F(i)$ is absent from the tree.
- $r_{i\to j}$ is the probability that node i is connected to the root s when i and j connected by a redundant edge and j is absent from the tree.

We will derive first the recursive equation for $d_{i\to j}, j \in S(i)$. When j is absent from the graph, then i is connected to the root s if at least one among this possibilities is realized:

1. its father $F(i)$ is connected to the root. The probability that such event does NOT happen is

$$\pi_1 = \left(1 - q_{iF(i)} d_{F(i)\to i}\right)$$

2. one of its sons $S(i)$ – except j – is connected to the root. The probability that such event does NOT happen is

$$\pi_2 = \prod_{k \in S(i) \setminus j} (1 - q_{ki} u_{k\to i})$$

3. one of the neighbours connected to i via a redundant link is connected to the root when i is absent. The probability that such event does NOT happen is

$$\pi_3 = \prod_{k=1}^{N} (1 - R_{ik} r_{k\to i})$$

The total probability that i is connected to the root when its son j is absent is thus given by $1 - \pi_1 \times \pi_2 \times \pi_3$, i.e.

$$d_{i\to j} = 1 - \left(1 - q_{iF(i)} d_{F(i)\to i}\right) \times \prod_{k \in S(i) \setminus j} (1 - q_{ki} u_{k\to i}) \prod_{m=1}^{N} (1 - R_{im} r_{m\to i}) \quad (1)$$

Following the same procedure we can write the equation for $u_{i\to j}$:

$$u_{i\to j} = 1 - \prod_{k\in S(i)} (1 - q_{ki} u_{k\to i}) \times \prod_{m=1}^{N} (1 - R_{im} r_{m\to i}) \qquad (2)$$

Finally, the equation for $r_{i\to j}$ is:

$$r_{i\to j} = 1 - \left(1 - q_{iF(i)} d_{F(i)\to i}\right) \times \prod_{k\in S(i)} (1 - q_{ki} u_{k\to i}) \prod_{m=1, m\neq j}^{N} (1 - R_{im} r_{m\to i}) \qquad (3)$$

Equations (1–3) constitute the self consistent equations of the problem. They are valid for any given realization of the random tree and redundant links. Equations (1–3) can be considered as describing messages running on the edges of the tree and on redundant edges, and they can be solved by simple iteration.

Once a solution to Eqs. (1–3) has been found, we can compute the total probability p_i that node i is connected to the root

$$p_i = 1 - \left(1 - q_{iF(i)} d_{F(i)\to i}\right) \times \prod_{k\in S(i)} (1 - q_{ki} u_{k\to i}) \prod_{m=1}^{N} (1 - R_{im} r_{m\to i}) \qquad (4)$$

Disregarding correlations, we can estimate the average fraction of served nodes *FoS* as

$$FoS = \frac{\sum_{i=1}^{N} p_i}{N} \qquad (5)$$

5 RESULTS

We now compare the results of our eqs. (1–3) to the numerical simulation of our self-healing procedure. In particular, we are considering the case of networks generated by random trees at which a fraction α of random recovery links are added. After an initial fraction f of links in the tree is deleted at random, recovery links are activated whenever they reduce the number of connected components. Finally, the *FoS* is calculated by checking the fraction of nodes connected to the origin via the surviving links plus the redundant. Notice that when averaging eq. (1–3) to solve the mean-field equations, we are using $\langle q_{ij} \rangle = f$ and $\langle R_{i,j} \rangle = \alpha/(N-1)$.

First, we perform simulations on random trees on a complete graph of 1000 nodes. The random trees are generated according a flat-sampling procedure in the space of possible trees (Broder 1989, Aldous 1990, Wilson 1996). Edges on the tree are removed at random; the fraction of removed edges is indicated as $f = 1 - \sum_{i,j} q_{ij} / |T|$, where $|T| = N - 1$. We parametrize with α the population of redundant link existing among two nodes i and j where the link i,j does not belong to T; thus, R_{ij} are random variables on $\{0,1\}$ where $R_{ij} = 1$ with probability $\alpha/(N-1)$. In each simulation, a random tree is generated, a random vertex is assumed to be the source, a fraction α of redundant links are added to the tree and a fraction f of links is erased at random from the tree; then the fraction of *FoS* of sites connected to the root (via links either in $T - q$ or in R) is calculated. The results for the average *FoS* are presented on Fig. 3.

We then consider the average behavior of Eqs. (1–3) over the randomness in the model, i.e. over the possible realizations of the q_j and C_j. Performing the average we obtain the following self consistent equations:

$$d = 1 - \left[1 - (1-f)d\right] e^{-\alpha r} \times \sum_k \frac{k(k-1)}{\langle k^2 \rangle - \langle k \rangle} P(k) [1 - (1-f)u]^{k-2} \qquad (6)$$

$$u = 1 - e^{-\alpha r} \frac{k}{\langle k \rangle} P(k) [1 - (1-f)u]^{k-1}$$

$$r = 1 - \left[1 - (1-f)d\right] e^{-\alpha r}$$

$$\sum_k \frac{k}{\langle k \rangle} P(k) [1 - (1-f)u]^{k-1}$$

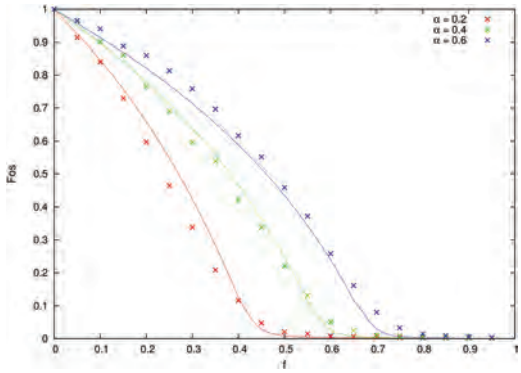

Figure 3. Comparison of simulations and analytical approximation. Depicted are the curves for the fraction of served nodes *FoS* (i.e. nodes connected at the origin after self-healing) versus the initial fraction of failed links f. Crosses correspond to average values of the *FoS* obtained by simulating random trees of 1000 nodes for different levels of redundancy $\alpha = 0.2$ (red X), $\alpha = 0.4$ (green X) and $\alpha = 0.6$ (blue X); the size of the symbols is of the order of thrice the error bars. As expected, curves are monotonically decreasing with f and monotonically increasing with α. Full lines correspond to the predictions of our analytical approximations eqs. (7).

where $P(k)$ is the degree distribution (i.e. the probability of having k neighbours) of nodes in the tree which are not leaves. In Fig. 3 we compare the theoretical predicted *FoS* obtained by averaging eq. (5) with the results of numerical simulations.

6 CONCLUSION

In this paper we have discusses the recovery of networks upon a minimal self-healing procedure that exploits the presence of redundant edges to recover the connectivity of the system. Our scenario is inspired by real-world distribution networks that are, often for economic reasons, tree-like and in the meantime are also often provided with alternative backup links that can be activated in case of malfunctioning; as an example, this is the case for low-voltage distribution networks (ENEL 2011).

Our model, albeit schematic, is realistic in the sense that it could be readily and easily implemented with the current technologies. In fact, routing protocols represent a vast available source of distributed algorithms able to maintain the connectivity of a system. Therefore, our scheme could be implemented by coupling an ICT network to current infrastructures. Our case is an example in which interdependencies enhance the resilience instead of introducing catastrophic breakdowns (Buldyrev et al. 2010). However, since in we are assuming that links capacities are infinite, our model applies to cases where the network is not stressed. For real flow networks, the physics of the flows and their constrains can forbid some of the possible reconnections that, in the worst cases, could even lead to cascading failures like he one observed in model power grids (Pahwa et al. 2014). Moreover, we are considering the case of a single source; in the case of multiple sources, leaving the system disconnected (islanding) could even improve its robustness (Mureddu et al. 2016). Notice that since our model predicts only the final level of service of a network, also timescales are an important element that should be introduced to allow for a characterization of the full resilience curve of the system.

In this paper we have introduced the cavity equation describing our model and compared an analytical approximation for the average values of the connectivity under random failures with numerical simulations. We find a promising accordance of such an approximation with numerical results opening the field for future investigations.

The first direction to be investigated is the study of our approximation when both the fraction of failures f and the fraction of redundant links α is small. In fact, in real systems the number of concurrent failures is small: this is the reason at the basis of the $N-1$ criterion in engineering. On the same pace, for economic reasons also the fraction α of redundant links is doomed to be small: hence, our approximation is valid for small f's and α's, where analytical expressions could be linearly expanded. On the other hand, if failures are not independent but happen in a correlated and perhaps catastrophic way like in cascading events (Pahwa et al. 2014), the approximation must be enhanced to hold for the entire f range; work in progress is done in this direction.

Most importantly, cavity equations (1–3) can be applied to single networks with a given topology and set of redundant links to calculate the *FoS* as an alternative method to numerical simulations. Having a set of closed equations allows then to easily analyze scenarios in which the set of redundant links is varied: coupling our approach with the introduction of a cost function for the links is of importance for the design of networks since it would allow to optimizing the redundancy. As an example, numerical simulations on planar topologies suggest that a very effective strategy to strengthen planar networks is to add long range links (Quattrociocchi et al. 2014): since such links are overly expensive in networks like electric distribution, the feasibility of such a strategy depends on cost-benefit analysis about their implementation of physical long-range links in *PNI*s. A further direction of study would be to consider the effects of more detailed structural characteristics on the dynamics of the system (D'Agostino et al. 2012). However, it is important to remember that in optimizing the system the cost of the links is as much important as the increase in resilience of the system. In fact, a simple constrain like keeping the number of redundant links fixed would lead to very unrealistic topologies in which the source is at the center of a star regardless of the length of the links (Quattrociocchi et al. 2014).

A new hybrid Bayesian network approach for modeling reliability

F. Petiet, O. François & L. Bouillaut
Grettia, Ifsttar, University of Paris Est, France

ABSTRACT: In this paper, a hybrid discrete-continuous Graphical Duration Models is proposed. Since the interest of the Weibull density was demonstrated for reliability analysis, this paper focuses on the use of Weibull densities for modeling sojourn times in each state of the system. This extension of the standard Graphical Duration Model (GDM) requires a specific structure that we call Weibull-Hybrid Graphical Duration Models (W-HGDM). The main contribution of this study lays in the proposal of a specific inference algorithm for such hybrid networks. Finally, comparisons of reliability estimation will be proposed for both standard GDM and W-HGDM.

1 INTRODUCTION

Reliability analysis is an integral part of system design and operating, especially for systems performing critical applications.

A wide range of works about reliability analysis is available in the literature.

Most of the time, the system failure is caused by the failure of one or more components. In this case, it is possible to use statistical distributions as the exponential distribution to model the lifetime. The Weibull Distribution (Weibull 1951) allows to describe each phase of the bathtub curve. In (Bertholon 2001) a new modeling of aging is proposed.

These distributions do not allow to focus on the dynamics of degradation. They cannot be applied to a system that is repaired when it fails. They cannot be used to assess the expected number of failures during the warranty period, or maintain a minimum mission reliability, or determine when to replace or overhaul a system. These methods are often called "classics".

Dynamic models explicitly take into account the temporal aspect modeling the evolution of the degradation of the system over time by stochastic methods (Cocozza-Thivent 1997).

Rather than considering the different components of the system, it is also possible to consider the whole system. Several methods are commonly used to model the different states of a dynamic system, in order to analyze its reliability, such as Markov Chain, Petri net, or Bayesian Network (Demri 2009).

Recent works have shown the interest of using Bayesian Networks (BN) (Jensen 1996) in the field of reliability. For example (Boudali & Dugan 2005) shows how to model the reliability of a complex system using Bayesian networks.

Weber and Jouffe (2003) explains how to use dynamic Bayesian networks (DBN) (Murphy 2002) to study the reliability of a multi-state system that depends on a certain context.

However DBN suppose that the sojourn time in each state are exponentially distributed, whereas most of the industrial applications underline non Markovian behaviors. In these cases, a Markovian degradation process modeling can introduce non negligible biases.

So an original Bayesian Network structure was proposed, named Graphical Duration Models (GDM), in order to fit systems whose sojourn time in each state are not necessary exponentially distributed (Donat, Leray, Bouillaut, & Aknin 2010). A GDM is characterized by a duration variable, allowing the use of any kind of distribution for modeling the sojourn time in each state of the considered system.

However the complexity is directly related to the size of the discrete space of the sojourn time variable. It can induce some technical problems in terms of storage capacity and computation time. A solution could be to consider a continuous duration variable.

In the theory of Bayesian Networks, there are several approaches that contain both continuous and discrete variables.

In hybrid Bayesian networks, where both discrete and continuous variables appear simultaneously, it is possible to apply inference schemes similar to those for discrete variables. The first model that allowed exact inference in hybrid networks was based on the Conditional Gaussian (CG) distribution (Lauritzen 1992).

The restriction of discrete variables with continuous parents in CG may also be partially lifted using logit or probit function, generalized in the multinomial case by the softmax function (Murphy 1999).

Another way to lift the restriction caused by discrete variables with continuous parents is the using of a mixture of exponentials (Koller, Lerner, & Angelov 1999), but the inference is approximated.

The Mixture of Truncated Exponential model has been introduced in (Moral, Rumí, & Salmerón 2001). The advantage with respect to CG is that discrete nodes with continuous parents are allowed and inference can be exact (Cobb & Shenoy 2006).

Given that hybrid approaches thus exist in the Bayesian Network framework, such a perspective could be envisaged in a Graphical Duration Model.

According to expert feedback, sojourn-time variables follow a Weibull distribution in many systems (Weibull 1951).

Our goal is to integrate sojourn-time variables following a Weibull distribution in a graphical duration model by proposing a new approach.

First, this paper will briefly describe the formalisms of the Bayesian Networks of the Graphical Duration Models. We then introduce the our proposed formalism named Weibull-Hybrid Graphical Duration Models (W-HGDM) and the inference algorithm associated.

Then a toy system is introduced. Before some conclusions and prospects, a comparison of reliability analysis results, obtained from both Graphical Duration Models and Weibull-Hybrid Graphical Duration Models approaches, will be done.

2 INTRODUCTION OF THE FORMALISM

2.1 *Bayesian Network*

Bayesian Networks (Jensen 1996) are mathematical tools relying on the probability theory and the graph theory. They allow to qualitatively and quantitatively represent uncertain knowledge.

Bayesian Networks are Probabilistic Graphical Models that allow to intuitively represent the distribution of a set of random variables $\mathbf{X} = (X_1,...,X_N)$. Basically, a BN is defined as a pair $\mathcal{M} = (\mathcal{G},(p_n)_{1\le n\le N})$. $\mathcal{G} = (\mathbf{X},\mathcal{E})$ is a Directed Acyclic Graph in which each node i is associated to a random variable X_i, that takes its values in a finite and countable set $\mathcal{X}_i$, and in which each directed arc $(i,j)\in\mathcal{E}$ represents dependencies between random variables X_i and X_j. $(p_n)_{1\le n\le N}$ is a set of Conditional Probability Distributions (CPD) such that each p_n denote the conditional probability distribution associated to random variable X_n given its parents X_{pa_n}, pa_n referring to the sequence of parents indices of the random variable X_n in $\mathcal{G}$.

The conditional independence relationships introduced by the arcs of the graph enable to factor the joint probability distribution of the set of random variables $\mathbf{X}$ as follows:

$$P(\mathbf{X}) = P(X_1,\ldots,X_N) = \prod_{n=1}^{N} P(X_n \mid X_{\mathrm{pa}_n}) \qquad (1)$$

Besides, tools have been developed to automatically learn the structure and the parameters of the graph and those of the CPD from complete or incomplete data or if a priori knowledge is available (e.g. expert opinion) (Neapolitan 2003).

Using BN is particularly interesting because of the possibility to propagate knowledge through the network. Indeed, various inference algorithms can be used to compute marginal probabilities of the system variables. One of the most classical inference procedures relies on the use of a junction tree (Lauritzen & Spiegelhalter 1988). Nevertheless, in our experiments, we use the elimination algorithm (Dechter 1999). This choice is motivated by the simplicity and the efficiency of the method.

2.2 *Dynamic Bayesian Network*

Inspired by the formalism of classical BN, the Dynamic Bayesian Networks (DBN) framework (Murphy 2002) allowed to unify many approaches from modeling of time series such as hidden Markov models. A DBN aims to model the probability distribution of a random variables set $(\mathbf{X}_t)_{1\le t\le T} = (X_{1,t},\ldots,X_{N,t})_{1\le t\le T}$. It consists of a pair of Bayesian Networks $(\mathcal{M}_1,\mathcal{M}_{\rightarrow})$. $\mathcal{M}_1$ defines the prior distribution $P(X_{1,1},\ \ldots,X_{N,1})$ as in (1). $\mathcal{M}_{\rightarrow}$ defines the transition model which describes the dependencies between variables in slice $t-1$ and variables in slice t, i.e. the distribution of $\mathbf{X}_t \mid \mathbf{X}_{t-1}$.

$$\begin{aligned} P(\mathbf{X}_t \mid \mathbf{X}_{t-1}) &= P(X_{1,t},\ldots,X_{N,t} \mid X_{1,t-1},\ldots,X_{N,t-1}) \\ &= \prod_{n=1}^{N} P(X_{n,t} \mid X_{\mathrm{pa}_{n,t}}) \end{aligned} \qquad (2)$$

where $\mathrm{pa}_{n,t}$ refers to the sequence of parents indices of the random variable $X_{n,t}$ in the graph of $\mathcal{M}_{\rightarrow}$.

A Dynamic Bayesian Network is actually a static Bayesian Network, that is repeated several times. So DBN inherit the convenient properties of static BN, particularly with regard to learning and inference.

The state of the system at future time $t+1$, $\mathbf{X}_{t+1}$, is decided by the system state at the current time t, $\mathbf{X}_t$, and does not depend on the state at earlier time

instants 1,…,$t-1$; and the conditional probability distributions of $\mathcal{M}_{\rightarrow}$ do not depend on the slice t; so the distribution of time spent in each state is geometric. Whereas most of industrial applications have not this behavior. Such a modeling can introduce non negligible biases in the estimations.

2.3 *Graphical Duration Model*

A Graphical Duration Model (Donat, Leray, Bouillaut, & Aknin 2010) relies on the two following variables: the system state X_t and the duration variable S_t describing the time spent in any system state (remaining sojourn time) (Fig. 1).

Firstly, the Conditional Probability Distribution associated with the distribution of the initial system state is defined as follows, over the discrete and finite domain $\Omega_X = \{1,\ldots,N_X\}$:

$$P(X_1 = i) = P_{X_1}(i) \tag{3}$$

The initial sojourn-time CPD gives the distributions for each initial state. This CPD is defined over the discrete and finite domain $\Omega_S = \{1,\ldots,N_S\}$:

$$P(S_1 = k \mid X_1 = i) = P_{S_1}(i,k) \tag{4}$$

Then, it is necessary to define the system state and the Sojourn-time transition CPDs.

A transition occurs if and only if $S_{t-1} = 1$.

$$P(X_t = j \mid X_{t-1} = i, S_{t-1} = 1) = Q^{sys}(i,j) \tag{5}$$

where Q^{sys} is a $N_X.N_X$ matrix, called static system transition matrix.

A new sojourn-time is selected according to the following CPD:

$$P(S_t = k \mid X_t = i, S_{t-1} = 1) = F^{sys}(i,k) \tag{6}$$

where F^{sys} is a $N_X.N_S$ matrix.

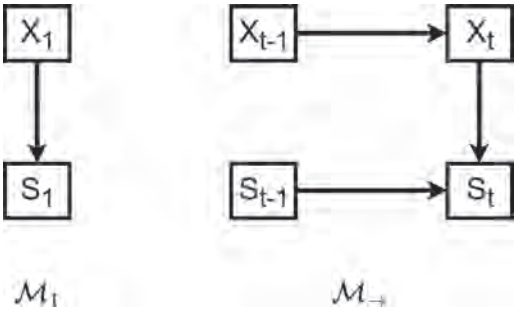

Figure 1. Discrete duration graphical model.

While there is no transition, the system deterministically remains in the previous state i:

$$P(X_t = j \mid X_{t-1} = i, S_{t-1} \geq 2) = I(i,j) \tag{7}$$

and the sojourn-time in the current state is decreased deterministically by one unit:

$$P(S_t = k \mid X_t = i, S_{t-1} = k' \geq 2) = \begin{cases} 1 & \text{if } k = k'-1 \\ 0 & \text{otherwise} \end{cases} \tag{8}$$

2.4 *Reliability computation*

Let assume that the set of system state Ω_X is partitioned into two sets $\mathcal{U}$ and $\mathcal{D}$ respectively for "up" states and for "down" states (i.e. OK and failure situations).

The discrete-time system reliability is defined as the function R: $\mathbf{N}^* \mapsto [0,1]$ where $R(t)$ represents the probability that the system has always stayed in an up state until moment t, i.e.

$$R(t) = P(X_1 \in \mathcal{U};\ldots;X_t \in \mathcal{U}).$$

In addition, it is possible to derive some interesting metrics such as the failure rate or the MTTF (Pham 2006) from the reliability definition.

Hence, this issue boils down to an inference problem, i.e. to the computation of $P(X_1 \in \mathcal{U};\ldots;X_t \in \mathcal{U})$.

The system cannot repair itself. The failure state is absorbing. The reliability is then equal to the availability, ie

$$R(t) = P(X_t \in \mathcal{U}) = 1 - P(X_t \in \mathcal{D}).$$

Then the reliability computation is reduced to the computation of the marginal distribution of X_t.

2.5 *Limitation of GDM*

The larger N_S is, the more accurate the representation of the sojourn-time distribution. On the other hand, choosing a too large N_S value will have immediate consequences on both the space needed to store the Conditional Probability Distributions, i.e. $N_X.N_S$ values, and the time complexity of inference.

That can induce some technical problems in terms of storage capacity and computation time. A solution could be to consider a continuous duration variable. With c the number of parameters needed by the chosen distribution, the CPD will be constituted of $N_X.c$ values, so the space needed to store the continuous CPD is smaller than if they are discrete.

Since the interest of the Weibull density was demonstrated for reliability analysis (Weibull

1951), this paper focuses on the use of Weibull densities for modeling sojourn times in each state of the system.

3 WEIBULL-HYBRID GRAPHICAL DURATION MODELS

In the following paragraphs, we propose a new formalism to represent the evolution of a dynamic system over time, in order to estimate its reliability. This particular model is called Weibull-Hybrid Graphical Duration Models (W-HGDM). In the following, we will describe its conditional probability distributions, and an inference algorithm in order to compute the reliability.

3.1 *Generalities*

The collection $(X_t)_{1\leq t\leq T}$ represents the system state over a sequence of length T. The collection $(S_t)_{1\leq t\leq T}$ represents the remaining time before a system state modification. More clearly, we refer to the random variable S_t as the remaining sojourn time in the current system state. These variables are called duration variables or sojourn-time variables. A Weibull-Hybrid Graphical Duration Model is illustrated in Figure 2.

Expressions (3), (4), (5), (6), (7) and (8) become expressions (9), (10), (12), (13), (14) and (15).

The Conditional Probability Distribution associated with the distribution of initial system state must be defined as follows, over the discrete and finite domain $\Omega_X = 1,\ldots,N_X$:

$$P(X_1 = i) = p_i^{ini} \tag{9}$$

The initial sojourn-time CPD gives the distribution for each initial state, it is defined over the continuous domain $\Omega_S =]0,+\infty[$:

$$f_{S_1|X_1=i} = f_{\mathcal{W}_{\alpha_i,\beta_i}} \tag{10}$$

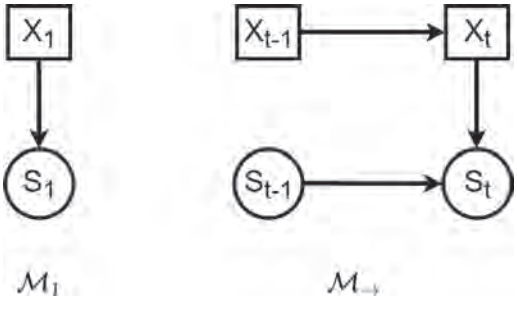

Figure 2. Continuous duration graphical model.

with

$$f_{\mathcal{W}_{\alpha,\beta}}(s) = \frac{\beta}{\alpha}\left(\frac{s}{\alpha}\right)^{\beta-1} e^{-\left(\frac{s}{\alpha}\right)^{\beta}} \tag{11}$$

where α is the scale parameter and β the shape parameter.

Then, it is necessary to define the system state and the sojourn-time transition CPD:

A transition occurs if and only if $S_{t-1} < 1$.

$$P(X_t = j \mid X_{t-1} = i, S_{t-1} < 1) = Q^{sys}(i,j) \tag{12}$$

where Q^{sys} is a $N_X.N_X$ matrix, called static system transition matrix.

A new sojourn-time is selected according to the following CPD:

$$f_{S_t=s|S_{t-1}<1,X_t=i} = f_{\mathcal{W}_{\alpha_i,\beta_i}}(s) \tag{13}$$

While there is no transition, the system deterministically remains in the previous state *i*:

$$P(X_t = j \mid X_{t-1} = i, S_{t-1} > 1) = I(i,j) \tag{14}$$

and the sojourn-time in the current state is decreased deterministically by one unit:

$$f(S_t = s \mid X_t = i, S_{t-1} = s' > 1) = \begin{cases} 1 & \text{if } s = s' - 1 \\ 0 & \text{otherwise} \end{cases} \tag{15}$$

3.2 *Inference*

As shown in 2.4, the reliability of a non-repairable system is equal to the availability of the system:

$$\begin{aligned} R(t) &= P(X_t \in \mathcal{U}) \\ &= 1 - P(X_t \in \mathcal{D}) \\ &= 1 - \sum_{\substack{X_1,\ldots,X_{t-1} \\ S_1,\ldots,S_{t-1}}} P(X_t \in D, X_{t-1},\ldots,X_1, S_{t-1},\ldots,X_1) \\ &= 1 - \sum_{\substack{X_1,\ldots,X_{t-1} \\ S_1,\ldots,S_{t-1}}} P(X_t \in D \mid \mathrm{pa}(X_t)) \end{aligned} \tag{16}$$

We have to compute successively the following distributions:

- $\Phi_{t,u} = P(X_t|X_u, S_{u-1})$ for $u \in [\![2;t-1]\!]$ and $\Phi_{t,1} = P(X_t|X_1)$.
- $\Lambda_{t,u} = P(X_t|X_u, S_{u-1})$ for $u \in [\![2;t]\!]$ and $\Lambda_{t,1} = P(X_t)$

The required distributions are expressed as follows:

For $u \in [\![2;t-1]\!]$

$$\Phi_{t,u} = \int_0^{\infty} P(X_t \mid X_u, S_u = s_u) f(S_u = s_u \mid X_u, S_{u-1}) \mathrm{d}s_u = \int_0^{\infty} \Lambda_{t,u+1} \times f(S_u = s_u \mid X_u, S_{u-1}) \mathrm{d}s_u \quad (17)$$

and

$$\Lambda_{t,u} = \sum_{x \in \Omega_{X_u}} P(X_t \mid X_u = x, S_{u-1}) P(X_u = x \mid X_{u-1}, S_{u-1}) = \sum_{x \in \Omega_{X_u}} \Phi_{t,u} \times P(X_u = x \mid X_{u-1}, S_{u-1}) \quad (18)$$

For $u = 1$

$$\Phi_{t,1} = \int_0^{\infty} P(X_t \mid X_1, S_1 = s_1) f(S_1 = s_1 \mid X_1) \mathrm{d}s_u = \int_0^{\infty} \Lambda_{t,2} f(S_1 = s_1 \mid X_1) \mathrm{d}s_u \quad (19)$$

and

$$\Lambda_{t,1} = \sum_{x \in \Omega_{X_1}} P(X_t \mid X_1 = x) P(X_1 = x) = \sum_{x \in \Omega_{X_1}} \Phi_{1,1} P(X_1 = x) \quad (20)$$

The elements required by the computation (17) are given by (18), (13) and (15); and those required by (19) are given by (18) and (10).

The elements required by the computation (18) are given by (17), (12) and (14); and those required by (20) are given by (17) and (9).

Equations 17, 18, 19, 20 define an iterative algorithm, that give at the end: $\Lambda_{t,1} = P(X_t)$, that allows to have the value of the reliability:

$$R(t) = 1 - P(X_t \in \mathcal{D}) = \sum_{x \in \mathcal{U}} P(X_t = x) \quad (21)$$

The computation in (17) and (18) can be developed as follows:

In (17):

$$P(X_t \mid X_{t-q}, S_{t-q-1} = s) = \quad (22)$$

$$\begin{cases} Q^{(q)} & \text{if} \quad s < 1 \\ Q^{sys} * Q^{(q-1)} & \text{if} \quad 1 < s < 2 \\ \quad \cdots & \\ Q^{sys} * Q^{(q-j)} & \text{if} \quad j < s < j+1 \\ \quad \cdots & \\ Q^{sys} & \text{if} \quad q < s < q+1 \\ I & \text{if} \quad q+1 < s \end{cases} \quad (23)$$

with $Q^{(q)}(x,y) = \sum_{k=1}^{q} \int_{k-1}^{k} f_{\mathcal{W}_{\alpha_x,\beta_x}}(s)\mathrm{d}s \times [\, Q^{sys} Q^{(q-k)}\,](x,y) + \int_q^{\infty} f_{\mathcal{W}_{\alpha_x,\beta_x}}(s)\mathrm{d}s \times I(x,y)$.

In (18):

$$P(X_t \mid X_{t-q-1}, S_{t-q-1} = s) = \quad (24)$$

$$\begin{cases} Q^{sys} * Q^{(q)} & \text{if} \quad s < 1 \\ Q^{sys} * Q^{(q-1)} & \text{if} \quad 1 < s < 2 \\ \quad \cdots & \\ Q^{sys} * Q^{(q-j)} & \text{if} \quad j < s < j+1 \\ \quad \cdots & \\ Q^{sys} & \text{if} \quad q < s < q+1 \\ I & \text{if} \quad q+1 < s \end{cases} \quad (25)$$

$Q^{sys} \cdot Q^{(q)}$ is actually the natural transition of the system between q slices.

4 ILLUSTRATIONS

The W-HGDM used has been implemented in MATLAB® environment, using the open source Bayes Net Toolbox (BNT). The objective of this study is the inference part, not the learning part. So toy systems are created. The parameters of Conditional Probability Distributions are not learned from data, they are determined.

4.1 *Test*

To validate this algorithm, we consider a two-state system, one of the states being "up", the other being "down". The reliability can be written as follows:

$$\begin{aligned} R_{sys}(t) &= P(X_1 \in \mathcal{U} \cap \ldots \cap X_t \in \mathcal{U}) \\ &= P(S_1 \geq t \mid X_1 \in \mathcal{U}) P(X_1 \in \mathcal{U}) \\ &= 1 - F_{\mathcal{W}_{\alpha_{\mathcal{U}},\beta_{\mathcal{U}}}}(t) \\ &= e^{-\left(\frac{t}{\alpha_{\mathcal{U}}}\right)^{\beta_{\mathcal{U}}}} \end{aligned} \quad (26)$$

The application of the inference algorithm presented in 3.2 to such a model is supposed to return a Weibull distribution.

The Figure 3 shows that the estimated reliability is exactly the reliability given by the Weibull distribution.

4.2 *Comparison with standard GDM*

Let's illustrate our approach using a GDM modeling the behavior of a 3-states production machine, i.e. $\Omega_X = \{1,2,3\}$, with $\mathcal{D} = \{3\}$. The transition rate between system states is given in Table 1. The param-

eter of the Weibull distribution that characterize the sojourn-time variable when a transition occurs are given in Table 2. The algorithm presented in subsection 3.2 was used to make the computations.

A standard GDM is then built. The state system variable of this standard GDM model has the same static system transition matrix as the W-HGDM (Table 1). The distribution of sojourn-time variable of this standard GDM model is constructed by discretizing the continuous Weibull distribution, with the same parameters as the W-HGDM (Table 2), and with $N_S = 150$ (Donat, Bouillaut, Aknin, Leray, & Bondeux 2008).

The method presented in 3.2 has been used to compute reliability estimations presented in Figure 4.

We obtain the same results with both methods.

5 CONCLUSIONS

In this paper, a new hybrid approach for the duration model in which sojourn-time follows a Weibull distribution, called Weibull-Hybrid Graphical Duration Model, has been proposed. An associated inference algorithm has been therefore developed and introduced allowing the estimation of the reliability of the system in such models.

Finally, first results introduced in this paper underline the feasibility of the proposed approach in terms of inference accuracy. This validates the interest we have had in proposing such a hybrid approach for the modeling of degradation dynamics. Indeed, the expected advantage of W-HGDM leads mainly in the non discretization of the sojourn variable in GDM that can become a drag to reliability computation for complexity reasons.

Now, many things can be done and investigated through this new approach. The first perspective is to go further in the algorithm validation, by comparing the complexities and the speeds between standard GDM and W-HGDM. We also have planned to add some nodes to the presented W-HGDM, such as context variables, and, of course, maintenance actions. The long-term goal of this study is to improve VirMaLab (Virtual Maintenance Laboratory), a generic decision support tool developed by the GRETTIA (Bouillaut, Aknin, Donat, & Bondeux 2011) in order to evaluate, optimize and compare maintenance strategies for discrete state space system, by allowing sojourn-time variables to follow a Weibull distribution.

ABSTRACT: The analysis of road network vulnerability is a challenging and important research subject in the field of transportation reliability engineering because of the complex coupling relationships among travelers, vehicles, roads and environment. In view of the deficiency of existing researches on the description of travelers' risk averse and bounded rational behavior characteristics, both random utility theory and random regret theory are used to describe travelers' decision-making behaviors. Then a traffic assignment model expressed by variational inequality is constructed, in which travelers' risk aversion and bounded rationality as well as resultant heterogeneity of travelers' decision-making behaviors are explicitly taken into account. Subsequently, the vulnerability index of road network based on accessibility is defined, and a vulnerability identification model is built, then corresponding heuristic algorithm is also proposed. The example results show that the consequences of link closures could be misjudged and the vulnerability rankings could be misidentified, if ignoring the effects of the congestion levels of road network, travelers' perception errors and regret aversion degrees, as well as travelers' route choice decision criteria. Therefore, it is necessary to capture the travelers' behavior characteristics in the process of vulnerability analysis.

1 INTRODUCTION

1.1 *Background*

Robust road traffic networks have been regarded as one of the preconditions for a high quality of life. However, a traffic network can be vulnerable to various natural or man-made disasters. For example, adverse weather such as heavy snow and flooding could severely degrade the network performance. Although the occurrence probability of these major incidents is low, their consequences could be sufficiently large to generate a major problem that threats remedial actions. Therefore, it is vital to understand the potential vulnerability of traffic networks under such major incidents, so as to manage their risks.

A key issue in the vulnerability analysis is to identify the critical links of a network, where the failures of those links would have the most serious impacts on the whole network (Chen et al., 2012, Yin and Xu, 2010). After identifying the critical links, the network robustness can be enhanced through reinforcing these identified critical links or constructing new alternative parallel paths (Matisziw and Murray, 2009).

Modeling travelers' behavioral responses to link failures is another key issue involved in critical link identification (Chen et al., 2012). Subjected to link failures, the high degree of demand uncertainty and/or link capacity degradation will inevitably yield travel time variability, and consequently imposes additional disutility on travelers. Many empirical studies have revealed the significant influence of travel time uncertainty on travelers' route choice behavior (Liu et al., 2004, Shao et al., 2006, Wu and Nie, 2011). Travelers under travel time uncertainty tend to choose reliable shortest path, not only dependent on travel time saving, but also on reduction of travel time variability. This risk averse behaviors under travel time uncertainty have received considerable attention (Shao et al., 2006, Lo et al., 2006, Siu and Lo, 2008). However, most of the previous studies adopt Expected Utility Theory (EUT) and/or Random Utility Theory (RUT) to quantify travelers' perceptions of network uncertainty, and assume that the travelers are homogeneous. It is well known that both EUT and RUT are based on the assumption that travelers are absolutely rational

when making route choice decisions. In reality, however, part of travelers' behaviors may be bounded rational, and can be influenced by his or her personality, psychological state, and environmental elements, etc. It goes without saying that the usefulness of EUT or RUT as a descriptive model of choice behaviour has been fiercely debated both inside and outside the transportation domain. It is particularly interesting to note that Regret Theory (RT) (Loomes and Sugden, 1982) and its extended Random Regret Theory (RRT) (Chorus, 2014), being widely considered one of the most prominent competitors of both EUT and RUT in the behavioral decision sciences, has been virtually ignored in the route choice domain. RT or/and RRT postulate that when choosing, people anticipate and try to avoid the situation where a non-chosen alternative outperforms the chosen one (which would cause post-decision regret). It is a pity that, to our best knowledge, travelers' risk aversion and bounded rationality as well as resultant travelers' heterogeneous behavior responses due to link closures have not yet been considered simultaneously in the studies of critical link identification.

In view of the above, this study proposed a method of road network vulnerability identification taking into account travelers' risk aversion, bounded rationality and heterogeneity simultaneously under travel time variations subjected to link failures. We assume that the total travel demand comprises of two parts, completely rational travelers and bounded rational travelers. A new vulnerability index based on accessibility is introduced to evaluate the consequences of a link closure with consideration of their effects.

1.2 *Outline*

The remainder of this paper is organized as follows. In Section 2, a stochastic mixed user equilibrium model is built. It follows with the definition of vulnerability index based on accessibility for evaluating the consequences of a link closure with consideration of travelers' risk aversion, bounded rationality and heterogeneity. In Section 4, numerical examples by means of the Nguyen and Dupuis network is provided to demonstrate the proposed model. Finally, the conclusions are given in Section 5, together with future research directions.

2 A STOCHASTIC MIXED USER EQUILIBRIUM MODEL

2.1 *Distributions of travel times under link closures*

Consider a road network represented by a strongly connected graph G = (N, A), where N and A are the sets of nodes and links respectively. Let W denote the set of Origin-Destination (OD), R_w represent the set of paths between OD pair w, w ∈ W.

Because of link failures, the high degree of demand uncertainty and/or link capacity degradation will inevitably lead to travel time uncertainty. Assume that a link travel time is a random variable. Let T_a represent the travel time on link a. Furthermore, assume that T_a follows the normal distribution with mean value t_a and variance $\rho_a t_a$, where ρ_a represents the variation coefficient of T_a. The mean travel time t_a can be described by the following BPR (Bureau of Public Roads) function:

$$t_a = t_a^0\left(1+\beta\left(\frac{v_a}{c_a}\right)^n\right), a \in A \tag{1}$$

where t_a^0 is the free-flow travel time on link a, v_a and c_a are the flow and the capacity on link a respectively, β and n are the constant parameters of BPR function.

Let the travel time on path k between the OD pair w be represented as T_k^w, which can be calculated according to the relationship of link and path, as follows:

$$T_k^w = \sum_{a\in A} T_a \delta_{a,k}^w, k \in R_w, w \in W \tag{2}$$

where $\delta_{a,k}^w$ is the link-path incidence variable, $\delta_{a,k}^w$=1 if link a is on path k, otherwise $\delta_{a,k}^w = 0$.

In order to simplify the problem, it is assumed that link travel times are independent of each other. Because a path is composed of several independent links, according to the Central Limit Theorem, a path travel time should obey the normal distribution approximately. According to equations (1) and (2), the mean and standard deviation of T_k^w can then be expressed as below:

$$t_k^w = \sum_{a\in A} \delta_{a,k}^w t_a^0\left(1+\beta\left(\frac{v_a}{c_a}\right)^n\right), k \in R_w, w \in W \tag{3}$$

$$\sigma_{T_k^w} = \sqrt{\sum_{a\in A} \delta_{a,k}^w \rho_a t_a}, k \in R_w, w \in W \tag{4}$$

where t_k^w and $\sigma_{T_k^w}$ are respectively mean and standard deviation of T_k^w.

The empirical researches show that, the travelers not only want to save travel time, but also hope to avoid the risk caused by the travel time uncertainty. Therefore, Lo et al. (2006) put forward the concept of Travel Time Budget (TTB), which is used to describe the route choice behavior of travelers avoiding travel risk. Let $\xi_k^w(\omega)$ be the TTB of route k between OD pair w, which can be expressed as follows:

$$\xi_k^w(\omega) = t_k^w + \Phi^{-1}(\omega)\sigma_{T_k^w}, k \in R_w, w \in W \tag{5}$$

where $\Phi^{-1}(\cdot)$ is the inverse function of standard normal distribution, ω denotes the reliability parameter reflecting the probability that the actual trip time is within the TTB.

1.2 *Travel decision model for completely rational travelers based on RUT*

Considering the travelers' risk aversion in route choice decisions, it is assumed that the completely rational travelers use TTB as their route choice criterion. In addition, because of the travelers may not have perfect information on the travel time distributions, the travelers' perception errors on the travel times should be also taken into account. Therefore, according to RTU, the travel disutility of the completely rational travelers can be regarded as a random variable, which can be expressed as follows:

$$U_{w,k}^{\mathrm{CR}} = \xi_k^w(\omega) + \zeta_{w,k}^{\mathrm{CR}},\ k \in R_w, w \in W \tag{6}$$

where $U_{w,k}^{\mathrm{CR}}$ and $\zeta_{w,k}^{\mathrm{CR}}$ respectively represent the perceived travel disutility and perception error when the completely rational traveler' choose the route k between the OD pair w.

Furthermore, assuming that the perception error $\zeta_{w,k}^{\mathrm{CR}}$ are identically and independently Gumbel distributed random variables with mean zero, then the probability that a completely rational traveler chooses the route k between OD pair w can be described as follows:

$$p_{w,k}^{\mathrm{CR}} = \frac{\exp\left(-\theta^{\mathrm{CR}}\xi_k^w(\omega)\right)}{\sum_{r\in R_w}\exp\left(-\theta^{\mathrm{CR}}\xi_r^w(\omega)\right)},\ k \in R_w, w \in W \tag{7}$$

where $\theta^{\mathrm{CR}} > 0$ is the perception error parameter of the completely rational travelers which is used to measure the degrees of travelers' perception errors. It is noted that a higher θ^{CR} means smaller perception errors.

1.3 *Travel decision model for bounded rational travelers based on RRT*

In reality, due to the influences of information conditions, personality, preferences and other factors, not all travelers' route choice behaviors are completely rational, and some travelers show bounded rationality when choosing a route. In this paper, RRT is used to describe this phenomenon. In contrast with RUT, which postulates that a route's disutility is a function of its own performance only, RRT postulates that in addition, the performance difference with the competing route codetermines a route's disutility. In other words: RRT assumes that the traveler is regret averse in travel decision-making, that is, when the traveler make choice among all alternatives, the total value of regret that the current choice scheme compares with the other alternatives is considered, and the scheme with minimum value of regret is chosen.

Based on the above analysis, assume that the bounded rational travelers are risk averse and regret averse, who take perceived regret value as their route choice criterion. According to RRT, the travel disutility of the bounded rational travelers can be represented as below:

$$U_{w,k}^{\mathrm{BR}} = u_{w,k}^{\mathrm{BR}} + \zeta_{w,k}^{\mathrm{BR}},\ k \in R_w, w \in W \tag{8}$$

where $U_{w,k}^{\mathrm{BR}}, u_{w,k}^{\mathrm{BR}}$ and $\zeta_{w,k}^{\mathrm{BR}}$ respectively represent the perceived travel disutility (the perceived regret value), mean of the perceived travel disutility (mean of the perceived regret value) and perception error when the bounded rational traveler' choose the route k between the OD pair w.

Suppose that the bounded rationality travelers use the TTB as the absolute travel disutility, a specifically functional form of $u_{w,k}^{\mathrm{BR}}$ that satisfies RRT requirements can be stated as follows:

$$u_{w,k}^{\mathrm{BR}} = \sum_{m\neq k, m\in R_w} \exp\left(\gamma(\xi_k^w(\omega) - \xi_m^w(\omega))\right),\ k \in R_w, w \in W \tag{9}$$

where $\gamma > 0$ is a regret aversion parameter. When γ increases, regret becomes more and more important.

Similarly, assuming that the perception error $\zeta_{w,k}^{\mathrm{BR}}$ are identically and independently Gumbel distributed random variables with mean zero, then the probability that a bounded rational traveler chooses the route k between OD pair w can be described as follows:

$$p_{w,k}^{\mathrm{BR}} = \frac{\exp\left(-\theta^{\mathrm{BR}}u_{w,k}^{\mathrm{BR}}\right)}{\sum_{r\in R_w}\exp\left(-\theta^{\mathrm{BR}}u_{w,r}^{\mathrm{BR}}\right)},\ k \in R_w, w \in W \tag{10}$$

where $\theta^{\mathrm{BR}} > 0$ is the perception error parameter of the completely rational travelers which is used to measure the degrees of travelers' perception errors.

1.4 *Stochastic mixed user equilibrium model*

It is assumed that there are two kinds of travelers in the road network, completely rational travelers and bounded rational travelers, respectively. The completely rational travelers use the perceived travel time budget as their travel disutility and the bounded rational traveler use the perceived regret value as their travel disutility. In the process of routes selection, two kinds of travelers try to find

the routes with the minimum travel disutility. The network is called to achieve the stochastic mixed user equilibrium state when each type of travelers can not decrease their travel disutility by unilaterally changing the routes.

According to the principle of stochastic user equilibrium (Sheffi, 1985; Huang, 1994), the network equilibrium condition can be expressed as follows:

$$f_{w,k}^{\mathrm{CR}} = q_w^{\mathrm{CR}} p_{w,k}^{\mathrm{CR}}, k \in R_w, w \in W \tag{11}$$

$$f_{w,k}^{\mathrm{BR}} = q_w^{\mathrm{BR}} p_{w,k}^{\mathrm{BR}}, k \in R_w, w \in W \tag{12}$$

$p_{w,k}^{\mathrm{CR}}$ and $p_{w,k}^{\mathrm{BR}}$ in formulas (11) and (12) are determined by formulas (7) and (10) respectively, and the following conditions of flow conservation constraint are required:

$$q_w = q_w^{\mathrm{CR}} + q_w^{\mathrm{BR}} = \sum_{k \in R_w} f_{w,k}^{\mathrm{CR}} + \sum_{k \in R_w} f_{w,k}^{\mathrm{BR}}, w \in W \tag{13}$$

$$f_{w,k} = f_{w,k}^{\mathrm{CR}} + f_{w,k}^{\mathrm{BR}}, k \in R_w, w \in W \tag{14}$$

$$f_{w,k}^{\mathrm{CR}} \geq 0, k \in R_w, w \in W \tag{15}$$

$$f_{w,k}^{\mathrm{BR}} \geq 0, k \in R_w, w \in W \tag{16}$$

$$v_a^{\mathrm{CR}} = \sum_{w \in W} \sum_{k \in R_w} f_{w,k}^{\mathrm{CR}} \delta_{a,k}^w, a \in A \tag{17}$$

$$v_a^{\mathrm{BR}} = \sum_{w \in W} \sum_{k \in R_w} f_{w,k}^{\mathrm{BR}} \delta_{a,k}^w, a \in A \tag{18}$$

$$v_a = v_a^{\mathrm{CR}} + v_a^{\mathrm{BR}}, a \in A \tag{19}$$

where $q_w^{\mathrm{CR}}, q_w^{\mathrm{BR}}$ and q_w respectively denote the completely rational travelers demand, the bounded rational travelers demand and the total demand between OD pair w; $f_{w,k}^{\mathrm{CR}}, f_{w,k}^{\mathrm{BR}}$ and $f_{w,k}$ respectively represent the completely rational travelers flow, the bounded rational travelers flow and total flow on route k between OD pair w; $v_a^{\mathrm{CR}}, v_a^{\mathrm{BR}}$ and v_a respectively represent the completely rational traveler flow, the bounded rational travelers flow and total flow on the link a.

The equilibrium conditions of (11) and (12) can be described by the following equivalent variational inequality (VI) model.

Find $f_{w,k}^{\mathrm{CR}*}, f_{w,k}^{\mathrm{BR}*} \in \Omega$, making it satisfy the condition:

$$\sum_{w \in W} \sum_{k \in R_w} \left(\xi_k^w(\omega) + \frac{1}{\theta^{\mathrm{CR}}} \ln \frac{f_{w,k}^{\mathrm{CR}*}}{q_w^{\mathrm{CR}}} \right) \left(f_{w,k}^{\mathrm{CR}} - f_{w,k}^{\mathrm{CR}*} \right) + \sum_{w \in W} \sum_{k \in R_w} \left(u_{w,k}^{\mathrm{BR}} + \frac{1}{\theta^{\mathrm{BR}}} \ln \frac{f_{w,k}^{\mathrm{BR}*}}{q_w^{\mathrm{BR}}} \right) \left(f_{w,k}^{\mathrm{BR}} - f_{w,k}^{\mathrm{BR}*} \right) \geq 0, \quad \forall f_{w,k}^{\mathrm{CR}}, f_{w,k}^{\mathrm{BR}} \in \Omega \tag{20}$$

where the superscript "*" is used to designate the solution of the VI problem; Ω is the feasible set for route flows satisfying the constraint condition formulated as formulas (13)–(16).

Let $\mathbf{f}^{\mathrm{CR}}$ and $\mathbf{f}^{\mathrm{BR}}$ denote the column vectors composed of $\left\{ f_{w,k}^{\mathrm{CR}}, k \in R_w, w \in W \right\}$ and $\left\{ f_{w,k}^{\mathrm{BR}}, k \in R_w, w \in W \right\}$ respectively, $\mathbf{v}^{\mathrm{CR}}(\mathbf{f})$ and $\mathbf{v}^{\mathrm{BR}}(\mathbf{f})$ denote the column vectors composed of $\left\{ \xi_k^w(\omega) + \frac{1}{\theta^{\mathrm{CR}}} \ln \frac{f_{w,k}^{\mathrm{CR}}}{q_w^{\mathrm{CR}}}, k \in R_w, w \in W \right\}$ and $\left\{ u_{w,k}^{\mathrm{BR}} + \frac{1}{\theta^{\mathrm{BR}}} \ln \frac{f_{w,k}^{\mathrm{BR}}}{q_w^{\mathrm{BR}}}, k \in R_w, w \in W \right\}$ respectively. Because $\mathbf{v}^{\mathrm{CR}}(\mathbf{f})$ and $\mathbf{v}^{\mathrm{BR}}(\mathbf{f})$ are continuous with respect to $\mathbf{f}^{\mathrm{CR}}$ and $\mathbf{f}^{\mathrm{BR}}$ respectively, and the feasible set Ω is a bounded closed convex set, there exists at least one solution of VI problem expressed by formula (20) according to the variational inequality theorem (Facchinei and Pang, 2003).

2 VULNERABILITY IDENTIFICATION MODEL OF ROAD NETWORK

The identification of key links and their criticality are important question in the road network vulnerability evaluation. The key links refers to the links that the failure will result a significant impact on the network vulnerability. In the literature, various vulnerability indices have been proposed to evaluate the consequences of link closures. For example, Jenelius et al. (2006) used the increase of the generalized cost, weighted by the demand, as a vulnerability measure to a link closure. Chen et al. (2007) proposed the utility-based accessibility index to take account of travelers' behavioral responses to the link closure. In this paper, the road network vulnerability is evaluated by the change of road network accessibility, and then identify the key links.

Accessibility can be defined as the convenience for travelers to arrive at a destination from a origin to a destination by the certain way in the certain period of time (Taylor et al., 2006, Taylor, 2008). The accessibility index of a single OD pair can be defined as follows:

$$AC_w = \frac{\sum_{w \in W} \left(q_w^{\mathrm{CR}} + q_w^{\mathrm{BR}} \right)}{\sum_{w \in W} \sum_{k \in R_w} \left(f_{w,k}^{\mathrm{CR}} + f_{w,k}^{\mathrm{BR}} \right) \xi_k^w(\omega)}, w \in W \tag{21}$$

where AC_w expresses the accessibility between the OD pair w.

As shown in the formula (21), it can be seen that when the travel time of a unit OD travel demand is higher, the accessibility index of the OD pair is lower, which indicates that the traveling relative convenience is lower.

According to the formula (21), the accessibility index of a road network can be defined as follows:

$$AC(G)=\frac{\sum_{w\in W}\left(q_w^{\mathrm{CR}}+q_w^{\mathrm{BR}}\right)AC_w}{\sum_{w\in W}\left(q_w^{\mathrm{CR}}+q_w^{\mathrm{BR}}\right)} \tag{22}$$

where $AC(G)$ express the accessibility of road network G.

In this paper, the road network vulnerability is evaluated by the relative change of road network accessibility before and after link failures. The road network vulnerability index under the failure of link a is defined as follows:

$$VUL_a=\frac{AC_0(G)-AC_a(G)}{AC_0(G)},a\in A \tag{23}$$

where $AC_0(G)$ is the road network accessibility under normal condition; $AC_a(G)$ indicates the road network accessibility under the failure of road link a (removing road link a from road network). Obviously, it reflects the change of road network accessibility caused by the failure of link a.

The failure of single link is the lightest case of link failures in a road network. It is also the basis for studying the multi-link failures. For simplicity, this paper selects the situation of single link failure to identify the road network vulnerability.

Based on the above analysis, the specific vulnerability evaluation scheme is given below:

Step 1: Calculate road network accessibility $AC_0(G)$ under normal condition. Method of successive average (MSA) algorithm is used to calculate the equilibrium route flows and every route's TTB under normal conditions. Subsequently, the road network accessibility under normal conditions is calculated according to formula (21) and formula (22).

Step 2: Remove each link from the road network in turn, and the road network accessibility $AC_a(G)$ after the removal of link a is calculated according to the formulas (21) and (22).

Step 3: Calculate the road network vulnerability VUL_a. According to $AC_0(G)$ and $AC_a(G)$ obtained from Step 1 and Step 2, the road network vulnerability index VUL_a after the failure of link a can be calculated in turn by formula (23). If the removal of link a would result the road network is no longer connected directly, then the link a is immediately identified as the most critical section, making it $VUL_a=\infty$.

Step 4: Identify the critical links. Sort the VUL_a in descending order, and $rank_a$ express the order value of VUL_a (namely critical degree), and the key links are selected from the first N links with the minimum values of the $rank_a$, where N is the number of key links set in advance.

Where the steps of MSA algorithm are as following:

Step 1: Initialization. Set error parameter ε = 0.01 and iteration counter n = 1; initialize the route flows. The reasonable initial route flows of the completely rational travelers are set as $\mathbf{f}^{\mathrm{CR}(n)}=\left\{f_{w,k}^{\mathrm{CR}(n)},k\in R_w,w\in W\right\}$, and the initial route flows of the bounded rational travelers are set as $\mathbf{f}^{\mathrm{BR}(n)}=\left\{f_{w,k}^{\mathrm{BR}(n)},k\in R_w,w\in W\right\}$.

Step 2: Based on the current path flow $\mathbf{f}^{\mathrm{CR}(n)}$ and $\mathbf{f}^{\mathrm{BR}(n)}$, the vector of TTB $\xi^{(n)}=\left\{\xi_k^{w(n)},k\in R_w,w\in W\right\}$ and the vector of mean regret value $\mathbf{u}^{\mathrm{BR}(n)}=\left\{u_{w,k}^{\mathrm{BR}(n)},k\in R_w,w\in W\right\}$ are calculated respectively.

Step 3: Seek the iterative direction of route flows for the completely rational travelers $\mathbf{g}^{\mathrm{CR}(n)}$ and that of the bounded rational travelers $\mathbf{g}^{\mathrm{BR}(n)}$. Let $\mathbf{g}^{\mathrm{CR}(n)}=\mathbf{f}^{\mathrm{CR}(n)'}-\mathbf{f}^{\mathrm{CR}(n)}$, $\mathbf{g}^{\mathrm{BR}(n)}=\mathbf{f}^{\mathrm{BR}(n)'}-\mathbf{f}^{\mathrm{BR}(n)}$. where $\mathbf{f}^{\mathrm{CR}(n)'}=\left\{f_{w,k}^{\mathrm{CR}(n)'},k\in R_w,w\in W\right\}$, $f_{w,k}^{\mathrm{CR}(n)'}=q_w^{\mathrm{CR}}\exp\left(-\theta^{\mathrm{CR}}\xi_{w,k}^{(n)}(\omega)\right)\Big/\sum_{r\in R_w}\exp\left(-\theta^{\mathrm{CR}}\xi_{w,r}^{(n)}(\omega)\right),k\in R_w$, $w\in W$; $\mathbf{f}^{\mathrm{BR}(n)'}=\left\{f_{w,k}^{\mathrm{BR}(n)'},k\in R_w,w\in W\right\}$, $f_{w,k}^{\mathrm{BR}(n)'}=q_w^{\mathrm{BR}}\frac{\exp\left(-\theta^{\mathrm{BR}}u_{w,k}^{(n)}(\omega)\right)}{\sum_{r\in R_w}\exp\left(-\theta^{\mathrm{BR}}u_{w,r}^{(n)}(\omega)\right)},k\in R_w,w\in W$.

Step 4: Update flow. Set $\mathbf{f}^{\mathrm{CR}(n+1)}=\mathbf{f}^{\mathrm{CR}(n)}+\frac{1}{n}\mathbf{g}^{\mathrm{CR}(n)}$ and $\mathbf{f}^{\mathrm{BR}(n+1)}=\mathbf{f}^{\mathrm{BR}(n)}+\frac{1}{n}\mathbf{g}^{\mathrm{BR}(n)}$.

Step 5: Check the convergence. If $\sum_{w\in W}\sum_{k\in R_w}\left|\frac{f_{w,k}^{\mathrm{CR}(n)}-f_{w,k}^{\mathrm{CR}(n-1)}}{f_{w,k}^{\mathrm{CR}(n)}}\right|+\sum_{w\in W}\sum_{k\in R_w}\left|\frac{f_{w,k}^{\mathrm{BR}(n)}-f_{w,k}^{\mathrm{BR}(n-1)}}{f_{w,k}^{\mathrm{BR}(n)}}\right|<\varepsilon$, then stop iteration, otherwise, set $n=n+1$, turn to Step 2.

3 NUMERICAL STUDIES

In this section, the Nguyen and Dupuis network (Nguyen & Dupuis,1984) shown in Figure 1 is provided to demonstrate the proposed model, which consists of 13 nodes, 19 links, 25 routes, and 4 OD pairs. The free-flow travel time and design capacity for each link are shown in Table 1.

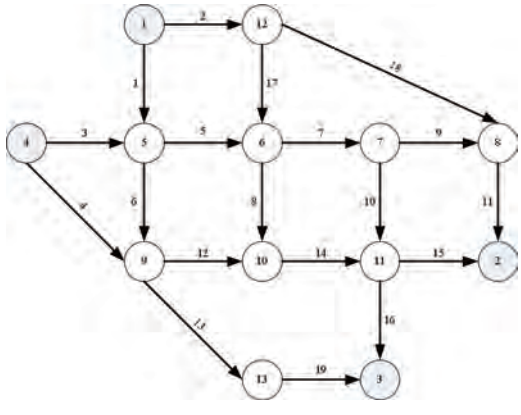

Figure 1. Nguyen and Dupuis network.

Table 1. Link characteristics.

Link	Free-flow travel time/min	Design capacity/pcu.h^{-1}
1	12	2500
2	12	2500
3	12	2500
4	24	2500
5	12	2500
6	12	2500
7	12	2500
8	12	2500
9	12	2500
10	12	2500
11	12	2500
12	12	2500
13	24	2500
14	12	2500
15	12	2500
16	12	2500
17	12	2500
18	36	1500
19	12	2500

For illustration purpose, the OD demand for each OD pair is described as follows:

$$q_w = \mu q_w^0 = \mu\left(q_w^{\mathrm{CR},0} + q_w^{\mathrm{BR},0}\right) = \mu\left(\eta q_w^0 + (1-\eta) q_w^0\right) \; w \in W \tag{24}$$

where q_w^0 represents the potentially maximum demand of OD pair w; μ is the multiplier of OD demand; η represents the proportion of completely rational travelers.

Other relevant parameters are set as: the parameters of BPR function in formula (1) are $\beta = 0.15$, $n = 4$; the variance coefficient $\rho_a = 0.5$, $a \in A$; the reliability parameter $\omega = 0.90$; the regret aversion parameter $\gamma = 0.15$; the perception error parameters $\theta^{\mathrm{CR}} = 1.0$ and $\theta^{\mathrm{BR}} = 0.2$ respectively; the maximum OD demands $q_{12}^0 = 5000$ (pcu·h^{-1}), $q_{13}^0 = 4000$ (pcu·h^{-1}), $q_{42}^0 = 4000$ (pcu·h^{-1}), and $q_{43}^0 = 3000$ (pcu·h^{-1}), respectively; the multiplier of OD demand $\mu = 0.5$; the proportion of completely rational travelers $\eta = 0.5$; the number of key links $N = 6$.

Table 2 shows the results of vulnerability evaluation for the 6 most critical links in the Nguyen and Dupuis network. It can be seen that the closures of these critical links decrease the network accessibility by 2% or more. The worst case is the closure of link 2, which leads to a 3.11% decrease in the network accessibility.

To test the effects of congestion level on network vulnerability, the consequences of link closures under various demand multipliers μ values are depicted in Table 3. From the table, it can be seen that as increases in demand level, the network vulnerability under link closures tends to go up. For example, when demand multiplier $\mu = 0.05$, the vulnerability index VUL_a is equal to 0.34% after the link 2 closure. However, when demand multiplier $\mu = 0.99$, the vulnerability index VUL_a rises to 5.45% under the link 2 closure. The results are not surprise because if the network is more congested, owing to closure, less spare capacity is available to absorb the rerouted traffic. In addition, From Table 3, it can be found that the vulnerability rankings may be varied owing to the congestion level. For instance, link 15 is ranked at $Rank_a = 5$ when $\mu = 0.05$. However, this link was ranked at $Rank_a = 6$ when $\mu = 0.49$, and $Rank_a = 7$ when $\mu = 0.99$.

In order to illustrate the effects of travelers' perception errors on network vulnerability in terms of different values of θ^{CR} and θ^{BR}, the results of link closures arising from various values of θ^{CR} and θ^{BR} are shown in Table 4. It should be pointed out

Table 2. The results of network vulnerability evaluation.

8	1	0.19%	1	1.76%	1	3.05%
9	3	0.17%	16	1.60%	16	2.83%
10	6	0.15%	3	1.57%	3	2.73%
11	4	0.15%	4	1.33%	4	2.43%
12	5	0.13%	5	1.26%	5	2.28%
13	16	0.12%	6	1.05%	6	1.83%
14	12	0.12%	18	0.92%	18	1.67%
15	17	0.11%	12	0.86%	12	1.50%
16	9	0.09%	17	0.80%	17	1.46%
17	18	0.09%	9	0.57%	9	1.02%
18	10	0.05%	10	0.43%	10	0.82%
19	8	–0.01%	8	0.27%	8	0.58%

that a higher θ^{CR} or θ^{BR} means smaller perception errors and vice versa. It can be observed from the table that travelers' perception errors can result in some impact on network vulnerability evaluation. Specifically, as change in values of θ^{CR} and θ^{BR}, the vulnerability rankings and the vulnerability index may be different accordingly. For example, link 13 is ranked at $Rank_a = 4$ when $\theta^{CR} = 5.0$ and $\theta^{BR} = 1.0$ whereas this link was ranked at $Rank_a = 7$ when $\theta^{CR} = 0.1$ and $\theta^{BR} = 0.02$.

Table 5 shows the impact of the regret aversion parameter on network vulnerability in terms of different values of γ. It can be found from Table 5 that the parameter γcan result in certain impact on network vulnerability evaluation. The vulnerability rankings may be varied due to the different γ values. For example, link 15 is ranked at $Rank_a = 4$ when $\gamma = 0.05$ whereas this link was ranked at $Rank_a = 6$ when $\gamma = 0.30$.

Table 6 depicts the impact of travelers' route choice decision criteria on network vulnerability according to different values of η. As shown in Table 6, with the variation on type structure of travelers, the vulnerability rankings and the vulnerability indices may change accordingly. For instance, when $\eta = 0.99$, which means that the completely rational travelers are dominant in the network, link 15 is ranked at $Rank_a = 6$ and the vulnerability index $VUL_a = 2.19\%$. However, this link was ranked at $Rank_a = 8$ and the vulnerability index $VUL_a = 2.06\%$ when $\eta = 0.01$.

The above analysis shows that ignoring the effects of the congestion levels of road network, travelers' perception errors and regret aversion

degrees, as well as travelers' route choice decision criteria could misjudge the consequences of link closures and misidentify the most critical links.

4 CONCLUSIONS AND FUTURE RESEARCH

This study proposed a method of road network vulnerability identification taking into account travelers' risk aversion and bounded rationality simultaneously under travel time variations subjected to link failures. It is assumed that there are two kinds of travelers in the road network, completely rational travelers and bounded rational travelers, respectively. The completely rational travelers use the perceived travel time budget as their travel disutility while the bounded rational traveler use the perceived regret value as their travel disutility. According to the travelers' postulated route choice decision criteria, a mixed stochastic traffic assignment model formulated as variational inequality is constructed, a new vulnerability index of road network based on accessibility is defined, and a vulnerability identification model is built, and corresponding heuristic algorithm is also proposed. Numerical examples on the Nguyen and Dupuis network made apparent that the consequences of link closures could be misjudged and the vulnerability rankings could be misidentified, if ignoring the effects of the congestion levels of road network, travelers' perception errors and regret aversion degrees, as well as travelers' route choice decision criteria. Therefore, it is necessary to capture travelers' behavior characteristics for the vulnerability analysis.

The proposed vulnerability analysis only considers the scenarios of single link closure, and the consideration of multiple link closures is an important extension. Another valuable extension of this study is to take into account day-to-day adjustment processes for modeling travelers' behavioral responses to link closures.

Safety analysis of autonomous driving using semi-Markov processes

Mattias Nyberg
Division of Mechatronics, Royal Institute of Technology (KTH), Stockholm, Sweden

ABSTRACT: The paper presents an approach of how safety of autonomous driving can be analysed by using semi-Markov processes. The approach can be used in development and assessment of vehicles implementing autonomous driving. Through a case study, it is indicated that a semi-Markov process model can capture relevant properties related to safety of autonomous driving. The case study particularly investigates if Level 3 autonomy, in which the driver is reponsible to take over when alerted by the system, can be made sufficiently safe. The paper also highlights how the current standard ISO26262 is insufficifient for autonomous driving where the system itself affects the exposure of operational situations. Therefore, as complement to ISO26262, it is shown how the proposed approach can be used to derive top level safety requirements.

1 INTRODUCTION

Autonomous driving is today one of the, if not *the*, major technological drivers in the area of on- and off-road vehicles. d new business opportunities. One of the main arguments for, and also main arguments against, autonomous driving is safety. It is argued that autonomous driving is safer that human driving, since a computer is always alert, always takes rational decisions etc. On the other hand, huge technological obstacles remain on how to realize autonomous driving in complex traffic situations, bad weather, and bad road conditions, where available commercial sensor technologies have yet to prove its sufficiency (Watzenig & Horn 2016).

Even though autonomous driving can be made safe, how can it be *proven* to be safe? In more technologically mature areas, there are applicable standards providing systematic methods to argue for safety, but this is still lacking in the area of autonomous driving. Current standards, such as ISO26262 (2011) cover only the case when a human driver is responsible for the driving.

To assess if autonomous driving is safe or not, systematic and formal analyses are needed. Therefore, as the main contribution, the present paper presents a method for formal analysis of safety of autonomous driving by using so called *semi-Markov processes*.

The use of Markov processes for analysis of dependability, including safety, is an established practice. The study of Markov processes has a long history but a mile-stone for its industrial usage for dependability analysis (Fuiqua 2003) was the introduction of the standard IEC61508 (2010). Since IEC61508 is a mother standard for many other standards, the usage of Markov processes has spread to many application areas. In particular, it is a large part of the ISO26262 standard, which uses continuous Markov-chains to asses reliability of hardware components. However, the literature is sparse on the usage of Markov processes for analysis of safety of autonomous driving. Markov process models of different kinds have indeed been used in the context of autonomous driving, but for the purpose of on-line perception or decision making, such as path planning, e.g. see (Hoekstra et al. 2013, Katrakazas et al. 2015, Wei et al. 2011). Also, there are studies on how to model *human* driving using Markov models, e.g. see (Mitrovic 2005, Oliver & Pentland 2000).

For reliability or safety analysis, the most common type of Markov processes used is discrete or continuous time Markov-chains (Fuiqua 2003). Markov chains are completely "memoryless" assuming that the probabilities of transitions are independent oftime, which implies that all transition times are assumed to be exponentially distributed. This is a limitation in modelling of real world systems, which do not always follow exponential distributions (Limnios 1997). Therefore, the present paper makes use of continuous-time so-called *semi-Markov processes*, introduced by Levy (1954) and Smith (1955). In semi-Markov processes, the probabilities of transitions from a state are allowed to depend on the time spent in the state. Thus, transition distributions in a semi-Markov process can be non-exponential.

The paper is focused around a case study, *Highway Pilot*, which is one typical autonomous driving function (Kirschbaum 2015). Autonomous driving

is classified into six levels (SAE 2016), and Highway Pilot is classified as Level 3 or 4. Level 3 means that the vehicle drives autonomously but requires the driver to be ready to take over whenever requested by the vehicle. Several manufacturers have argued that Level3 is not feasible since drivers can not be expected to be as alert as needed to manage the takeover reliably. However, other manufacturers argue that Level 3 is indeed possible as an intermediate step before Level 4, in which the driver has no responsibility. This is an example of a controversy in the area of autonomous driving. This is also an example where the semi-Markov analysis method proposed by the present paper can bring clarity and help answering questions such as: under what conditions can Level 3 be sufficiently safe, and, is it really easier to reach safety using Level 3 instead of Level 4?

The paper is organized as follows. In Sec. 2, selected parts of the theory of semi-Markov processes are shortly summarized. Then, in Sec. 3, a semi-Markov based approach for analysis of safety is presented. The approach utilizes the steady-state distribution in combination with an assessment of safety based upon the decision-theoretic concepts loss and risk. In Sec. 4 the case study highway pilot is presented, and also modeled by using a semi-Markov process. Then Sec. 5, based on the model, analyses the overall safety of highway pilot. Sec. 6 performs a sensitivity analysis on the parameters in the model and addresses the above mentioned questions related to Level 3 vs 4. Finally, Sec. 7 discusses how the proposed approach can be used in an engineering context.

2 SEMI-MARKOV PROCESSES

This section shortly introduces *continuous-time semi-Markov processes* in accordance with literature, e.g. (Limnios & Oprisan 2001, Limnios 1997). The purpose, and only focus, is to give the background theory needed for reading the rest of the paper.

Consider a system with a finite set of states $\{1,2,\quad,N\}$. Let X_n be a random variable representing the state after the n:th transition where $n \in \mathbb{Z}_{\geq 0}$. Let U_n be a random variable representing the time spent in state X_n, called the *sojourn* time. A semi-Markov process can then be described using a *transition function* in the form of a so called *semi-Markov kernel*, which is a matrix Q with elements

$$Q_{ij}(t) = \begin{cases} P(X_{n+1} = j, U_n \leq t \,|\, X_n = i) & i \neq j \\ 0 & i = j \end{cases} \tag{1}$$

Let M be the matrix of transition probabilities of the *embedded Markov chain*, i.e. $M_{ij} = P(X_{n+1} = j \,|\, X_n = i)$ which can be obtained from the semi-Markov kernel as $M_{ij} = \lim_{t\to\infty} Q_{ij}(t)$.

2.1 *Continuous-time Markov chains*

A special case of semi-Markov processes is so called *continuous-time Markov chains*, where the sojourn time U_n follows an exponential distribution, and the semi-Markov kernel takes the form

$$Q_{ij}(t) = \begin{cases} \frac{\lambda_{ij}}{\lambda_i}\left(1 - e^{-\lambda_i t}\right) & i \neq j \\ 0 & i = j \end{cases} \tag{2}$$

where $\lambda_i = \sum_{j\neq i} \lambda_{ij}$ and the parameters λ_{ij} are called *transition rates*. This further implies that the embedded Markov chain becomes $M_{ij} = 0$ for $i = j$ and

$$M_{ij} = \frac{\lambda_{ij}}{\lambda_i} \quad \text{for} \quad i \neq j \tag{3}$$

2.2 *Steady-state distribution*

Let $X(t)$ denote the random variable representing the state at time t. We now present how to compute the *steady-state distribution* of the semi-Markov process, defined by a vector π with elements $\pi_i = \lim_{t\to\infty} P\left(X(t) = i\right)$ for $i = 1, \quad, N$. To compute π, we will below use a formula containing two vectors $\mathbf{v}$ and $\mathbf{m}$.

Let $\mathbf{v}$ be the steady-state distribution of the embedded-Markov chain, which means that it is a row vector satisfying $\mathbf{v}M = \mathbf{v}$ and $\sum v_i = 1$. Note that $\mathbf{v}$ can be computed for example as $\mathbf{v} = \left[\,01\right]\Psi^T(\Psi\Psi^T)^{-1}$, where $\Psi = \left[\,(M - I)\,1\right]$, and 0 and 1 are vectors of 0's and 1's.

Let $\mathbf{m}$ be the column vector of expected sojourn times of the different states, i.e. $m_i = \mathrm{E}[U_n \,|\, X_n = i]$. Let $H_i(t)$ be the cumulative distribution function of the sojourn time of state i, i.e. $H_i(t) = P(U_n \leq t \,|\, X_n = i)$. Using one of the standard formulas for expectation, m_i can then be computed as

$$m_i = \int_0^\infty 1 - H_i(t)\,\mathrm{d}t = \int_0^\infty 1 - \sum_j Q_{ij}(t)\,\mathrm{d}t \tag{4}$$

The process is assumed to be *recurrent* meaning that it is possible, i.e. with a non-zero probability, to reach any state from any state, and the expected return time to any state is finite. Then the steady-state distribution of the semi-Markov process can be computed as

$$\pi = \frac{diag(\mathbf{v})\,\mathbf{m}}{\mathbf{v}\mathbf{m}} \tag{5}$$

where diag(**v**) is the diagonal matrix with the elements of **v** on its diagonal.

3 ANALYSING SAFETY BY USING SEMI-MARKOV PROCESSES

Inspired by the approach of *operational situations* in ISO26262 (2011), this section proposes a general loss- and risk-based framework for the analysis of safety. Although general, the intended target is here safety of autonomous driving.

3.1 *Loss and risk based measure of safety*

In accordance with so called decision theory (Berger 1985), each state *i* is associated with a *loss* denoted $L(i) \in \mathbb{R} \geq 0$ representing the level of "dangerousness" of being in state *i*. Then, expected loss, often referred to as *risk*, can be used as an overall measure of the dangerousness of the system. To obtain a measure independent of initial condition, we use the limiting expected loss:

$$\begin{aligned} &\lim_{t\to\infty} \mathrm{E}\left[L(X(t))\right] = \lim_{t\to\infty} \sum_i P(X(t)=i) L(i) = \\ &= \sum_i \lim_{t\to\infty} P(X(t)=i) L(i) = \sum_i \pi_i L(i) \end{aligned} \tag{6}$$

The actual value of the loss/dangerousness of being in state *i* can be chosen based on several principles. One approach is the one adopted in ISO26262 (2011), where metrics of *severity* and *controllability*, obtained from standardized tables, are combined into what here corresponds to loss. However, in the present paper, the dangerousness of being in state *i* will be assessed using the probability of fatality as a result of being in state *i*.

3.2 *Using probability of fatality as loss*

We consider two extra states, $\mathcal{F}$ and $\leftarrow\mathcal{F}$, residing in its own dimension, and where $\mathcal{F}$ represents "fatal accident" and is absorbing. Let the random variable $Y(t) \in \{\mathcal{F}, \neg\mathcal{F}\}$ represent if a fatal accident has occured or not at time *t*. We assume an exponential distribution of transition time from state $\leftarrow\mathcal{F}$ to state $\mathcal{F}$ but with a transition rate $\lambda_i^{\mathcal{F}}$ dependent on state *i*, i.e.

$$\begin{aligned} F_i(t) = P(Y(t) = \mathcal{F} \,|\, Y(0) = \neg\mathcal{F}, \forall \tau \in \\ [0,1]. X(\tau) = i) = = 1 - e^{-\lambda_i^{\mathcal{F}} t} \end{aligned}$$

While the transitions of *Y* have a dependency of *X*, we make the simplifying assumption that transitions of *X* do not depend on *Y*.

In accordance with ISO26262, we will evaluate safety based upon an assumption of 1 hour of driving. Therefore we use loss $L(i) = F_i(1\mathrm{h})$. It can then be realized that

$$\begin{aligned} &\lim_{t\to\infty} P(Y(t+1\mathrm{h}) = \mathcal{F} \,|\, Y(t) = \neg\mathcal{F}) \approx \\ &\approx \sum_i F_i(1\mathrm{h}) \lim_{t\to\infty} P(X(t) = i) = \sum_i L(i)\,\pi_i \end{aligned}$$

This means that the loss-based measure of safety (6) in fact corresponds to the limiting probability of fatality during 1h of operation.

4 MODELLING AUTONOMOUS DRIVING

This section presents the case study *Highway Pilot* (HP). HP is a general and well known function (Kirschbaum 2015), but the case study has been done in collaboration with Scania CV, a global manufacturer of heavy trucks. After giving an overview of HP, the approach for modelling and safety assessment presented in Sec. 2 and 3 is used to set up a semi-Markov process model of HP.

4.1 *Highway pilot*

When highway pilot is activated by the driver, the driving of the vehicle is completely taken over by the electronic system in the vehicle, and the driver does not need to be involved in the driving, not even monitoring. HP can only be activated when the vehicle is on a highway and the vehicle will continue to follow the highway as long as HP is on. HP is designed to function in a range of speeds, for example up to 120 km/h for a passenger car and 90 km/h for heavy trucks.

At the time of writing this paper, there is not yet a commercially available vehicle with HP. One reason is that there are a number of technical challenges present. One is the reliability of commercial radar and camera sensors. In more complicated road, weather, and traffic situations, the required performance is insufficient. But also under perfect conditions, these sensors have a relatively low reliability level causing them to miss or detect false objects at a non-negligible probability level. Independent of the reason, the situation when the sensors of the vehicle are fault free but still unable to obtain a correct interpretation of the surrounding environment, will in the following be referred to as *bad conditions*. Bad conditions may be detected by the system itself, but may also be undetected for a significant amount of time.

Another reason for the sensors to make an incorrect interpretation of the surrounding environment is that faults appear and become active. In contrast to bad conditions, which will always disappear after some time, faults do not disappear unless the system is repaired.

When HP is on and either bad conditions or faults are detected by the system, the system can not immediately deactivate HP. The reason is that the driver may not be ready to take over driving, e.g. he/she may be sleeping. Therefore, upon detection of badconditions or faults, the system will enter so called *degraded driving*. In degraded driving, faulty or unreliable sensors may be shut off. This typically causes perception accuracy or reliability to be lower. To compensate for this in the autonomous driving, a more safe driving style with more safety margins is typically adopted, including reducing the speed of the vehicle. During degraded driving, the system also tries to get attention from the driver so that he/she takes over the driving.

4.2 *States*

The states and transitions of the model are illustrated in Figure 1. Each of the states and their outgoing transitions are described below.

State S1 HP is off and the driver manually drives the vehicle. When the driver activates HP, there is a transition to S2.

State S2 HP is on and the electronic system of the vehicle drives the vehicle. The driver can at anytime deactivate HP which triggers a transition to S1. Alternatively, at any time, bad conditions or a fault can occur, which triggers transitions to S3 and S4 respectively.

State 3 HP is on and the electronic system of the vehicle drives the vehicle. However, undetected bad conditions are present so there is a greater risk for incorrect perception potentially leading to an incorrect and dangerous control action by the electronic system. The driver can at anytime deactivate HP which triggers a transition to S1. Alternatively, the system may detect the bad conditions and this triggers a transition to S5.

State 4 HP is on and the electronic system of the vehicle drives the vehicle. However, at least one undetected fault is present potentially leading to an incorrect control action by the electronic system. The driver can at anytime deactivate HP which triggers a transition to S1. Alternatively, the system may detect the fault[s] and this triggers a transition to S5.

State 5 HP is on but the system has detected bad condition or a fault so the driving is in a degraded mode. There is a warning indicated to the driver who is thereby urged to take over the driving by deactivating HP. If the driver deactivates HP, this triggers a transition to S1. If the driver does not deactivate HP within a predetermined time limit of 10 s, the system will initiate emergency stopping which means a transition to S6.

State 6 HP is on and the system is performing an emergency stopping. During emergency stopping, the system controls the brakes and steering of the vehicle in order to stop the vehicle as quickly as possible but in a controlled manner, e.g. making sure that the vehicle stops along the side, and not in the middle, of the road. The emergency stopping procedure does not involve the driver, and the driver is not able to terminate the procedure. When the vehicle reaches zero speed, there is a transition to S7.

State 7 HP is off and the vehicle is completely stopped, i.e. having a speed 0 km/h. When the driver again starts the vehicle, there is a transition to S1.

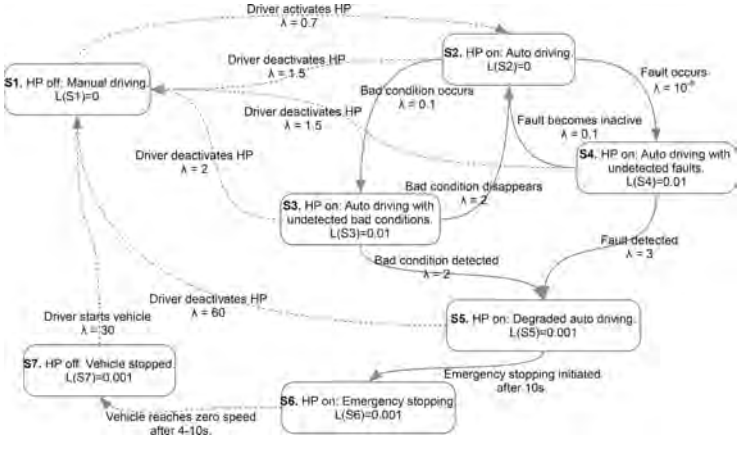

Figure 1. States and transition of highway pilot. Solid lines are used for transitions whose transition function is possible to affect by the design, and dashed lines for those not possible to affect by the design.

It can be noted that ISO26262 (2011) covers only safety with respect to faults, i.e. the right path (S2-S4-S5) of the model.

4.3 *Parameters of the model*

The model contains a number of parameters that need to be determined:

- The transition rate λ_{ij} for transitions respecting the Markov assumption, i.e. where the distribution of the sojourn time is exponential. These implicitly define the transition function $Q_{ij}(t)$ according to (2).
- Transition functions $Q_{ij}(t)$, for states with non-exponential distribution of sojourn times,
- The loss $L(i)$ associated with each state.

Now follows, for each state in the model, an explanation of the chosen parameter values in the model. All parameter values were derived by studying data and statistics from prototype systems and also from discussions with engineers. It should however be mentioned that the available data was limited or in many cases not applicable, due the prototype statusof the system, but also due to confidentiality reasons.

A general principle used is that as long as there is no clear argumentation for not choosing an exponential distribution, an exponential distribution is chosen. In all cases, transition rates are chosen by considering the resulting expected sojourn time, probability distribution of transitions to succeeding states, and for each succeeding state, the probability of transition within certain time periods.

State S1 The transition to S2 is considered to have constant rate $\lambda_{12} = 0.7$ and this corresponds to an expected soujourn time of 85 min and a probability of transition to S2 within 1 h to equal 0.50. The loss is $L(1) = 0$ since only loss (dangerousness) associated with usage of HP is considered.

State S2 The transition back to S1 is assumed to have a constant probability, with rate $\lambda = 1.5$. The transition to S3 is assumed to have constant rate $\lambda = 0.1$ and transition to S4 a constant rate $\lambda = 10^{-9}$. These three ratesresult in an expected sojourn time of 37 min. The probability of a transition back to S1 within 1 h becomes 0.75 while the corresponding probabilities of transitions to S2 and S3 respectively, become 0.05 and 10^{-9}. The loss is $L(2) = 0$ since S2 corresponds to when HP is working perfectly without any bad conditions or any active faults.

State S3 All transitions from S3 are assumed to occur with constant rates. The rate of the transition to S1 is assumed to be $\lambda_{31} = 2$, a bit higher than for the corresponding transition from S2 since when conditions are bad, the driver is likely to observe this and therefore deactivate HP. The rate of transition to S5 is assumed to be $\lambda_{53} = 2$ which corresponds to a probability of detecting the bad conditions within one hour to equal 0.49 and within 10 min to equal 0.24. The transition rate back to S2 were chosen to be also $\lambda = 2$. All this means that being in state S3, there in an equal probability of transitions to S1, S2, and S5. The expected sojourn time becomes 10 min. In contrast to the previous states, being in S3 isassociated with a non-zero loss due to possible incorrect perception caused by bad conditions. The loss is assumed to be $L(3) = 0.01$, but remember that this corresponds to the probability when being in state S3 for 1 hour and since the expected sojourn is only 10 min, the probability of fatality will be lower.

State S4 All transitions from S4 are assumed to occur with constant rates. The rate of the transition to S1 is assumed to be $\lambda_{41} = 1.5$, i.e. equal to the rate of corresponding transition from S2, since an undetected fault is likely notto change the behavior of the vehicle, and consequently not increase the probability of the driver to deactivate HP. The rate of the transition to S5 is assumed to be $\lambda_{45} = 3$, which is set a little bit higher than the rate of the corresponding transition from S3. The rate of transition back to S2 is set to $\lambda_{42} = 0.1$, which corresponds to an assumption that faults never disappears, but may become inactive. The loss of being in state S4 is estimated to be $L(4) = 0.01$, i.e. the same as for state S3.

State S5 During degraded driving the driver is alerted to take over driving so a transition to state S1 is set to a high and constant rate $\lambda_{51} = 60$. A transition to S6 will occur deterministically after 10 s, which means that this is not a constant rate and the sojourn time does not follow an exponential distribution. This implies that the probability of having a transition to S1 is $M_{51} = 1 - e^{-\lambda_{51} \cdot 10/3600} \approx 0.154$, and the probability of having a transition to S6 is $M_{56} = 1 - M_{51}$. This further implies

$$Q_{51}(t) = \begin{cases} 1 - e^{-\lambda_{51} t} & t < 10 \\ M_{51} & t \geq 10 \end{cases}$$

$$Q_{56}(t) = \begin{cases} 0 & t < 10 \\ M_{56} & t \geq 10 \end{cases}$$

The expected sojourn time can be computed using the formula (4):

$$m_5 = \int_0^\infty 1 - Q_{51}(t) - Q_{56}(t)\,\mathrm{d}t = \int_0^{10} 1 - \left(1 - e^{-\lambda_{51} t}\right)\mathrm{d}t = 9.2\mathrm{s}$$

In state S5, the loss is estimated to be $L(5) = 0.001$, i.e. significantly lower than in state S3 or S4. The reason is that the increased safety margin resulting from degraded driving.

State S6 From S6, the only possible transition is to S7 and it occurs at the time it takes to stop the vehicle. Since there are a number of uncertainties, e.g. road conditions and tire conditions, the time

is assumed to have a probability density function constant in the interval 4 to 10 s, and zero outside this interval. This means that the expected sojourn time is 7 s. The loss in S6 is estimated to be the same as in S5, i.e. $L(6) = 0.001$.

State S7 From S6, the only possible transition is to the starting S1. The transition is set to a fixed rate of $\lambda = 30$ which corresponds to an expected sojourn time of 2 min. The risk in S6 is estimated to be the same as in states S5 and S6, i.e. $L(7) = 0.001$. On one hand, the vehicle is standstill meaning that it can on its own not cause an accident. On the other hand, doing an emergency stop on a highway may result in stopping in a dangerous position on the road, thus increasing the probability of being hit by another vehicle.

5 COMPUTING THE RISK

To compute the risk, i.e. the limiting expected loss, according to (6), we first need to compute the steady-state distribution. For this, we will use (5) which requires **v**, the steady-state distribution of the embedded Markov-chain M, and **m**, the expected sojourn times.

For the states S1, S2, S3, S4, and S7, the corresponding rows in the matrix M, defining the embedded Markov-chain, are obtained by inserting the transition rates given in Section 4.3 into equation (3). For S6, there is only one possible transition so the row in M becomes by $M_{67} = 1$ and the other entries 0. For S5, both M_{51} and M_{56} have already been derived in Sec. 4.3, and the other entries are 0.

The expected sojourn times have all been given in Sec. 4.3. The resulting vector is

$$\mathbf{m} = [\,85\text{min}, 37\text{min}, 10\text{min}, 13\text{min}, 9.2\text{s}, 7\text{s}, 2\text{min}\,]$$

Now using (5) results in the steady-state distribution shown in Figure 2. Note that since we are only interested in the safety of HP, we condition on HP on, i.e. the bar chart shows the value $\lim_{t\to\infty} P(X(t) = i \,|\, \text{HP on})$ for each state i.

The risk, can now be computed by using (6), but use conditional expectation, conditioned by HP on:

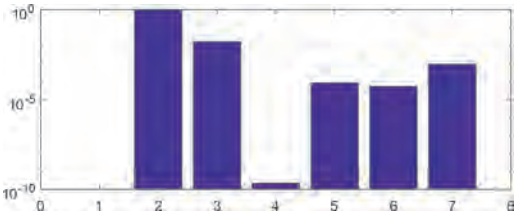

Figure 2. Steady-state distribution normalized for HP on.

$$\lim_{t\to\infty} \mathrm{E}[L(X(t)) \,|\, \text{HP on}] = 0.000165$$

This value is clearly too high. To investigate the explanation and to find means to reduce the value, the next section presents a sensitivity analysis with respect to the parameters in the model.

6 SENSITIVITY ANALYSIS

The model contains in total 14 transitions. Of these, 12 transitions are parameterized by a transition rate parameter λ_{ij}. The remaining two are the transitions from S5 to S6 and S6 to S7. The transition from S5 to S6 is therefore instead parameterized by the time of degraded autonomous driving, and the transition from S6 to S7 is parameterized directly by the expected sojourn time.

Each parameter is varied logarithmically from 10^{-6} to 10^{5} times the original value, and the resulting new risk is computed. For each parameter, the risk is plotted in Figure 3. In the figure, it is seen that some parameters have no effect on the total risk while other have a significant effect. For each of the 14 plots, a short interpretation of the observed behavior is now given.

S1 → S2 and S2 → S1 Since we measure the safety given that HP is on, solely activation and deactivation of HP does not affect the safety.

S2 → S3 If bad conditions rarely occurs (left part of the plot), then HP is very safe.

S2 → S4 If HP failure rate is changed, safety is not affected, since it is dominated by the effect of bad conditions.

S3 → S1 If the presence of undetected bad conditions are eliminated by the driver disabling HP, HP becomes very safe.

S3 → S5 If detection of bad condition is made more efficient, HP becomes safer since driver will faster disable HP. But to a limit, since driver reaction time from being alerted until action is not affected.

S3 → S2 If bad conditions quickly disappears, HP becomes very safe.

S4 → S1 The driverâ€™s rate of disabling HP, when a fault has occurred, does not affect HP safety. Since fault occurence is such a rare event.

S4 → S5 Increased efficiency in detecting faults does not affect safety since faults are anyway so rare.

S4 → S2 If faults quickly become inactive, HP becomes very safe.

S5 → S1 If the driver faster disables degraded HP, safety is not affected. Since degraded driving is comparably quite safe anyway.

S5 → S6 To more quickly, or slowly, activate emergency stopping, does not change safety. More time increases chance that driver disables HP, but also increase time of dangerous driving.

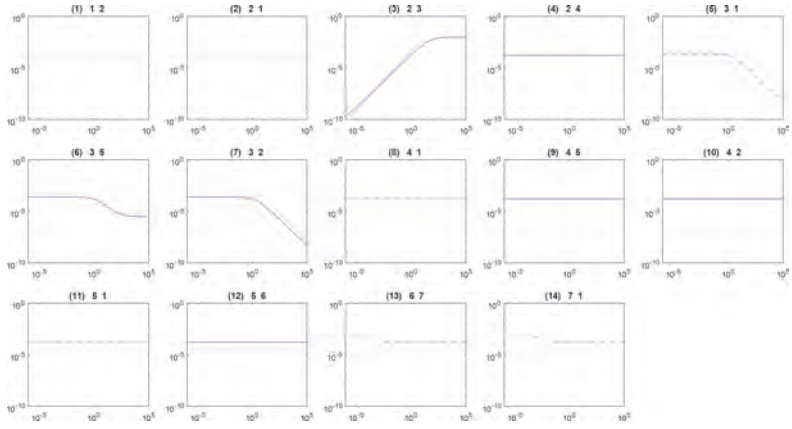

Figure 3. Sensitivity analysis where the probability of fatality is plotted w.r.t. variations in each of the 14 parameters in the model. Solid lines correspond to parameters possible to affect in the design of the HP, and dashed lines to parameters not affected by the design.

S5 → **S6** To more quickly start the emergency stopping after detection of fault, does not affect safety. Since fault detection is anyway so rare.

S6 → **S7** Stopping time can in fact not be affected, but if, then extreme long stopping time decreases safety, since time spent stopping is more dangerous than auto driving.

S7 → **S1** Time to restart vehicle after stopping can in fact not be affected, but if, then extreme long time before restart time decreases safety, since time spent stopping is more dangerous than auto driving.

6.1 *Conclusions of sensitivity analysis*

From the sensitivity analysis we can conclude that the model seems to be able to capture relevant properties of HP and their effects on safety. Another important conclusion is that the only way to reach sufficient safety of HP is to reduce time spent in state S3, i.e. to reduce transition rate from S2 to S3, i.e. to make sure that bad conditions do not occur, and according to the plot, the new value of the transition rate λ_{23} needs to be 10^{-6} times the original value 0.1, i.e. $\lambda_{23} = 10^{-7}$.

But then, it becomes Level 4 autonomous driving, i.e. the extra safety gained by demanding the driver to take over when bad conditions are detected is only marginal and not significant. However, to really know that we obtain Level 4 autonomous driving if $\lambda_{23} = 10^{-7}$, a second sensitivity analysis was performed with $\lambda_{23} = 10^{-7}$ and only the parameter λ_{51} varied. Although not shown in the paper due to space limitation, the result is that the risk is not dependent on λ_{51}. This implies that it truly becomes Level 4 autonomous driving.

7 USING THE MODEL IN ENGINEERING

This section discusses how a conceptual model of a technical function, like the one developed and analysed in the sections 4, 5, and 6, can be used generally by engineers to develop safe systems, in particular within automotive industry.

We will here view a transition function $Q_{ij}(t)$ for a transition dependent on the design (exemplified by the solid lines in Fig. 3) as a requirement on the system. This is a requirement to be taken as input to the succeeding engineering design activities. As a requirement it has to be formulated taking into account what is technically and commercially viable. In the case study, for example the transition function $Q_{56}(t)$ corresponds to the requirement

> "Emergency stopping shall start exactly 10 s after bad conditions or fault have been detected."

This requirement is in fact unrealistic in the sense that it is not so important that emergency stopping starts *exactly* after 10 s. And also, it is technically not feasible to build such a system since all components have tolerances. By following the principle of how safety requirements are formulated in industry with a Safety Integrity Level (SIL), such as ASIL in ISO26262, an example of a more realistic requirement is

P("Emergency ... ... detected.") ≥ 1 – 10^{-8}

This requirement corresponds in fact to a whole set of transition functions, namely all $Q_{56}(t)$ where there is a step somewhere between 8–12 s, and the integral of the corresponding density function is ≤10^{-8} excluding the step.

In conclusion, the transition function for each transition depending on the design must match the actual requirement and to align with principles of how requirements are written in industry, not one but a set of transition functions must be used. By using this insight, the following procedure summarizes how the proposed approach of the paper can assist the conceptual phase of engineering:

1. Set up a semi-Markov process with states and transitions modelling the system considered.
2. Identify the transition function $Q_{ij}(t)$ for the transitions not dependent on the design, e.g. transitions depending on the operator or other parts of the system (examplified by the dashed ones in Fig. 3).
3. Estimate the loss/dangerousness $L(i)$ of each state i, for example by estimating probability of fatality as result of being in the state a certain time.
4. For each transition depending on the design, specify a requirement and corresponding set of transition functions $Q_{ij}(t)$.
5. By using the formula (5), compute steady state distribution π, for each valid combination of transition functions picked from the sets in step 3, possible by using sampling if the set is too large.
6. For all steady-state distributions computed, compute the risk, i.e. limiting expected loss (6). If not acceptable, go back to step 4 and modify, possibly by first doing a sensitivity analysis, the requirements and corresponding transition functions $Q_{ij}(t)$.
7. Design the system according to the obtained requirements.

It can be noted that, in relation to the method of *hazard analysis and risk assessment* in ISO26262 (2011), the steady-state distribution, and the steps 1, 2, 4, and 5 leading up to it, replace the concept of *operational situations* in ISO26262. However, while the steady-state distribution is a result of the chosen requirements, the operational situations is a fixed input to the requirements elicitation and consequently, ISO26262 does not acknowledge themutual interplay between identification of requirements and the operational situations.

8 CONCLUSIONS

The paper has presented an approach of how safety of autonomous driving can be analysed using semi-Markov processes. The approach can be used both to complement the often informal discussion of whether autonomous driving is safe or not. But more importantly, the approach can be used also in development and assessment of vehicles implementing autonomous driving.

The case study has indicated that a semi-Markov process model can capture relevant safety related properties of autonomous driving. The case study also concludes that the extra safety obtained by Level 3 autonomous driving is only marginal and in fact, tomake Level 3 sufficiently safe, it needs to be Level 4.

The paper has highlighted how the current standard ISO26262 is insufficient for complex functions like autonomous driving where the system itself affect the exposure of operational situations. Instead of using the concept of operational situations from ISO26262, it has been shown how the proposed approach of semi-Markov processes can be used to derive top level requirements.

Research on bayesian reliability growth evaluation method for mechanical products

Jinyong Yao, Hao Wu & Tongmin Jiang
School of Reliability and Systems Engineering, Beihang University, Beijing, China

Yiliu Liu
Department of Mechanical and Industrial Engineering Faculty of Engineering, NTNU, Trondheim, Norway

ABSTRACT: The probability of failure of mechanical products often conforms to the Weibull distribution. If the Weibull distribution is used to construct the likelihood function, the Bayesian method is used to estimate the reliability, which involves a large number of integral operations and is not easy to select the appropriate prior distribution. In order to reduce the computational workload and improve the efficiency of the evaluation, based on the mature exponential distribution Bayesian method, this paper transformed the Weibull distribution into exponential distribution and chose the obverse-Gamma distribution as the prior distribution. Through a series of derivation and calculation, we obtain the Weibull distribution Life parameter estimation, and finally gives the corresponding examples to verify the feasibility of the method.

1 INTRODUCTION

Mechanical reliability growth technology is an important part in mechanical reliability theory. It exists in the whole lifespan of design, production and usage. Mechanical reliability growth technology aims to evaluate mechanical product reliability with the synthesized knowledge of different kinds, such as mechanical engineering, statistics and management. In the whole lifespan of the products, reliability growth test (RGT), data analysis and management are effective and economical methods to enhance the reliability stage.

Reliability growth test often faces the problem of too little data volume, especially for some mechanical products. The reliability test usually takes a long time and costly, and the test uses small samples or even very small samples, which makes the product reliable In the process of assessing small sample data. Bayes method can use the current test information together with the historical test data of prior information and similar products, which can be well applied to small sample data Statistical inference problems (Zhang 2000, Zhang 2003). The basic principle of Bayesian theory is to calculate the posterior distribution by using the pre-test distribution and sample information, so as to estimate the point estimate and confidence interval of the variable and further derive the estimated values of other related reliability features.

The specific method is generally based on a parameter as a random variable, through the construction of the likelihood function and pre-test distribution function, using the Bayesian formula to derive the form of a posterior distribution function, and then use the reliability test to get the failure data as a sample. Estimate the probability density function or distribution function of the relevant parameters, and finally get the reliability index. In this process. The determination of transcendental function and the construction of the likelihood function are the key points, and the difficulty is parameter estimation. Many scholars at home and abroad have done a lot of research on parameter estimation.

In engineering practice, the failure probability of mechanical products usually obeys Weibull distribution. The Bayesian parameter estimation of Weibull distribution is used to make mathematical derivation step by step by using the most direct method (Shi 1992). A large number of integral calculations are used, and the whole process is calculated Both the amount and computational complexity are high, increasing the workload for reliability assessment. The Weibull distribution is converted to the extreme distribution and then calculated using the Bayesian formula (Liu et al. 2005). Although the calculation is simplified, the workload is still very large. In response to this problem, this paper seeks a new method of evaluation and calculation to avoid a large number of integral calculations and reduce the computational workload. In the literature (Mao 1999), an exponential distribution evaluation method is introduced. The exponential distribution is a commonly used form of distribution, while the gamma distribution is the conjugate prior distribution of the exponential distribution. It is also suitable for describing the characteristic life of the mechanical and electrical products. Therefore, Bayes estimation of exponential

distribution, the choice of gamma distribution as a prior distribution, which will greatly simplify the calculation, compared to the direct use of Weibull Bayesian derivation, the efficiency is significant.

Based on this idea, this paper presents a method for Bayes reliability growth evaluation based on model transformation. We first convert the Weibull distribution obeying the product to an exponential distribution, and then return to the Bayes estimation of the parameter obeying the exponential distribution and finally return the parameters of the exponential distribution estimation to the parameters of the Weibull distribution, respectively, to obtain the estimate. At the end of this article, we use a practical case to verify the feasibility of the method.

2 MODEL DISTRIBUTION CONVERSION

Suppose the mechanical product life T obey Weibull distribution, the distribution function is:

$$F(t)=1-e^{-(t/\eta)^{\beta}},t>0,\beta,\eta>0 \tag{1}$$

Its probability density function is:

$$f(t)=\frac{\beta}{\eta}(t/\eta)^{\beta-1}\mathrm{e}^{-(t/\eta)^{\beta}} \tag{2}$$

where t is the time, β is the shape parameter, η is the characteristic life.

The cumulative probability distribution function is the integration of the probability density at time t_s:

$$F(t)=\int_0^{t_s}\frac{\beta}{\eta}(t/\eta)^{\beta-1}\mathrm{e}^{-(t/\eta)^{\beta}}dt \tag{3}$$

Assume $z = t^{\beta}$, which can be introduced as $dz=\beta t^{\beta-1}dt$, then the equation (3) can be expressed as:

$$F(t)=\frac{1}{\eta^{\beta}}\int_0^{t_s^{\beta}}\mathrm{e}^{-z/\eta^{\beta}}dz \tag{4}$$

Here the equation (4) can be further simplified as:

$$F(t)=\frac{1}{\theta}\int_0^{X}\mathrm{e}^{-z/\theta}dz \tag{5}$$

where $\theta=\eta^{\beta}$, $X=t_s^{\beta}$.

So, the equation (5) is the exponential distribution function, whose probability density function at time z is:

$$f(x)=\frac{1}{\theta}\mathrm{e}^{-x/\theta} \tag{6}$$

Among them, the exponential distribution function parameters are respectively: $\theta=\eta^{\beta}$, $x=t^{\beta}$.

That is to say, if the lifetime t obeys the Weibull distribution of the shape parameter β and the characteristic lifetime η, after exponential transformation, the experimental time can be expressed as an exponential distribution of x and the average life expectancy θ.

As can be seen from Equation (6), x is a random variable for the parameters t and β, and $1/\theta$ is an exponential distribution parameter which is related to the parameters η and β.

If β is known, then x can be treated as a random variable equivalent to the parameter t. The parameter $1/\theta$ depends only on the parameter η. The pre-test distribution of θ is equal to the pre-test distribution of η, and then the Bayes theory is used to infer it.

If β is unknown, θ depends on the parameters η and β simultaneously, which can be extrapolated using the multiple Bayes method, which is not discussed here.

In general, β as a shape parameter, for the same type of batch products, its value is often unchanged.

3 PRIOR DISTRIBUTION DETERMINATION

The basic principle of Bayes is to use the sample information to correct the prior information and estimate the approximate value closer to the truth. The formula is:

$$h(\theta|x)=\frac{p(x|\theta)\pi(\theta)}{m(x)}\propto p(x|\theta)\pi(\theta) \tag{7}$$

where $h(\theta|x)$ is the posterior distribution; $p(x|\theta)$ is the likelihood function; $\pi(\theta)$ is the prior distribution; $m(x)$ is the edge distribution.

Since $m(x)$ does not depend on the parameter θ, it plays a negligible role in calculating the posterior distribution of θ as a regularization factor. Therefore, the posterior distribution depends on the joint distribution density function and prior distribution.

When the β value has been determined based on prior information, then the prior distribution parameter θ depends on the feature life η.

According to the engineering experience, the prior distribution of the characteristic life η of mechanical products generally obeys the inverse gamma distribution, then the prior distribution of θ can be determined as:

$$\pi(\theta)\sim IGa(a,b) \tag{8}$$

Its distribution form is:

$$\pi(\theta)=\frac{b^{a}}{\Gamma(a)}\left(\frac{1}{\theta}\right)^{a+1}e^{-\frac{b}{\theta}} \tag{9}$$

And the mean and variance of the distribution respectively are:

$$E(\theta)=\frac{b}{a-1}$$
$$V(\theta)=\frac{b^2}{(a-1)^2(a-2)} \quad (10)$$

It can collect the corresponding fault information, calculate the average and variance statistics, and can calculate the value of hyper parameters a and b.

4 RELIABILITY ASSESSMENT

Assuming the end of a mechanical product reliability test using the censored method, in which the sample number n, the failure number is r, then the equation (6) of the likelihood function can be expressed as:

$$L(x,\theta)=f(x_1,x_2,...,x_r,\theta)=\frac{n!}{(n-r)!}\theta^{-r}\exp(-X_r/\theta)\propto\theta^{-r}\exp(-X_r/\theta) \quad (11)$$

where $X_r=\sum_{i=1}^{r}x_i+(n-r)x_r$

Then the posterior distribution of θ is:

$$h(\theta|x)\propto p(x|\theta)\pi(\theta)=\frac{b^a}{\Gamma(a)}\left(\frac{1}{\theta}\right)^{a+r+1}e^{-\frac{b+X_r}{\theta}}\propto\theta^{a-r-1}e^{-(b+X_r)/\theta} \quad (12)$$

At this point, the mean of θ is its point estimate, which is:

$$\hat{\theta}=\frac{b+X_r}{a+r-1} \quad (13)$$

It is known that the posterior distribution of θ obeys the inverse gamma distribution and parameter $1/\theta$ obeys the gamma distribution.

According to $\theta^{-1}\propto Ga(a+r,b+X_r)$, so:

$$2(b+X_r)\theta^{-1}\propto Ga\left(\frac{2(a+r)}{2},\frac{1}{2}\right)=\chi^2[2(a+r)] \quad (14)$$

According to the chi-square distribution, it can be concluded that the confidence interval is $1-\alpha$, the interval of θ is estimated as:

$$\left[\frac{2(b+X_r)}{\chi^2_{1-\alpha/2}(2(a+r))},\frac{2(b+X_r)}{\chi^2_{\alpha/2}(2(a+r))}\right] \quad (15)$$

The Bayes method can be used to estimate the corresponding parameters, and the corresponding reliability features can also be obtained. The mean time between failures (MTBF) of the product is:

$$MTBF=\eta\Gamma\left(1+\frac{1}{\beta}\right) \quad (16)$$

5 SIMULATION CASE CALCULATION

The data in this paper refer to the product failure time data in the paper (Zhang et al. 2005) as the historical data, which can be seen in Table 1. The product in this paper is a typical mechanical product. The distribution of failure interval obeys Weibull distribution. According to the data in the paper (Zhang et al. 2005), the shape parameter $\beta=1.3612$ of the Weibull distribution can be calculated by the least square method, and the value is taken as the shape parameter of the Weibull distribution in the failure interval of a certain mechanical product, and remain unchanged.

From the historical information data of the mechanical product in Table 1, when the parameter β is known, it can be seen from the calculation that the mean and variance of η_1^β, η_2^β,…, η_n^β are:

$$E(\eta_i^\beta)=11008.454,\quad V(\eta_i^\beta)=130857196.8$$

From equation (10), hyper parameters can be calculated as:

a = 3, b = 21203.

So, we can determine the prior distribution of the failure interval of mechanical products according to the inverted gamma ray distribution $IGa(3,21203)$.

According to known Weibull distribution shape parameters β, and the known parameter η^β, so the characteristic life parameter η can be calculated as 931.62h.

Using Monte Carlo simulation method, a set of 8 random number sequences obeying the Weibull distribution of two parameters (the shape parameter is 1.3612 and the size parameter is 931.62) are generated and arranged in order of size $t_1,t_2,\ldots,t_8$ as simulation test data. Assuming the experimental program for the sample size of 8 sets of the same batch of mechanical products, the number of failures for the censored is 5, the test data processing shown in Table 2, where n is the sample size, T is the censored time, $t_i^\beta(i=1,2,\ldots,5)$ is the β power of fault data, X_s is the sum of t_i^β and r is the truncation number.

Set the reliability of $1-\alpha$ is 90%, according to equation (13) ~ (15), get the following data:

The posterior point of θ is estimated as 9264.4.

θ interval is estimated as:

$$\left[\frac{129701.7}{\chi^2_{0.1}(16)},\frac{129701.7}{\chi^2_{0.9}(16)}\right]=[5509.8,13931.4]$$

Table 3. Data processing and analysis.

	β	η	MTBF (h)	Sample size (sets)	Test time (h)
Historical experience data	1.3612	922.14	852.06	33	2841.1
Simulation test data	1.3612	932.18	764.025	8	1644.8
Bayes method data	1.3612	820.4	758.05	8	735

Furthermore, the point estimate and interval estimation of η are 820.4 and [560.07,1107.07] respectively, and the estimated value of MTBF is 758.05 h.

Table 3 shows the comparison of empirical information and experimental data with several evaluation methods. The least squares method is used to estimate the historical data in the paper (Zhang et al. 2005), which represents the empirical information. The Bayes method combines the prior information and the experimental (Simulation) information, the calculation results and simulation data are similar, but the test time is about half.

6 CONCLUSION

In this paper, we presents a method for Bayes reliability growth evaluation based on model transformation, which can effectively solve several difficult issues in mechanical products reliability evaluation. It can be adopted in the following researches, but not limited to

1. this method avoids the complicated model of Weibull distribution, reduces the computational complexity of Bayes estimation, simplifies the calculation process and improves the efficiency of the algorithm;
2. this method also saves test time, and greatly reduces the number of samples.

Importance measure method for joint clearance of mechanism

Zhongchao Sun, Tianxiang Yu, Weimin Cui & Bifeng Song
School of Aeronautics, Northwestern Polytechnical University, Xi'an, Shaanxi, China

ABSTRACT: A method to measure the contribution of random joint clearances to mechanism output error, termed as Error Importance (EI), is presented in this paper. In this method, the 2-order original moment is used to characterize the deviation of mechanism output error and joint clearances from their ideal values, i.e. zero. Then the 2-order original moment of mechanism output error is decomposed into a series of fractions. These fractions are divided into two categories: individual effects and interaction effects. The total effect of one joint clearance is defined as the sum of the corresponding main effects and the interaction effects, and total importance index, i.e. EI index, is defined as the value of its total effect relative to 2-order original moment of mechanism output error. Similarly, the total importance index of a group of joint clearances are defined also. Then the mathematical and physical properties of the EI indices are discussed, and a Monte Carlo based evaluation method is offered. At last, the EI indices are applied to cabin door mechanism of aircraft landing gear. Simulation results revealed that the EI indices can reflect honestly the contribution of joint clearances to mechanism output error.

1 INTRODUCTION

Uncertainty joint clearances are inevitable in linkage mechanisms (Han et al. 2002, Zhang et al. 2015), and lead to mechanism output error (Li et al. 2015). The output error caused by joint clearances cannot be compensated with any kind of calibration (Chen et al. 2013). Furthermore, mechanism produce different error in different positions (Kumaraswamy et al. 2013), traditional calibration cannot ensure the motion accuracy across the whole workspace. With respect to these problems, joint clearances should be controlled under specified level, so as to ensure the mechanism output accuracy. In order to improve mechanism output accuracy maximally under limited resources, the study of *how different joint clearances contribute to mechanism output error* is very necessary.

Joint clearances are random variables of always positive. Thus the deviation of joint clearances from the ideal value, i.e. zero, is composed of variation and mean shift. Under the combined action of various joint clearances, the deviation of mechanism output from the ideal or design value is also composed of variation and mean shift, as shown in Figure 1. In engineering practice, not only the variation, we care about also the deviation of mechanism output from the ideal or design value. Thus both the contribution of variation and mean shift should be taken into account in EI of joint clearances.

With respect to the problem of identifying the most important joint clearances, Sensitivity Analysis (SA) of random variables is the most related

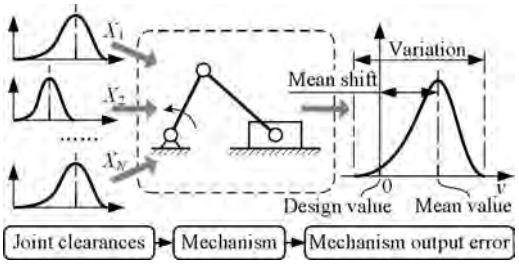

Figure 1. Mechanism output error under the joint effect of various joint clearances.

practice. SA is defined as "*the study of how the uncertainty in the output of a model (numerical or otherwise) can be apportioned to different sources of uncertainty in the model input*" (Saltelli 2002). There are mainly two kinds of SA methods, i.e. Local Sensitivity Analysis (LSA) methods and Global Sensitivity Analysis (GSA) methods (Sobol 2001, Borgonovo et al. 2016, Pianosi et al. 2016). GSA are also called uncertainty Importance Measure (IM) in some literatures (Aven et al. 2010, Borgonovo 2007).

SA methods have already been used by many researchers to study the relative importance of input errors. Caro et al. (2009) proposed partial derivatives based sensitivity indices for the geometric parameters and actuated variables of 3-RPR planar parallel manipulators. Hanzaki et al. (2009) use partial derivatives to study predict how the steering error is affected by manufacturing tolerances, assembly errors, and clearances. GSA methods, e.g. variance

based method, are also used to identify the most important factors that influence the output errors (Cheng et al. 2014, 2015).

However, the current SA methods are not suitable for the problem this paper addressed. From the definition of SA one can get that the present SA methods focus mainly on "uncertainty", rather than the deviation from the ideal or design values. Take variance based methods as an example, they use variance to characterize "uncertainty", implying that the deviation from the "mean values" is what we interested in. However, the mean value of joint clearance can never be zero. Thus variance based SA methods will produce unreasonable results if they are used to measure the contribution of joint clearances to mechanism output error. Similar conclusions can also be derived for other SA methods.

With respect to this problem, an importance measure method of joint clearances that can take into consideration both the contribution of variation and mean shift is presented in this paper. In addition, the presented method should satisfy the requirements of be "*global, quantitative, and model free*" that claimed by Saltelli (2002), and should be convenient to implement.

The following of the paper is organized as follows. In section 2, EI indices for one and a group of joint clearances are proposed based on the decomposition of the 2-order original moment of model output, and a Monte Carlo based evaluation method is offered. In section 3, the mathematical and physical properties of the presented EI indices are discussed. In section 4, an application case to cabin door mechanism of aircraft landing gear is offered. Section 5 provided a summary and some concluding remarks.

2 IMPORTANCE MEASURE METHOD FOR JOINT CLEARANCES

2.1 *2-order original moment decomposition of mechanism output error*

As the basement of IM method, a reasonable index to characterize the deviation of joint clearances and mechanism output from their design or ideal values is necessary. Taguchi et al. (1989) proposed the quadratic quality loss function to measure the deviation of parameters from design values. It took into consideration both the mean shift and variation, and has been adopted by many researches in error or tolerance allocation (Jin et al. 2015). The ideal values of both joint clearances and mechanism output errors are all zero. In this respect, we use the 2-order original moment to measure the deviation of input or output errors from their design values.

Assume a mechanism with N joint clearances, i.e. $\boldsymbol{X} = (X_1, X_2, \ldots\ldots, X_N)$, and one output, i.e. Y. The output error depends only on joint clearances. The PDFs of $\boldsymbol{X}$ are $f_{X1}(x_1), f_{X2}(x_2), \ldots, f_{XN}(x_N)$, and that of Y is $f_Y(y)$. The functional relationship between $\boldsymbol{X}$ and Y can be written as the following form:

$$y = g(\boldsymbol{x}) = g(x_1, x_2, \cdots, x_N) \tag{1}$$

If there are no joint clearances, the mechanism output error Y will obviously be zero, thus the following equation holds:

$$y = g(0) = 0 \tag{2}$$

Assume that the function $g(\boldsymbol{x})$ is $(m+1)$ times differentiable at the point of $\boldsymbol{x} = 0$. The m-th order Taylor expansion is performed to Equation 1:

$$\begin{aligned} y = g(\mathbf{x}) = g(0) &+ \sum_{i_1=1}^{N} \frac{\partial g(0)}{\partial x_{i_1}} \cdot x_{i_1} + \frac{1}{2!}\sum_{i_1=1}^{N}\sum_{i_2=1}^{N} \frac{\partial g(0)}{\partial x_{i_1}\partial x_{i_2}} \cdot x_{i_1}x_{i_2} + \frac{1}{3!}\sum_{i_1=1}^{N}\sum_{i_2=1}^{N}\sum_{i_3=1}^{N} \frac{\partial g(0)}{\partial x_{i_1}\partial x_{i_2}\partial x_{i_3}} \cdot x_{i_1}x_{i_2}x_{i_3} \\ &+ \cdots + \frac{1}{m!}\sum_{i_1=1}^{N}\sum_{i_2=1}^{N}\cdots\sum_{i_m=1}^{N} \frac{\partial g(0)}{\partial x_{i_1}\partial x_{i_2}\cdots\partial x_{i_m}} \cdot x_{i_1}x_{i_2}\cdots x_{i_m} + \frac{1}{(m+1)!}\sum_{i_1=1}^{N}\sum_{i_2=1}^{N}\cdots\sum_{i_{m+1}=1}^{N} \frac{\partial g(\theta \boldsymbol{x})}{\partial x_{i_1}\partial x_{i_2}\cdots\partial x_{i_{m+1}}} \cdot x_{i_1}x_{i_2}\cdots x_{i_{m+}} \end{aligned} \tag{3}$$

where the last item is Lagrange reminder, with $0 \le \theta \le 1$. Because $g(0) = 0$, the first item in the right side of Equation 3 always be zero. Without the considering of the Lagrange reminder, Equation 3 can be simplified into the following form:

$$\begin{aligned} y \approx &\sum_{i_1=1}^{N}\left(a_{i_1} \cdot x_{i_1}\right) + \sum_{i_1=1}^{N}\sum_{i_2=1}^{N}\left[a_{i_1,i_2} \cdot \left(x_{i_1}x_{i_2}\right)\right] \\ &+ \cdots \sum_{i_1=1}^{N}\sum_{i_2=1}^{N}\cdots\sum_{i_m=1}^{N}\left[a_{i_1,i_2,\cdots i_m} \cdot \left(x_{i_1}x_{i_2}\cdots x_{i_m}\right)\right] \end{aligned} \tag{4}$$

where the polynomial coefficient, say, $a_{i1, i2, \ldots, is}$ can be computed as follows:

$$a_{i_1,i_2,\cdots i_s} = \frac{1}{s!} \cdot \frac{\partial^{(s)} g(0)}{\partial x_{i_1}\partial x_{i_2}\cdots\partial x_{i_s}} \quad (s = 1,2,\cdots,m) \tag{5}$$

Computing the 2-order original moment of Equation 4, we get:

$$A^{(2)}(Y) = E(Y^2) = E\left[\left(\sum_{i_1=1}^{N} a_{i_1} \cdot x_{i_1} + \sum_{i_1=1}^{N} \sum_{i_2=1}^{N} a_{i_1,i_2} \cdot x_{i_1} x_{i_2} + \cdots + \sum_{i_1=1}^{N} \sum_{i_2=1}^{N} \cdots \sum_{i_m=1}^{N} a_{i_1,i_2,\cdots,i_m} \cdot x_{i_1} x_{i_2} \cdots x_{i_m} \right)^2 \right] \tag{6}$$

One can get that the right side of Equation 6 is also a polynomial of $M = m^2$ orders with the lowest order of 2. The equation can be expanded into the sum of a series of items. But in condition of high order Taylor expansion and a large number of variables, the expansion of Equation 6 will be very complicated. For convenience, we use $A_{i1, i2, \ldots, is}$ ($s = 2, 3, \ldots, M$) here to denote the polynomial coefficients, and Equation 6 can be written as the following form:

$$\begin{aligned} A^{(2)}(Y) &= E(Y^2) = E\left[\sum_{i_1=1}^{N} \sum_{i_2=1}^{N} A_{i_1,i_2} \cdot x_{i_1} x_{i_2} + \sum_{i_1=1}^{N} \sum_{i_2=1}^{N} \sum_{i_3=1}^{N} A_{i_1,i_2,i_3} \cdot x_{i_1} x_{i_2} x_{i_3} + \cdots \sum_{i_1=1}^{N} \sum_{i_2=1}^{N} \cdots \sum_{i_M=1}^{N} A_{i_1,i_2,\cdots,i_M} \cdot x_{i_1} x_{i_2} \cdots x_{i_M} \right] \\ &= \sum_{i_1=1}^{N} \sum_{i_2=1}^{N} A_{i_1,i_2} E\left(x_{i_1} x_{i_2}\right) + \sum_{i_1=1}^{N} \sum_{i_2=1}^{N} \sum_{i_3=1}^{N} A_{i_1,i_2,i_3} E\left(x_{i_1} x_{i_2} x_{i_3}\right) + \cdots + \sum_{i_1=1}^{N} \sum_{i_2=1}^{N} \cdots \sum_{i_M=1}^{N} A_{i_1,i_2,\cdots,i_M} E\left(x_{i_1} x_{i_2} \cdots x_{i_M}\right) \end{aligned} \tag{7}$$

In fact, the polynomial coefficients, say, $A_{i1, i2, \ldots, is}$ need not to be evaluated. Items in Equation 7 can be divided into two categories:

1. The individual effects. The items that include only one joint clearance, e.g. ($A_{j,j}E(x_j^2)$, $A_{j,j,j}E(x_j^3)$, …, $A_{j,j\ldots,j}E(x_j^M)$, $j = 1, 2, \ldots, N$). They represents the individual contribution of one joint clearance to the 2-order original moment of mechanism output error.
2. The interaction effects. The items that include at least two different joint clearances, e.g. ($A_{i1,i2}$ $E(x_{i1}x_{i2}$, $A_{i1,i2,i3}$ $E(x_{i1}x_{i2}x_{i3}$, …., $A_{i1, i2,\ldots, iM}$ $E(x_ix_{i2}\cdots$ $x_{iM})$). They represent the interaction effects of the corresponding joint clearances.

The contribution that one joint clearance made to the mechanism output error should includes the corresponding individual effects and interaction effects. Thus we defined the "total effect" of X_j as the sum of its main effects and all the interaction effects that include X_j. In summary, the individual effect (termed as $A_M^{(2)}(X_j)$), the interaction effect (termed as $A_I^{(2)}(X_j)$), and the total effect (termed as $A_T^{(2)}(X_j)$) of X_j are illustrated as follows:

$$\begin{cases} A_M^{(2)}(X_j) = B_j^{(2)} E\left(x_j^2\right) + B_j^{(3)} E\left(x_j^3\right) + \cdots + B_j^{(M)} E\left(x_j^M\right) \\ A_I^{(2)}(X_j) = \sum\limits_{\substack{i_2=1 \\ i_2 \neq j}}^{N} B_{j,i_2} E\left(x_j x_{i_2}\right) + \left[\sum\limits_{i_2=1}^{N} \sum\limits_{i_3=1}^{N} B_{j,i_2,i_3} E\left(x_j x_{i_2} x_{i_3}\right) - B_j^{(3)} E\left(x_j^3\right) \right] \\ \qquad + \cdots + \left[\sum\limits_{i_2=1}^{N} \sum\limits_{i_3=1}^{N} \cdots \sum\limits_{i_M=1}^{N} B_{j,i_2,i_3,\cdots,i_M} E\left(x_j x_{i_2} x_{i_2} \cdots x_{i_M}\right) - B_j^{(M)} E\left(x_j^M\right) \right] \\ A_T^{(2)}(X_j) = A_M^{(2)}(X_j) + A_I^{(2)}(X_j) \end{cases} \tag{8}$$

where the polynomial coefficients, i.e. B, are only used to represent the model structure, and need not to be evaluated in the importance measures. In Equation 8, the lower the degree of nonlinearity between $\boldsymbol{X}$ and Y, the small of the polynomial coefficients in the higher order items, both in main effects and in interaction effects.

2.2 *Definition of the importance indices*

The value of one item divided by the 2-order original moment of Y, say, $A^{(2)}(Y)$ is used to denote the ratio of the item's contribution. With respect to X_j, the total importance index, denoted as EI_j, is defined as the value of its total effect relative to $A^{(2)}(Y)$:

$$EI_j = \frac{A_T^{(2)}\left(X_j\right)}{A^{(2)}\left(Y\right)} = \frac{A_M^{(2)}\left(X_j\right) + A_I^{(2)}\left(X_j\right)}{A^{(2)}\left(Y\right)} \tag{9}$$

With respect to a group of joint clearances, say, ($X_{j,1}$, $X_{j,2}$, ……, $X_{j,n}$), the total importance index, denoted as $EI_{j1, j2,\ldots, jn}$, can be defined in the same manner:

$$\begin{aligned} EI_{j1,j2,\ldots,jn} &= \frac{A_T^{(2)}\left(X_{j,1}, X_{j,2}, \cdots, X_{j,n}\right)}{A^{(2)}\left(Y\right)} \\ &= \frac{A_M^{(2)}\left(X_{j,1}, X_{j,2}, \cdots, X_{j,n}\right) + A_I^{(2)}\left(X_{j,1}, X_{j,2}, \cdots, X_{j,n}\right)}{A^{(2)}\left(Y\right)} \end{aligned} \tag{10}$$

where $A_M^{(2)}(X_{j,1}, X_{j,2}, \ldots\ldots, X_{j,n})$ denote the sum of the all the main effects of ($X_{j,1}$, $X_{j,2}$, ……, $X_{j,n}$) and all the interaction effects among ($X_{j,1}$, $X_{j,2}$, ……, $X_{j,n}$); $A_I^{(2)}(X_{j,1}, X_{j,2}, \ldots\ldots, X_{j,n})$ denote the sum of all the interaction effects between ($X_{j,1}$, $X_{j,2}$, ……, $X_{j,n}$) and the others; $A_I^{(2)}(X_{j,1}, X_{j,2}, \ldots\ldots, X_{j,n})$ denotes the

total effect, defined as the sum of the main effects and the interaction effects.

2.3 *Monte Carlo based evaluation method*

The derivation of EI indices is based upon the assumption that the model is m times differentiable. However, this assumption not always holds in engineering practice. Even this assumption holds, the computational burden induced by the evaluation of the high order partial derivatives is unaffordable, especially for complicated and implicit models. Thus an efficient method is desirable for the evaluation of the presented EI indices.

Looking at the expression of the main effects and the total effect of X_j, we noticed that each of their items can be seen as the multiplication of X_j with the others. In this respect, if X_i is assigned a value of zero, then not only the main effects, all the items that contain X_i will also be zero. This phenomena inspired an evaluation method for EI indices: given X_j equals zero, evaluate the conditional 2-order original moment of Y, i.e. $A^{(2)}(Y|X_j = 0)$. $A^{(2)}(Y|X_j = 0)$ represents the $A^{(2)}(Y)$ minus all the effects (including the main effects and the interaction effects) relevant to X_j. Then we minus $A^{(2)}(Y|X_j = 0)$ from $A^{(2)}(Y)$ and thus we get the total effect of X_j:

$$A_T^{(2)}\left(X_j\right) = A^{(2)}\left(Y\right) - A^{(2)}\left(Y \mid X_j = 0\right) \tag{11}$$

EI indices of X_j can be evaluated as follows:

$$EI_j = \frac{A^{(2)}\left(Y\right) - A^{(2)}\left(Y \mid X_j = 0\right)}{A^{(2)}\left(Y\right)} \tag{12}$$

Similarly, the evaluation method for the EI indices of a group of joint clearances can be defined as follows:

$$EI_{j1,j2,\ldots,jn} = \frac{A^{(2)}(Y) - A^{(2)}\left(Y \mid X_{j,1}, X_{j,2}, \cdots, X_{j,n} = 0\right)}{A^{(2)}(Y)} \tag{13}$$

The EI indices involve the evaluation of the conditional and unconditional 2-order original moment of Y. The most direct and simple method is the Mote Carlo method. The basic procedure is as follows:

1. Take L samples of $\boldsymbol{X}$ randomly based on their PDFs;
2. Run mechanism model to obtain the corresponding output error values y_i;
3. The 2-order original moment can be evaluated by the following equation:

$$A^{(2)}\left(Y\right) = \frac{1}{L}\sum_{i=1}^{L} y_i^2 \tag{14}$$

The larger the number of samples is, the more accurate the simulation results are.

4. In the same manner, the conditional 2-order original moment of Y, i.e. $A^{(2)}(Y|X_j = 0)$, can also be evaluated given $X_j = 0$.
5. EI indices of X_j can be evaluated based on Equation 12.

3 PROPERTIES DISCUSSION

Saltelli (2002) argued that SA should satisfy the requirements of "*global, quantitative and model free*". By global one means that the technique allows to take into consideration the entire input distribution. By model independent one means that no assumptions on the model functional relationship to its inputs is necessary in order for the SA method to produce accurate results.

With respect to X_j, the individual effects are averaged across the whole distribution range of X_j in the presented EI index. Thus all the possible values of X_j are considered in. Similarly, we average the interaction effects over the whole distribution range of the joint clearances they involved. Thus the presented EI index reflects the contribution of X_j over the whole distribution range of all the joint clearances. At the same time, the linear effect, the higher order effects, and the interaction effects are all considered in. Consequently, the presented EI index possess the property of "global". Same conclusion can also be derived for the EI index of a group of joint clearances.

Although the partial derivatives are used to deduce the importance indices, they need not to be computed in the evaluation of the importance indices. In addition, there are no extra assumptions about nonlinearity and monotonicity of the system model. Thus the indices possess the property of "model free". The presented EI indices reflect the contribution of system input errors to output error, clearly they have the property of "quantitative". Besides, the method presented here can handle the problem of a group of factors.

4 APPLICATION TO CABIN DOOR MECHANISM OF AIRCRAFT LANDING GEAR

4.1 *Problem statement*

The cabin door mechanism is used to cover the landing gear cabin when aircraft has taken off, and is an important subsystem of aircraft landing gear, as shown in Figure 2. Based on kinematic analysis one can get that the components in actuator and linkage mechanism are all under pulling or press forces,

thus they can be simplified into two-force rods. The cabin door is under bending moment, and can be simplified into a beam. In addition, the components can be seen to move in the same plane. Hence the cabin door mechanism can be simplified into a planar linkage mechanism, as shown in Figure 3.

4.2 *Synthesis of joint clearances*

With respect to two-force rods, the joint clearances can be synthesized into the rod length. Based on multi-body dynamic analysis we know that the rod R_{AB}, R_{BD}, R_{BE}, and R_{EF} are all under pulling force, thus their equivalent length can be evaluated:

$$L_{ij} = L_{ij}^0 + e_i + e_j \tag{15}$$

where $L_{i,j}$ denotes the equivalent length of the rod R_{ij}, L_{ij}^0 denotes its design length, and e_i denotes the clearance of the ith joint. Rod R_{CE} is under press force, thus its equivalent length is:

$$L_{CE} = L_{CE}^0 - e_C - e_E \tag{16}$$

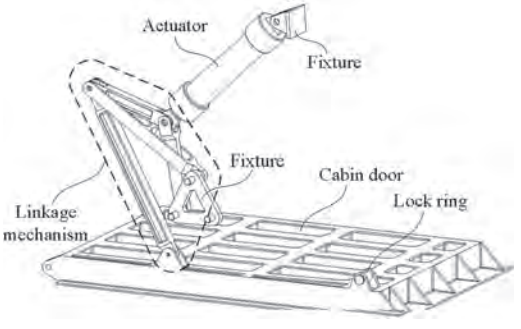

Figure 2. The cabin door mechanism.

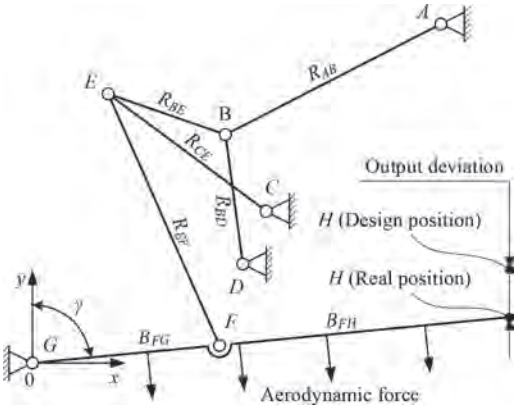

Figure 3. The simplified cabin door mechanism.

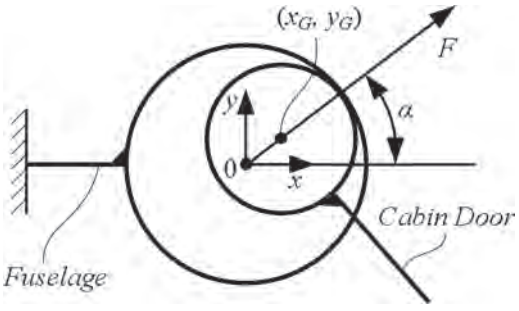

Figure 4. The joint center variation of joint G.

where L_{CE} denotes the equivalent length, L_{CE}^0 is the design length, and e_C and e_E are the clearance of joint C and joint E respectively.

Because the cabin door is under bending moment, the clearance of joint G should be integrated into the variation of the joint center:

$$\begin{cases} x_G = e_G \cdot \cos\alpha \\ y_G = e_G \cdot \sin\alpha \end{cases} \tag{17}$$

where x_G and y_G are the real coordinate of the joint G, e_G is the clearance of joint G, and the angle α is defined as the angle between x axis and the direction of force F, force F is the force applied on fuselage by cabin door, as illustrated in Figure 4.

4.3 *Results and discussion*

The position of joint A, C, D, G, and the design value of rods length are shown in Table 1. The joint clearances are all considered to follow truncated normal distribution, and their distribution parameters are shown in Table 2. In the tables, x_i^0 and y_i^0 denote the joint center position in the coordinate system illustrated in Figure 3, L_i^0 denotes the design value of the rod length, e_i denotes the value of the ith joint clearance.

The importance indices of joint clearances are evaluated by the variance based method, moment independent method, and the presented EI indices respectively. In addition, the partial derivatives (PD) of the output error with respect to joint clearances at zero points are also evaluated. Simulation results are shown in Figure 5. From Figure 5 and Table 1 one can get that e_C has the biggest PD value, mean value, and standard deviation. Thus it should contributes the most to the output error of latch hook. The ranking results of all the three methods consistent with this conclusion. In addition, the three methods produced the same ranking. In order to study the effects variation of distribution parameters on position error of latch hook, importance

Table 1. Design value of joints position and rods length.

Part name	Design value/mm	Part name	Design value/mm
x_A^0	800	L_{AB}^0	510
y_A^0	800	L_{BD}^0	270
x_C^0	510	L_{BE}^0	260
y_C^0	310	L_{CE}^0	420
x_D^0	450	L_{EF}^0	540
y_D^0	200	L_{FG}^0	408
x_G^0	0	L_{FH}^0	592
y_G^0	0		

Table 2. Distribution parameters of joint clearances.

Variable	Mean value/mm	Standard deviation/mm
e_A	0.14	0.06
$e_{B,AB}$	0.12	0.04
$e_{B,BE}$	0.12	0.04
e_C	0.16	0.08
e_D	0.16	0.08
$e_{E,BE}$	0.08	0.04
$e_{E,EF}$	0.08	0.04
e_F	0.08	0.04
e_G	0.06	0.03

indices are evaluated under different mean values and variations of of e_A. Simulation results are shown in Figure 6 and Figure 7 respectively.

From Figure 6 and Figure 7 one can get that: (1) By both the moment independent method and variance based method, importance indices of e_A increased accordingly along with the increase of σ_A, and the importance value of other joint clearances all have different degrees of decline; (2) By both the moment independent method and variance based method, importance indices of all the joint clearances kept roughly constant as μ_A increases; (3) By the presented EI indices, along with the increase of μ_A and σ_A, the importance value and order of e_A are all increased accordingly. Clearly the results of the presented EI indices consistent with with common sense, while that the other two methods are not. This is because the current SA methods, e.g. moment independent method and variance based method, focuses mainly on "uncertainty", rather than on mean shift from the ideal or design values.

In conclusion, the error importance measure is more appreciable when studying the contribution of joint clearances to mechanism output error. Furthermore, under the same modification level of μ_A and σ_A, a bigger variation of EI_A is caused by the shift of μ_A. It means that μ_A has a bigger influence on the variation of EI_A than σ_A. Based on this conclusion,

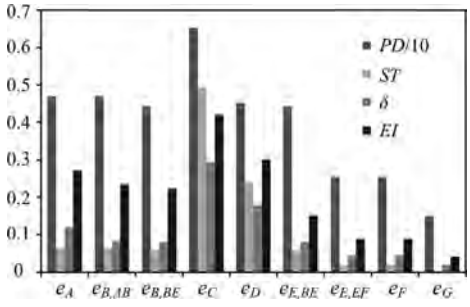

Figure 5. Importance values of joint clearances by different methods.

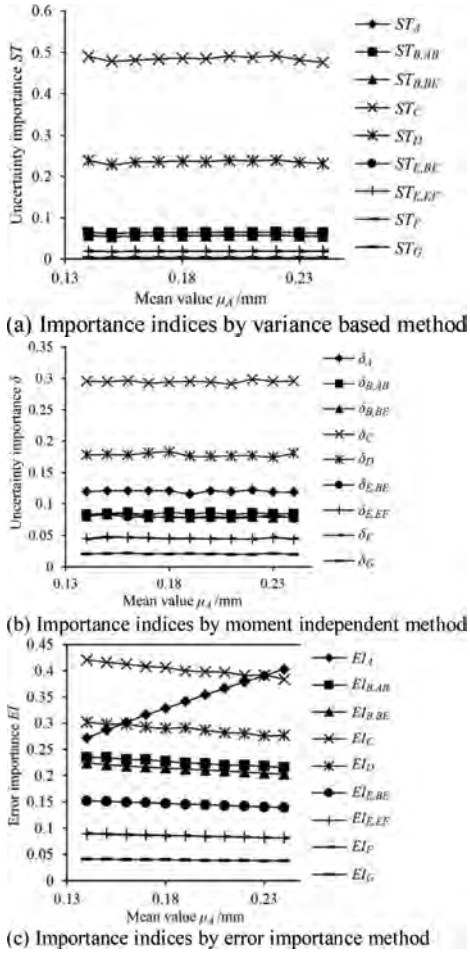

Figure 6. Variation of importance indices along with the shift of μ_A.

more attention should be paid on the decrease of μ_A so as to decrease the contribution of e_A to the position error of the latch hook.

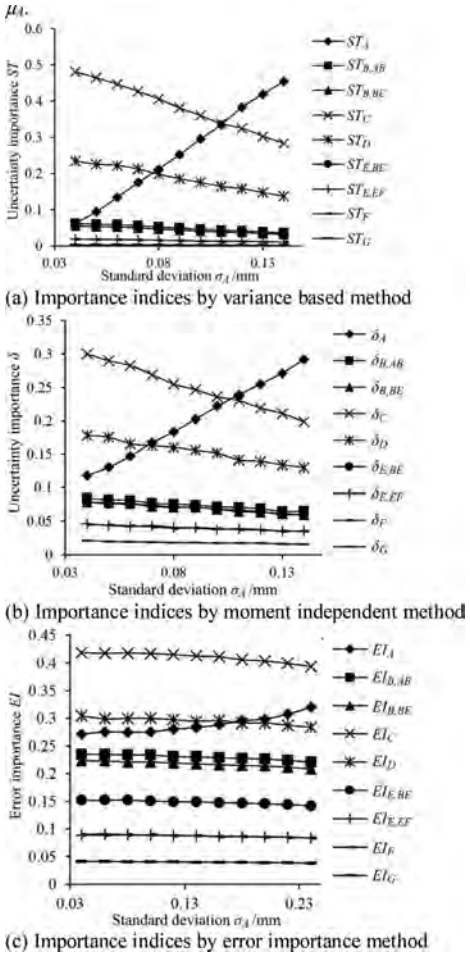

Figure 7. Variation of importance indices along with the shift of σ_A.

5 CONCLUSIONS

In this paper, EI indices to measure the contribution of joint clearances to mechanism output error is presented. The 2-order original moment is used to characterize the deviation of joint clearances or mechanism output error from their design values, i.e. zero. The 2-order original moment of output error is decomposed into a serial of fractions, and the total importance indices for one or a group of joint clearances are defined respectively. The presented importance indices possess the properties of quantitative, model free, and global. An evaluation method based on Monte Carlo simulation is offered, making it convenient to employ.

At last, the presented EI indices is applied to cabin door mechanism of aircraft landing gear. In the application case, the EI indices are used to measure the contribution of joint clearances to the position error of latch hook. For comparison, the variance based method and the moment independent method are also employed. Simulation results revealed that: The presented EI indices can reflect the effects of both variation and mean shift of joint clearances, and the variance based and moment independent methods reflect mainly the effects of variance. Consequently, the presented EI indices is more appreciable for the study of the contribution of joint clearances to mechanism output error.

Multiaxial fatigue life prediction for turbine blades using finite element analysis

Jie Zhou, Hong-Zhong Huang, Yan-Feng Li, Junyu Guo & Xiang-Yu Li
Center for System Reliability and Safety, University of Electronic Science and Technology of China, Chengdu, Sichuan, P.R. China

ABSTRACT: The High-Pressure (HP) turbine blade of aero-engine is subjected to high temperature and high pressure, whose life is mainly governed by the fatigue. In order to model the working condition and obtain the critical area, the Finite Element Analysis (FEA) software ANSYS is typically used as a mathematical tool to solve the problems. Besides, the Chaboche model is employed as a constitutive model to describe the response behaviors of the materials under cyclic loadings in the software. The Fatemi-Socie (FS), Wang-Brown (WB) and Redefined Smith-Watson-Topper (Re-SWT) models are utilized to estimate the life of turbine blades on the basis of the critical plane criteria, which considers the effects of hardening due to non-proportional cyclic loading and mean stress on the multiaxial fatigue life of material. Furthermore, these models are applied to proportional and non-proportional loadings. The analysis results indicate that the critical region of HP turbine blade which should be enhanced the intensity or redesigned to reduce the stress concentration.

1 INTRODUCTION

It is known that the relationship between the fatigue life and characteristic of structure is very difficult to describe accurately in engineering applications because of variable working conditions. Fatigue life prediction plays a quite important role in the fatigue failure analysis. The blade in the engine is one of the highest risk components. According to the failure data of components in aircraft, 70% of those are ascribed to the blades (Tao et al., 2000). The blade should have good operating characteristics under different working conditions, and its life may be governed by a series of failure mechanisms, such as fatigue, creep, fracture, yielding, wear, corrosion, erosion, and so on. In order to decrease the incidence of turbine blades failure, all the aspects that degrade engine performances should be taken into account, such as material properties, loading spectrum, structure and working environment. To identify the mechanical behaviors of HP turbine blades in service, it is necessary to take advantage of the mechanical analysis software to model the blade and its working condition.

2 PREDICTION METHODS

The uniaxial fatigue life prediction models may be not suitable for turbine blade which suffers multiaxial loadings during flight missions. The methods of multiaxial fatigue life prediction can be divided into three categories based on different criteria: equivalent stress or equivalent strain criteria, the critical plane theory, and energy-based method. The critical plane theory is one of the most popular and potential theory in multiaxial fatigue life prediction, which is suitable for various loading condition, and it needs another effort to get the LCF (low cycle fatigue) data as preparatory work of multiaxial fatigue life prediction (Socie and Marquis, 1999).

A classical formulation (Kandil et al., 1982) was proposed to solve the multiaxial problems under biaxial loadings, in which the maximum shear strain range $\Delta\gamma_{\max}$ is taken as the main factor leading to failure, and the normal strain $\Delta\varepsilon_n$ on the same plane is regarded as the secondary damage parameter, given as

$$\begin{aligned} &\frac{\Delta\gamma_{\max}}{2}+s\Delta\varepsilon_n=A\frac{\sigma_f'}{E}\left(2N_f\right)^b+B\varepsilon_f'\left(2N_f\right)^c \\ &A=1+v_e+s\left(1-v_e\right) \\ &B=1+v_p+s\left(1-v_p\right) \end{aligned} \tag{1}$$

where v_e and v_p are the elastic and plastic Poisson's ratio; σ_f' is the fatigue strength coefficient; ε_f' fatigue ductility coefficient; b is fatigue strength exponent, c is fatigue ductility exponent, E is the Young modulus, N_f is the number of cycles to failure, s is a material parameter can be obtained from Eq. (2); τ_f' and b_1 are the shear fatigue strength coefficient and exponent, respectively; γ_f' and c_1

are shear fatigue strength ductility coefficient and exponent, respectively; G is the shear modulus, $G = E/2(1+v_e)$.

$$s = \frac{\frac{\tau'_f}{G}\left(2N_f\right)^{b_1} + \gamma'_f\left(2N_f\right)^{c_1} - \left(1+v_e\right)\frac{\sigma'_f}{E}\left(2N_f\right)^{b} - \left(1+v_p\right)\varepsilon'_f\left(2N_f\right)^{c}}{\left(1-v_e\right)\frac{\sigma'_f}{E}\left(2N_f\right)^{b} + \left(1-v_p\right)\varepsilon'_f\left(2N_f\right)^{c}} \quad (2)$$

Besides, the properties related to shear strain-life can be estimated by (Zhu et al., 2017)

$$\tau'_f \approx \frac{\sigma'_f}{\sqrt{3}}, \gamma'_f \approx \sqrt{3}\varepsilon'_f, b \approx b_1, c \approx c_1 \quad (3)$$

Considering the mean stress $\sigma_{n,mean}$ on the maximum shear strain plane, and may result in the loss of fatigue life. A modification of Eq. (1) based on the Morrow model is defined as (Wang & Brown, 1996)

$$\frac{\Delta\gamma_{\max}}{2} + S\Delta\varepsilon_n = A\frac{\sigma'_f - 2\sigma_{n,mean}}{E}\left(2N_f\right)^{b} + B\varepsilon'_f\left(2N_f\right)^{c} \quad (4)$$

Similarly, Fatemi-Socie used the normal tress to supersede the normal strain term in Eq. (4), then presented an improvement involving tension-torsion loadings and non-proportional hardening, shown as (Fatemi and Socie, 1988)

$$\frac{\Delta\gamma_{\max}}{2}\left(1 + k\frac{\sigma_{n,\max}}{\sigma_y}\right) = \frac{\tau'_f}{G}\left(2N_f\right)^{b_1} + \gamma'_f\left(2N_f\right) \quad (5)$$

where σ_y represents the yield strength; and k is the material constant which can be inferred by the uniaxial experimental data, shown in Eq. (6).

$$k = \left[\frac{\frac{\tau'_f}{G}\left(2N_f\right)^{b_1} + \gamma'_f\left(2N_f\right)^{c_1}}{\left(1+v_e\right)\frac{\sigma'_f}{E}\left(2N_f\right)^{b} + \left(1+v_p\right)\varepsilon'_f\left(2N_f\right)^{c}} - 1\right]\frac{2\sigma_y}{\sigma'_f\left(2N_f\right)^{b}} \quad (6)$$

In addition, Smith-Watson-Topper also established a formulation involving the mean stress effect under uniaxial cyclic loadings, and it also can be applied to the multiaxial loads under proportional or nonproportional conditions, and included the principal strain range $\Delta\varepsilon_1$ and the maximum stress $\sigma_{n,\max}$ on the principal strain range plane, given as (Smith et al., 1970)

$$\sigma_{n,\max}\frac{\Delta\varepsilon_1}{2} = \frac{\sigma'^2_f}{E}\left(2N_f\right)^{2b} + \sigma'_f\varepsilon'_f\left(2N_f\right)^{b+c} \quad (7)$$

Similarly, applying the SWT method on the on the maximum shear strain plane, the Eq. (7) can be rewritten as

$$\tau_{\gamma,\max}\frac{\Delta\gamma_{\max}}{2} = \frac{\tau'^2_f}{G}\left(2N_f\right)^{2b_1} + \tau'_f\gamma'_f\left(2N_f\right)^{b_1+c_1} \quad (8)$$

where $\tau_{\gamma,\max}$ is the maximum shear stress on the maximum shear strain plane

There is a simple assumption to decide the critical plane for SWT theory, if $\tau_{\gamma,\max} \geq \sigma_{n,\max}/\sqrt{3}$, Eq. (8) is applied to predict the fatigue life, or Eq. (7) is chosen. The Redefined-SWT (Re-SWT) model is shown in Eq. (9).

$$\begin{cases} \sigma_{n,\max}\dfrac{\Delta\varepsilon_1}{2} = \dfrac{\sigma'^2_f}{E}\left(2N_f\right)^{2b} + \sigma'_f\,\varepsilon'_f\left(2N_f\right)^{b+c}, \\ \qquad \tau_{\gamma,\max} < \sigma_{n,\max}/\sqrt{3} \\ \tau_{\gamma,\max}\dfrac{\Delta\gamma_{\max}}{2} = \dfrac{\tau'^2_f}{G}\left(2N_f\right)^{2b_1} + \tau'_f\gamma'_f\left(2N_f\right)^{b_1+c_1}, \\ \qquad \tau_{\gamma,\max} \geq \sigma_{n,\max}/\sqrt{3} \end{cases} \quad (9)$$

In general, the WB, FS and SWT models have already gained a certain acceptance in the life prediction field of multiaxial fatigue. Additional efforts of uniaxial experimental data (tensile or torsion test) are required to guarantee the accuracy of the models.

3 MODELLING OF HIGH-PRESSURE TURBINE BLADE

In order to ensure the accuracy of the results and reduce the difficulties of meshing, a simplified version of the three-dimensional model for the 1/n HP turbine disc (remain one fir-tree mortise) segment is created, illustrated in Figure 1. The blade-disc coupled system is modeled to gain the critical region of fir-tree mortise, which uses a nonlinear contact analysis technique.

The centrifugal forces and thermal stresses have a significant effect on the static analysis of turbine blade in LCF. The HP turbine blade is cast by high-temperature alloy GH4169, which has good performances of corrosion resistance, high temperature and high strength. The working temperature of blades is about 600–700°*C*. The material properties of GH4169 can be found in (Sun et al., 2010; Shi et al., 2001; Yu et al., 2017), listed in Table 1, where

K' and n' denote the cyclic strength coefficient and cyclic strain hardening exponent, respectively.

The Chaboche model is introduced to model the nonlinear kinematic hardening behavior of GH4169, which considers the effect of viscosity on elasticity (Chaboche, 2008), and it is exploited to model isotropic and kinematic hardening effect in the FEA. The Chaboche model with three evolution parts ($M = 3$) is given as

$$\frac{\Delta\sigma}{2} = \sigma_y + \sum_{i=1}^{M} \frac{C_i}{\gamma_i} \tanh(\gamma_i \frac{\Delta\varepsilon_p}{2}) \tag{10}$$

where the parameters C_i and γ_i $(i = 1,2,\cdots,M)$ can be obtained by the uniaxial test data.

In accordance with the flight mission and filed test for 800 hours of HP turbine blades, the loading spectrum can be specified by 3 different statements: S1 (0-max-0), S2 (idle-max-idle), and S3 (cruise-max-cruise).

After a series of prepared work, the stress-strain analysis of HP turbine blade is simulated to specify the stress concentration region, the fir-tree mortise, where begins with the cracks initiation, cracks propagate under continued cyclic loading, finally leads to the rupture or failure, shown in Figure 2.

4 EXPERIMENTAL VALIDATION

Referring to the estimation of the applicability and efficiency of the FS, WB and Re-SWT models,

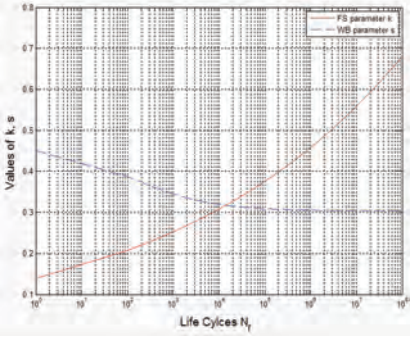

Figure 3. The FS and WB parameters vs. the fatigue life for GH4169.

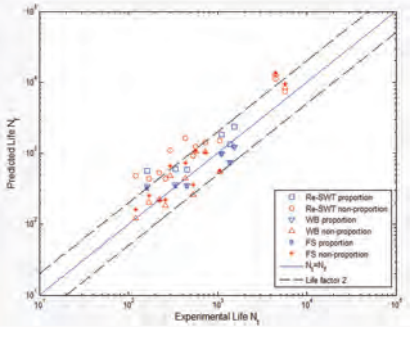

Figure 4. Predicted life N_f vs. the experiment life N_t for GH4169 at $T = 650$°C.

multiaxial fatigue experimental data were conducted on turbine blade alloy GH4169. It complied with the principle of proportional and non-proportional loading introduced in (Sun et al., 2010), which was intended for tension-torsion fatigue test at 650°*C*. Based on the material properties illustrated in Table 1, the material parameters *s* and *k* can be determined by Eqs. (2) and (6), as depicted in Figure 3. The predicted life cycles of Re-SWT, WB and FS models for multiaxial loading are compared with experimental data, is illustrated in Figure 4.

Figure 4 shows a good agreement for WB and FS models, which can be observed for most of the predicted results within the ±2 life factor. The Re-SWT model shows non-conservative results under non-proportional conditions compared with experimental lives.

5 APPLICATION

According to the loading spectrum and results of FEA, the predicted lives of Re-SWT, WB and FS models for HP turbine blade are summarized in Table 3. The life cycle of S3 trends to infinity, the damage is equal to 0. Here, the Miner rule (Miner, 1945), given in Eq. (11), is used to calculate the total damage of 800 hours. Furthermore, the predicted lives, formulated as Eq. (12), are calculated and illustrated in Table 4.

$$D_{800} = \frac{n_1}{N_{f1}} + \frac{n_2}{N_{f2}} + \frac{n_3}{N_{f3}} \tag{11}$$

$$T = 800 \cdot \frac{1}{D_{800}} \tag{12}$$

Table 3. Fatigue life prediction of HP turbine blade.

	S1	S2	S3
n_i	1306	2006	24326

6 CONCLUSIONS

In this paper, a set of experimental data for blade material GH4169 under proportional and non-proportional loadings are used to evaluate Re-SWT, WB and FS models, and the Re-SWT model is not suitable to predict the fatigue life for non-proportional loadings. Furthermore, these three models are also used to estimate the fatigue life based on the FEA of HP turbine blade under serious working conditions, and the prediction results of Re-SWT and WB models are more conservative than that of the FS model.

Maintenance of a drone fleet

A. Segal & Y. Bot
BQR Reliability Engineering Ltd., Rishon LeZion, Israel

ABSTRACT: Maintenance and logistics optimization was applied to a fleet of drones, operating from three sites with a central stock. The optimization achieved a Life Cycle Cost reduction of 34% while the fleet availability increased. This paper presents the optimization process, methods and results. Similar methods can be applied to a variety of other fleets.

1 INTRODUCTION

1.1 *Motivation*

The drone industry is one of the fastest growing markets today (Forny & van der Meulen 2017). Drone failures pose both safety and financial risks, yet the drone failure rate is much higher than the failure rate of manned aircraft (Bone & Bolkcom 2003) Therefore, a great need exists for logistics and maintenance optimization of drone fleets.

In this paper we present an example for modelling and optimizing the maintenance policy of a fleet of drones.

1.2 *Case description*

A fleet of 11 surveillance drones, operating from 3 different sites is considered (4 drones in site 1, 4 drones in site 2, and 3 drones in site 3). A central stock services the three sites.

Site surveillance is considered as not operational when more than 1 drone is failed. During such downtime a penalty is paid by the drone operator to the site owner.

In order to optimize the fleet logistics and maintenance policy, the fleet operation had to be modeled. Following is a list of the parameters which were used to create a detailed model of the fleet behavior:

Reliability Data
- Component failure distribution
- Component failure modes
- Drone redundancies
- Operation profile

Maintenance Data
- Component repair/discard policy
- Repair time
- Corrective maintenance
- Preventive maintenance
- Inspections

Logistic Data
- Spare parts
- Transportation times
- Procurement time

Financial Data
- Cost of spare parts
- Penalties due to operation agreement
- Corrective maintenance
- Preventive maintenance
- Inspections

Figure 1 (see next page) presents the fleet breakdown tree. The fleet tree includes three main branches (one for each operation site), and under each branch the drones and their components are described. This study focused on several drone sub-systems: Navigation, GPS, Inertial Measurement Unit (IMU), and the flaps.

The "Reliability Model" column in Fig. 1 describes the relevant model for each sub-system. For example: the GPS sub-system includes two redundant GPS units (parallel model).

The "Distribution Type" column in Fig. 1 presents the failure distribution type for each component. Electronic components were assigned an Exponential failure distribution whereas the mechanical gyros and flaps were given a Normal distribution that describes their ageing behavior.

2 CALCULATION DETAILS

A commercial software (apmOptimizer) was used for the optimization. The software employs a combination of analytic methods (Birolini 1999) for calculating the fleet Life-Cycle Cost (LCC), and identifying cost and failure drivers. The analytic methods include:

- Markov chains for modelling spare parts supply, demand, and spare waiting times.
- Block mean failure rate calculations that account for component failure distributions, reliability models, scheduled maintenance, inspections and the mission profile.

While analytic calculation is not as flexible as Monte-Carlo simulations, the analytic method is much faster. The speed of evaluating each model allowed for a fast optimization of the maintenance and logistic policies using modified Dynamic Programming.

Dynamic Programming algorithms (Cormen et al. 2009) are ideal for bottom-up optimization of trees where the tree branches are independent.

However, in the fleet case the branches are not completely independent: A central stock services the three sites, therefore a failure in one site affects spare part availability in the other sites. A modified dynamic programming algorithm was used to account for the inter-site dependencies. For example: The Markov chain model that describes the GPS voter spare parts supply and demand accounts for all 11 operating units, serviced by a single central stock.

The optimization goal is to achieve high reliability and availability while minimizing the LCC. Optimization was achieved by using the following optimization modules:

- Optimal LOR: Level Of Repair Analysis—Optimization i.e. Repair/Discard policy. Repair is usually cheaper than buying a new component, however, long repair time (compared to procurement time) may require large and expensive safety stock. Therefore, the discard strategy is sometimes advantageous even when repair is cheaper than buying a new component.
- Optimal PM: Preventive Maintenance Optimization. Periodic maintenance is required for components that exhibit an ageing behavior (failure rate increases with time) and cannot be inspected for degradation. In our case scheduled maintenance is relevant to the mechanical gyros.
- Optimal PdM: Predictive Maintenance Optimization—inspections schedule. Periodic inspections are used to identify flap degradation. Beyond a degradation threshold, preventive maintenance is used to rejuvenate the flaps.
- Optimal I: Inventory Optimization. Optimal I finds the optimal combination of spare parts that minimizes the fleet LCC. The optimal spare part combination is as cheap as possible while ensuring a low probability of downtime due to stock out.

In order to emulate the case of under-maintained fleets, an initial maintenance policy was defined with few spare parts, inspections and scheduled maintenance events. In each optimization step some maintenance actions/spare parts were changed in order to find the optimal combination.

3 RESULTS

Fleet availability at each site as well as the fleet LCC were calculated at each step of the optimiza-

Table 1. Summary of fleet availabilities at the various sites and the total LCC at each optimization step.

Site	Initial A_0	Optimal-LOR	Optimal-PM	Optimal-PdM	Optimal-I
1	99.15%	99.15%	99.15%	99.4%	99.4%
2	99.15%	99.15%	99.15%	99.4%	99.4%
3	99.36%	99.36%	99.36%	99.5%	99.5%
LCC	$47.84M	$46.9M	$45.58M	$31.96M	$31.5M

tion process. Table 1 presents a summary of fleet availabilities at the various sites and the total LCC at each optimization step:

It can be seen from Table 1 that the optimizations resulted in increased fleet Availability and LCC reduction of 34%. Optimal-LOR, Optimal-PM, and Optimal-I decreased the LCC but had a small effect on site availabilities. Optimal-PdM had a strong effect on both availability and LCC. This is not surprising since increased availability means a lower downtime financial penalty.

4 CONCLUSIONS

Fleet operators can reduce operation costs without jeopardizing performance by using analytic tools such as the apmOptimizer.

The modelling and optimization methods which were used in the example are applicable to any fleet, and are therefore relevant to many industries: defense, rolling stock, aviation, and mining.

Furthermore, the method is also good for modelling MRI medical machines, industrial printers, and other sets of identical machines that are operated at different sites and are maintained by the OEM.

Statistical test planning using prior knowledge—advancing the approach of Beyer and Lauster

A. Grundler, M. Bartholdt & B. Bertsche
Institute of Machine Components, University of Stuttgart, Stuttgart, Germany

ABSTRACT: An approach is presented to include prior knowledge in the test planning of product reliability based on the approach of Beyer and Lauster (Beyer and Lauster, 1990) such that several and different sources of prior knowledge can be accounted for. Furthermore, this advanced approach is independent from Beyer/Lauster's prerequisite that the confidence C of the prior knowledge in the form of $R_0(t)$ is to be at $C = 63.2\%$. A nomogram is presented consistent with the pragmatic suggestions of Beyer/Lauster (Beyer and Lauster, 1990) yet extending the original version's applicability. This paper provides a mathematically sound extension to the original paper broadening its applicability to more than one source of prior knowledge while liberating the constraint of $C(R_0(t)) = 63.2\%$ while also allowing for a partial transfer of prior knowledge and accounting for accelerated lifetime tests.

1 INTRODUCTION

Physical product testing is an important tool to validate a product's maturity with respect to reliability. It is used to demonstrate the product's reliability. When planning such a validation test, budget, time and accuracy have restrictive effects. Budget may be limited and time to market may be constrained while accuracy of the derived conclusion is to be maximized. To meet the requirements of efficient and yet effective reliability validation, prior knowledge can be used, which could stem from former development stages, previous product generations or similar products such as benchmarks etc.

2 APPROACH OF BEYER AND LAUSTER

The approach of Beyer and Lauster is based on Bayes' theorem, which allows to link information on the product's reliability from current tests with information from prior knowledge, e.g. tests at a former development stage, previous product generations etc. Beyer and Lauster differentiate the approach in (Beyer and Lauster, 1990) into one part dealing with constant failure rates and consequently one part with non-constant failure rates ($\lambda_0 = f(t)$, i.e. $\beta_0 \neq 1$).

2.1 *Test planning with constant failure rate* λ_0

The failure probability of test samples with constant failure rates is based on the Poisson distribution (Kececioglu, 2002). The confidence level is then calculated by equation (1).

$$C = 1 - \sum_{i=0}^{x} \frac{\left(nt_t \lambda_{max}\right)^i}{i!} e^{-nt_t \lambda_{max}} \tag{1}$$

where n stands for the number of samples, t_t test time, λ_{max} the desired maximum failure rate and x the number of failures during the test.

Prior knowledge is considered through the corresponding failure rate λ_0 with t_{t0} and sample size n_0 ("0" connoting the prior knowledge). If the test to which the prior knowledge relates to is passed without failed samples, the failure rate's density function is then given by (2) with $n_0 t_{p0} = 1/\lambda_0$.

$$f(\lambda) = \frac{1}{\lambda_0} e^{-\frac{\lambda}{\lambda_0}} \tag{2}$$

If a Poisson distribution is supposed to describe the conditional probability of the current test results, the confidence as shown by (3) is calculated by means of Bayes' theorem.

$$C = 1 - \sum_{i=0}^{x} \frac{1}{i!} \left(\left(nt_t + \frac{1}{\lambda_0} \right) \lambda_{max} \right)^i e^{-\left(nt_t + \frac{1}{\lambda_0} \right) \lambda_{max}} \tag{3}$$

Note that the prior knowledge in form of the constant failure rate λ_0 needs to satisfy $C_0(\lambda_0) = 63.2\%$ which limits the approach's applicability.

2.2 *Test planning with non constant failure rates*

If failed samples are not replaced during a test—which is typically the case in practice—the Poisson

distribution fails to be able to describe the product's reliability. The density of reliability R is then described by means of a Beta distribution, cf. (4) for no failures.

$$f\left(R_0\right) = n_0 R_0^{n_0 - 1} \tag{4}$$

After combining the prior knowledge from (4) with the result of the current test encompassing n samples with x failures, a lifetime ratio L_V (test time t_l over the desired lifetime t_s) and shape parameter β of the underlying Weibull distribution, the confidence can be calculated by (5).

$$C = 1 - \sum_{i=0}^{x} \binom{n + \frac{n_0}{L_v^{\beta}}}{i} R\left(t_s\right)^{L_v^{\beta}(n-i)+n_0} \left(1 - R\left(t_s\right)^{L_v^{\beta}}\right)^{i} \tag{5}$$

The basic relation between the confidence level and the reliability in general, i.e. without failures and neglecting lifetime ratios etc. follows (6).

$$C_0 = 1 - R_0^{n_0} \tag{6}$$

With C_0 = 63.2%, an expression for n_0 results from (6) not containing a C_0 which is fixed.

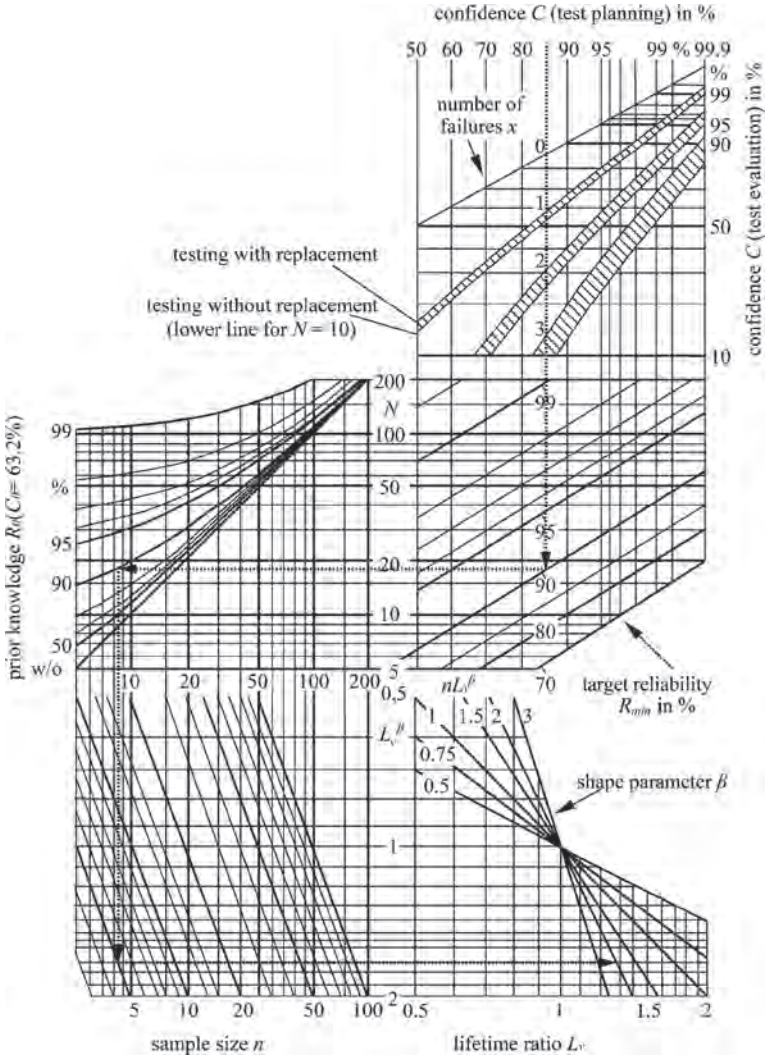

Figure 1. Nomogram for test planning with prior knowledge in the form of R_0 (C_0 = 63.2%) (Beyer and Lauster, 1990).

$$n_0 = \frac{1}{\ln\left(\frac{1}{R_0}\right)} \tag{7}$$

Equation (7) combined with (5) results in (8):

$$C = 1 - R(t_s)^{L_v^\beta n + 1/\ln\left(\frac{1}{R_0}\right)} \cdot \sum_{i=0}^{x} \binom{n + \frac{1}{L_v^\beta \ln\left(\frac{1}{R_0}\right)}}{i} \left(\frac{1 - R(t_s)^{L_v^\beta}}{R(t_s)^{L_v^\beta}} \right)^i \tag{8}$$

Please note that Equation (8) is only valid for $C_0 = 63.2\%$. For $R_0 \rightarrow 0$, i.e. for inexistent prior knowledge, (8) is reduced to (9):

$$C = 1 - R(t_s)^{L_v^\beta n} \sum_{i=0}^{x} \binom{n}{i} \left(\frac{1 - R(t_s)^{L_v^\beta}}{R(t_s)^{L_v^\beta}} \right)^i . \tag{9}$$

Equation (9) cannot be derived directly. Prior knowledge has to be transferred fully. In (Beyer and Lauster, 1990) a nomogram is offered for the practical application of equations (8) and (9) for test planning, cf. Figure 1. (The nomogram is also published and discussed in (Krolo, 2004, pp. 41–47)).

3 EXTENSION OF THE APPROACH OF BEYER AND LAUSTER

The extension of the original approach by Beyer and Lauster (cf. Chapter 2) is motivated by the following aspects:

- The consideration of prior knowledge in the form of R_0 at arbitrary confidence levels C_0.
- The consideration of several sources of prior knowledge.
- The consideration of accelerated lifetime tests by introducing an acceleration factor r in line with (Krolo *et al.*, 2002).
- The consideration of a nuanced incorporation of the existing prior knowledge by introducing a transformation factor Φ.

In order to allow for the fact that the prior knowledge might stem from previous product generations, former development stages or similar products, a transformation factor Φ is suggested in (Krolo, 2004). It ensures the ability to nuance the transfer of prior knowledge other than 100%, i.e. $0 \leq \Phi \leq 1$. Ways to quantify the transformation factor, i.e. the degree to which products or product generations are similar, are found in e.g. (Krolo, 2004; Hitziger and Bertsche, 2005; Schweizer *et al.*, 2015).

Ways to quantify the acceleration factor r are found in e.g. (Jakob *et al.*, 2017).

Both the acceleration factor r and the transformation factor Φ can be included in (8). Thus, (10) results, where the presumed confidence of R_0 is still $C_0(R_0) = 63.2\%$.

$$C = 1 - R(t_s)^{L_v^{\beta_t} r^{\beta_t} n + \Phi/\ln\left(\frac{1}{R_0}\right)} \cdot \sum_{i=0}^{x} \binom{n + \frac{\Phi}{L_v^{\beta_t} r^{\beta_t} \ln\left(\frac{1}{R_0}\right)}}{i} \left(\frac{1 - R(t_s)^{L_v^{\beta_t} r^{\beta_t}}}{R(t_s)^{L_v^{\beta_t} r^{\beta_t}}} \right)^i \tag{10}$$

Equation (10) contains a shape parameter β_t accounting for a possibly different shape of the Weibull distribution observed in the results of the accelerated test with the acceleration factor r as compared to the one observed in the field under regular conditions. It can be observed, that β_t tends to be slightly greater than β while it is commonly assumed that $\beta_t = \beta$ (Juskowiak and Bertsche, 2016).

From (6) results (11), similar to (7):

$$n_0 = \frac{ln(1 - C_0)}{\ln(R_0)} . \tag{11}$$

Prior knowledge with individually arbitrary confidence levels C_{0j} can be combined in the way (12) suggests. A total sample size n_{0sum} is thus calculated stemming from k different sources of prior knowledge. In doing so, individual transformation factors Φ_j account for different degrees of similarity between the product of interest and the source of prior knowledge.

$$n_{0sum} = \sum_{j=1}^{k} \Phi_j \frac{ln(1 - C_{0j})}{\ln(R_{0j})} \tag{12}$$

With (12), (10) is amended to (13):

$$C = 1 - \left(R(t_s)^{L_v^{\beta_t} r^{\beta_t} n + \sum_{j=1}^{k} \Phi_j \frac{\ln(1 - C_{0j})}{\ln(R_{0j})}} \right) \cdot \sum_{i=0}^{x} \binom{n + \sum_{j=1}^{k} \Phi_j \frac{\ln(1 - C_{0j})}{L_v^{\beta_t} r^{\beta_t} \ln(R_{0j})}}{i} \left(\frac{1 - R(t_s)^{L_v^{\beta_t} r^{\beta_t}}}{R(t_s)^{L_v^{\beta_t} r^{\beta_t}}} \right)^i . \tag{13}$$

4 A NOMOGRAM ENHANGING THE TEST PLANNING'S APPLICABILITY

4.1 *The Nomogram as proposed by (Beyer and Lauster, 1990)*

Beyer and Lauster offer in (Beyer and Lauster, 1990) a nomogram which aids decision makers at including prior knowledge into statistical test planning. Figure 2 shows the original version able to account for one source of prior knowledge in the form of $R_0(t)$ with confidence C_0 = 63.2%. This prior knowledge is assumed to be fully transferrable to the current product's version and the current tests need to be not accelerated.

4.2 *Example #1 – Beyer and Lauster's approach*

This example is extracted from (Beyer and Lauster, 1990). It is used in order to demonstrate consistency with the advanced approach for statistical test planning elaborated in this paper.

The target reliability level of a given product is set to be $R_{min}(t_s$ = 20000 h) = 90%, i.e. B_{10} = 20000 h. This reliability target is to be established with a confidence of C = 85%. From a previous and

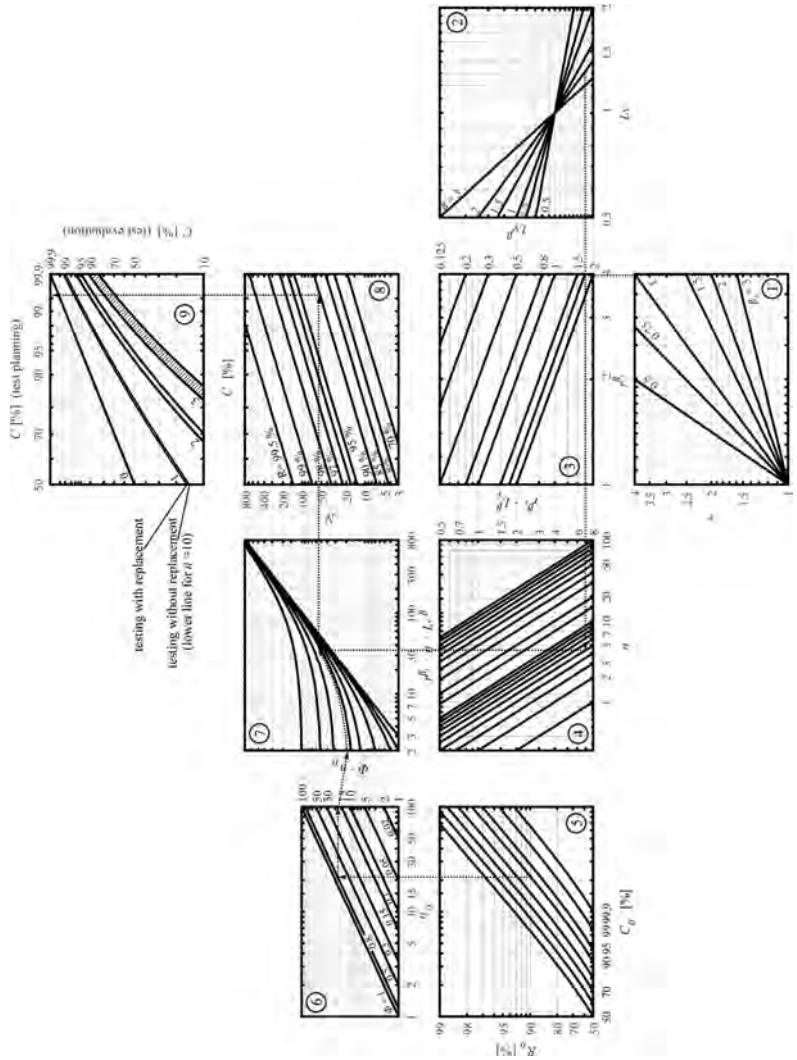

Figure 2. Nomogram for test planning with prior knowledge in the form of R_0 (C_0) according to the advanced approach.

very similar product generation it is known that $R_0 = 90\%$ and the then derived $R_0(t_s)$ follows a Weibull distribution with a shape parameter of $\beta_0 = 2$ and $\beta_0 = \beta$. From Figure 2 it follows, that

$$n \cdot L_v^{\beta} = 8.5 \tag{14}$$

If e.g. $n = 5$ samples are allowed for, then the lifetime ratio $L_v \approx 1.3$. The failure free test time per sample therefore amounts to about 26000 h, cf. (13). It becomes clear from (8) that if prior knowledge was neglected, 5 additional samples would be required to demonstrate the target reliability under the otherwise same conditions.

4.3 *Development of a nomogram for the advanced approach*

A nomogram is developed aiding at practical test planning in line with this paper's ambition as described above. It accounts for prior knowledge (R_{0j} with C_{0j}), which can be partially or fully transferred to the current product for which a certain reliability is to be demonstrated and whose demonstration tests may see accelerated test conditions.

Figure 2 illustrates the adapted version of the nomogram. Herein, example #2 is implemented. Its different fields are numbered.

Field 1: The acceleration factor r (here, $1 \le r \le 4$) of the current product's test (or the test of the product's current state) is taken to the power of β_t.

Field 2: The lifetime ratio L_v (test time t_t/t_s) of the current product's test is taken to the power β.

Field 3: The results from field 1 and field 2 get multiplied. The product is found by extending the resulting point in field 1 vertically and that of field 2 horizontally, followed by an extension parallel to the oblique lines in field 3 upon arrival at field 3.

Field 4: The result from field 3 gets multiplied with the sample size of the current product's test n. The sample size can be chosen in the form of one of the oblique lines. The point found in field 3 is horizontally extended to the given sample size line. The then found point in field 4 is extended vertically to serve as input to field 7.

Field 5: The prior knowledge is put into consideration here. Its reliability level R_0 as well as the corresponding confidence level C_0 are chosen. C_0 is represented by one of the oblique lines. Field 5 calculates what could be considered the sample size of the prior knowledge n_0:

$$n_0 = \frac{\ln\left(1 - C_{0j}\right)}{\ln\left(R_{0j}\right)}. \tag{15}$$

This version of the nomogram deals with one source of prior knowledge, albeit it can be seen from (12) and (13) that k sources can be dealt with. The prior knowledge's fictional sample size n_0 would then simply be the sum of the n_{0j} found through field 5.

Field 6: The result from field 5 (cf. (13)) gets multiplied with the transformation factor Φ which is represented by the oblique line adequate to the degree to which the prior knowledge is trusted to represent the current product (or the current product's state). The thus found point in field 6 is extended horizontally toward field 7.

Field 7: Here, the results from fields 4 and 6 are summed up to what could be considered the total sample size N containing the sample size n of the current product's test as well as the fictional sample size n_0 calculated previously. The corresponding point in field 7 is where the result from field 6, extended along the adequate plotted line in field 7 (i.e. the one entered at) intersects with the vertically extended line off of field's 4 resulting point.

Field 8: The desired reliability $R(t_s)$, represented by the corresponding oblique line, is taken to the power of N. C results if no failures were observed during the test of the n specimen, cf. (13).

Field 9: Field 9 accounts for the number of observed failures x during the test of the n specimen. Here, $0 \le x \le 3$. The resulting C can be concluded upon by extending the point of intersection of field 9 horizontally to the right. Each upper of the two equidistant lines represents the relationship between C and the number of failures with the supposed replacement of the failed units. In case that failed units are not replaced, Beyer and Lauster's suggestion is followed since (13) cannot be illustrated in the same way as (8) (Beyer and Lauster, 1990). A hatched area is introduced which is valid for large n. For large n, C from (13) is approximately equal to C from (8). Although it is suggested in (Beyer and Lauster, 1990) that this assumption holds true for $n \ge 10$, the authors recommend it for $n \ge 20$ (the deviation then amounting to 2,1%, given the conditions of example #1).

Note that the order of application through the described fields depends on the goal of the given lifetime test planning or evaluation. If the goal is to determine a confidence C which can be assured by the combination of a given test with prior knowledge, the order is one to nine. If the goal is to determine how many specimen n need to be tested under given conditions in order to assure a certain reliability R with a specific C_0, then the order is 9 through 4 and 1 through 4.

4.4 *Example #2*

This example adds an acceleration factor r, a confidence level C_0 and a transformation factor Φ to example #1. If $r = 2$, $C_0 = 90\%$ and $\Phi = 0.8$, then $C = 99.55\%$ results. As compared to the original Beyer and Lauster approach, where $C_0 = 63.2\%$, the resulting confidence was thus increased by $\approx 15\%$.

The implementation of this example is shown in Figure 2. The line laid over the structure described in chapter 4.3 constitutes the conditions of example #2 and their exemplary implementation in the developed nomogram.

5 SUMMARY

An extension to Beyer and Lauster's approach for including prior knowledge into statistical test planning was presented. For both, the original and the extended version of the approach, a nomogram was developed. It aids at the practical implementation of the definition of test plans and at analyzing given test settings in terms of the reliability's confidence $C(R)$.

The presented extension is capable of accounting for more than one source of prior knowledge with arbitrary confidences, results from accelerated tests of arbitrary length. Furthermore, it allows for a just partial transfer of prior knowledge to the product's current state based on the assessment of their similarity.

ABSTRACT: Component Fault Trees (CFTs) were invented in 2003 as a compositional extension to fault trees to better reflect the technical architecture of a system in its safety analysis model. Since then, a lot of research has been contributed regarding semantic extensions, evaluation techniques, and tighter linking between system and safety models. This paper addresses three main objectives. First, we summarize the most important contributions and shape a vision of better integrated system modeling and safety analysis. Second, we push forward standardization and sketch a new evaluation scheme for quantitative analysis using mdd. Lastly, an outlook on future improvement ideas is given to make CFTs a viable technique for loosely coupled systems and Cyber-Physical Systems.

1 INTRODUCTION

Fault Tree Analysis (FTA) is one of the most prominent safety and reliability analysis techniques. FTA has been applied for over 50 years and was standardized by several official or de facto industry standards like Vesely et al. (1981) and IEC 61025. Standardization in practice has also taken place through available tool solutions, such as Fault-Tree+, BlockSim, SafetyOffice, medini analyze and many more. Its application is recommended or even required by various safety standards such as IEC 61508 and ISO 26262.

FTA helps engineers identifying causes and influence factors for a supposed failure (called top event) by iteratively seeking backwards in the causal chain. Top events can be hazards (situations that may provoke accidents) in safety engineering, or system failures and unavailability in the domain of reliability engineering. Causes and influence factors are represented in a tree structure. The intermediate failures in the tree structure are joined by so-called gates, in particular the AND gate (indicating that all influencing factors together are necessary to cause the output failure) or the OR gate (indicating that at any of the influence factors causes the output failure). Originally, only Boolean logic connectives such as AND, OR, and N-out-of-M (sometimes called voter gate) were provided, as well as NOT (which cannot be handled by all evaluation algorithms). In later years, dynamic extensions like the Priority-AND gate or gates formulating constraints, such as the Sequence-Enforcing gate have been introduced. However, these gates require a closer look into their semantics, as they do no longer express Boolean proposition logic. The gates are usually represented by American style logic symbols, as used in circuit diagrams, or by European style rectangular symbols. At the leaves of the tree, the fundamental causes (basic events) for failures are represented. In the context of propositional logic, basic events represent failure conditions or failed states of technical components (e.g. "Relay 3 short circuit"). For quantitative analysis, failure probabilities (instantaneous values or functions over time) are assigned to the basic events. This is usually done by specifying a probability density function (e.g. exponential or Weibull) for the transition to the failed state along with its parameters, such as the

failure rate λ. Due to the tree structure, it is not possible to graphically indicate that a basic event may lead to different consequences in the tree (e.g. power supply failure influencing multiple parts of the system). This information can only be provided to evaluation tools by labeling the respective basic event as *repeated event*.

Fault Trees (FTs) can be analyzed in different ways. The most common qualitative analysis is the identification of "Prime Implicants" or "Minimal Cut Sets (MCSs)", i.e. combinations of basic events that cause the top-level failure or hazard. Cut Sets with only one element indicate single points of failures. The most important quantitative analysis is calculating the top-level failure probability (e.g. hazard probability or system unavailability). Other kinds of quantitative analysis are, for instance, importance analyses that unveil the relative importance of single failures w.r.t. the top event probability and give valuable indications where optimization makes sense and where not.

1.1 *Traditional ways of structuring fault trees*

FTs for real industry systems tend to be quite large, often comprising more than 1000 basic events. Therefore, it is not possible to present them on a single page, so some structuring measures are necessary. Traditionally, there are two means of structuring: (1) the transfer symbol and (2) splitting the trees into independent subtrees (modules). While the first method is purely graphical, the second has a semantic connotation, since it is possible to calculate the probability of failure of a subtree and include it in the parent tree as a basic event. This reduces computing time and enables IP protection by allowing component suppliers to deliver the aggregated failure rate instead of having to disclose the entire tree structure. Obviously, the second method is only feasible if a component's FT is a true subtree without any shared events. Multi-instancing of components is possible by allowing several instances of a module. Unfortunately, most available tools do not support this and the user has to copy and paste subtrees, which is prone to errors. Graphically, both methods appear the same, because subtrees are also separated by using the transfer symbol. Both methods are not formally related to the technical architecture of the system, so it is up to the user to divide the FT into meaningful parts that correspond to the components of the technical system.

1.2 *Introduction to CFTs*

To overcome these and other restrictions of traditional FTs, Component Fault Trees (CFTs) were proposed as a new component concept by Kaiser et al. (2003). The idea was to cut out parts of FTs that correspond to technical components and turn them into reusable units with input and output failure ports. At the same time, the tree structure was extended towards a Directed Acyclic Graph (DAG) structure. This avoids the artificial splitting of common cause errors into multiple "repeated events". Instead, it is possible for more than one path to start from the same basic event or subgraph. In addition, it is possible to have more than one top event, such as an accident when a primary failure coincides with the failure of a countermeasure, but only a system unavailability when the same primary failure occurs while the countermeasure is working. This saves analysts time, since large parts of the failure logic can be shared between the two top events.

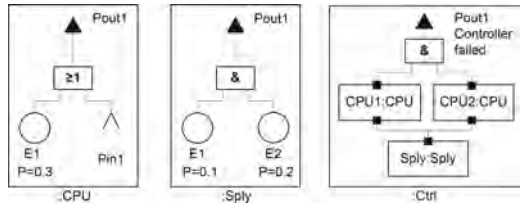

Figure 1. Example of a simple CFT.

Fig. 1 shows an exemplary controller system, including two redundant CPUs (two instances of the same component) and one power supply (which would be a repeated event in traditional FTA). The controller is unavailable if both CPUs are in the state "failed". The inner FT of the component type CPU is shown on a separate screen; as the CPUs are of identical type, they only have to be modeled once. The failure of a CPU can be caused by some inner basic event "E1" (the repetition of the ID "E1" in several components is not a problem, as each component constitutes its own name space). The failure of the CPU can also be caused by an external failure cause which is connected via an input port. As both causes result in a CPU failure, they are joined via a 2-input OR gate. The power supply is modeled as a separate component. Instead of a single large FT, the model consists of small, reusable and easy-to-review components.

1.3 *Quantitative evaluation using BDDs*

The most important quantitative analysis for CFTs, just as for traditional FTs, is the calculation of top event probabilities. The result is usually expressed as probability for a given time period or point in time, or by an equivalent failure rate. For traditional FTs, two approaches are commonly used: collecting all MCSs or prime implicants and to sum up their probabilities, or to transform the Boolean term represented by the FT into a Binary Decision Diagram (BDD). In the latter case, the

Figure 2. BDD fragments for the example CFT: main component (left) and subcomponent C1 (right).

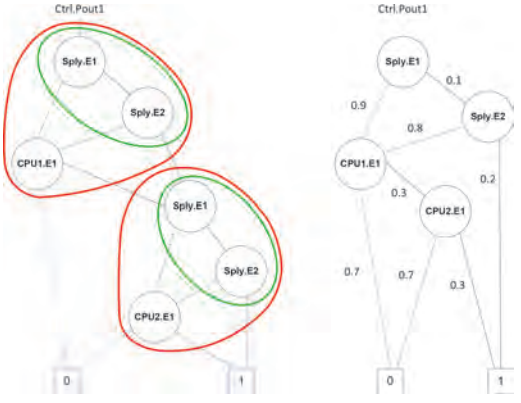

Figure 3. BDD integration, reduction and probability calculation.

event probabilities along each edge are multiplied and the final result calculated as the sum of probabilities of all paths. This BDD-based algorithm works also for CFTs. An example is given in Fig. 2 where the BDD for the main CFT in Fig. 1 is shown.

Fig. 3 shows the integrated BDD after inserting the fragments for the sub components into the main component at the position of the output port nodes. In this example, the probability is calculated as $P_{system\_fail} = 0.1 * 0.2 + 0.9 * 0.3 * 0.3 = 0.101$. Note that we use fixed probabilities to facilitate understanding, while in most cases in practice failure rates are applied.

When nodes representing CFT ports occur in the BDD, they have to be replaced by the sub-BDD that represents the corresponding FT segment with its root at that port. The algorithm for CFTs is explained in detail by Förster (2006).

Kaiser (2005) showed that CFTs not only help structuring large FTs in a more intuitive way, but that they also accelerate the quantitative analysis significantly. The reason is that the logical structure of the FT fragment of a component can be parsed and precompiled into a BDD, which makes up a significant part of the computation time. While optimizing a BDD by finding the lowest number of required nodes is NP-complete and thus not feasible in practice (see Bollig and Wegener 1996), the component concept leads to smaller BDD fragments that reduce the number of variables even if the ordering is not optimal. Furthermore, the nodes that belong to internal failure events of each component can be combined in one part, and the nodes that belong to input ports can be combined in the other part of the reduced structure of the BDD fragment. By a set of examples it could be shown empirically that this leads to an acceptably good variable ordering. The reduced BDD fragments for each port of each component can then be stored for later use. They can be instantiated many times if multiple instances of a component exist in a system (e.g. train braking system with multiple wheel brakes). Kaiser (2005) showed an algorithm to store precompiled and optimized BDD fragments and insert them into one virtual BDD node when instating.

The possibility of reducing/ordering and storing BDD fragments also helps suppliers to protect their intellectual property. In many cases, industrial companies refuse to hand over their safety analysis in full detail to the OEM, because a well-structured and well-documented FTA or FMEA allows reverse engineering the product to some extent. CFTs allow handing over just the signature of a component (name and types of failure input and output ports) plus a precompiled BDD. The BDD contains the full logical terms and the probability distribution of the inner failure events, but with the variables in a random order and without the names of any internal or immediate failure events. This is very similar to the principle of information hiding in software engineering, where compiled binaries and header files with signatures are handed out, but not the full program code.

2 SUBSEQUENT EXTENSIONS

2.1 *Integration with Markov Chains (MCs)*

An important extension was presented by Zocher (2005), which allows to consider not only stochastically independent events (which was the hypothesis of standard FTs) but also mutually exclusive events (e.g. failure modes "too high" and "too low"). Zocher managed to do so by replacing BDDs with Multi-Valued Decision Diagrams (MDDs) in the analysis. Instead of the binary logic TRUE/FALSE (which is interpreted as "working"/"failed" in FTA), now several mutually exclusive values are possible, e.g. "Working"/"in Failure Mode 1"/"in Failure Mode 2" etc. For tool vendors there are several software libraries available for handling MDDs (e.g. MEDDLY, Sylvan), but in the case that only a standard BDD engine is at work, Zocher also presents a canonical transformation of MDDs to BDDs. Zocher's main intention was to allow embedding MCs as subcomponents into

CFTs. However, his approach is useful in general, because mutually exclusive failure modes are often used and classic FTA cannot handle these correctly.

An example is given in Fig. 4. A Markov Chain subcomponent exports two failure states S1 and S2 for usage in the FTA, while the other internal states are hidden. For better understanding of the calculation, the fictitious probabilities of two failure states are given (instead of transition rates) and they have been chosen very high. On superordinate level, a CFT OR gate joins both failure modes to form the top event. Usually, the resulting probability according to the OR gate's formula would be calculated as $P_1 + P_2 - P_1 * P_2$.

Applying the MDD-based algorithm, the resulting MDD constellation would be identical to that described in Fig. 5. After integration and reduction, the probability is calculated correctly as $P_1 + P_2$ (there is no cut set of two mutually exclusive conditions), see Fig. 6. Putting an AND gate above the two mutually exclusive failure modes would correctly produce the output probability zero.

The same task of integrating MCs with more than one exported failure mode has been solved by

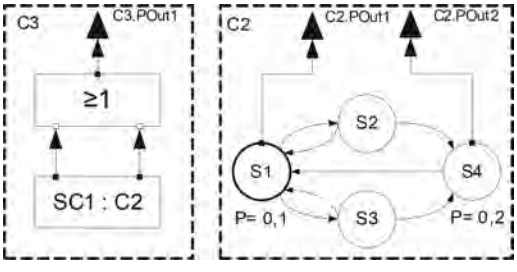

Figure 4. MC with several exported failure modes in a CFT.

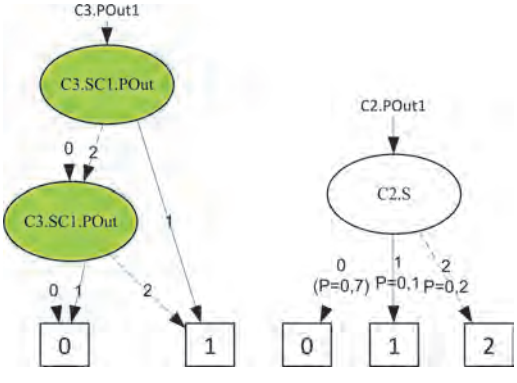

Figure 5. MDD fragments for the system and its subcomponent.

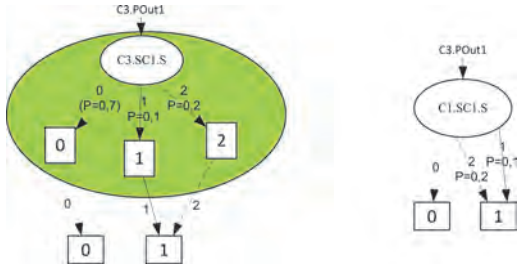

Figure 6. MDD after integration and reduction.

Adler et al. (2007) under the term "Hybrid CFTs". For more information, see Fig. 2 in the cited paper. Unlike Zocher, they do not use MDDs for analysis, but refer to another way of representing multi-state FTs, as proposed by Zang et al. (2003). However, both approaches ultimately produce the same quantitative result and the choice is simply a matter of taste.

2.2 *Component-integrated component fault trees*

Domis (2012) enhanced the CFT approach to enable traceability to system and architectural design models (C2FTs). The traces between CFT artifacts and architecture artifacts make it easier to maintain the fault models when changes are made to the design. Syntactically, the integration is realized by connecting (1) a CFT with a component and (2) every input or output failure port of the CFT with an architectural port of its connected component. While the syntactical enhancement has prevailed, we decided to revise the initial naming and stick to the term CFT.

2.3 *CFT generation from system models*

Many approaches have been proposed for modeling systems in UML, SysML and Simulink and expanding them for the generation of CFTs. Kaiser et al. (2015) show the highly-automated derivation of CFTs from SysML models. The Integration of CFTs with UML using a meta-model has been proposed by Adler et al. (2010). For that purpose, a UML profile was created that provides all necessary elements. As the UML addresses the modeling of software, using this profile makes it possible to model CFTs for the designed software.

The automated derivation of CFT frames from Simulink data flow models has been proposed and implemented by Ramich (2014) and has been validated by a small practical case study by Buono et al. (2015). A prototypical tool reads a hierarchy of Simulink models and transforms it into a hierarchy of CFT components. The integration is merely on topology level (each Simulink compo-

nent produces a CFT, each Simulink signal port a set of CFT ports, CFT edges reflect the Simulink connections). The internal failure logic must be inserted manually by a safety analyst, as in traditional FTA.

2.4 *Enhancement by failure taxonomies*

The introduction of failure type classifications has paved the way towards better semantic integration of system models and CFTs. Domis and Trapp (2008) and Domis (2012) systematically derive and integrate CFTs with a data flow based system architecture, providing a canonical procedure using interface-focused FMEA (IF-FMEA) and a hierarchical failure mode classification scheme. Möhrle et al. (2017a) automate the composition of CFTs on system level using semantic type annotations. For that purpose, architectural ports of components are annotated with flow types that classify the type of interaction (e.g. digital signals, material flows, or energy). For each flow type, safety engineers create a collection of failure types to classify related undesired behavior. These types are used to annotate interfacing model elements in CFTs to abstract from textual descriptions and provide a machine-readable vocabulary.

Fig. 7 shows a taxonomy including four layers. Layer L0 contains the root node *failure* as the most abstract failure type. In each subsequent layer, the undesired behavior is refined further into mutually exclusive sub-items. Taxonomies serve (1) as a template when creating CFTs and (2) as a means for automating the interconnection of ports when composing CFTs. For that purpose, a matching algorithm connects ports according to the relationship of their assigned types. Inconsistencies can be detected and located quickly by analysis tools. This allows a tight coupling between system model and safety analysis model since new CFTs can be generated with minimal effort when making changes to the architecture.

The idea of using failure taxonomies is also exploited by Kaiser et al. (2015). The system architecture is specified in SysML and annotated with semi-formal contracts (assumptions and guarantees) that specify expectations about the nominal externally observable behavior of the system

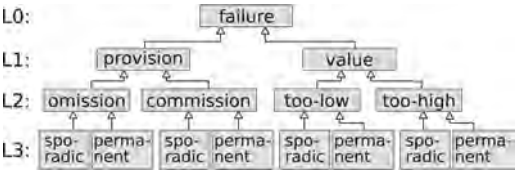

Figure 7. Excerpt of an example failure type taxonomy.

and each of its components. A contract can, for instance, contain the assertion (guarantee) that some value at an output port (e.g. voltage) shall always be in the range [0, 100], provided that all assumptions are met by the environment. A failure is consequently defined as contract violation. In the given example, a value lower than 0 would constitute the failure mode "too low" ("too high" analogously). With contract specification languages that also allow expressing temporal behavior, failure modes like "too late" can be expressed as well. Analyzing whether or not an output event is generated too late is not done inside the CFT analyzer, but must be performed in some discrete-state or hybrid analysis, model checking or simulation framework. Another proposed way to guess the failure propagation logic is to combine fault injection with simulation of the system models. For the CFT analyzer, the question whether or not an assertion is violated is still of Boolean nature. The failure mode classification scheme defined by Domis and Trapp (2008) has been used here as well, but can be refined as appropriate. In the same paper, a new graphical notation is used where the ports from the architecture model appear in the CFT as rectangular box around the triangular input and output failure ports (see Fig. 10a).

However, when switching to the technical viewpoint, potential technical failures like bit-flips, wire-breaks, failures of electronic components and the like will arise.

2.5 *Exploiting behavioral models to derive CFT failure models*

For traditional FTs, several proposals exist to also exploit behavioral models of components (e.g. State Diagrams) for deriving failure modes and failure propagation automatically. Of particular interest in the domain of CFTs is the approach by Berres and Schumann (2016), which can exploit behavioral models to generate CFTs by focusing on each component and its behavior individually.

2.6 *CFTs for layered architectures*

Höfig et al. (2015) describe a methodology called Architecture Layer FailuRE Dependency (ALFRED) which extends CFTs to better maintain the independence of model elements in different layers of a vertically decomposed system architecture. The approach uses so-called ALFRED connections to allow for CFTs on different layers of an architecture. These connections are used to generate a FT for the entire system and over all different architectural layers. This way, for every failure dependency relation, all basic events that are included in the CFT of the dependency

element are added to all output failure modes of the dependent component using OR gates.

ALFRED connections ease the modeling of common cause failures without explicitly modeling dependencies using information flow elements such as ports. This keeps layers in the model independent and supports compositional development. The approach can be used to reuse software on different hardware and ease the evaluation of different deployment variants in terms of safety. Using ALFRED connections, existing safety analysis models can be reused more effectively to support early safety assessments and head towards an automated safety qualification of future cps. The ALFRED approach is already being successfully applied for certification tasks in the railway domain.

2.7 *CFTs for product variants*

Möhrle et al. (2017b) extend CFTs further towards an automated exploration of the system design space in terms of safety. For that purpose, mutable parts of the architecture for which more than one design alternative exist are modeled as variants rather than concrete components. A variant specifies a functional interface by its type-annotated architectural ports (e.g. integer signals, energy flow). The failure logic to be connected to these ports is provided for each realizing entity (component or subsystem). For instance, multiple sensors may be applicable to measure the fill level in an oil tank. Hence, a variant is defined for the level measurement and one realization of the failure logic provided for each sensor. By including variants in the functional system model, multiple architectures can be derived for which CFTs are generated automatically. This way, FTA becomes a benchmark comparing various design alternatives in terms of safety.

3 PRACTICAL EXPERIENCE WITH CFTs

CFTs have been applied in several case studies and industrial projects. Below we present a case study of a situation display system, which was taken from a real world application. In the study, the modeling of the system was done by industrial engineers with some support from modeling experts.

The input to the system is sensor data of the world outside the system. The GPS receiver also obtains information from outside the system, but this information comes from a central authority and is not acquired by the situation display itself. The information is transmitted over two redundant channels and then collected and compared in the channel interface. Finally, it is transmitted to the processing component. During processing, sensor and GPS data are combined to obtain information of the situation outside the system. This information is redundant, since the outside world is evaluated by two independent sources. The system is shown in the center of Fig. 8.

Fig. 9 shows a classic FTA of the system for two top events. The top event *Loss of position data* implies that no information about the outside situation is available. This is the case if both signals are lost. The top event *Partial loss of position data* implies that either the GPS or the sensor data is not available. In this case, the analysts decided to make a worst case assumption by using an OR gate instead of the more precise XOR gate. The top event *Erroneous position data* is not depicted but it is shaped like the FT for the top event *Loss of position data* with only OR gates and erroneous basic events for each component. It models the situation where the data displayed is inaccurate. The analysts decided to create a pessimistic tree for this top event as well, where any failure in one of the components can contribute to the top event.

Fig. 8 shows the CFT analysis that was carried out for this system. The CFTs that are related to system components are depicted as breakout boxes. The CFT for the channel components is redundant

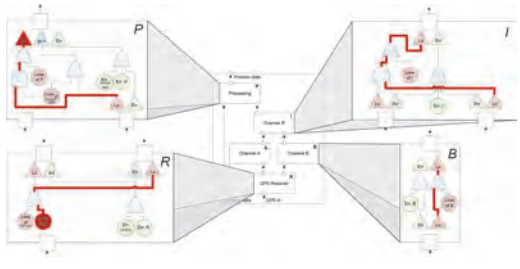

Figure 8. CFT analysis of the situation display system.

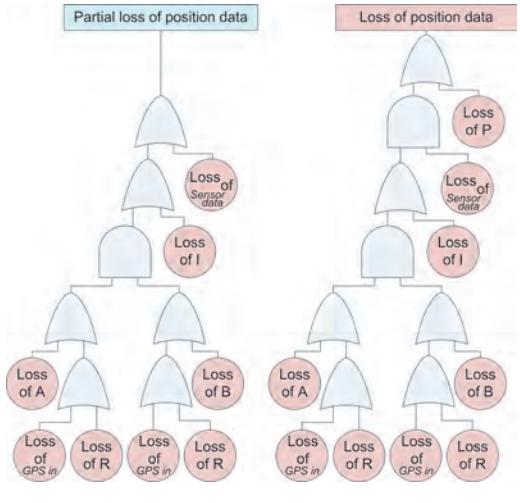

Figure 9. Classic FTA of the situation display system.

and therefore only depicted once. The triangles connected to the output port of the processing component represent the top events of the system, which are the same as for the classic FTA. *Lo* refers to *Loss of position data*, *pLo* refers to *Partial loss of position data* and *err* refers to *Erroneous position data* accordingly. CFTs facilitate the use of interfaces from the system model. For example, the triangles labeled *Lo* and *Err* connected to the right input port of the processing component model the failure modes *loss of* and *erroneous* that propagate over the interface from the component *channel interface* to component *processing*.

During the case study, some findings were observed. Some of them are related to benefits or drawbacks of the modeling strategies used, other findings can be used as hints for proper modeling.

Deep trees: It is a common practice during FTA to follow the chain of actions backwards through the system and document the intermediate failure modes. An example is provided in Fig. 9, where the FTs are deep instead of forming a flat structure as disjunction of all combinations that lead to the top event. Since CFTs follow the system structure, we can see that CFTs promote deep structures instead of flat disjunctions. CFTs therefore should start with the top event at the last processing component (actuator). The failure analysis is then done backwards or upstream to the participating components until all possible causes are identified, ending at the system inputs (sensors).

Localization: When changes need to be made, CFTs facilitate searching for affected parts of the failure analysis. Changes that can be narrowed down to a single component are constrained to a single CFTs. In the classic FT approach, restoring consistency after making changes lies in the hand of the analyst.

Redundancy: In classic FTs, homogeneous redundancy requires a precise distinction between repeated events and redundant, but not identical events. In the CFT approach, redundant components are expressed by simply duplicating the respective CFT, while common cause failures (which have to be identified by common cause analysis) stay outside the component and are connected via ports. In the situation display system, the channel components are redundant and the duplication of the CFT facilitates the modeling and the analysis of the system.

Organizational structures: As systems grow, classic FTs do not provide a proper divide-and-conquer strategy to cope with the increasing complexity. In CFTs, the entire failure behavior (internal) and failure propagation (interfaces) is documented at once. Large distributed development teams can take advantage of the clear structure and interact with one another using consistent interfaces for functional modeling and safety modeling. Hence, CFTs are a better choice for breaking down the complexity of a system in complex organizational structures.

Systemic faults: Uncovering systematic faults in critical applications is of great importance. If systems grow in complexity, failures resulting from flawed collaboration become more significant in comparison to local component failures. CFTs align with component interfaces in system models which often match different developer teams and therefore foster communication about overlooked failures.

Simplification and easier maintenance: The case study has several top events and therefore requires several FTs in classical FTA. This not only causes extra work, but increases the susceptibility to errors and impairs maintenance, as changes have to be applied to every affected tree. When changing details in a component, potential effects on all top events have to be checked. As CFTs filter only the relevant component failures for each top event, the analysis is facilitated for complex systems where many top events exist.

Prepared for later reuse: Reusing a component together with its CFT in later projects appears attractive and enables Off-the-shelf components ("safety element out of context"). However, caution is needed as safety issues may arise when reusing a previously verified component in a new environment. Yet, a reused CFT is a good starting point for new analyses. The combination with contract-based development, which logs assumptions and guarantees for each component, can mitigate the risk of blind reuse. If components are reused across many projects, they and their CFTs go through a maturing process and the chances of all potential failures being detected increase.

4 CONSOLIDATION TOWARDS "CFT 2.0"

After years of various new contributions since CFTs were initially proposed, it is time to collect the ideas and define "CFT 2.0". This hopefully encourages tool builders to support this method.

4.1 *Integration with architectural models*

A first proposal is discarding the term "Component-Integrated Component Fault Trees (C2FTs)" and refer to the overall concept as CFTs. CFTs can either be used as a safety analysis technique alone, or linked to functional or technical static architecture models, in particular SysML Internal Block Diagrams (IBDs). When used in combination with SysML IBDs, we suggest that it shall be mandatory that

1. for each component in the SysML architecture, there is exactly one corresponding CFT with the same name
2. the nesting hierarchy in the SysML IBD and the CFT is the same

3. cause-consequence edges in the CFT exist wherever and only where corresponding signal or service flows exist in the SysML IBD architecture
4. for each incoming flow port, at least one failure input port shall be assigned in the CFT (the same applies for outgoing flow ports and output ports)
5. for each required or provided service port (lollipop symbol), several failure input and output ports can be assigned, since failure consequences can be passed from service provider to requester and vice versa. Safety engineers are responsible for avoiding cycles in the causal chains.
6. all CFT failure ports are bound to one architectural port; graphically represented either by drawing the rectangular architectural port around its triangular failure ports, or by drawing edges between them.

Integration with other signal-flow-based modeling techniques should be standardized as well, in particular the integration with Simulink, e.g. based on the work of Ramich (2014) and Buono et al. (2015). Like for SysML IBD flow ports, the failure causality flow follows the signal flow. Attention must be paid because these models often contain cycles in the signal flows due to closed-loop control. These cycles must not lead to cycles in the causal edges of the FT, which are illegal. Avoiding cycles can be achieved by skillful modeling (e.g. modeling failure consequences on the open-loop signal chain sensors—controller—actuators), but there are also proposals how to resolve cycles automatically, see Vaurio (2007) and Domis (2012). However, these aspects should be handled externally and are not included in the CFT standard.

4.2 *Mutually exclusive failure modes*

We suggest BDD or MDD based evaluation of the resulting failure probabilities as the default algorithms for CFTs. Embedding MC components (which are not part of the CFT method) is a recommended practice for CFT tools. Using the MDD evaluation method, exporting more than one failure mode from a MC, as shown in Fig. 5, is possible and produces correct results. Even without embedding MCs, it should be possible to model mutually exclusive failure modes like "too low" and "too high" and notifying the tool about their special relationship. To allow this, we suggest as an extension to CFTs, that several basic events can be surrounded by a rectangular frame as shown in Fig. 10a), indicating that they form a mutually exclusive group. Similarly, failure ports encapsulated by the same rectangular architectural port shall be treated as mutually exclusive.

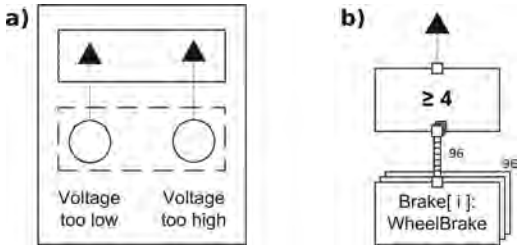

Figure 10. a) Two mutually exclusive failure modes b) Multiinstance component connected to a multi-input gate.

4.3 *Multiple instances and variants of components*

Another innovation we suggest for CFT2.0 is exploiting the multi-instance capabilities in a more convenient way for highly-redundant systems by introducing a multi-instance symbol and gates with multi-input ports. Imagine a train braking system with 96 wheel brakes of the same type, where a hazard is present whenever at least 4 wheel brakes have failed. Instead of manually creating 96 individual instances and connecting them to an n-out-of-m gate with 96 inputs, a tool can offer a multi-instance symbol like in Fig. 10b) with a parameter – 96 in this example—to indicate how many replicas are available. Note the input port symbol at the gate that indicates a multi-port and the different style of line indicating a multi-line. Of course, the parameter can easily be changed for later projects, so that only one parameter needs to be changed to adapt the model for a train with 72 wheel brakes. This enables efficient safety analysis for product lines. The semantics is straightforward because this is merely a matter of graphical representation.

To further support the product line approach, we suggest that also the variant approach from Möhrle et al. (2017b) be part of CFT2.0. Modelers can specify variants by modeling the signature (number and types of ports), and the concrete CFT model is attached later, selected from a model library and guided by a variants database. For example, if a hydraulic brake is replaced by an electric brake, only one more model needs to be added and the different solutions can be easily compared. However, this aspect is mainly a question of tool support and not of the CFT semantics themselves.

5 CONCLUSION AND FURTHER RESEARCH

By collecting and integrating scientific contributions from many researchers over more than a decade, we have provided an overview of the state-of-the-art in CFTs and made some proposals on

how to update their specification under the term CFT2.0. By referencing larger case studies, we aim to encourage tool developers and safety analysts to use CFTs in industrial projects and provide feedback for further method improvements. We are convinced that the CFTs have reached maturity for industrial use in safety-relevant projects. Nevertheless, we are inclined to work on further developments. We will further elaborate on a more formal integration of CFTs with SysML/UML by combining safety analysis with contract-based development. With regard to UML/SysML, we are working on integrating not only flow ports (dataflow oriented interaction) but also service ports (lollipop symbol), as this type of interaction (often asynchronous) is typical not only for software systems, but also for open networked systems and systems with user interaction. Here we will have to deal with the fact that failure propagation can occur in both directions over the architecture port. We will continue working on approaches to derive the internal failure propagation and mitigation logic of CFTs, in particular by combining failure injection and simulation. Also more traditional analytic approaches like FMEA or Hip-Hops to find inner failure modes and failure propagation should be better integrated with CFTs. We plan to extend the presented variability approach also towards runtime variance, which is important as spontaneously networking CPSs, so called System-of-Systems (SoSs) become ubiquitous. This would mean that for every legal configuration of an SoS (e.g. vehicle platoon or sensor network), parametric CFT templates will have to be re-combined and checks carried out whether or not the desired constellation is safe or reliable enough.

ABSTRACT: With the increase in computing power and the rise of "big data", many machine learning algorithms have been developed or given a new lease of life. Their application is proved to be really efficient in various fields. However their implementation in the industrial sector, such as nuclear power generation, seems less widespread. This paper presents a comparison of several techniques on a case study from the nuclear industry. Their performance on the real dataset are compared and a discussion is proposed on their practical use, advantages and disadvantages, precaution for use and relevance in an industrial context.

1 INTRODUCTION

1.1 *Industrial context*

Shutdowns of nuclear power reactors are regularly planned for refueling and carrying out maintenance operations. The state of the reactor during its shutdown can be characterized by an indicator which is measured during the shutdown. If this indicator is higher than a given fixed threshold, it may impact the scheduled planning and lead to an extension of the shutdown. In addition to this indicator, around twenty parameters describing the operation conditions of the reactor just before the shutdown are available.

There currently exists neither physical-based model nor computer simulation code to characterize the indicator and predict if it will be higher than the given threshold. That is why, in order to anticipate the required logistical support for maintenance during the reactor shutdown, it seems relevant to "learn from the data" and try to take advantage of the information brought by the operation conditions before the shutdown to foresee the state of the reactor during its shutdown. The use of a "black-box" machine learning algorithm seems to be a promising solution in order to build the prediction function between the state before and the one during the shutdown.

Indeed, with the increase in computing power and the rise of "big data", many machine learning algorithms have been developed or given a new lease of life. Their application is proved to be really efficient for prediction purpose in various fields: banking, insurance, media, information technology, healthcare, transportation, sports… However their implementation in the industrial sector, such as nuclear power generation, seems less widespread and their relevance and effectiveness have to be confirmed in this area of application where data may be less voluminous.

1.2 *Objectives*

Different supervised machine learning techniques have been tested on the available data and the main objective of this paper is to present a comparison of the obtained results.

The remainder of this article is organized as follows. Section 2 describes the fundamental principles of the families of machine learning algorithms that have been used. Section 3 presents how the performance of the predictive models can be assessed and compared and it gives the main results obtained on the dataset. A general discussion is proposed in Section 4 on the practical use of the techniques, by exposing their advantages and disadvantages, precaution for use and relevance in an industrial "relatively small data" context.

2 PRESENTATION OF THE DIFFERENT FAMILIES OF MACHINE LEARNING ALGORITHMS

2.1 *Notations and preliminary assumptions*

Y will denote the indicator characterizing the state of the reactor during its shutdown. Y is a qualitative (or categorical) random variable taking two values: AT (for "Above Threshold") and BT (for "Below Threshold"). For more convenience, we will represent it by two equivalent numerical variables, Z and $\tilde{Z}$, using binary codes: $Z = 1$ if $Y = AT$ and $Z = 0$ if $Y = BT$, so that $Z = \mathbb{I}_{\{Y=AT\}}$ with $\mathbb{I}_{\{.\}}$ the indicator function, and $\tilde{Z} = 1$ if $Y = AT$ and $\tilde{Z} = -1$ if $Y = BT$. $\boldsymbol{X} = (X^{(1)},\ldots,X^{(p)})$ will denote the vector made of the p parameters describing the operation conditions of the reactor before its shutdown. In our case, $p = 25$. Each variable $X^{(j)}$, $1 \le j \le p$, can be either deterministic or random and either qualitative or quantitative (or continuous). If $X^{(j)}$ is qualitative with k_j levels, we will consider its numeric version using dummy coding of its levels and equivalently introduce $k_j - 1$ binary variables, only one of which is "on" at a time: $(\mathbb{I}_{\{X^{(j)}=h\}})_{1\le h\le k_j-1}$. If $X^{(j)}$ is quantitative, we will assume it is a standardized variable. n will denote the number of joined observations of $(Y_i, \boldsymbol{X}_i)_{1\le i\le n}$. In our dataset, $n = 89$. We will make the assumptions that $(Y_i, \boldsymbol{X}_i)_{1\le i\le n}$ are independent observations of (Y, X) and are not subject to measurement uncertainty.

Regarding the data $(Y_i, \boldsymbol{X}_i)_{1\le i\le n}$, we seek for a function, denoted by $f(\boldsymbol{X})$ (sometimes called a "classifier" since Y is a binary variable), for predicting Y given the predictor inputs $\boldsymbol{X}$. In the literature, this issue is called a "supervised" learning problem because of the presence of the two possible outcomes for Y (or equivalently for Z or $\tilde{Z}$) to guide the learning process and build classification function $f(.)$. Depending on the type of algorithm, $f(.)$ can predict either directly a value $\hat{Y}_i = f(\boldsymbol{X}_i) \in \{AT; BT\}$, $1 \le i \le n$, or an estimated probability that Y_i equals AT depending on $\boldsymbol{X}_i$. In that case, our decision rule will be to assign value AT if the estimated probability is higher than 0.35 (this conservative value has been tuned to obtain the best results in terms of performance indicators – see Sections 3.1 and 3.2).

2.2 *Logistic regression, stepwise, LASSO, Ridge, PLS and Sparse PLS*

From a general point of view, the logistic regression model can be used to estimate the probability of a binary response based on one or more predictor variables. A standard parametrization uses the logit function to link the target probability $\mathbb{P}(Y = AT \mid \boldsymbol{X}) = \mathbb{P}(Z = 1 \mid \boldsymbol{X})$ with predictors $\boldsymbol{X}$:

$$\begin{aligned} \log it\left(\mathbb{P}(Z=1\mid \boldsymbol{X})\right) &= \log\left(\frac{\mathbb{P}(Z=1\mid \boldsymbol{X})}{1-\mathbb{P}(Z=1\mid \boldsymbol{X})}\right) \\ &= \beta_0 + \sum_{j=1}^{p}\beta_j X^{(j)} \end{aligned} \quad (1)$$

$$\Leftrightarrow \left(\mathbb{P}(Z=1\mid \boldsymbol{X})\right) = \frac{\exp\left(\beta_0 + \sum_{j=1}^{p}\beta_j X^{(j)}\right)}{1+\exp\left(\beta_0 + \sum_{j=1}^{p}\beta_j X^{(j)}\right)} \quad (2)$$

with β_0 a constant called intercept and $(\beta_1, \ldots, \beta_p)$ a vector of regression coefficients to be estimated from the data. We will denote $\boldsymbol{\beta} = (\beta_0, \ldots, \beta_p)$.

One interest of this parametric model is its interpretability, since $\exp(\beta_j)$, $1 \le j \le p$, quantifies the increase in $\mathbb{P}(Z = 1 \mid \boldsymbol{X})$ when (supposing) continuous variable $X^{(j)}$ increases by 1 unit.

Regarding $(Z_i, \boldsymbol{X}_i)_{1\le i\le n}$, $\boldsymbol{\beta}$ can be estimated by $\hat{\boldsymbol{\beta}}^{ML}$ using the Maximum Likelihood (ML) statistical inference method:

$$\begin{aligned} \hat{\boldsymbol{\beta}}^{ML} &= \underset{\boldsymbol{\beta}\in\mathbb{R}^{p+1}}{\arg\min}(-2\ell(\boldsymbol{\beta})) \\ &= \underset{\boldsymbol{\beta}\in\mathbb{R}^{p+1}}{\arg\min}\Big(-2\sum_{i=1}^{n} Z_i \log\big(\mathbb{P}(Z_i=1\mid \boldsymbol{X}_i)\big) \\ &\quad + (1-Z_i)\log\big(\mathbb{P}(Z_i=0\mid \boldsymbol{X}_i)\big)\Big) \end{aligned} \quad (3)$$

which is equivalent to:

$$\begin{aligned} \hat{\boldsymbol{\beta}}^{ML} = \underset{\beta_0,\ldots,\beta_p\in\mathbb{R}}{\operatorname{argmin}}\Big(&-2\sum_{i=1}^{n} Z_i\Big(\beta_0 + \sum_{j=1}^{p}\beta_j X^{(j)}\Big) \\ &- \log\Big(1+\exp\Big(\beta_0 + \sum_{j=1}^{p}\beta_j X^{(j)}\Big)\Big)\Big) \end{aligned} \quad (4)$$

where $\ell(\boldsymbol{\beta})$ denotes the log-likelihood function.

In order to improve the prediction accuracy and the interpretability of regression models, it may be interesting to alter the model fitting process to select only a subset of the provided predictors $\boldsymbol{X}$ for use in the final model rather than using all of the $X^{(j)}$, $1 \le j \le p$. A standard procedure for subset selection is the stepwise-selection strategy. The forward-stepwise selection starts with the intercept β_0, and then sequentially adds into the model the predictor that most improves the fit. The backward-stepwise selection starts with the full model including $\boldsymbol{X}$, and sequentially deletes the predictor that has the least impact on the fit. We used a hybrid stepwise-selection strategy that considers both forward and backward moves at each step, and selects the "best" of the two. The step function uses the Akaike Information Criterion (AIC) for weighing the choices, which takes proper account of the number of parameters to be fitted. At each step, an add or drop will be performed that minimizes the AIC score:

$$\mathrm{AIC} = 2(p^* + 1) - 2\ell(\hat{\boldsymbol{\beta}}^{ML}) \tag{5}$$

with $1 \le p^* \le p$ the number of predictors included in the model.

Because it is a discrete process—variables are either retained or discarded, stepwise procedure may not reduce the prediction error of the full model. Shrinkage methods are more continuous and do not suffer as much from high variability. Several shrinkage variants of the logistic regression are available. LASSO (for Least Absolute Shrinkage and Selection Operator) shrinks the regression coefficients $\boldsymbol{\beta}$ by imposing a $\mathbb{L}_1$ penalty on their size. It forces the sum of the absolute value of the regression coefficients to be less than a fixed value, which forces certain coefficients to be set to zero, effectively choosing a simpler model that does not include those coefficients:

$$\hat{\boldsymbol{\beta}}^{LASSO} = \underset{\boldsymbol{\beta}\in\mathbb{R}^{p+1}}{\operatorname{argmin}}(-2\ell(\boldsymbol{\beta})) \text{ subject to } \sum_{j=1}^{p} |\beta_j| \le t \tag{6}$$

The smaller the value of the tuning parameter t, the fewer the number of nonzero components in $\hat{\boldsymbol{\beta}}^{LASSO}$, thus leading to what is called "sparse" models. Thus LASSO does a kind of continuous subset selection. If t is chosen larger than $\sum_{j=1}^{p} \left|\hat{\beta}_j^{ML}\right|$, LASSO estimates are the same as the ML's. For $t = \frac{\sum_{j=1}^{p} \left|\hat{\beta}_j^{ML}\right|}{2}$ say, then the ML coefficients are shrunk by about 50% on average. Parameter t has to be carefully chosen in order to minimize an estimate of expected prediction error.

A "good" value of t can be obtained by cross-validation. Cross-validation is a general process which can be applied to many types of issues. It consists in dividing the dataset $(Z_i, \boldsymbol{X}_i)_{1\le i\le n}$ randomly into a certain number of equal parts, say 10. LASSO regression with a given value for t is fitted with the nine-tenths of the data (this dataset is called the "training dataset"), and the prediction error is computed on the remaining one-tenth (called the "test observations"). This process is done in turn for each one-tenth of the data, and the ten prediction error estimates are averaged. From this we can obtain an estimated prediction error curve as a function of t, enabling to identify a relevant value for t minimizing the estimated prediction error.

Ridge is another shrinkage method, but it shrinks the regression coefficients $\boldsymbol{\beta}$ by imposing a $\mathbb{L}_2$ penalty on their size:

$$\hat{\boldsymbol{\beta}}^{Ridge} = \underset{\boldsymbol{\beta}\in\mathbb{R}^{p+1}}{\operatorname{argmin}}(-2\ell(\boldsymbol{\beta})) \text{ subject to } \sum_{j=1}^{p} \beta_j^2 \le t \tag{7}$$

Contrary to LASSO and because of the $\mathbb{L}_2$ penalty, Ridge shrinks the size of the coefficients, but it does not set any of them to zero.

When there are many correlated predictors in a regression model (also called multicollinearity among $\boldsymbol{X}$), their coefficients $\boldsymbol{\beta}$ can become poorly determined. In this situation the coefficient estimates $\hat{\boldsymbol{\beta}}$ of the regression may change erratically in response to small changes in the model or the data and thus may suffer from unstability. By imposing a size constraint on the number of coefficients to be estimated, as in (6) or (7), this problem is alleviated. However another solution is to consider m new inputs, $1 \le m \le p$, denoted by $T^{(j)}$, $1 \le j \le m$, derived from the original predictors $\boldsymbol{X}$ and used in place of the $X^{(j)}$, $1 \le j \le p$, in the regression model:

$$\begin{aligned} \operatorname{logit}\left(\mathbb{P}\left(Z=1|\boldsymbol{T}\right)\right) &= \log\left(\frac{\mathbb{P}\left(Z=1|\boldsymbol{T}\right)}{1-\mathbb{P}\left(Z=1|\boldsymbol{T}\right)}\right) \\ &= \beta_0 + \sum_{j=1}^{m} \beta_j T^{(j)} \end{aligned} \tag{8}$$

Generally, m is chosen to be small and the $T^{(j)}$, $1 \le j \le m$, are orthogonal linear combinations of the $X^{(j)}$, $1 \le j \le p$, in order to avoid estimation unstability.

Partial Least Squares (PLS) constructs a set of linear combinations of the inputs for regression, by using Y in addition to $\boldsymbol{X}$ for this construction. It finds a linear regression model by projecting Y and $\boldsymbol{X}$ to a new space. It tries to find the multidimensional direction in the $\boldsymbol{X}$-space that explains the maximum multidimensional variance direction in the Y-space. A detailed mathematical description of how the $T^{(j)}$, $1 \le j \le m$, are defined can be found in (Wold et al. 1983).

Sparse PLS is a hybrid method, which can be viewed as a combination of LASSO and PLS. Details on this approach can be found in (Chun et al. 2010).

Stepwise, LASSO, Ridge, PLS and Sparse PLS are all variants of the logistic regression and they share the same advantage of being interpretable models, with fully explicit expressions for the estimated target probability depending on $\boldsymbol{X}$.

2.3 *Classification trees, bagging and boosting*

A classification tree is a directed acyclic graph consisting of nodes and directed edges. It has three types of nodes: a root node that has no incoming edges and zero or more outgoing edges; internal nodes, each of which has exactly one incoming edge and two or more outgoing edges; leaf or terminal nodes, each of which has exactly one incoming

edge and no outgoing edges. The full dataset sits at the root node at the top of the tree. Each leaf node is assigned a class label corresponding to one value of the target variable (Y in our case). The non-terminal nodes, which include the root and other internal nodes, contain attribute test conditions based on the predictors $\boldsymbol{X}$ to separate observations that have different characteristics, as shown in Figure 1. Stumps (or decision stumps) are trees with a single split (the root is directly connected to the leaves).

Algorithms for constructing classification trees usually work top-down and recursively, by choosing an input variable among the p and a split-value at each step that best split the set of observations into two data subsets. The process is continued until some stopping rule is applied.

A key advantage of the recursive binary tree is its interpretability, since it finally gives a set of fully understandable decision rules, as illustrated in Figure 1.

Different algorithms use different metrics for measuring "best". These generally measure the homogeneity of the target variable within the subsets. These metrics are applied to each candidate subset, and the resulting values are combined to provide a measure of the quality of the split.

How large should we grow the tree? Clearly a very large tree might overfit the data, while a small tree might not capture the important structure of the dataset $(Y_i, \boldsymbol{X}_i)_{1\le i\le n}$. Tree size is a tuning parameter governing the model's complexity, and a "good" tree size can be adaptively chosen from the data. A strategy is to grow the full initial tree, denoted by T_0, stopping the splitting process only when some minimum node size is reached (in our case 6). Then this large tree is pruned using a process called cost-complexity pruning. We define a subtree $T \subset T_0$ to be any tree that can be obtained by pruning T_0, that is collapsing any number of its internal (non-terminal) nodes. We index terminal nodes by

Figure 1. Illustration of a classification tree.

m, with node m representing data subset S_m. Let $|T|$ denote the number of terminal nodes in T, n_m, $1 \le n_m \le n$, the number of observations in subset S_m and $\hat{\mathbb{P}}_m$ the proportion of observations with value $Y = AT$ in node m: $\hat{\mathbb{P}}_m = \frac{1}{n_m}\sum_{\boldsymbol{X}_i \in S_m} \mathbb{I}_{\{Y_i = AT\}}$. We define the cost complexity criterion by:

$$C_\alpha(T) = \sum_{m=1}^{|T|} n_m Q_m(T) + \alpha|T| \tag{9}$$

where $Q_m(T)$ is an "impurity measure", in our case the Gini index defined by $Q_m(T) = 2\hat{\mathbb{P}}_m\left(1-\hat{\mathbb{P}}_m\right)$. We classify the observations in node m to class $Y = AT$ if $\hat{\mathbb{P}}_m > 0.5$ (that is to say if value $Y = AT$ is majority in node m), and to class $Y = BT$ otherwise. The idea is to find, for each $\alpha > 0$, the subtree $T_\alpha \subseteq T_0$ to minimize $C_\alpha(T)$. The tuning parameter α governs the tradeoff between tree size and goodness of fit to the data. Large values of α result in smaller trees T_α, and conversely for smaller values of α. With $\alpha = 0$, the solution is the full tree T_0. The determination of a "good" value for α can be achieved by cross-validation.

In order to avoid overfitting (see Section 3.2 for a detailed discussion on this issue), bagging (for "bootstrap aggregation") can be used. It consists in drawing randomly with replacement from the original dataset $(Y_i, \boldsymbol{X}_i)_{1\le i\le n}$ a large number $B > 1$ of new datasets of same size n. For each new dataset, a classification tree is built and the final bagged classifier is obtained by selecting the class between $Y = AT$ or $Y = BT$ with the most "votes" from the B trees. A deeper introduction to bagging can be found in (Breiman 1996).

For large problems, the performance of classification trees can be improved using a procedure called boosting. If we consider numerical target variable $\tilde{Z}$ introduced in Section 2.1, given the predictor variables $\boldsymbol{X}$, a classifier $f(\boldsymbol{X})$ produces a prediction taking one of the two values -1 ($Y = BT$) or 1 ($Y = AT$). The error (or misclassification) rate of $f(.)$ on the dataset is $err_n = \frac{1}{n}\sum_{i=1}^{n} \mathbb{I}_{\{Y_i \ne f(\boldsymbol{X}_i)\}}$. A weak classifier is one whose error rate is only slightly better than random guessing. The purpose of boosting is to sequentially apply a weak classification algorithm to repeatedly modified versions of the data, thereby producing a sequence of weak classifiers $f_m(X)$, $1 \le m \le M$. The predictions from all of them are then combined through a weighted majority vote to produce the final prediction:

$$f(\boldsymbol{X}) = \text{sign}\left(\sum_{m=1}^{M} \alpha_m f_m(\boldsymbol{X})\right) \tag{10}$$

where $\alpha_1, \ldots, \alpha_m$ weight the contribution of each respective $f_m(\boldsymbol{X})$. Their effect is to give higher influence to the more accurate classifiers in the sequence. The data modifications at each boosting step consist of applying weights $\omega_1, \ldots, \omega_n$ to

each of the observations $(Y_i, \boldsymbol{X}_i)_{1\le i\le n}$. Initially all of the weights are set to $\omega_i = \frac{1}{n}$, so that the first step simply trains the classifier on the data in the usual manner. For each successive iteration $m = 2,\ldots,M$, the observation weights are individually modified and the classification algorithm is reapplied to the weighted observations. At step m, those observations that were misclassified by the classifier $f_{m-1}(\boldsymbol{X})$ induced at the previous step have their weights increased, whereas the weights are decreased for those that were classified correctly. Thus as iterations proceed, observations that are difficult to classify correctly receive ever-increasing influence. Each successive classifier is thereby forced to concentrate on those training observations that are missed by previous ones in the sequence.

In our study, we used stumps as weak classifiers, $\alpha_m = \log\left(\frac{1-err_m}{err_m}\right)$ with $err_m = \frac{\sum_{i=1}^{n}\omega_i \mathbb{I}_{\{Y_i \neq f_m(X_i)\}}}{\sum_{i=1}^{n}\omega_i}$ and for each successive iteration $m = 2,\ldots,M$, the observation weights were modified as follows: $\omega_i \leftarrow \omega_i \exp\left(\alpha_m \mathbb{I}_{\{Y_i \neq f_m(X_i)\}}\right), 1 \le i \le n$.

Contrary to standard binary trees, bagging and boosting techniques lead to classification rules that are not easy to interpret. Indeed, since they aggregate results obtained from different trees, it is difficult to identify how the inputs concretely affect the output.

2.4 *Neural networks*

The name "neural networks" derives from the fact that they were first developed as models for the human brain. Each unit within the model represents a neuron and the connections (links in Figure 2) represent synapses. The term neural network encompasses a large class of models. Here we describe the most widely used neural network, often called the "single hidden layer back-propagation network" or the "single layer perceptron".

The central idea is to extract linear combinations of the inputs as derived features, and then model the target as a nonlinear function of these features. More formally, in our case, a neural network is a two-stage classification model. Derived features $\sigma(\sum ne_j\omega_j)$ and $\sigma(\sum ne_j\gamma_j)$ are created from linear combination of the inputs $\left(X^{(1)}, \quad , X^{(p)}\right) = \left(ne_1, \quad , ne_p\right)$ and then output Z is modeled as a function of linear combinations of these derived features: $g\left(\Theta\sigma\left(\sum ne_j\omega_j\right) + \Psi\sigma\left(\sum ne_j\gamma_j\right)\right)$.

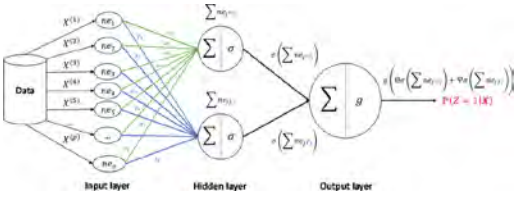

Figure 2. Illustration of a neural network.

$\sigma(.)$ is called the activation function and is usually chosen to be the sigmoid: $\sigma(v) = \frac{1}{1+\exp(-v)}$. $g(.)$ allows a final transformation and is usually chosen to be the logistic. $\boldsymbol{\beta} = \left(\left(\omega_j, \gamma_j\right)_{1\le j\le p}, \Theta, \Psi\right)$ are unknown parameters, often called weights, and we seek values for them that make the model fit the data "well", for instance by minimizing twice the opposite of the log-likelihood function $\ell(\boldsymbol{\beta})$ defined in Equation (3). The generic approach to this optimization problem is by gradient descent, called back-propagation in this setting. Because of the compositional form of the model, the gradient can be easily derived using the chain rule for differentiation. This can be computed by a forward and backward sweep over the network, keeping track only of quantities local to each unit. Details on the back-propagation algorithm can be found in (Rumelhart et al. 1986).

In our specific case, a neural network can be seen as a nonlinear generalization of the logistic regression model presented in Section 2.2. However, it lacks its interpretability and is often perceived as the "ultimate black-box model".

2.5 *Support vector machine*

In our classification context, a Support Vector Machine (SVM) consists of constructing a hyperplane that separates the data into two classes corresponding to the possible values for Y. Intuitively, if we suppose the two classes are linearly separable, a good separation is achieved by the hyperplane that has the largest distance to the nearest data point of any class, as in Figure 3.

More formally, a hyperplan is defined by:

$$\left\{\boldsymbol{X} \in \mathbb{R}^p : h(\boldsymbol{X}) = \beta_0 + \sum_{j=1}^{p}\beta_j X^{(j)} = \beta_0 + \boldsymbol{X}^T\boldsymbol{\beta} = 0\right\} \tag{11}$$

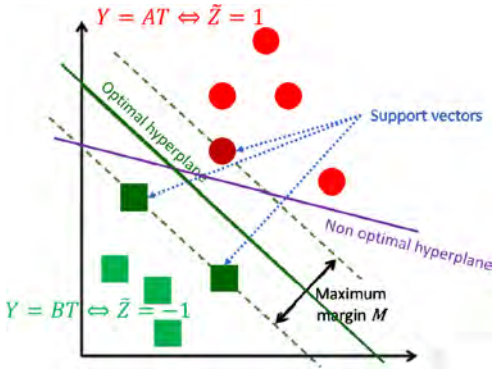

Figure 3. Illustration of an optimal separating hyperplane (in green) and a non optimal one (in purple).

with $\boldsymbol{\beta}$ a unit vector: $\boldsymbol{\beta} = 1$. If we consider target variable $\tilde{Z}$, the classification rule induced by $h(.)$ is $f(\boldsymbol{X}) = \text{sign}(\beta_0 + \boldsymbol{X}^T\boldsymbol{\beta})$.

If the two classes are separable, we want to find a function $h(\boldsymbol{X}) = \beta_0 + \boldsymbol{X}^T\boldsymbol{\beta}$ with $\tilde{Z}_i h(\boldsymbol{X}_i) > 0, \forall i = 1,\ldots,n$, that creates the biggest margin M between the data for class −1 and 1. The following optimization problem formalizes this idea:

$$\max_{\beta_0 \in \mathbb{R}, \boldsymbol{\beta} \in \mathbb{R}^p} (M) \text{ subject to } \tilde{Z}_i(\beta_0 + \boldsymbol{X}_i^T\boldsymbol{\beta}) > M, 1 \le i \le n. \tag{12}$$

If the two classes overlap, one way to deal with this overlap is to still maximize margin M, but allow for some points to be on the wrong side of the margin. Define the slack variables $\boldsymbol{\xi} = (\xi_1, \ldots, \xi_n)$. One way to modify the constraint in Equation (12) is:

$$\tilde{Z}_i(\beta_0 + \boldsymbol{X}_i^T\boldsymbol{\beta}) > M(1 - \xi_i), \forall i = 1,\ldots,n \tag{13}$$

with $\xi_i \ge 0, 1 \le i \le n$, and $\sum_{i=1}^n \xi_i \le$ constant. ξ_i in constraint (13) is the proportional amount by which the prediction $h(\boldsymbol{X}_i)$ is on the wrong side of its margin. Hence by bounding the sum $\sum_{i=1}^n \xi_i$, we bound the total proportional amount by which predictions fall on the wrong side of their margin. Misclassifications occur when $\xi_i > 1$, so bounding $\sum_{i=1}^n \xi_i$ at a value C say, bounds the total number of misclassifications at C.

Whereas the original problem may be stated in the original space, it often happens that the two sets to discriminate are not linearly separable in that space. For this reason, it is proposed that the original finite dimensional space be mapped into a much higher dimensional space, presumably making the linear separation easier in that space, as illustrated in Figure 4. This transformation is called the "kernel trick".

To keep the computational load reasonable, the mappings used by SVM schemes are designed to ensure that dot products may be computed easily in terms of the variables in the original space, by defining them in terms of a kernel function $\phi(\boldsymbol{X}, \boldsymbol{U})$ selected to suit the problem. The hyperplanes in the higher dimensional space (which may be nonlinear in the original input space) are defined as the set of points whose dot product with a vector in that space is constant. The vectors defining the hyperplanes can be chosen to be linear combinations with parameters α_i of images of feature vectors $\boldsymbol{X}_i, 1 \le i \le n$. With this choice of a hyperplane, the points $\boldsymbol{X}$ in the feature space that are mapped into the hyperplane are defined by the relation: $\sum_i \alpha_i \phi(\boldsymbol{X}_i, \boldsymbol{X}) = \text{constant}$. If $\phi(\boldsymbol{X}, \boldsymbol{U})$ becomes small as $\boldsymbol{U}$ grows further away from $\boldsymbol{X}$, each term in the sum measures the degree of closeness of the point $\boldsymbol{X}$ to the corresponding data base point $\boldsymbol{X}_i$. In this way, the sum of kernels above can be used to measure the relative nearness of each test point to the data points originating in one or the other of the sets to be discriminated. In our case, we tested four different kernel functions: linear $\phi(\boldsymbol{X}, \boldsymbol{U}) = \boldsymbol{X}^T\boldsymbol{U}$, Gaussian radial $\phi(\boldsymbol{X}, \boldsymbol{U}) = \exp(-\sigma\boldsymbol{X} - \boldsymbol{U}^2), \sigma \in \mathbb{R}$, inhomogeneous polynomial (of order $d \in \mathbb{N}$) $\phi(\boldsymbol{X}, \boldsymbol{U}) = (\gamma \boldsymbol{X}^T\boldsymbol{U} + r)^d, \gamma, r \in \mathbb{R}$, and hyperbolic tangent $\phi(\boldsymbol{X}, \boldsymbol{U}) = \tanh(\kappa \boldsymbol{X}^T\boldsymbol{U} + \theta), \kappa, \theta \in \mathbb{R}$. We chose $d = 2$ and "good" values for tuning parameters $\sigma, \gamma, r, \kappa$ and θ minimizing the estimated prediction error can be found by cross-validation as presented in Section 2.2. Further elements on SVM can be found in (Burges 1998).

As for neural networks, SVM provides a "black-box model" which does not allow any interpretable description of how the inputs affect the output.

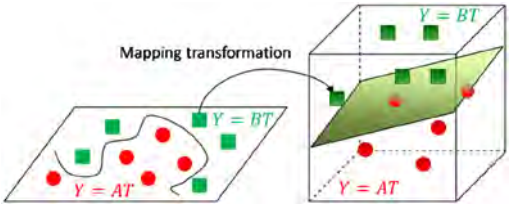

Figure 4. Illustration of the mapping transformation.

3 RESULTS

3.1 *Performance indicators*

Before showing the results obtained with the different families of machine learning algorithms presented in the previous sections, one must introduce indicators that will allow to assess and compare the performance of the techniques on the dataset.

These indicators are based on the "confusion matrix" (also called "error matrix") presented in Table 1. Once the prediction function $f(.)$ has been built using one of the available machine learning algorithms, it is easy to compare for each observation $(Y_i, \boldsymbol{X}_i)_{1 \le i \le n}$ if the predicted value $\hat{Y}_i = f(\boldsymbol{X}_i)$ is the same as the real Y_i observed in the dataset. Each row of the matrix represents the instances in a class predicted with the model while each column represents the instances in an actual class.
with $TP + FP + FN + TN = n$.

Error rate or misclassification rate on the dataset is defined as:

$$err_n = \frac{1}{n}\sum_{i=1}^n \mathbb{I}_{\{Y_i \ne f(\boldsymbol{X}_i)\}} = \frac{1}{n}\sum_{i=1}^n \mathbb{I}_{\{Y_i \ne \hat{Y}_i\}} = \frac{FP + FN}{TP + FP + FN + TN} \tag{14}$$

err_n lies between 0 and 100% and the lower err_n is, the better classifier $f(.)$ fits the data from a general point of view. Since the case when the

Table 1. Illustration of a confusion matrix.

		Actual class	
		$Y = AT$	$Y = BT$
Predicted class	$\hat{Y} = AT$	True Positive (TP)	False Positive (FP)
	$\hat{Y} = BT$	False Negative (FN)	True Negative (TN)

indicator characterizing the state of the reactor during its shutdown exceeds the fixed threshold is more critical than the other one, we prefer to correctly predict the class $Y = AT$ and that is why we also introduce the sensitivity defined as:

$$se_n = \frac{TP}{TP + FN} \tag{15}$$

se_n lies between 0 and 100% and the higher se_n is, the better classifier $f(.)$ is able to predict the observations where $Y_i = AT$, among the n of the dataset $\left(Y_i, \boldsymbol{X}_i\right)_{1 \le i \le n}$.

3.2 *Overfitting and bootstrap*

A prediction model $f(.)$ is built using some set of "training data", that is to say exemplary situations for which the desired output is known. Of course, the goal is that $f(.)$ has good performance on the training dataset but also performs well on predicting the output when fed "validation data" (or "test data") that was not encountered during its training. "Overfitting" (sometimes called "overtraining") is the production of a prediction model that corresponds too closely or exactly to a particular set of data, and may therefore fail to fit additional new data or predict future observations reliably. Overfitting occurs when a model begins to "memorize" training data rather than "learning" to generalize from a trend. The potential for overfitting depends not only on the number of parameters and data but also the conformability of the model structure with the data shape, and the magnitude of model error compared to the expected level of noise or error in the data. To lessen the chance of, or amount of, overfitting, several techniques are available, among which cross-validation, as introduced in Section 2.2, or bootstrap. These procedures consist of testing the model's ability to generalize by evaluating its performance on a set of data not used for training, which is assumed to approximate the typical unseen data that a model will encounter.

The basic idea of a bootstrap iteration, indexed by $b, 1 \le b \le B$, is to randomly draw without replacement from the original data $\left(Y_i, \boldsymbol{X}_i\right)_{1 \le i \le n}$ two complementary subsets: one training subset, of size $1 < N < n$ (in our case $N = \frac{3}{4} n$), which will be used to fit prediction model $f(.)$, and one validation subset, of size $n - N$, on which $f(.)$ will be applied to assess its performance on data that were not used to train it. On this test subset, one can evaluate error rate err_b and sensitivity se_b using Formulas (14) and (15) applied to the $n - N$ validation data. This is done B times (in our case $B = 1000$), producing B bootstrap training and validation datasets. We refit the model to each of the B bootstrap learning datasets and systematically test it on the B bootstrap test datasets, leading to B values for error rate and sensitivity $\left(err_b, se_b\right)_{1 \le b \le B}$. From these B values, one can assess the bootstrap average error rate and the bootstrap average sensitivity:

$$\widehat{err}_{Boot} = \frac{1}{B} \sum_{b=1}^{B} err_b \quad \text{and} \quad \widehat{se}_{Boot} = \frac{1}{B} \sum_{b=1}^{B} se_b \tag{16}$$

These two quantities better estimate the "real" performance of classifier $f(.)$ than err_n and se_n do and easily allow to identify a potential overfitting issue if $\left(\widehat{err}_{Boot}, \widehat{se}_{Boot}\right)$ is far from $\left(err_n, se_n\right)$.

3.3 *Results*

To implement the different algorithms, we used R, an open source language and software environment for statistical computing (https://www.r-project.org/). More precisely, the following packages were used: 'stats' for stepwise logistic regression, 'glmnet' for Ridge and LASSO, 'plsRglm' for PLS, 'spls' for Sparse PLS, 'rpart' for classification trees, 'adabag' for bagging, 'ada' for boosting, 'nnet' for neural network and 'e1071' for the different SVM versions.

Table 2 gives the performance indicators $\left(\widehat{err}_{Boot}, \widehat{se}_{Boot}\right)$ for each of the machine learning algorithms that have been applied to our dataset.

Table 2. Summary of the results obtained with the different algorithms.

Algorithm	$\widehat{err}_{Boot}$ (%)	$\widehat{se}_{Boot}$ (%)
Stepwise	4.49	92.59
Ridge	13.48	66.67
LASSO	10.11	74.07
PLS	3.38	93.24
Sparse PLS	14.61	93.87
Classification tree	5.72	96.15
Bagging	5.61	95.71
Boosting	**3.37**	**96.32**
Neural network	4.69	96.17
Linear SVM	4.39	90.86
Gaussian radial SVM	3.46	91.03
Polynomial SVM	5.62	88.89
Hyperbolic tangent SVM	7.86	85.11

4 DISCUSSION

Boosting is the most efficient approach, with both the lowest $\widehat{err}_{Boot}$ and the highest $\widehat{se}_{Boot}$. PLS logistic regression and neural network come in second position. Classification tree and bagging have promising sensitivity but somewhat disappointing error rate. The different SVM kernels give quite close medium results. The two shrinkage variants of the logistic regression, Ridge and LASSO, give the worst models, quite far behind all the other techniques.

Based on this single study, it is of course impossible to draw any general conclusions about the potential superiority of one algorithm over the others. Many other numerical tests should be carried out on simulated (and not real industrial) data to achieve such an ambitious goal. Nevertheless it is interesting to highlight that the performance indicators are rather good, even excellent, compared with the size of the dataset. Indeed, in our case, we are far from what is called "big data", since we only have $n = 89$ observations and $p = 25$ variables to predict our binary target output. This finding runs counter the popular belief that machine learning algorithms necessarily require a huge amount of data. Nevertheless one must not be mistaken: it is unrealistic to imagine these black-boxes will solve any problems and always be efficient, even with little data.

From the perspective of the decision maker, even if boosting is the most efficient algorithm in our case study, he may prefer a more interpretable model, such as the PLS logistic regression. Indeed this approach has a quite honorable prediction performance and provides at the same time an interpretable description of how the inputs affect the output (see Equation (8)). If the interpretability and the explanation of the fundamental principles of the model are not necessary in various fields, they become significant arguments when trackability, auditability, transparency or physical justification are required, as in nuclear industry.

Otherwise it is often pointed out that machine learning algorithms are greedy ones requiring prohibitive computational time and/or memory to train the models or predict the outputs. With our small dataset, it was not an issue on a standard computer, even when carrying out bootstrap procedure. We should also mention that open source statistical software, such as R, make such machine learning algorithms financially accessible to any companies, even if their use requires relevant expertise in order to properly parametrize the algorithms and avoid the potential pitfalls (for instance overfitting). The transferability outside R&D divisions of such black-box predictive models is also a real issue, in particular to engineering divisions which often only have spreadsheet application software to make calculations.

Last but not least: before applying any machine learning algorithm, quality of the input data must first be ensured. Moreover, it can only be profitable that the data scientist, who designs and manipulates these black-boxes, discusses with the experts of the technical application field.

5 CONCLUSION AND PROSPECTS

Thirteen supervised machine learning techniques have been tested on a real dataset from the nuclear industry. The fundamental principles of these algorithms have been presented and their prediction performance has been assessed on the case study.

The most efficient methods give really promising results, especially compared to the small size of the available data. Nevertheless one would be well advised not to draw any general conclusions about the efficiency of these techniques.

Several prospects and extensions of this study can be envisaged. Other machine learning algorithms, such as discriminant analysis or random forests, could be tested on the same dataset to assess how they perform. An intensive study based on simulated data could also be carried out to try to identify if some algorithms are more efficient than others on datasets with characteristics close to those met in the nuclear industry.

New resilience performance indices based on the *k*-terminal reliability of the complete graph

C. Tanguy
Orange Labs, Orange/IMT/OLN/GDM/TRM, Châtillon, France

ABSTRACT: In network reliability, the best-known performance measure is the so-called all-terminal reliability $\mathrm{Rel}_A(G)$, i.e., the probability that all the nodes of the network (or its underlying graph G) are connected. A particular family of graphs, namely the complete graphs K_n, in which each node is connected to the $n-1$ others, have long been a key issue in this field. Brown, Cox and Ehrenborg have recently proposed new performance indices for networks based on the all-terminal reliability $\mathrm{Rel}_A(K_n)$: (i) the average reliability $\overline{\mathrm{Rel}_A}(K_n)$, (ii) the "average of the average" all-terminal reliability AvgAvg (G, n) of all the graphs with n vertices and at most one edge between two nodes. They showed that as n increases, these measures tend to 1. In this work, we generalize their idea to the *k*-terminal reliability—the probability that k nodes are connected—which can also be used to describe a network's resilience. The new measures can be derived from the *k*-terminal reliability of the complete graph. Since we are interested in the application of these indices to large systems (n >> 1), we have performed numerical investigations to assess their variations with n. We have identified the leading, analytical correction (in $1/n$) to unity. This corroborates a previous conjecture made on the asymptotic value of $\overline{\mathrm{Rel}_A}(K_n)$. These new results could be helpful as simple, ready-to-use evaluations/orders of magnitude of the resilience of a network, when its size is so large as to make exact or approximate computations either impossible or very cumbersome.

1 INTRODUCTION

Complete graphs are graphs in which each vertex is connected to all other vertices (see Figure 1 for the first examples of K_n, the complete graph with n vertices). They have attracted interest for a very long time. Among the pioneering papers on random graphs (Erdös and Rényi 1959, Gilbert 1959), one focused on the possible application to the probability P_N that N telephone central offices can call each other (Gilbert 1959), or that two offices can be connected (with probability R_N), assuming that the probability of connection between two nodes is p. The following simple expressions were given (Gilbert 1959, Frank and Gaul 1982)

$$P_N \sim 1 - N q^{N-1}, \tag{1}$$

$$R_N \sim 1 - 2q^{N-1}, \tag{2}$$

where $q = 1 - p$.

More recently, complete graphs K_n have been investigated in the context of the resilience of large networks (Sekine and Imai 1998, Imai et al. 1999, Tsitsiashvili 2011), and in particular for wireless networks (Park 2016). They also appear in performance measures recently defined by Brown and collaborators (Cox 2013, Brown et al. 2014).

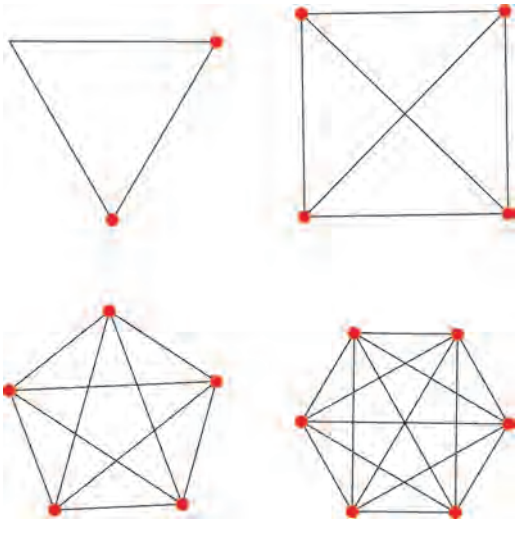

Figure 1. First complete graphs K_n ($3 \le n \le 6$).

The first one is simply the average all-terminal reliability of a graph G over the interval [0,1]:

$$\overline{\mathrm{Rel}_A}(G) = \int_0^1 \mathrm{Rel}_A(G;p)\,dp. \tag{3}$$

The second one is the "average of the average" reliability of simple graphs (a "simple" graph is such that there is at most one link/edge between two given vertices) G with n vertices, AvgAvg(G, n), which can be expressed (Cox 2013) as

$$\mathrm{AvgAvg}(G,n) = 2\int_0^{1/2} \mathrm{Rel}_A\left(K_n;p\right)dp. \quad (4)$$

Cox and collaborators (Cox 2013, Brown et al. 2014) showed that in the $n \to \infty$ limit, these two averages should go to one.

Multicast procedures in modern networks call for accurate assessments of the k-terminal reliabilities $\mathrm{Rel}_k(p)$ too. Let us recall that the k-terminal reliability is the probability that the k vertices of interest are connected. In this context, it is hardy surprising that the resilience of such procedures has stimulated a lot of work, from very mathematical approaches to more pragmatic ones. Its definition may also vary among authors: some of them (Colbourn 1993, Farley and Colbourn 2009) associate it with the number of nodes that are still connected, whereas others (Cox 2013, Brown et al. 2014, Heidtmann 2016) compute it as the average of all possible connections between k nodes of the system.

In a recent work (Tanguy 2017), we improved the asymptotic expansions of P_N and R_N, and generalized them to the k-terminal reliability for the complete graph K_n. We also provided an estimate of the asymptotic expansion of $\overline{Rel_A}\left(K_n\right)$, derived from numerical simulations.

In this work, we have addressed the generalization of equations (3) and (4) to the k-terminal reliability of k specific nodes of the system:

$$\overline{\mathrm{Rel}_k}(G) = \int_0^1 \mathrm{Rel}_k\left(G;p\right)dp. \quad (5)$$

The second generalization is the "average of the average" reliability of simple graphs G with n vertices, AvgAvg(G, n), which can be expressed (Cox 2013) as (see below for a justification)

$$\mathrm{AvgAvg}\left(\mathrm{Rel}_k;G,n\right) = 2\int_0^{1/2} \mathrm{Rel}_k\left(K_n;p\right)dp. \quad (6)$$

When all the link reliabilities are equal to p, all nodes are equivalent. The above expressions give therefore a direct expression for the resilience as viewed by Cox (2013), Brown et al. (2014) and (Heidtmann 2016).

This paper is organized as follows: we describe in Section 2 how to compute the k-terminal reliability for the complete graph K_n, and the associated averages. We then show in Section 3 a few figures showing how these averages approach 1 when n goes to infinity. We describe in Section 4 the determination of the first-order correction to unity for several values of k, from which we propose a closed-formed expression. We finally apply these results to the case of the all-terminal reliability of the complete graph K_n.

2 MATHEMATICAL PROCEDURES AND DEFINITIONS

2.1 *Asymptotic expansions of the reliabilities of the complete graph K_n*

The all-terminal reliability $\mathrm{Rel}_A\left(K_n;p\right) \equiv A_n$ can be obtained recursively by (Gilbert 1959).

$$A_n = 1 - \sum_{j=1}^{n} C_{n-1}^{j-1} A_j (1-p)^{j(n-j)}, \quad (7)$$

$$A_1 = 1, \quad (8)$$

where C_n^k is the binomial coefficient

$$C_n^k = \frac{n!}{(n-k)!k!}. \quad (9)$$

The k-terminal reliability $\mathrm{Rel}_k\left(K_n;p\right) \equiv B_n$ is *then* deduced from all the A_j's ($1 \le j \le n$) by

$$B_n = \sum_{j=k}^{n} C_{n-k}^{j-k} A_j (1-p)^{j(n-j)}, \quad (10)$$

2.2 *Asymptotic expansions of A_n and B_n*

In our previous work (Tanguy 2017), we extended Gilbert's results (Gilbert 1959) for the asymptotic expansions in the case of large n and fixed q's.

$$A_n \to 1 - n q^{n-1} + \frac{n(n-1)}{2}\left(-1+2q\right)q^{2n-4} + \cdots. \quad (11)$$

from which we derived

$$B_n \to 1 - k\,q^{n-1} + q^{2n-4}\left\{C_k^2 - k\left(n-1\right)\left(1-q\right) + C_{n-k}^{2-k}\left(1-q\right)\right\} + \cdots. \quad (12)$$

Equation (12) will be used in the following.

2.3 *Average k-terminal reliabilities*

We first start by defining, for k specific nodes,

$$\overline{\mathrm{Rel}_k}\left(K_n\right) = \int_0^1 \mathrm{Rel}_k\left(K_n;p\right)dp. \quad (13)$$

The second generalization is the "average of the average" reliability of simple graphs G

with n vertices, AvgAvg(G, n), which can be expressed (Cox 2013) as

$$\mathrm{AvgAvg}\left(\mathrm{Rel}_k;G,n\right)=\int_0^1 \mathrm{Rel}_k\left(K_n;p/2\right)dp. \qquad (14)$$

The origin of equation (14) is simple: all the k-terminal reliabilities are affine functions of each individual link reliability. Since we consider all possible graphs on n vertices, each link will be present (or not). The average is thus given by the corresponding reliability of the complete graph K_n, for which each link has a reliability equal to $(0+p)/2 = p/2$. We can thus write

$$\mathrm{AvgAvg}\left(\mathrm{Rel}_k;G,n\right)=2\int_0^{1/2} \mathrm{Rel}_k\left(K_n;t\right)dt. \qquad (15)$$

We deduce that

$$\mathrm{AvgAvg}\left(\mathrm{Rel}_k;G,n\right)=2\overline{\mathrm{Rel}_k}\left(K_n\right)-1 + 2\int_{1/2}^1\left(1-\mathrm{Rel}_k\left(K_n;t\right)\right)dt. \qquad (16)$$

Because of equation (12), the last integral in the above equation vanishes as $(2\,k)/(n\,2^n)$ when n goes to infinity. Consequently, the asymptotic expansions of the averages are linked by

$$1-\mathrm{AvgAvg}\left(\mathrm{Rel}_k;G,n\right)\sim 2\left(1-\overline{\mathrm{Rel}_k}\left(K_n\right)\right). \qquad (17)$$

By studying the behavior of $\overline{\mathrm{Rel}_k}\left(K_n\right)$ when $n \gg 1$, we can get the asymptotic expansion of AvgAvg(Rel_k; G, n) too.

3 EXAMPLES FOR $2 \le K \le 4$

In this section, we present the results of our numerical calculations of $\overline{\mathrm{Rel}_k}\left(K_n\right)$ and AvgAvg(Rel_k; G, n) as functions of n, for the first values of k.

We obtained the different $\mathrm{Rel}_k(K_n; p)$ from equation (10). Since they are polynomials in p with integral coefficients, the integrals in equations (13) and (14) were easily obtained.

3.1 $\overline{Rel_k}\left(K_n\right)$

We have represented in Figures 2–4 their variations with n. Obviously, these quantities go rapidly to 1, so much so that the curves cannot be distinguished from unity when $n \ge 200$.

3.2 *AvgAvg(Rel$_k$; G, n)*

We have displayed in Figures 5–7 the variation with n of AvgAvg(Rel_k; G, n) for $2 \le k \le 4$. Even though

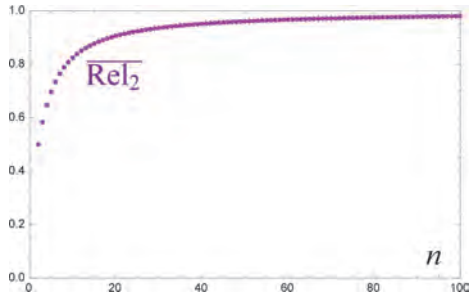

Figure 2. Variation of $\overline{\mathrm{Rel}_2}\left(K_n\right)$ with n.

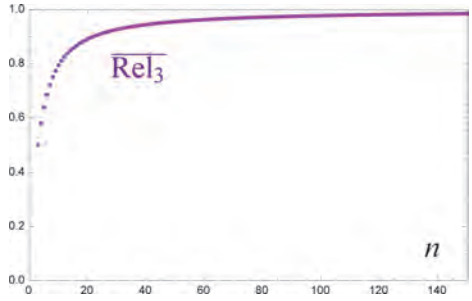

Figure 3. Variation of $\overline{\mathrm{Rel}_3}\left(K_n\right)$ with n.

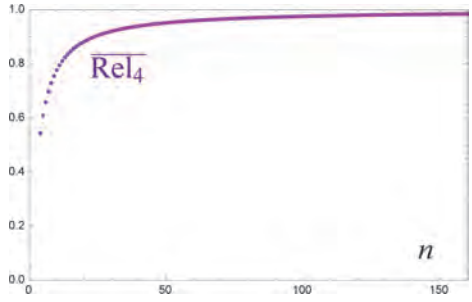

Figure 4. Variation of $\overline{\mathrm{Rel}_4}\left(K_n\right)$ with n.

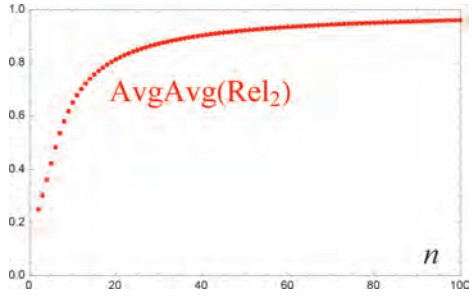

Figure 5. Variation of AvgAvg(Rel_2; G, n) with n.

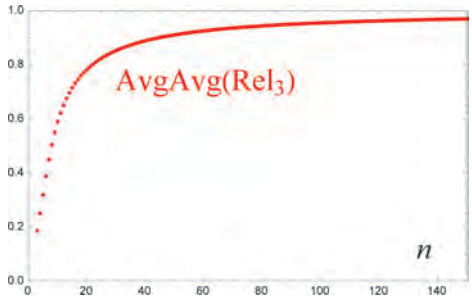

Figure 6. Variation of AvgAvg(Rel_3; G, n) with n.

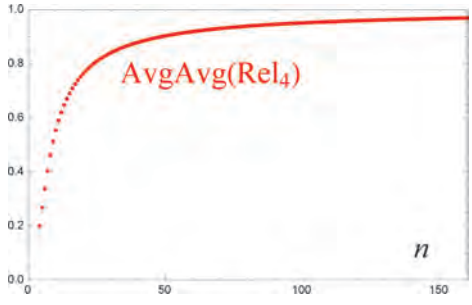

Figure 7. Variation of AvgAvg(Rel_4; G, n) with n.

the values go to 1 as n increases, they do so less rapidly than the average reliabilities of the preceding paragraph, in agreement with equation (17).

4 ASYMPTOTIC EXPANSIONS OF THE AVERAGES

From the numerical values obtained in Section 3, we were able to see that

$$\overline{\mathrm{Rel}_k}(K_n) = 1 - \frac{C_k}{n} + o\left(\frac{1}{n}\right). \tag{18}$$

The determination of C_k has been done by using "convergence acceleration methods". Even though the convergence to 1 is rather slow, it is possible to assess the limit C_k by using the Richardson extrapolation (Bender and Orszag 1999). Performing these computations, we found that $C_2 \approx 2.00000000$, $C_3 \approx 2.24999999$, and $C_4 \approx 2.4444444$, implying that C_2, C_3 and C_4 may well be 2, $\frac{9}{4}$, and $\frac{22}{9}$, respectively. This was a strong indication that all the C_k's are rational numbers. Using large values of n (up to 700), we were able to increase the accuracy of our evaluations of the first constants, the identifications of which are given in Table 1.

Table 1. Values of the first constants C_k ($2 \le k \le 10$).

k	C_k
2	2
3	$\frac{9}{4}$
4	$\frac{22}{9}$
5	$\frac{125}{48}$
6	$\frac{137}{50}$
7	$\frac{343}{120}$
8	$\frac{726}{245}$
9	$\frac{6849}{2240}$
10	$\frac{7129}{2268}$

The last part of the study was to infer the general formula for C_k. By trial and error, and taking the factorization of the denominators into account, we were able to find that

$$C_k = \frac{k}{k-1} H_{k-1}, \tag{19}$$

where $H_k = 1 + \frac{1}{2} + \cdots + \frac{1}{k}$ is the so-called harmonic number of order k.

As k increases, the precision of C_k gets greater. We have checked that equation (21) still gives satisfactory values; for instance, in the case $k = 150$, the difference between our estimate and C_{150} is less than 10^{-100}.

4.1 *Consequence for* $\overline{Rel_A}(K_n)$

In (Tanguy 2017), we had computed the average $\overline{\mathrm{Rel}_A}(K_n)$ as a function of n, and proposed that

$$\overline{\mathrm{Rel}_A}(K_n) \sim 1 - \frac{ln\, n + \mathbf{C}}{n}, \tag{20}$$

where $\mathbf{C}$ is the Euler gamma constant (using the notation of Gradshteyn and Ryzhik $\mathbf{C} \approx 0.5772156649$). This assumption was correct since for the all-terminal reliability, we have to replace k by n, and because

$$H_n \to \ln n + \mathbf{C} \tag{21}$$

as $n \to \infty$.

4.2 *Asymptotic expansion of* $AvgAvg(Rel_k; G, n)$

If we now turn to AvgAvg(Rel_k; G, n), we deduce from equation (17)

$$\mathrm{AvgAvg}\left(\mathrm{Rel}_k; G, n\right) \sim 1 - \frac{2\,k\,H_{k-1}}{k-1}\frac{1}{n}. \tag{22}$$

A by-product of this expression is of course

$$\mathrm{AvgAvg}\left(\mathrm{Rel}_A; G, n\right) \sim 1 - 2\frac{ln\,n + \boldsymbol{C}}{n}. \tag{23}$$

5 CONCLUSION AND OUTLOOK

We have generalized the asymptotic expansions of (Cox 2013, Brown et al. 2014) for averaged k-terminal reliabilities of the complete graph K_n, which are performance measures recently introduced for the resilience of large networks. The first correction to unity, as n goes to infinity, has a very simple form, and confirms the assumption made in a previous work (Tanguy 2017) on the averaged all-terminal reliability for the complete graph. Other performance measures for the complete graph are currently under investigation, and will be presented elsewhere.

ACKNOWLEDGMENTS

I wish to express my gratitude to my Orange colleagues Christian Bourliataud and Thomas Rivera for using their computing facility, and Éric Gourdin for discussions leading to this work.

A mathematical programming approach to railway network asset management

C. Fecarotti & J. Andrews
Resilience Engineering Research Group, Department of Civil Engineering, The University of Nottingham, Nottingham, UK

ABSTRACT: A main challenge in railway asset management is selecting the maintenance strategies to apply to each asset on the network in order to effectively manage the railway infrastructure given that some performance and safety targets have to be met under budget constraints. Due to economic, functional and operational dependencies between different assets and different sections of the network, optimal solutions at network level not always include the best strategies available for each asset group. This paper presents a modelling approach to support decisions on how to effectively maintain a railway infrastructure system. For each railway asset, asset state models combining degradation and maintenance are used to assess the impact of any maintenance strategy on the future asset performance. The asset state models inform a network-level optimisation model aimed at selecting the best combination of maintenance strategies to manage each section of a given railway network in order to minimise the impact of the assets conditions on service, given budget constraints and performance targets. The optimisation problem is formulated as an integer-programming model. By varying the model parameters, scenario analysis can be performed so that the infrastructure manager is provided with a range of solutions for different combination of budget available and performance targets.

1 INTRODUCTION

The railway system is the result of the interaction of a number of different systems and infrastructure with the ultimate aim of transporting people and goods safely and on time. It consists of a diverse portfolio of assets, each bounds to deliver a specific function but all together contributing to ultimately provide a reliable and safe service. Each railway asset is subject to degradation and failure processes, and maintenance is performed in order to control the state of the assets and ensure that each asset's function is performed to the required standard. Maintenance policies are developed as a combination of periodic inspection, routine and emergency maintenance, enhancement and renewal activities, and these are specific to each railway asset. As maintenance resources and budget are limited, decisions have to be made on how to optimally allocate the available resources among all the asset on the network. Infrastructure asset management is the process of allocating maintenance resources among the assets comprising the system with the aim of minimising the whole-life costs while maximising the system performance. Optimal asset management involves decision making and selection of the best intervention strategy for each asset along the network in order to ensure that the required level of service reliability and safety risk is achieved within budget. Determining the best set of strategies for a given network does not simply consist in choosing the strategy which is optimal for each asset. When a network perspective is adopted dependencies among different assets and different sections of the network arise, due for example to resource availability. This implies that intervention strategies that are optimal when an asset is considered individually, might not be optimal when decisions are made at a network level.

1.1 *Modelling approaches to infrastructure asset management optimisation*

Optimisation models have been presented in the literature to support infrastructure asset management from different perspectives and to address different aspects of the problem. Two main approaches to the optimisation of infrastructure asset management can be identified: asset-level and system-level optimisation. Assetlevel optimisation aims at determining optimal maintenance policies for an individual asset, while systemlevel optimisation seeks the optimal combination of maintenance policies for all the assets comprising the system. The focus of this paper is on system-level optimisation; in the following, the modelling

approaches developed in the literature to determine the optimal set of maintenance policies for infrastructure systems composed of multiple assets are briefly discussed.

The authors in Yeo et al. (2012) address the problem of planning maintenance for a system of heterogeneous facilities undergoing stochastic deterioration over a finite time horizon. They develop a twostage bottom-up approach according to which optimal maintenance policies are first determined for each facility. The deterioration of each facility is modelled as a Markov process. The state of the facilities is known at the beginning of every year when inspection is performed and maintenance activities are selected year by year. The authors apply a dynamic programming approach to find the optimal activity as well as the alternative near optimal activities and associated costs for each facility. Then, a system-level optimisation is developed to obtain the combination of activities, one for each facility, that minimise the system expected cost-to-go while the agency cost (cost of the maintenance activities) is kept within a given budget. All facilities in the system are considered to be independent and the system-level optimisation problem is formulated as a constrained combinatorial problem.

A similar approach has been used in Furuya & Madanat (2013) with application to a hypothetical railway system, where facility-level and system-level optimisation are combined to obtain the best combination of activities for all facilities in a given network. The authors demonstrate their approach on a hypothetical dual redundant railway network. A number of facilities are associated to each link in the network, and a set of available maintenance activities is considered for each facility. As in Yeo et al. (2012), the degradation and maintenance of the railway assets is modelled as a Markov process, and the facility-level optimisation problem is formulated as a Markov decision process solved through dynamic programming. In the system-level optimisation problem, the budget constraint includes the cost reduction that can be achieved when adjacent facilities are maintained simultaneously. Constraints are also formulated on the minimum capacity to be guaranteed between an origin and a destination node and for each individual route. This enables to consider the loss of throughput due to maintaining adjacent facilities simultaneously. A numerical example is solved, which demonstrates how including both economic (opportunistic maintenance) and functional (capacity loss) dependencies arising between the assets when performing maintenance, has an impact on the optimal decision and associated lifecycle cost.

In Robelin & Madanat (2008) the authors address the optimisation of maintenance policies for a system of bridge decks with the objective of determining the optimal set of policies based on the current system conditions as well as the prediction of future conditions. The deterioration model of an individual deck is Markovian, where each state is defined in terms of the current condition of the deck, the last maintenance action performed and the time since the last intervention. The condition of a deck is given by its instantaneous probability of failure. A two-steps approach is suggested. First, a facility-level optimisation is solved to obtain the optimal cost of maintenance and replacement for each facility. The facility-level optimisation problem is solved for a discrete range of failure probabilities. Then, at system level, the cost of the system given by the combination of the cost for each facility, is minimised subject to budget constraint, and the optimal threshold of failure probability is obtained. This threshold is used backward within the facilitylevel optimisation to obtain the set of policies for each deck which are optimal at system level. Some of the assumptions the optimisation model in Robelin & Madanat (2008) is based on are too restrictive to be applied to the railway system. Many of the railway assets exhibit multiple failure modes, each with different probabilities and frequencies of occurrence. Different failure modes usually have different effects on system performance and must be therefore considered individually. Decisions on maintenance policies must account for the different failure modes so that different effects on service performance can be distinguished, and both safety and performance requirements can be addressed in a cost effective manner. Another simplifying assumption made in this paper is that at system level, the optimal threshold of probability of failure is the same for all the facilities. While this makes the optimisation problem easier to solve, it also produces a less realistic model. In real systems the location of the assets on the network may play an important role within the decision making process. The railway network includes lines and routes with different criticalities corresponding to different safety and service performance targets. It is often the case that in the trade-off between cost and performance, more expensive policies are likely to be implemented on assets located on lines with higher criticality, while lower performance is accepted on lower criticality lines.

The author in Durango-Cohen (2007) presents a method to simultaneously address the conditions and costs forecasting problem and the optimisation of maintenance action for transportation infrastructure facilities. Facilities deterioration is represented as an autoregressive moving average with exogenous input model (ARMAX). Decision variables can be investment levels or maintenance

rates and the optimisation problem is formulated as a dynamic program seeking the minimum expected discounted cost over the planning horizon. Decisions are made based on the information available at the beginning of the planning period. The use of the ARMAX model is based on the assumption that the effects of maintenance actions are linear and additive. This assumption however is too restrictive for many railway assets (e.g. track) as it completely disregards the complexity of the combined effects of different interventions on the future asset state and the consequent impact on costs.

The approach presented in the aforementioned papers is aimed at selecting the maintenance policies to be adopted year by year over a given time horizon. Inspection is not considered as part of the policies as it is assumed to be carried out at the beginning of every year. However, the frequency of inspection is an important aspect of every maintenance policy as it allows to reveal the conditions of an asset before failures occur or unacceptable degraded states are reached. Indeed it is the optimal combination of inspection frequency, threshold values for assets conditions triggering interventions and the time required to perform maintenance that make an effective maintenance strategy. Furthermore, most of the contributions use a Markov approach to model the degradation and maintenance processes of the assets. However, the Markov approach has a few limitations that prevent it from being an effective modelling tool for many of the railway assets. A significant limitation is the requirement of Markov models to restrict transitions between states on the model (generally representing degradation or repair) to occur at a constant rate. This means that the state residence times are exponentially distributed. The memoryless property of the Markov approach restricts the ability of the model to consider the maintenance history which is important in some of the railway asset components such as the track ballast. Furthermore, the size of a Markov model can experience a state-space explosion with the number of components considered, thus making difficult to model assets with many different components or formed linking several sections of track. One final significant limitation is its inability to represent a route or network perspective. If Markov models exist for two assets and it is required to account for their dependencies in constructing a route model, this can only be accomplished by the generation of a completely new model.

An alternative modelling technique that overcomes some of the limitations of the Markov approach in modelling railway asset degradation and maintenance is the Petri Net (PN) method. PNs are a formalism for modelling complex, dynamic systems characterised by concurrency and dependencies, synchronisation and resource sharing. PNs provide a valuable mathematical and graphical description of the system behaviour. PNs is a stochastic technique which allows far greater detail in comparison to the alternatives when modelling assets degradation and complex management strategies, whilst maintaining a manageable model size. PNs account for any distribution of degradation and failure times; thus increasing failure rate typical of components subject to wear-out can be considered. PNs also enable the modelling of complex maintenance processes including condition and risked based inspection and maintenance, replacement prior to failure based on either age, condition or use, reactive repair, refurbishment and renewal and all the rules for the implementation of such activities. The resulting PN models are usually smaller in size than the alternative Markov representation. An additional and very desirable feature of PN models is their modularity. Models of assets consisting of many interacting components can be built up in parts giving the model a modular structure which is easier to analyse. Monte Carlo simulation is the most common solution technique for PN models and produces distributions for the output variables of interest. The PN approach is suggested in this paper as a valid modelling technique to produce models that combine the degradation and maintenance processes involving the railway assets. Such models can be used as a tool to investigate the effectiveness of a variety of maintenance strategies for each railway asset, covering a range of performance and costs, so to provide the decision maker with a set of potential strategies among which the ones which are best from a system perspective can be selected.

2 THE METHODOLOGY

This paper presents a modelling approach to support decisions on how to effectively maintain a railway infrastructure system. First, for each railway asset, a modelling tool is required to assess the asset response to the implementation of a range of feasible maintenance strategies. Such modelling tools, called *asset state models* combine the degradation/failure processes affecting the asset with the intervention activities that can be performed in order to predict the future asset state. The asset state models developed for each asset inform a network-level optimisation model aimed at selecting the best combination of maintenance strategies to manage all the assets on a railway network under budget and performance constraints. The network-level optimisation model is formulated as an integer program with multiple constraints (Hillier and

Lieberman 2009). The model is bounded to select one option for each individual asset located in the considered railway network. Constraints are formulated on the overall available budget and on the availability required of each railway line. Different lines in the network may have a different criticality depending on the effect that failures have on service. This is strictly linked to the frequency of the service running on each line. Different lines criticality are accounted for by imposing different thresholds to the availability of each line. This modelling approach has the advantage to enable the evaluation of a variety of different scenarios by changing the model parameters such as the available budget or the threshold levels set for the lines availability.

2.1 *Network segmentation for strategic planning purposes*

The UK railway network is segmented for policy decisions. The whole network is divided into 19 Strategic Routes, each divided into a number of Strategic Route Sections (SRSs). An SRS is a section of the railway network characterised by broadly homogeneous infrastructure type and traffic levels. Therefore strategy decisions are taken at SRS level. It is assumed that the same maintenance strategy will be applied within the same SRS. Asset state models are developed for each asset type existing on each SRS and are used to assess the impact of a range of maintenance strategies on the assets' performance.

2.2 *Asset state models*

The PN method is adopted as the modelling approach to develop the asset state models. PNs are a formalism for modelling complex distributed systems characterised by concurrency and dependency, synchronization and resource sharing. Petri nets provide a valuable mathematical and graphical description of the system behaviour. A PN is a directed, weighted bi-partite graph where nodes are places and transitions connected by arcs (Murata 1989). A PN can be formally defined as follows.

Definition 1. A PN is a 5-tuple $PN = (P, T, A, W, M_0)$ where: $P = \{p_1, p_2, ..., p_m\}$ is the non-empty set of places, $T = \{t_1, t_2, ..., t_n\}$ is the non-empty set of transitions, $P \cap T = \varnothing$, $A \subseteq (P \times T) \cup (T \times P)$ is the set of arcs, $W : A \to \{1,2,\ldots\}$ is the multiplicity function, $M_0 : P \to \{0,1,2,\ldots\}$ is the initial marking.

Places may represent physical resources, conditions or the state of a component. Tokens are held in places and the number of tokens in each place defines the marking of the Petri net which represents the state of the system at a given time. The flow of tokens through the network is determined by transitions and represents the evolution of the system state over time. Transitions represent events that make the status of the system change. Arcs only connect places with transitions (input arcs) and vice versa (output arcs). Inhibitor arcs are defined as well, which can be used to stop the firing of a transition under certain circumstances. Arcs are characterised by a multiplicity. The marking and the multiplicity of the arcs determine the enabling conditions for each transition. Transitions can be deterministic or stochastic. The former have an associated constant firing time, while the latter sample their firing time from stochastic distributions. Firing of transitions is ruled as follow:

- If the number of tokens contained in the input places is at least equal to the multiplicity of the associated input arcs, and the number of tokens in the places connected by inhibitor arcs is lower than the arcs multiplicity, then the transition is enabled.
- Once the transition is enabled, it will fire after a time interval which is fixed for deterministic transitions. For stochastic transitions the firing time is sampled from a probabilistic distribution.
- When the firing time is reached and the transition fires, a number of tokens is removed from the input places and added to the output places according to the arcs multiplicity.

For the purpose of maintenance, a number of discrete states are usually considered, corresponding to levels of degradation that trigger maintenance interventions with different levels of urgency. The degradation process can therefore be represented as a chain of places and transitions as shown in Figure 1. Places $P_{deg,i}$ indicate different states which are relevant from a maintenance perspective, namely each state (except for the new state P_{new}) triggers maintenance with different level of urgency depending on the level of degradation. Transitions $T_{deg,i}$ represent the degradation from one state to the next (worse). These are stochastic transitions whose firing time is sampled from a stochastic distribution representing the distribution of times to degrade between two consecutive states. Asset conditions requiring a speed restriction or a line closure can be included as well, these being usually the last two levels of degradation. Inspection is performed periodically to reveal the current asset

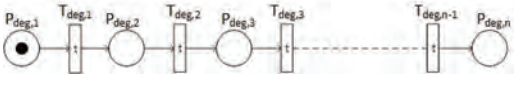

Figure 1. Degradation.

condition so that degraded states can be discovered and maintenance planned accordingly. In Figure 2) transitions $T_{rev,i}$ are timed deterministic and fire at a fixed frequency. Once a degraded condition is revealed, maintenance in planned depending on the level of urgency. Maintenance interventions are represented by transitions $T_{rep,i}$ (Figure 3). After maintenance, the asset is usually restored to a good condition (P_{good}) rather than to new, unless a renewal is carried out. If necessary, it is possible to account for the effectiveness of maintenance by adopting a probabilistic routing policy for transitions $T_{rep,i}$ so that the state after maintenance can be any of the degraded state with a given probability. It is also possible to keep track of the number of maintenance interventions performed. This is achieved by monitoring the marking of place *PI* which is marked every time an intervention is performed (and therefore any of transitions $T_{rep,i}$ fires). For some assets, the degradation might depend on the past maintenance history; an example is the ballast for which the rate of degradation increases with the number of tamping interventions performed. This can be accounted for if transitions $T_{deg,i}$ update their distributions of times to degrade according to number of interventions performed on the asset. This modelling approach enables the evaluation of a wide range of maintenance strategies, for each of which it is possible to specify the inspection frequency, the thresholds on the asset conditions that

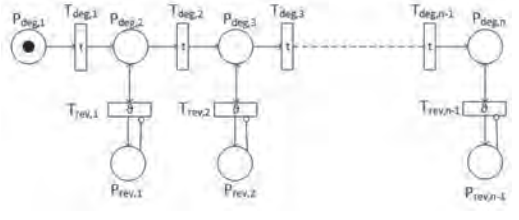

Figure 2. Degradation and inspection.

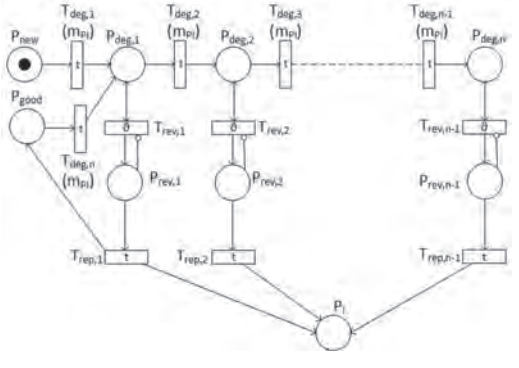

Figure 3. Degradation, inspection and repair.

trigger maintenance, the mean time to schedule and perform any maintenance activity. Furthermore, by keeping track of the marking during the simulation, it is possible to evaluate the probability of being in any of the considered states as well as the number of interventions performed. The probability of having a speed restriction and a line closure is of particular interest to evaluate the impact of a given strategy on service and safety risk.

This modelling structure can be used as a *modelling template* to describe a variety of railway asset exhibiting degradation during their lifetime. The number and features of places and transitions representing the degradation processes and the maintenance activities can be easily fitted to characteristics of the specific asset to be modelled. Example of degradation and maintenance models adopting a similar structure have been proposed in the literature for a number of railway assets such as track (Andrews 2012, Prescott & Andrews 2013, Andrews, Prescott, & De Rozieres 2014) and bridges (Le & Andrews 2016, Le, Andrews, & Fecarotti 2017).

2.3 *Network-level strategies optimisation*

The analysis conducted by means of the asset state models results in a set of potential asset management strategies covering a range of performance levels for each asset group. Given a set of potential strategies for each asset group, the infrastructure manager is faced with the task of selecting one strategy for each asset on the network given that a limited budget is available. Performance and safety targets are usually set for each route and line along the network, and these targets can be different depending on the route criticality. Decisions are therefore bounded by the available budget and are made with the aim of minimising the disruption caused to the railway service, while a certain level of availability is ensured for each line depending on the line criticality. Whatever asset fails, the impact on trains service is due to either a speed restriction, leading to delays, or a section closure leading to journeys cancellation. The extent of the disruption depends on both the duration of such control actions and the location of the section(s) involved. If a speed restriction or a section closure is imposed on a section belonging to a high frequency line, or to more than one line, then the number of journey affected by the disruption will be high. With regard to the impact of failures on service, for each section in the network is therefore fair to define two failure modes, each with a different effect on service: (i) section subject to speed restriction, and (ii) section subject to closure.

Let us define a Strategic Route as a set of SRSs $R = \{R_1, R_2, \ldots, R_i, \ldots, R_{n_R}\}$. Railway

services run along a set of railway lines $L=\{L_1,L_2,\ldots,L_l,\ldots,L_{n_L}\}$, each railway line consists of one or more SRSs. Therefore each railway line can be represented as a subset of set R, $L_l \subseteq R, \forall l=1,\ldots,n_L$. A railway line L_l will be unavailable if any of its SRS is unavailable. If a is the number of asset groups considered and b is the number of strategies available for each asset group, then the set of maintenance strategies for each SRS is given by all the possible combinations of the individual asset groups' strategies $n_S = a \cdot b$. The set $S=\{S_1,S_2,\ldots,S_j,\ldots,S_{n_S}\}$ is defined, containing n_S potential strategies available for each SRS, each corresponding to a given combination of the individual asset strategies. From now on the term strategy will be used to indicate a strategy for the individual SRS, among the available ones in set S. The index $j=1,2,\ldots,n_S$ will be used to refer to a generic strategy within set S while the index $j=1,2,\ldots,n_R$ will be used to refer to a generic SRS within set R. The vector of decisional variables X has components x_{ij} such that $x_{ij}=1$ if strategy j is applied to SRS i, 0 otherwise. The infrastructure manager is bounded to choose only one strategy per SRS. Following the implementation of a given strategy, each SRS will be subjected to a given probability, average number and duration of imposed speed restrictions and section closure during the considered planning period. Section closure contributes to define the availability of the SRS. In fact a section closure means that the section is not available for use and therefore all the journeys that use that section are cancelled or rerouted if possible. If a speed restriction is imposed, trains can still run but at a reduced speed; this implies delays and sometimes journey cancellations. Therefore we assume that the number and duration of imposed speed restrictions implicitly provide an indication of the impact on service delay. Similarly, we assume that the number and duration of imposed section closure implicitly provide indication of the deleted services due to section unavailability. The problem is formulated as follows:

$$\min Z(X)=\sum_{i=1}^{n_R}\sum_{j=1}^{n_S} n_{ij}^{(SR)} \cdot d_{ij}^{(SR)} \cdot f_i \cdot x_{ij} \quad s.t \tag{1}$$

$$\sum_{j=1}^{n_S} x_{ij}=1 \quad \forall\ i=1,2,\ldots n_R, \tag{2}$$

$$\sum_{i=1}^{n_R}\sum_{j=1}^{n_S} c_{ij} x_{ij} \le B, \tag{3}$$

$$Q_{L_l}(x_{ij}) \le Q_{L_l}^* \quad \forall L_l \in L, \tag{4}$$

$$x_{ij} \in \{0,1\} \quad \forall\ i=1,2,\ldots n_R; \quad j=1,2,\ldots n_S. \tag{5}$$

where the model parameters are:

- $n_{ij}^{(LC)}$ the average number of closures in SRS i following implementation of strategy j,
- $d_{ij}^{(LC)}$ the average duration of closures in SRS i following implementation of strategy j,
- $n_{ij}^{(SR)}$ the average number of speed restriction imposed on SRS i following implementation of strategy j,
- $d_{ij}^{(SR)}$ the average duration of speed restriction imposed on SRS i following implementation of strategy j,
- $q_{ij}^{(LC)}$ the probability of a closure in SRS i following implementation of strategy j,
- $Q_{L_l}^*$ the threshold on the unavailability of line L_l,
- c_{ij} the cost of strategy j implemented on SRS i,
- f_i the frequency of trains travelling on SRS i,
- B the available budget.

The objective function $Z(X)$ is representative of the impact that the selected combination of strategies has on service delay, which allows to compare different solutions. It represent the expected number of trains affected by a service disruption during the considered time horizon. Each term $n_{ij}^{(SR)} \cdot d_{ij}^{(SR)} \cdot f_i \cdot x_{ij}$ gives an indication of the contribution of each SRS to the overall service disruption. This contribution is proportional to the average number of speed restrictions imposed on the SRS and its average duration, and on the frequency of trains travelling through the SRS. The train frequency is used to weight each SRS proportionally to the normalised amount of flow travelling on the SRS. The frequency also implicitly weight each SRS based on the its centrality, namely its role in serving more than one line. The set of constraints 2 indicates that only one strategy can be selected for each link. Constraint 3 adds a bound on the overall costs according to the available budget. The set of constraints 4 put a threshold on the minimum value of unavailability of each line. A line is unavailable if any of its SRSs is closed. Therefore, the probability of line L_l being closed $Q_{L_l}(x_{ij})$ can be written as

$$Q_{L_l}(X)=1-\prod_{\forall i | R_i \in L_l}\left(1-\sum_{\forall j | S_j \in S} q_{ij}^{(LC)} \cdot x_{ij}\right) \tag{6}$$

The optimal solution X^* is given by the feasible combination of strategies that will provide the minimum impact on service as represented by the objective function $Z^*(X)$. The objective function in 1 $Z(X)$ is linear in X, as constraints (1) and (2), while constraints (3) are non-linear. Problem 1 is therefore a non-linear integer otpimisation problem.

2.3.1 *Solution method*

There are no general-purpose solution methods yielding the global optimum for non-linear (non-convex) constrained optimisation problems and

approximate solution algorithms are usually used. However, it possible to solve a linear approximation of the original problem if the non-linear functions (objective function and/or constraints) can be converted to an acceptable linear form.

Problem 1 is transformed into a linear integer programming model by replacing the left hand side of constraint 4 with its *rare event approximation* (Andrews & Moss 2002) as follows:

$$Q_{L_l}(X) = 1 - \prod_{\forall i | R_i \in L_l} \left(1 - \sum_{\forall j | S_j \in S} q_{ij}^{(LC)} \cdot x_{ij} \right) \leq \sum_{\forall i | R_i \in L_l} \sum_{\forall j | S_j \in S} q_{ij}^{(LC)} \cdot x_{ij}. \quad (7)$$

The rare event approximation is an upper bound to the top event exact probability and can be used when the probability of the basic events is low. This an acceptable approximation for the problem at hand as the probability of a link closure is usually small.

Integer programming is NP-hard, namely it can be solved in non-polynomial time. Therefore, depending on the problem size it can be difficult to solve in reasonable computational time. In such circumstances, the associated relaxed problem obtained through Continuous relaxation can be studied. The relaxed problem is a linear continuous programming model which can be solved by means of the simplex method. The optimal solution of the relaxed problem is a lower bound of the global optimum of the original problem.

3 NUMERICAL EXAMPLE

The optimisation approach presented in this paper has been applied to select the best combination of maintenance strategies for a set of SRSs comprising one of the UK Strategic Routes, the East Midlands (EM) Route. Details of the EM route and it SRSs can be found in (NetworkRail 2015). A schematic representation of part of the EM route showing seven of its eleven SRSs is given in Figure 4. The set of SRSs considered in this example are listed in Table 1 along with the train frequency.

Railway services running along the EM Route which have been considered here are listed in Table 2 along with the service type (Long distance high speed—LDHS, interurban and local), while Table 3 lists the SRSs included within each service.

For each railway service, different availability requirements are considered depending on the type of service. Three potential maintenance strategies are considered, $S = \{S_1, S_2, S_3\}$. The evaluation of

the maintenance strategies through the PN asset models yields the input parameters to the optimisation model. The values of the model parameters used to run this numerical example are detailed in Table 4 where c_i, q_i and n_i^{SR} indicate the cost, unavailability and number of speed restriction due to the implementation of the available strategies.

The optimisation model has been solved for eight different values of the available budget B_1 = 350, B_2 = 400, B_3 = 450, B_4 = 500, B_5 = 550, B_6 = 600, B_7 = 650, B_8 = 700, while the thresholds on the unavailability of each railway service remain unchanged and equal to $Q_{L_1}^*$ = 0.98, $Q_{L_2}^*$ = 0.98, $Q_{L_3}^*$ = 0.98, $Q_{L_4}^*$ = 0.95, $Q_{L_5}^*$ = 0.9. The results of the scenario analysis are summarised in Table 5 and Figure 5. Table 5 details the optimal maintenance strategies for each SRS, while Figure 5 shows the corresponding value of the objective function which is indicative of the expected number of trains affected by a speed restriction.

1	–	–	–	–	–	–	–
2	–	–	–	–	–	–	–
3	–	–	–	–	–	–	–
4	–	–	–	–	–	–	–
5	S_3	S_3	S_3	S_3	S_1	S_1	S_2
6	S_3	S_3	S_3	S_3	S_1	S_3	S_3
7	S_3	S_3	S_3	S_3	S_3	S_3	S_3
8	S_3	S_3	S_3	S_3	S_3	S_3	S_3

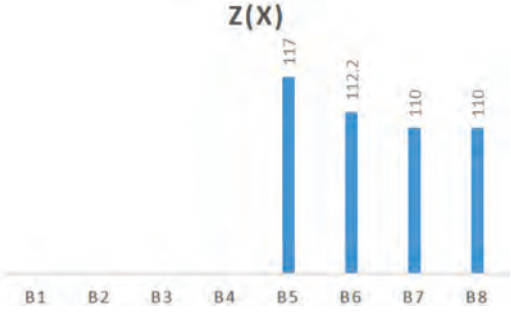

Figure 5. Expected number of disrupted trains for different available budgets.

Results show that no feasible solution can be found for budgets B_1 to B_4 as the strategies that would be achievable within the available budget do not ensure the required level of availability for each railway service. If the budget is increased solutions can be found. Budget B_5 is enough to find a feasible solution but does not allow the selection of the best strategy available for each SRSs. The algorithm selects less expensive strategies for SRSs 05, 06 and 07 as they belong to those railway services for which a less restrictive value of availability is required. Furthermore, the train frequency on those sections is lower than in the others. By further increasing the available budget, better strategies can be chosen and the impact on service decreases.

4 CONCLUSIONS

This paper presents a modelling approach to support decisions on how to effectively maintain a railway infrastructure system. First, for each railway asset, a modelling tool is required to assess the asset response to the implementation of a range of feasible maintenance strategies. Such modelling tools, called *asset state models* combine the degradation/failure processes affecting the asset with the intervention activities that can be performed in order to predict the future asset state. The modelling approach suggested to develop the asset state models is the PN method. A modelling template based on the PN method have been presented, which can be specified to represent a variety of railway assets undergoing degradation and ageing. The asset state models developed for each asset inform a network-level optimisation model aimed at selecting the best combination of maintenance strategies to manage all the assets on a railway network under budget and performance constraints. The network-level optimisation model is formulated as an integer program with multiple constraints. A numerical example has been presented to show the capabilities of the optimisation model. An advantage of mathematical programming formulation is that the model is not a black box. Furthermore, when the problem size is such that global solutions cannot be found in reasonable computational time, the mathematical programming formulation allows the use of tools to

estimate the goodness of approximate solutions. By varying the model parameters, scenario analysis can be performed so that the infrastructure manager is provided with a range of solutions for different combination of budget available and performance targets.

Operation and climate-weather change impact on maritime ferry safety

K. Kołowrocki & E. Kuligowska
Gdynia Maritime University, Poland

ABSTRACT: The paper is concerned with an application of the recently developed, a general safety analytical model of a critical infrastructure under the influence of an operation process related to climate-weather change process. The model is presented and applied to the prediction of the maritime ferry safety characteristics. As a result of this application, the ferry unconditional safety function and the risk function at changing in time operation and climate-weather conditions are determined. Moreover, the other significant safety indicators, i.e. the mean lifetime up to the exceeding a critical safety state, the moment when the risk function value exceeds the acceptable safety level, the intensities of ageing and the coefficients of the operation and climate-weather impact on the ferry intensities of ageing are presented.

1 INTRODUCTION

The paper presents the operation and climate-weather change influence on the safety of a critical infrastructure. The maritime ferry operation process is described in (Kołowrocki & Soszyńska-Budny 2011), whether the climate-weather change process for the ferry operating area is modeled in (Kuligowska 2017). The identification of the ferry operation process related to climate-weather change is performed in (Kołowrocki et al. 2017a). Having these processes identified, the safety prediction of the considered ferry under the operation process and climate-weather change influence is performed.

An analytical safety model of a complex technical system under the influence of the operation process related to climate-weather change process is proposed (Kołowrocki et al. 2017b). It is the integrated model of complex technical system safety, linking its multistate safety model and the model of its operation process related to climate-weather change process at its operating area, considering variable at the different climate-weather states impacted by them the system safety structures and its components safety parameters.

The maritime ferry safety characteristics, i.e. the unconditional safety function and the risk function at changing in time operation and climate-weather conditions (in February) are determined. Moreover, the safety and resilience indicators are presented: the mean lifetime up to the exceeding a critical safety state, the moment when the risk function value exceeds the acceptable safety level, the intensities of ageing and the coefficients of the operation and climate-weather impact on the maritime ferry safety.

2 CRITICAL INFRASTRUCTURE OPERATION PROCESS RELATED TO CLIMATE-WEATHER VARIABLE CONDITIONS

2.1 *Critical infrastructure operation process*

We assume that the critical infrastructure during its operation process is taking ν, $\nu \in N$, different operation states $z_1, z_2, \ldots, z_\nu$. Moreover, we assume that the critical infrastructure operation process $Z(t)$ is a semi-Markov process with the conditional sojourn times θ_{bl} at the operation states z_b when its next operation state is z_l, $b,l = 1,2, \ldots, \nu$, $b \neq l$.

Under these assumptions, the critical infrastructure operation process may be described by (Kołowrocki & Soszyńska-Budny 2011):

- the vector $[p_b(0)]_{1\times\nu}$ of the initial probabilities $p_b(0) = P(Z(0) = z_b)$, $b = 1,2, \ldots,\nu$, of the critical infrastructure operation process $Z(t)$ staying at particular operation states at the moment $t = 0$;
- the matrix $[p_{bl}]_{\nu\times\nu}$ of probabilities p_{bl}, b, $l = 1,2, \ldots,\nu$, $b \neq l$, of the critical infrastructure operation process $Z(t)$ transitions between the operation states z_b and z_l;
- the matrix $[H_{bl}(t)]_{\nu\times\nu}$ of conditional distribution functions $H_{bl}(t) = P(\theta_{bl} < t)$, $t \in <0,+\infty)$, $b,l = 1,2,\ldots,\nu$, $b \neq l$, of the critical infrastructure operation process $Z(t)$ conditional sojourn times θ_{bl} at the operation states.

The limit values of the critical infrastructure operation process $Z(t)$ transient probabilities $p_b(t) = P(Z(t) = z_b)$, $t \in <0,+\infty)$, $b = 1,2,\ldots,\nu$, at the particular operation states, can be found using the procedure given in (Kołowrocki & Soszyńska-Budny 2011).

2.2 *Climate-weather change process at the critical infrastructure operating area*

To model the climate-weather change process for the critical infrastructure operating area we assume that the process is taking w, $w \in N$, different climate-weather states c_1, c_2,…, c_w. Further, we define the climate-weather change process $C(t)$, $t \in <0,+\infty)$, with discrete operation states from the set $\{c_1, c_2,\ldots, c_w\}$. Assuming that the climate-weather change process $C(t)$ is a semi-Markov process it can be described by (Kołowrocki, Soszyńska-Budny & Torbicki 2017a,b):

- the vector $[q_b(0)]_{1\times w}$ of the initial probabilities $q_b(0) = P(C(0) = c_b)$, $b = 1,2,\ldots, w$, of the climate-weather change process $C(t)$ staying at particular climate-weather states c_b at the moment $t = 0$;
- the matrix $[q_{bl}]_{w\times w}$ of the probabilities of transitions q_{bl}, $b,l = 1,2,\ldots, w$, $b \neq l$, of the climate-weather change process $C(t)$ from the climate-weather states c_b to c_l;
- the matrix $[C_{bl}(t)]_{w\times w}$ of the conditional distribution functions $C_{bl}(t) = P(C_{bl} < t)$, $t \in <0,+\infty)$, $b,l = 1,2,\ldots, w$, of the conditional sojourn times C_{bl} at the climate-weather states c_b when its next climate-weather state is c_l, $b,l = 1,2,\ldots, w$, $b \neq l$.

The limit values of the climate-weather change process $C(t)$ transient probabilities $q_b(t) = P(C(t) = c_b)$, $t \in <0,+\infty)$, $b = 1,2,\ldots,w$, at the particular climate-weather states, can be found using the procedure given in (Kołowrocki, Soszyńska-Budny & Torbicki 2017a).

2.3 *Critical infrastructure operation process related to climate-weather change*

We assume as in (Kołowrocki et al. 2017c), that the critical infrastructure operation process related to climate-weather change $ZC(t)$, $t \in <0,+\infty)$, can take νw, ν, $w \in N$, different operation states $zc_{11}, zc_{12},\ldots, zc_{\nu w}$, described by:

- the vector $[pq_{bl}(0)]_{1\times \nu w}$ of initial probabilities of the critical infrastructure operation process related to climate-weather change $ZC(t)$ staying at the initial moment $t = 0$ at the operation and climate-weather states zc_{bl}, $b = 1,2,\ldots,\nu$, $l = 1,2,\ldots,w$;
- the matrix $[pq_{bl\,\tilde{b}\tilde{l}}]_{\nu w\times \nu w}$ of the probabilities of transitions of the critical infrastructure operation process related to climate-weather change $ZC(t)$ between the operation states zc_{bl} and $zc_{\tilde{b}\tilde{l}}$, $b = 1,2,\ldots,\nu$, $l = 1,2,\ldots,w$, $\tilde{b} = 1,2,\ldots,\nu$, $\tilde{l} = 1,2,\ldots,w$;
- the matrix $[HC_{bl\,\tilde{b}\tilde{l}}(t)]_{\nu w\times \nu w}$ of the conditional distribution functions of the critical infrastructure operation process related to climate-weather change $ZC(t)$ conditional sojourn times $\theta C_{bl\,\tilde{b}\tilde{l}}$, $b = 1,2,\ldots,\nu$, $l = 1,2,\ldots,w$, $\tilde{b} = 1,2,\ldots,\nu$, $\tilde{l} = 1,2,\ldots,w$, at the operation state zc_{bl}, $b = 1,2,\ldots,\nu$, $l = 1,2,\ldots,w$, when the next operation state is $zc_{\tilde{b}\tilde{l}}$, $\tilde{b} = 1,2,\ldots,\nu$, $\tilde{l} = 1,2,\ldots,w$.

Assuming that we have identified the unknown parameters of the critical infrastructure operation process related to climate-weather change $ZC(t)$, we can predict this process basic characteristics, e.g. the limit transient probabilities $pq_{bl}(t) = P(ZC(t) = zc_{bl})$, $t \in < 0, +\infty)$, $b = 1,2,\ldots,\nu$, $l = 1,2, \ldots, w$, at the particular states, according to the procedure given in (Kołowrocki et al. 2017c).

3 CRITICAL INFRASTRUCTURE SAFETY AT VARIABLE OPERATION CONDITIONS RELATED TO CLIMATE-WEATHER CHANGE

In the safety analysis of critical infrastructures at the variable operation conditions related to climate-weather change, to define the critical infrastructure with degrading components we assume that the changes of the process $ZC(t)$ states have an impact on the critical infrastructure's components and its structure (Kołowrocki 2014, Kołowrocki et al. 2017b). We denote the critical infrastructure asset A_i, $i = 1,2,\ldots,n$, conditional lifetime in the safety state subset $\{u, u + 1, \ldots, z\}$, while the operation process related to climate-weather change $ZC(t)$ is at the state zc_{bl}, $b = 1, 2, \ldots, \nu$, $l = 1,2, \ldots, w$, by $[T_i^4(u)]^{(bl)}$. Moreover, in this section we assume that the critical infrastructure assets at particular states have the exponential safety functions. According to (Kuligowska & Soszyńska-Budny 2017b), the conditional critical infrastructure safety function is defined by the vector

$$[S_i^4(t,\cdot)]^{(bl)} = [1,[S_i^4(t,1)]^{(bl)},\ldots,S_i^4(t,z)]^{(bl)}],t \in <0,+\infty),$$
$$b = 1,2,\ldots,\nu,\ l = 1,2,\ldots,w,\ i = 1,2,\ldots,n, \quad (1)$$

with the coordinates

$$[S_i^4(t,u)]^{(bl)} = P([T_i^4(u)]^{(bl)} > t \mid ZC(t) = zc_{bl}) = \exp[-[\lambda_i^4(u)]^{(bl)}t],\ t \in < 0, +\infty),$$
$$b = 1,2,\ldots,\nu,\ l = 1,2, \ldots, w,\ i = 1,2, \ldots, n, \quad (2)$$

where the intensities of ageing of the critical infrastructure assets related to operation and climate-weather impact, existing in (2), are given by

$$[\lambda_i^4(u)]^{(bl)} = [\rho_i^4(u)]^{(bl)} \cdot \lambda_i^0(u),\ u = 1, 2,\ldots, z,$$
$$b = 1,2,\ldots,\nu,\ l = 1,2, \ldots, w,\ i = 1,2,\ldots, n, \quad (3)$$

and $\lambda_i^0(u)$ are the intensities of ageing of the system components without operation and climate-weather impact and

$$[\rho_i^4(u)]^{(bl)},\ u = 1,2,\ldots,z,\ b = 1,2, \ldots, \nu,\ l = 1,2, \ldots,$$
$$w,\ i = 1,2,\ldots,n, \quad (4)$$

are the coefficients of operation and climate-weather change impact on the critical infrastructure assets' intensities of ageing without operation and climate-weather change impact.

Further, we denote the critical infrastructure unconditional lifetime in the safety state subset $\{u,u+1,\ldots,z\}$ by $T^4(u)$ and the system unconditional safety function by

$$\boldsymbol{S}^4(t,\cdot) = [1, \boldsymbol{S}^4(t,1), \ldots, \boldsymbol{S}^4(t,z)], \tag{5}$$

with the vector's coordinates defined by

$$\boldsymbol{S}^4(t,u) = P(T^4(u) > t),\ t \in <0,+\infty),\quad u = 1,2,\ldots,z. \tag{6}$$

In the case when the critical infrastructure operation time θC_{bl} is large enough, the coordinates of the unconditional safety function of the system defined by (5) are given by

$$\boldsymbol{S}^4(t,u) \cong \sum_{b=1}^{v}\sum_{l=1}^{w} pq_{bl}[\boldsymbol{S}^4(t,u)]^{(bl)},\ t \in <0,+\infty),\quad u = 1,2,\ldots,z, \tag{7}$$

where $[\boldsymbol{S}^4(t,u)]^{(bl)}$, $u = 1,2,\ldots,z$, $b = 1,2,\ldots,v$, $l = 1,2,\ldots,w$, are the coordinates of the system conditional safety function defined by (2)–(4) and pq_{bl}, $b = 1,2,\ldots,v$, $l = 1,2,\ldots,w$, are the system operation process limit transient probabilities (see section 2.3).

Further, we determine the mean values $\mu^4(u)$ and the standard deviations $\sigma^4(u)$ of the unconditional lifetimes of the critical infrastructure in the safety state subsets $\{u,u+1,\ldots,z\}$, $u = 1,2,\ldots,z$, the mean values $\overline{\mu}^4(u)$ of the unconditional lifetimes of the critical infrastructure in the particular safety states u, $u = 1,2,\ldots,z$, the risk function $\boldsymbol{r}^4(t)$ and the moment τ^4 when the critical infrastructure risk function exceeds a permitted level δ, after substituting for $\boldsymbol{S}^4(t,u)$, $u = 1,2,\ldots,z$, the coordinates of the unconditional safety functions given by (6).

4 MARITIME FERRY OPERATION PROCESS RELATED TO CLIMATE-WEATHER CHANGE

The maritime ferry technical system consists of a navigational subsystem S_1, a propulsion and controlling subsystem S_2, a loading and unloading subsystem S_3, a stability control subsystem S_4 and an anchoring and mooring subsystem S_5, which form a series structure. The detailed scheme and system description may be found in (Kołowrocki & Soszyńska-Budny 2011). The maritime ferry safety structure and the assets' safety depend on its changing in time operation and climate-weather states.

Taking into account the expert opinions and according to section 2.3 and (Kołowrocki et al. 2017a), the maritime ferry operation process related to climate-weather change process $ZC(t)$, $t \in <0,+\infty)$, can take

$$v \cdot w = 18 \cdot 6 = 108, \tag{8}$$

different operation states

$$\begin{aligned}&zc_{1\,1}, zc_{2\,1}, \ldots, zc_{18\,1};\\ &zc_{1\,2}, zc_{2\,2}, \ldots, zc_{18\,2};\\ &\ldots,\\ &zc_{1\,18}, zc_{2\,18}, \ldots, zc_{18\,18}.\end{aligned} \tag{9}$$

Considering the results of the identification of the unknown parameters of the maritime ferry operation process related to climate-weather change (Kołowrocki et al. 2017), it was possible to predict this process' basic characteristics. The limit values of the maritime ferry operation process related to climate-weather change process $ZC(t)$ transient probabilities pq_{bl}, $b = 1,2,\ldots,18$, $l = 1,2,\ldots,6$, at the particular states zc_{bl}, are given in the vector

$$\begin{aligned}[pq_{bl}]_{1\times 108} \cong [&0.015352, 0.000418, 0.017138, 0.00038, 0.004712, 0;\\ &0.000808, 0.000022, 0.000902, 0.00002, 0.000248, 0;\\ &0.02093, 0.004342, 0.000208, 0, 0.000182, 0.000338;\\ &0.02898, 0.006012, 0.000288, 0, 0.000252, 0.000468;\\ &0.287496, 0.067155, 0, 0, 0.005808, 0.002541;\\ &0.010244, 0.000416, 0.008086, 0.00078, 0.006474, 0;\\ &0.00197, 0.00008, 0.001555, 0.00015, 0.001245, 0;\\ &0.006304, 0.000256, 0.004976, 0.00048, 0.003984, 0;\\ &0.014578, 0.000592, 0.011507, 0.00111, 0.009213, 0;\\ &0.000788, 0.000032, 0.000622, 0.00006, 0.000498, 0;\\ &0.001182, 0.000048, 0.000933, 0.00009, 0.000747, 0;\\ &0.006304, 0.000256, 0.004976, 0.00048, 0.003984, 0;\\ &0.277992, 0.064935, 0, 0, 0.005616, 0.002457;\\ &0.02737, 0.005678, 0.000272, 0, 0.000238, 0.000442;\\ &0.01932, 0.004008, 0.000192, 0, 0.000168, 0.000312;\\ &0.001212, 0.000033, 0.001353, 0.00003, 0.000372, 0;\\ &0.00202, 0.000055, 0.002255, 0.00005, 0.00062, 0;\\ &0.005252, 0.000143, 0.005863, 0.00013, 0.001612, 0].\end{aligned} \tag{10}$$

5 MARITIME FERRY SAFETY PREDICTION INCLUDING OPERATION AND CLIMATE-WEATHER CHANGE IMPACT

5.1 *Maritime ferry safety parameters*

After discussion with experts, taking into account the safety of the operation of the ferry, we fix 5 ($z = 5$) safety states of the ferry technical system and we distinguish the following safety states:

- a safety state 4 – the ferry operation is fully safe;
- a safety state 3 – the ferry operation is less safe and more dangerous because of the possibility of environment pollution;

– a safety state 2 – the ferry operation is less safe and more dangerous because of the possibility of environment pollution and causing small accidents;
– a safety state 1 – the ferry operation is much less safe and much more dangerous because of the possibility of serious environment pollution and causing extensive accidents;
– a safety state 0 – the ferry technical system is destroyed.

Moreover, by the expert opinions, we assume that there are possible the transitions between the components' safety states only from better to worse ones.

Considering the assumptions and agreements from the previous sections, we assume that the components $E_{ij}^{(\upsilon)}$, $i = 1,2,\ldots,k$, $j = 1,2,\ldots,l_i$, of the subsystem S_υ, $\upsilon = 1,2,3,4,5$, at the system states z_{bl}, $b = 1,2,\ldots,18$, $l = 1,2,\ldots,6$, have the exponential safety functions, i.e. the coordinates of the vector

$$[S_{ij}^{4(\upsilon)}(t,\cdot)]^{(bl)} = [1,[S_{ij}^{4(\upsilon)}(t,1)]^{(bl)},\ldots,[S_{ij}^{4(\upsilon)}(t,4)]^{(bl)}],$$
$$t \in <0,+\infty), i = 1,2,\ldots,k, j = 1,2,\ldots,l_i, \upsilon = 1,2,3,4,5,$$
$$b = 1,2,\ldots,18, l = 1,2,\ldots,6, \tag{11}$$

are given by

$$[S_{ij}^{4(\upsilon)}(t,u)]^{(bl)} = P([T_{ij}^{4(\upsilon)}]^{(bl)}(u) > t \,|\, ZC(t) = zc_{bl}) = \exp[-[\lambda_{ij}^{4(\upsilon)}(u)]^{(bl)} t],$$
$$t \in <0,+\infty), u = 1,2,3,4, i = 1,2,\ldots,k, j = 1,2,\ldots,l_i,$$
$$\upsilon = 1,2,3,4,5, b = 1,2,\ldots,18, l = 1,2,\ldots,6. \tag{12}$$

Existing in the above formula the intensities of ageing of the components $E_{ij}^{(\upsilon)}$, $i = 1,2,\ldots,k$, $j = 1,2,\ldots,l_i$, of the subsystem S_υ, $\upsilon = 1,2,3,4,5$, at the system operation process states zc_{bl}, $b = 1,2,\ldots,18$, $l = 1,2,\ldots,6$, i.e. the coordinates of the vector of intensities

$$[\lambda_{ij}^{4(\upsilon)}(\cdot)]^{(bl)} = [0,[\lambda_{ij}^{4(\upsilon)}(1)]^{(bl)},\ldots,[\lambda_{ij}^{4(\upsilon)}(4)]^{(bl)}],$$
$$i = 1,2,\ldots,k, j = 1,2,\ldots,l_i, \upsilon = 1,2,3,4,5, b = 1,2,\ldots,18,$$
$$l = 1,2,\ldots,6, \tag{13}$$

are given by

$$[\lambda_{ij}^{4(\upsilon)}(u)]^{(bl)} = [\rho_{ij}^{4(\upsilon)}(u)]^{(bl)} \lambda_{ij}^{0(\upsilon)}(u), u = 1,2,3,4,$$
$$i = 1,2, \quad ,k, j = 1,2, \quad ,l_i, \upsilon = 1,2,3,4,5, \tag{14}$$
$$b = 1,2, \quad ,18, l = 1,2, \quad ,6,$$

where $\lambda_{ij}^{0(\upsilon)}(u)$, $u = 1,2,3,4$, $i = 1,2,\ldots,k, j = 1,2,\ldots,l_i$, are the intensities of ageing of the components $E_{ij}^{(\upsilon)}$, $i = 1,2,\ldots,k$, $j = 1,2,\ldots,l_i$, of the subsystems S_υ, $\upsilon = 1,2,3,4,5$, without of any impact, i.e. the coordinates of the vector

$$[\lambda_{ij}^{(\upsilon)}(\cdot)] = \left[0, \lambda_{ij}^{(\upsilon)}(1), \lambda_{ij}^{(\upsilon)}(2), \lambda_{ij}^{(\upsilon)}(3), \lambda_{ij}^{(\upsilon)}(4)\right],$$
$$i = 1,2,\ldots,k, j = 1,2,\ldots,l_i, \upsilon = 1,2,3,4,5, \tag{15}$$

and

$$[\rho_{ij}^{4(\upsilon)}(u)]^{(bl)}, u = 1,2,3,4, i = 1,2, \quad ,k, j = 1,2, \quad ,l_i,$$
$$\upsilon = 1,2,3,4,5, b = 1,2, \quad ,18, l = 1,2, \quad ,6, \tag{16}$$

are the coefficients of the operation and climate-weather change impact on the components $E_{ij}^{(\upsilon)}$, $i = 1,2,\ldots,k$, $j = 1,2,\ldots,l_i$, of the subsystems S_υ, $\upsilon = 1,2,3,4,5$, intensities of ageing at the system states zc_{bl}, $b = 1,2,\ldots,18$, $l = 1,2,\ldots,6$, i.e. the coordinates of the vector

$$[\rho_{ij}^{4(\upsilon)}(\cdot)]^{(bl)} = \left[\ 0, [\rho_{ij}^{4(\upsilon)}(1)]^{(bl)}, [\rho_{ij}^{4(\upsilon)}(2)]^{(bl)}\ \right]$$
$$i = 1,2,\ldots,k, j = 1,2,\ldots,l_i, \upsilon = 1,2,3,4,5, \tag{17}$$
$$b = 1,2,\ldots,18, l = 1,2,\ldots,6.$$

According to expert opinions, changing the maritime ferry operation process states have influence on changing the system safety structures and its selected components' safety parameters as well. For this system, the intensities of components' departure from the safety states subsets {1,2,3,4}, {2,3,4}, {3,4}, {4} without of any impact are given in (Kołowrocki, Soszyńska-Budny & Torbicki 2017d), whereas the intensities of departure related to the operation process influence on ferry safety are given in (Kołowrocki et al. 2017c). The intensities of departure related to the climate-weather influence on the maritime ferry safety are calculated as a multiplication of the coefficients given in Table 1 in the Appendix and the intensities without of any impact. Thus, considering the above results, the new intensities of departure related to the operation and climate-weather influence on the maritime ferry safety are calculated according to formula (14), where the coefficients of the operation and climate-weather change impact on the components' intensities of ageing at the particular states are calculated as follows:

$$[\rho_{ij}^{4(\upsilon)}(u)]^{(bl)} = [\rho_{ij}^{1(\upsilon)}(u)]^{(bl)} [\rho_{ij}^{3(\upsilon)}(u)]^{(bl)}, i = 1,2, \quad ,k,$$
$$j = 1,2, \quad ,l_i, \upsilon = 1,2,3,4,5, u = 1,2,3,4, b = 1,2, \quad ,18,$$
$$l = 1,2, \quad ,6,$$

where $[\rho_{ij}^{\xi(\upsilon)}(u)]^{(bl)}$, $\xi = 1,3$, are respectively the coefficients of operation impact and climate-weather change impact on the components' intensities of ageing at the particular states.

5.2 *Maritime ferry safety characteristics*

In (Kołowrocki & Soszyńska-Budny 2011), it is fixed that the maritime ferry technical system safety structure and its subsystems and components safety depend on its changing in time opera-

tion states. The influence of the system states changing on the changes of the system safety structure and its components safety functions is given in (Kołowrocki et al. 2017b). Thus, in the case when the operation time is large enough, according to (7) the maritime ferry technical system unconditional safety function is given by the vector

$$\boldsymbol{S}^4(t,\cdot) = [1, \boldsymbol{S}^4(t,1), \boldsymbol{S}^4(t,2), \boldsymbol{S}^4(t,3), \boldsymbol{S}^4(t,4)], \quad t \in \langle 0,+\infty), \tag{18}$$

where according to (7), the vector coordinates are given respectively for $t \in \langle 0,+\infty)$, $u = 1,2,3,4$, by

$$\boldsymbol{S}^4(t,u) \cong \sum_{b=1}^{18} \sum_{l=1}^{6} pq_{bl} [\boldsymbol{S}^4(t,u)]^{(bl)}, \tag{19}$$

where $[\boldsymbol{S}^4(t,u)]^{(bl)}$, $u = 1,2,3,4$, $b = 1,2,\ldots,18$, $l = 1,2,\ldots,6$, are the coordinates of the system conditional safety functions defined by (2)-(4) and pq_{bl}, $b = 1,2,\ldots,18$, $l = 1,2,\ldots,6$, are the system operation process limit transient probabilities given by (10).

The graph of the five-state maritime ferry technical system safety function is presented in Figure 1.

Considering (19), the expected values and standard deviations, given in years, of the maritime ferry technical system lifetimes in the safety states subsets {1,2,3,4}, {2,3,4}, {3,4}, {4}, respectively are

$$\mu^4(1) \cong 5.785139,\ \mu^4(2) \cong 3.161191,\ \mu^4(3) \cong 2.342224,\ \mu^4(4) \cong 1.879662; \tag{20}$$

$$\sigma^4(1) \cong 5.56368,\ \sigma^4(2) \cong 3.077813,\ \sigma^4(3) \cong 2.28222,\ \sigma^4(4) \cong 1.830362. \tag{21}$$

Consequently, the mean values of the maritime ferry technical system lifetimes in the particular safety states 1, 2, 3, 4, respectively are:

$$\overline{\mu}^4(1) = 2.623948,\quad \overline{\mu}^4(2) = 0.8189667,\quad \overline{\mu}^4(3) = 0.4625623,\quad \overline{\mu}^4(4) = 1.879662. \tag{22}$$

By (20) and (21), the mean and the standard deviation of the maritime ferry lifetime up to exceeding critical safety state $r = 2$ are

$\mu^4(2) = 3.161191$ years, $\sigma^4(2) = 3.077813$ years.

Since the critical safety state is $r = 2$, then the system risk function of the maritime ferry technical system, is given by

$$\boldsymbol{r}^4(t) = 1 - \boldsymbol{S}^4(t,2), \tag{23}$$

where $\boldsymbol{S}^4(t,2)$ is given by (19) and illustrated in Figure 1.

Hence, considering (23), the moment when the system risk function exceeds a permitted level, for instance $\delta = 0.05$, is given as follows

$$\tau^4 = \boldsymbol{r}^{4-1}(\delta) \cong 0.17 \text{ year}. \tag{24}$$

The maritime ferry intensities of ageing according to (Kołowrocki et al. 2017b) and considering (19) are:

$$\boldsymbol{\lambda}^4(t,u) = -\frac{d(\boldsymbol{S}^4(t,u))}{dt} \cdot \frac{1}{\boldsymbol{S}^4(t,u)}, \tag{25}$$

where particularly

$$\boldsymbol{\lambda}^4(t,1) \cong 0.216514,\ \boldsymbol{\lambda}^4(t,2) \cong 0.3860834,\ \boldsymbol{\lambda}^4(t,2) \cong 0.516497,\ \boldsymbol{\lambda}^4(t,3) \cong 0.6449959.$$

The graphs of the intensities of ageing for the maritime ferry are shown in Figure 3.

Considering (20) and applying (57) from (Kołowrocki et al. 2017d), the coefficients of the operation and climate-weather impact on the maritime ferry safety are

$$\boldsymbol{\rho}^4(t,1) \cong \frac{1/\mu^4(1)}{1/\mu^0(1)} \cong \frac{1/5.785139}{1/6.246} \cong 1.079663,$$
$$\boldsymbol{\rho}^4(t,2) \cong \frac{1/\mu^4(2)}{1/\mu^0(2)} \cong \frac{1/3.161191}{1/3.390} \cong 1.072381,$$
$$\boldsymbol{\rho}^4(t,3) \cong \frac{1/\mu^4(3)}{1/\mu^0(3)} \cong \frac{1/2.342224}{1/2.503} \cong 1.068642,$$
$$\boldsymbol{\rho}^4(t,4) \cong \frac{1/\mu^4(4)}{1/\mu^0(4)} \cong \frac{1/1.879662}{1/2.007} \cong 1.067745. \tag{26}$$

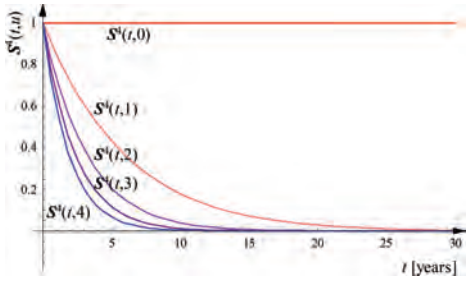

Figure 1. The graph of the maritime ferry safety function coordinates.

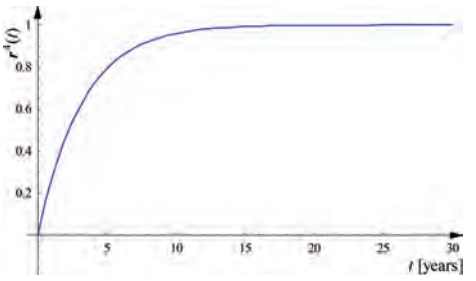

Figure 2. The graph (the fragility curve) of the maritime ferry risk function.

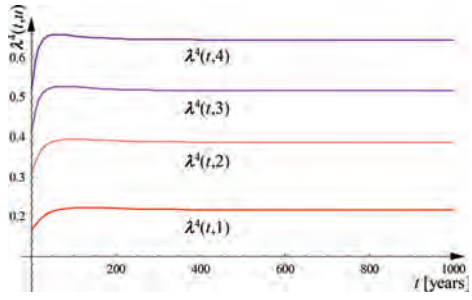

Figure 3. The graph of the intensities of ageing of the maritime ferry.

The resilience indicator, i.e. the coefficient of maritime ferry resilience to operation process and climate-weather change process impact is

$$\boldsymbol{RI}^4(t) = \frac{1}{\boldsymbol{\rho}^4(t,2)} \cong 0.9325047 \cong 93.25\%. \qquad (27)$$

6 CONCLUSIONS

The simplified impact model of critical infrastructure safety related to operation and climate-weather change impact was applied to the safety and risk evaluation for the maritime ferry operating at Baltic Sea waters. The predicted maritime ferry safety characteristics are different from those determined for this system operating at constant conditions without considering operation and climate-weather influence.

Safety and Reliability – Safe Societies in a Changing World – Haugen et al. (Eds)

Operating environment threats and climate-weather hazards impact on maritime ferry safety

K. Kołowrocki & E. Kuligowska
Gdynia Maritime University, Poland

ABSTRACT: In this paper, a general safety analytical model of a critical infrastructure under the influence of an operation process including operating environment threats related to climate-weather change is applied to safety prediction of maritime ferry. The main safety characteristics of the ferry in its corresponding operating area are evaluated. Namely, there are determined the unconditional safety function, the risk function, the mean lifetime up to the exceeding a critical safety state, the moment when the risk function value exceeds the acceptable safety level, the intensities of ageing and the coefficients of the operation and climate-weather impact on the ferry intensities of ageing.

1 INTRODUCTION

The paper is concerned with the operating environment threats and climate-weather hazards influence on the safety of a critical infrastructure. The maritime ferry operation process related to operating environment threats is described in (Kołowrocki et al. 2017a), whether the climate-weather change process for the ferry operating area is modeled in (Kuligowska 2017). The identification of the ferry operation process related to operating environment threats and climate-weather hazards is performed in (Kołowrocki et al. 2017b). Having these processes identified, the safety prediction of the considered ferry under the operation process including operating environment threats and climate-weather change influence is performed. The maritime ferry safety characteristics, i.e. the unconditional safety function and the risk function at changing in time operation including threats and climate-weather conditions (in February) are determined. Moreover, the safety and resilience indicators are presented: the mean lifetime up to the exceeding a critical safety state, the moment when the risk function value exceeds the acceptable safety level, the intensities of ageing and the coefficients of the operation and climate-weather impact on the maritime ferry safety.

2 CRITICAL INFRASTRUCTURE OPERATION PROCESS RELATED TO OPERATING ENVIRONMENT THREATS AND EXTREME WEATHER HAZARDS

2.1 *Critical infrastructure operation process related to operating environment threats*

We assume as in (Kołowrocki et al. 2017c) that the system during its operation process is taking ν', $\nu \in N$, different operation states $z'_1, z'_2, ..., z'_{\nu'}$. Further, we define the critical infrastructure operation process $Z'(t)$, $t \in < 0, +\infty)$ related to the critical infrastructure operating environment threats with discrete operation states from the set $\{z'_1, z'_2, ..., z'_{\nu'}\}$. Moreover, we assume that the critical infrastructure operation process $Z'(t)$ related to its operating environment threats is a semi-Markov process with the conditional sojourn times θ'_{bl} at the operation states z'_b when its next operation state is z'_l, $b,l = 1, 2, ..., \nu'$, $b \neq l$.

Under these assumptions, the critical infrastructure operation process may be described by (Kołowrocki, Kuligowska & Soszyńska-Budny 2017c):

– the vector $[p'_b(0)]_{1\times\nu'}$ of the initial probabilities $p'_b(0) = P(Z'(0) = z'_b)$, $b = 1, 2, \ldots, \nu'$, of the

process $Z'(t)$ staying at particular states at the moment $t = 0$;
- the matrix $[p'_{bl}]_{\nu' \times \nu'}$ of probabilities p'_{bl}, $b,l = 1, 2, ..., \nu'$, $b \neq l$, of the process $Z'(t)$ transitions between the operation states z'_b and z'_l;
- the matrix $[H'_{bl}(t)]_{\nu' \times \nu'}$ of conditional distribution functions $H'_{bl}(t) = P(\theta'_{bl} < t)$, $t \in <0,+\infty)$, $b,l = 1, 2, \ldots, \nu'$, $b \neq l$, of the system operation process $Z'(t)$ conditional sojourn times θ'_{bl} at the operation states.

The limit values of the process $Z'(t)$ transient probabilities $p'_b(t) = P(Z'(t) = z'_b)$, $t \in <0, +\infty)$, $b = 1, 2, ..., \nu'$, at the particular states can be found using the procedure given in (Kołowrocki, Kuligowska & Soszyńska-Budny 2017c).

2.2 *Climate-weather change process at the critical infrastructure operating area*

The climate-weather change process $C(t)$, $t \in <0, +\infty)$, for the critical infrastructure operating area is defined and modelled in (Kołowrocki, Soszyńska-Budny & Torbicki 2017a,b). We assume that the process is taking w, $w \in N$, different climate-weather states $c_1, c_2, \ldots, c_w$ and that this is a semi-Markov process. The process' parameters are described in (Kołowrocki & Kuligowska 2018), whereas the process' characteristics, e.g. the limit values of the climate-weather change process $C(t)$ transient probabilities $q_b(t) = P(C(t) = c_b)$, $t \in <0, +\infty)$, $b = 1, 2, ..., w$, at the particular climate-weather states, can be found using the procedure given in (Kołowrocki, Soszyńska-Budny & Torbicki 2017a).

2.3 *Critical infrastructure operation process related to operating environment threats and climate-weather hazards*

We assume as in (Kołowrocki et al. 2017a), that the critical infrastructure operation process $Z'C(t)$, $t \in < 0, + \infty)$, related to operating environment threats and climate-weather hazards can take $\nu' w$, ν', $w \in N$, different operation states $z'c_{11}, z'c_{12}, ..., z'c_{\nu w}$, described by:

- the vector $[p'q_{bl}(0)]_{1 \times \nu' w}$ of initial probabilities of the critical infrastructure process $Z'C(t)$ staying at the initial moment $t = 0$ at the particular states $z'c_{bl}$, $b = 1, 2, ..., \nu$, $l = 1, 2, ..., w$;
- the matrix $[p'q_{bl\tilde{b}\tilde{l}}]$ $\nu' w \times \nu' w$ of the probabilities of transitions of the critical infrastructure process $Z'C(t)$ between the states $z'c_{bl}$ and $z'c_{\tilde{b}\tilde{l}}$, $b = 1, 2, \ldots, \nu'$, $l = 1, 2, ..., w$, $\tilde{b} = 1, 2, ..., \nu'$, $\tilde{l} = 1, 2, ..., w$;
- the matrix $[H'C_{bl\,\tilde{b}\tilde{l}}(t)]_{\nu' w \times \nu' w}$ of the conditional distribution functions of the critical infrastructure process $Z'C(t)$ conditional sojourn times $\theta' C_{bl\,\tilde{b}\tilde{l}}$, $b = 1, 2, \ldots, \nu'$, $l = 1, 2, ..., w$, $\tilde{b} = 1, 2, ..., \nu'$, $\tilde{l} = 1, 2, ..., w$, at the state $z'c_{bl}$, $b = 1, 2, ..., \nu'$, $l = 1, 2, ..., w$, when the next state is $z'c_{\tilde{b}\tilde{l}}$, $\tilde{b} = 1, 2, ..., \nu'$, $\tilde{l} = 1, 2, ..., w$.

Assuming that we have identified the unknown parameters of the critical infrastructure operation process $Z'C(t)$ related to operating environment threats and climate-weather hazards, we can predict this process basic characteristics, e.g. the limit transient probabilities $p'q_{bl}(t) = P(Z'C(t) = z'c_{bl})$, $t \in <0, +\infty)$, $b = 1, 2, ..., \nu'$, $l = 1, 2, ..., w$, at the particular states, according to the procedure given in (Kołowrocki, Kuligowska & Soszyńska-Budny 2017a).

3 CRITICAL INFRASTRUCTURE SAFETY RELATED TO OPERATING ENVIRONMENT THREATS AND CLIMATE-WEATHER CHANGE PROCESS

In the safety analysis of critical infrastructures at the variable operation conditions under the influence of operating environment threats and related to climate-weather change, to define the critical infrastructure with degrading components we assume that the changes of the process $Z'C(t)$ states have an impact on the critical infrastructure's components and its structure (Kołowrocki 2014, Kołowrocki et al. 2017b). We denote the critical infrastructure asset A_i, $i = 1, 2, ..., n$, conditional lifetime in the safety state subset $\{u, u + 1, ..., z\}$, while the process $Z'C(t)$ is at the state $z'c_{bl}$, $b = 1, 2, ..., \nu'$, $l = 1, 2, ..., w$, by $[T_i^5(u)]^{(bl)}$. Moreover, in this section we assume that the critical infrastructure assets at particular states have the exponential safety functions. According to (Kołowrocki et al. 2017b), the conditional critical infrastructure safety function is defined by the vector

$$[S_i^5(t,\cdot)]^{(bl)} = [1, [S_i^5(t,1)]^{(bl)}, ..., S_i^5(t,z)]^{(bl)}], \; t \in <0, +\infty), \; b = 1, 2, ..., \nu', \; l = 1, 2, ..., w, \; i = 1, 2, ..., n, \tag{1}$$

with the coordinates

$$[S_i^5(t,u)]^{(bl)} = P([T_i^5(u)]^{(bl)} > t \mid Z'C(t) = z'c_{bl}) = \exp[-[\lambda_i^5(u)]^{(bl)}t], \; t \in <0, +\infty), \; b = 1, 2, ..., \nu', \; l = 1, 2, ..., w, \; i = 1, 2, \ldots, n, \tag{2}$$

where the intensities of ageing of the critical infrastructure assets related to operating environment threats and climate-weather impact, existing in (2), are given by

$$[\lambda_i^5(u)]^{(bl)} = [\rho_i^5(u)]^{(bl)} \cdot \lambda_i^0(u), \; u = 1, 2, ..., z, \; b = 1, 2, ..., \nu', \; l = 1, 2, ..., w, \; i = 1, 2, ..., n, \tag{3}$$

and $\lambda_i^0(u)$ are the intensities of ageing of the system components without any impact and

$$[\rho_i^5(u)]^{(bl)},\ u = 1, 2, ..., z,\ b = 1, 2, ..., \nu',\ l = 1, 2, ..., w,\ i = 1, 2, ..., n, \quad (4)$$

are the coefficients of operation and climate-weather change impact on the critical infrastructure assets' intensities of ageing without operation and climate-weather change impact.

Further, we denote the critical infrastructure unconditional lifetime in the safety state subset $\{u, u + 1, ..., z\}$ by $T^5(u)$ and the system unconditional safety function by

$$\boldsymbol{S}^5(t,\cdot) = [1, \boldsymbol{S}^5(t, 1), ..., \boldsymbol{S}^5(t,z)], \quad (5)$$

with the vector's coordinates defined by

$$\boldsymbol{S}^5(t, u) = P(T^5(u) > t),\ t \in <0, +\infty),\ u = 1, 2, ..., z. \quad (6)$$

In the case when the critical infrastructure operation time $\theta' C_{bl}$ is large enough, the coordinates of the unconditional safety function of the system defined by (5) are given by

$$\boldsymbol{S}^5(t,u) \cong \sum_{b=1}^{\nu'} \sum_{l=1}^{w} p'q_{bl}[\boldsymbol{S}^5(t,u)]^{(bl)},\ t \in < 0, +\infty),\ u = 1, 2, ..., z, \quad (7)$$

where $[\boldsymbol{S}^5(t,u)]^{(bl)}$, $u = 1, 2, ..., z$, $b = 1, 2, ..., \nu'$, $l = 1, 2, ..., w$, are the coordinates of the critical infrastructure conditional safety function defined by (2)-(4) and pq_{bl}, $b = 1, 2, ..., \nu$, $l = 1, 2, ..., w$, are the system operation process limit transient probabilities (see section 2.3).

Further, we determine the mean values $\mu^5(u)$ and the standard deviations $\sigma^5(u)$ of the unconditional lifetimes of the critical infrastructure in the safety state subsets $\{u, u + 1, ..., z\}$, $u = 1, 2, ..., z$, the mean values $\bar{\mu}^4(u)$ of the unconditional lifetimes of the critical infrastructure in the particular safety states u, $u = 1, 2, ..., z$, the risk function $r^5(t)$ and the moment τ^5 when the critical infrastructure risk function exceeds a permitted level δ, after substituting for $\boldsymbol{S}^5(t, u)$, $u = 1, 2, ..., z$, the coordinates of the unconditional safety functions given by (6).

4 MARITIME FERRY OPERATION PROCESS RELATED TO OPERATING ENVIRONMENT THREATS AND CLIMATE-WEATHER HAZARDS

Taking into account the expert opinions concerned with the operation process of the considered ferry technical system (Kołowrocki et al. 2017d), we assume that the maritime ferry operation process and safety may depend on operating environment threats and we distinguish the following 3 unnatural threats:

- ut_1 – a human error,
- ut_2 – a terrorist attack,
- ut_3 – a heavy sea traffic.

After assuming that the maritime ferry operation process including operating environment threats and the climate-weather change process at its operating area are independent, it is possible to evaluate the unknown basic parameter of the maritime ferry process $Z'C(t)$. Considering these identification results (Kołowrocki et al. 2017a), it was possible to predict this process' basic characteristics. The limit values of the process $Z'C(t)$ transient probabilities $p'q_{bl}$, $b = 1, 2, \ldots, 72$, $l = 1, 2, \ldots, 6$, at the particular states $z'c_{bl}$, are given in the vector

$$[p'q_{ij}]_{1\times 432} \cong [0.014948, 0.000407, 0.016687, 0.00037, 0.004588, 0;$$

5 MARITIME FERRY SAFETY PREDICTION RELATED TO OPERATING ENVIRONMENT THREATS AND CLIMATE-WEATHER HAZARDS

5.1 *Maritime ferry safety parameters*

There are distinguished z = 5 safety states for the considered maritime ferry described in (Kołowrocki & Kuligowska 2018). Moreover, by the expert opinions, we assume that there are possible the transitions between the components' safety states only from better to worse ones.

Considering the assumptions and agreements from the previous sections, we assume that the components $E_{ij}^{(\upsilon)}$, $i = 1, 2, ..., k$, $j = 1, 2, ..., l_i$, of the subsystem S_υ, $\upsilon = 1, 2, 3, 4, 5$, at the particular states $z'c_{bl}$, $b = 1, 2, ..., 72$, $l = 1, 2, ..., 6$, have the exponential safety functions, i.e. the coordinates of the vector

$$[S_{ij}^{5(\upsilon)}(t,\cdot)]^{(bl)} = [1,[S_{ij}^{5(\upsilon)}(t,1)]^{(bl)}, ..., [S_{ij}^{5(\upsilon)}(t,4)]^{(bl)}],$$
$$t \in <0,+\infty), i = 1, 2, ..., k, \ j = 1, 2, ..., l_i,$$
$$\upsilon = 1, 2, 3, 4, 5, b = 1, 2, ..., 72, l = 1, 2, ..., 6, \quad (9)$$

are given by

$$[S_{ij}^{5(\upsilon)}(t,u)]^{(bl)} = P([T_{ij}^{5(\upsilon)}]^{(bl)}(u) > t \,|\, Z'C(t) = z'c_{bl}) = \exp[-[\lambda_{ij}^{5(\upsilon)}(u)]^{(bl)}t],$$
$$t \in <0,+\infty), \ u = 1, 2, 3, 4, i = 1, 2, ..., k, \ j = 1, 2, ..., li,$$
$$v = 1, 2, 3, 4, 5, b = 1, 2, ..., 72, l = 1, 2, ..., 6. \quad (10)$$

Existing in the above formula the intensities of ageing of the components $E_{ij}^{(\upsilon)}$, $i = 1, 2, \ldots, k$, $j = 1, 2, \ldots, l_i$, of the subsystem S_υ, $\upsilon = 1, 2, 3, 4, 5$, at the system states $z'c_{bl}$, $b = 1, 2, \ldots, 72$, $l = 1, 2, \ldots, 6$, i.e. the coordinates of the vector of intensities

$$[\lambda_{ij}^{5(\upsilon)}(\cdot)]^{(bl)} = [0,[\lambda_{ij}^{5(\upsilon)}(1)]^{(bl)},\ldots,[\lambda_{ij}^{5(\upsilon)}(4)]^{(bl)}], \quad i = 1,2,\ldots,k,\ j = 1,2,\ldots,li, \quad \upsilon = 1,2,3,4,5, b = 1,2,\ldots,72, l = 1,2,\ldots,6, \tag{11}$$

are given by

$$[\lambda_{ij}^{5(\upsilon)}(u)]^{(bl)} = [\rho_{ij}^{5(\upsilon)}(u)]^{(bl)}\lambda_{ij}^{0(\upsilon)}(u), \quad u = 1, 2, 3, 4, i = 1, 2, \ldots, k, j = 1, 2, \ldots, l_i, \quad \nu = 1, 2, 3, 4, 5, b = 1, 2, \ldots, 72, l = 1, 2, \ldots, 6, \tag{12}$$

where $\lambda_{ij}^{0(\upsilon)}(u)$, $u = 1, 2, 3, 4$, $i = 1, 2, \ldots, k$, $j = 1, 2, \ldots, l_i$, are the intensities of ageing of the components $E_{ij}^{(\upsilon)}$, $i = 1, 2, \ldots, k$, $j = 1, 2, \ldots, l_i$, of the subsystems S_υ, $\upsilon = 1, 2, 3, 4, 5$, without of any impact and $[\rho_{ij}^{5(\upsilon)}(u)]^{(bl)}$, $u = 1, 2, \ldots, k$, $j = 1, 2, \ldots, l_i$, $\upsilon = 1, 2, 3, 4,5$, $b = 1, 2, \ldots, 72$, $l = 1, 2, \ldots, 6$, are the coefficients of the operation impact including threats and climate-weather change impact on the components $E_{ij}^{(\upsilon)}$, $i = 1, 2, \ldots, k, j = 1, 2, \ldots, l_i$, of the subsystems S_υ, $\upsilon = 1, 2, 3, 4,5$, intensities of ageing at the states $z'c_{bl}$, $b = 1, 2, \ldots, 72$, $l = 1, 2, \ldots, 6$.

According to expert opinions, changing the maritime ferry operation process states have influence on changing the system safety structures and its selected components' safety parameters as well. For this system, the intensities of components' departure from the safety states subsets {1,2,3,4}, {2,3,4}, {3,4}, {4} without of any impact are given in (Kołowrocki et al. 2017d), the intensities of departure related to the climate-weather influence on the maritime ferry safety are given in (Kołowrocki & Kuligowska 2018) and the intensities of departure related to the operating environment threats influence on ferry safety are given in (Kołowrocki et al. 2017d). Thus, the intensities of departure related to the operating environment threats and climate-weather hazards influence on ferry safety are calculated according to formula (12), where the coefficients of the operation, operating environment threats and climate-weather change impact on the components' intensities of ageing at the particular states are the multiplication of the above mentioned coefficients of impact on the components' intensities of ageing at the particular states.

5.2 *Maritime ferry safety characteristics*

Assuming that the maritime ferry technical system safety structure and its subsystems and components safety depend on its changing in time operation states, the influence of the system states changing on the changes of the system safety structure and its components safety functions is given in (Kołowrocki et al. 2017b). Thus, in the case when the operation time is large enough, according to (7) the maritime ferry unconditional safety function is given by the vector

$$\boldsymbol{S}^5(t,\cdot) = [1, \boldsymbol{S}^5(t,1), \boldsymbol{S}^5(t,2), \boldsymbol{S}^5(t,3), \boldsymbol{S}^5(t,4)], \quad t \in <0, +\infty), \tag{13}$$

where according to (7) the vector coordinates are given respectively for $t \in <0, +\infty)$, $u = 1, 2, 3, 4$, by

$$\boldsymbol{S}^5(t,u) \cong \sum_{b=1}^{72}\sum_{l=1}^{6} p'q_{bl}[\boldsymbol{S}^5(t,u)]^{(bl)}, \tag{14}$$

where $[\boldsymbol{S}^5(t,u)]^{(bl)}$, $u = 1, 2, 3, 4$, $b = 1, 2, \ldots, 72$, $l = 1, 2, \ldots, 6$, are the coordinates of the system conditional safety functions defined by (2)–(4) and $p'q_{bl}$, $b = 1, 2, \ldots, 72$, $l = 1, 2, \ldots, 6$, are the limit transient probabilities given by (8).

The graph of the five-state maritime ferry technical system safety function is presented in Figure 1.

Considering (14), the expected values and standard deviations, given in years, of the maritime ferry technical system lifetimes in the safety states subsets {1,2,3,4}, {2,3,4}, {3,4}, {4}, respectively are

$$\mu^5(1) \cong 5.778643,\ \mu^5(2) \cong 3.157926,\ \mu^5(3) \cong 2.339679,\ \mu^5(4) \cong 1.877708; \tag{15}$$

$$\sigma^5(1) \cong 5.557708,\ \sigma^5(2) \cong 3.07524,\ \sigma^5(3) \cong 2.280044,\ \sigma^5(4) \cong 1.828565. \tag{16}$$

Consequently, the mean values of the maritime ferry technical system lifetimes in the particular safety states 1, 2, 3, 4, respectively are:

$$\overline{\mu}^5(1) = 2.620717,\ \overline{\mu}^5(2) = 0.8182476,\ \overline{\mu}^5(3) = 0.4619703,\ \overline{\mu}^5(4) = 1.877708. \tag{17}$$

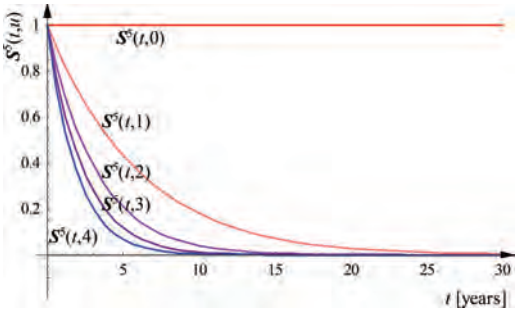

Figure 1. The graph of the maritime ferry safety function coordinates.

By (15) and (16), the mean and the standard deviation of the maritime ferry lifetime up to exceeding critical safety state $r = 2$ are

$$\mu^5(2) = 3.157926 \text{ years}, \quad \sigma^5(2) = 3.07524 \text{ years}.$$

The system risk function of the maritime ferry technical system, is given by

$$\boldsymbol{r}^5(t) = 1 - \boldsymbol{S}^5(t,2), \tag{18}$$

where $\boldsymbol{S}^5(t,2)$ is given by (14) and illustrated in Figure 2.

Hence, considering (18), the moment when the system risk function exceeds a permitted level, for instance $\delta = 0.05$, is given as follows

$$\tau^5 = \boldsymbol{r}^{5-1}(\delta) \cong 0.17 \text{ year}. \tag{19}$$

The maritime ferry intensities of ageing according to (Kołowrocki et al. 2017b) and considering (14) are:

$$\boldsymbol{\lambda}^5(t,u) = -\frac{d(\boldsymbol{S}^5(t,u))}{dt} \cdot \frac{1}{\boldsymbol{S}^5(t,u)}, \tag{20}$$

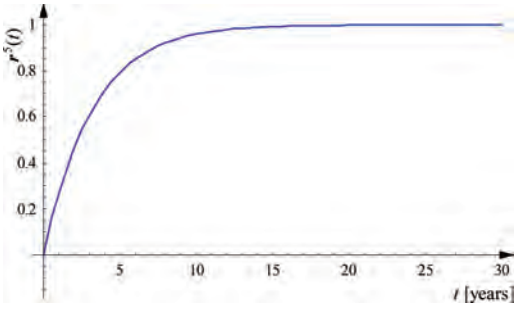

Figure 2. The graph (the fragility curve) of the maritime ferry risk function.

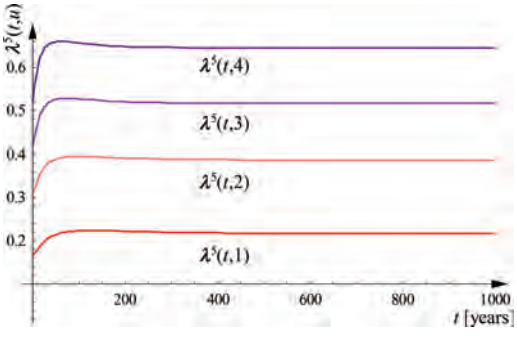

Figure 3. The graph of the intensities of ageing of the maritime ferry.

where particularly

$$\boldsymbol{\lambda}^5(t,1) \cong 0.2165163, \quad \boldsymbol{\lambda}^5(t,2) \cong 0.3860834,$$
$$\boldsymbol{\lambda}^5(t,2) \cong 0.5164971, \quad \boldsymbol{\lambda}^5(t,3) \cong 0.644996.$$

The graphs of the intensities of ageing for the maritime ferry are shown in Figure 3.

Considering (15) and applying (57) from (Kołowrocki, Soszyńska-Budny & Torbicki 2017d), the coefficients of operating environment threats and climate-weather change impact on the ferry safety are

$$\boldsymbol{\rho}^5(t,1) \cong \frac{1/\mu^5(1)}{1/\mu^0(1)} \cong \frac{1/5.778643}{1/6.246} \cong 1.080877,$$
$$\boldsymbol{\rho}^5(t,2) \cong \frac{1/\mu^5(2)}{1/\mu^0(2)} \cong \frac{1/3.157926}{1/3.390} \cong 1.073489,$$
$$\boldsymbol{\rho}^5(t,3) \cong \frac{1/\mu^5(3)}{1/\mu^0(3)} \cong \frac{1/2.339679}{1/2.503} \cong 1.069805,$$
$$\boldsymbol{\rho}^5(t,4) \cong \frac{1/\mu^5(4)}{1/\mu^0(4)} \cong \frac{1/1.877708}{1/2.007} \cong 1.068856. \tag{21}$$

The resilience indicator, i.e. the coefficient of maritime ferry resilience to operation process including threats and climate-weather change process impact is

$$\boldsymbol{RI}^5(t) = \frac{1}{\rho^5(t,2)} \cong 0.9315416 \cong 93.15\%. \tag{22}$$

6 CONCLUSIONS

The simplified impact model of critical infrastructure safety related to operating environment threats and climate-weather change impact was applied to the safety and risk evaluation for the maritime ferry operating at Baltic Sea waters. The predicted maritime ferry safety characteristics are different from those determined for this system operating at constant conditions without considering any impact. This approach makes the systems safety prediction much more precise.

Discussion on probabilistic and interval approaches applied to the Eurocode 7

Sónia H. Marques
Doctor in Geotechnics and Senior Professional Civil Engineer of the Portuguese Institution of Engineers, Portugal

ABSTRACT: The capabilities of nontraditional models for engineering computation under uncertainty have been under continuous review so that several nonprobabilistic approaches have been developed. The first applications of nonprobabilistic interval analysis in geotechnical engineering have been recently explored, considered a research area formally motivated by input information characterised by imprecision. Thus, the conventional probabilistic approach to uncertainty may be extended to include imprecise information in the form of intervals. For demonstration, results are provided on the analysis of a strip spread foundation designed by the Eurocode 7 methodology. A limit state imprecise interval analysis for bearing capacity is presented in the format of a sensitivity analysis. The limit state charts to safety assessment are separately sketched for the cases cohesion and friction angle interval scenario wherein the random variables are bounded on different levels of probability. The corresponding optimisation-based probability box structures are then sketched. The extension for high dimensional cases is as well considered through a limit state three-dimensional joint view to safety assessment, considered simultaneously the interval variables cohesion and friction angle. At last, the Eurocode 7 partial factor design is discussed on the basis of distinct levels of credibility.

1 INTRODUCTION

In recent years, several nonprobabilistic approaches have been developed to include uncertainties described by scarce information. If reliability is seen as a probability related to the satisfactory performance of a system under given circumstances, a nonprobabilistic concept of reliability holds on the acceptable range of performance fluctuations. According to the discussion of Haim & Elishakoff (1995), when considered only input interval variables, the nonprobabilistic concept of reliability is approached only by bounds as the safety margin is as well expressed in the interval format. Among nonprobabilistic approaches, the ordinary interval analysis involves the mapping of interval input to interval output quantities. The main advantage is the evaluation of the analytical enclosure of the true solution. Thereby, a considerable number of papers devoted to interval versus stochastic analysis have been published. Intervals represent an appropriate model to describe uncertainty in cases when a possible range between bounds is known and no other information concerning frequencies is available. Apart from, interval quantities may as well be included in computation based on other uncertainty models. Interval probabilities emerge from the consideration of a set of plausible probabilistic models in order to find the lower and upper probability bounds. This procedure is particularly convenient for sensitivity analysis, a very efficient tool to identify important design parameters and to address the performance level of real engineering systems in the context of optimisation procedures. Thus, whenever some probabilistic information is available, a mixed approach gathering imprecise information in the form of intervals may be explored. Vicig & Seidenfeld (2012) discuss the idea of replacing one exact probability value by introducing an indecision interval with two different exact one-sided values as endpoints. As the solution of practical problems in geotechnical engineering often requires judgement based on limited information, the assumption of interval-valued parameters in a mixed approach that admits as well probabilistic information verily complies with the imprecision of the input scenario. For demonstration, results are provided for a strip spread foundation designed by the Eurocode 7 methodology (EN 1997-1 2004), wherein the shear strength parameters of the foundation soil are implemented as intervals and then combined with other uncertain parameters in the form of random variables bounded on different levels of probability. A limit state imprecise interval analysis for bearing capacity is then presented in the format of a sensitiv-

ity analysis wherein the safety margin is as well expressed in the interval format.

2 LIMIT STATE IMPRECISE INTERVAL ANALYSIS

On the limit state imprecise interval analysis some selected parameters are separately or simultaneously implemented as imprecise intervals and then combined with other uncertain parameters in the form of random variables bounded under dependence; thereby, the random variables are bounded by using imprecise interval quantities in order to express different levels of probability. A brief explanation of the methodology for minimisation and maximisation which considers dependence is summarised next. The step by step optimisation algorithm is supported by transformations derived in compensative probability to express the performance function in the standard normal space of uncorrelated random and interval variables:

[Step 1] Express the distributions and the statistics of basic input variables;
[Step 2] Express the equivalent standard normal correlation matrix;
[Step 3] Express the outcome matrix from the Cholesky decomposition of the equivalent standard normal correlation matrix;
[Step 4] Express the set of random and interval variables vector in the standard normal space of uncorrelated random and interval variables;
[Step 5] Express the performance function and the limit state in the standard normal space of uncorrelated random and interval variables;
[Step 6] Express the set of constraints and whenever required the set of guess values for initialisation of the suboptimisation algorithm;
[Step 7] Select the suboptimisation algorithm properly and run the iterative process in a multistart approach;
[Step 8] Estimate the pair minimum-maximum and the corresponding coordinates in the standard normal space of uncorrelated as well as in the original space of correlated random and interval variables.

Thereby, the performance function in the standard normal space of uncorrelated variables is expressed by the following equivalent transformations $xi = \mathrm{f}(yi)$ and $\mathrm{f}(xi) = yi$ straightforwardly derived by the next Equation (1) in compensative probability:

$$xi = \mathrm{F_{Xi}}^{-1}\left[\Phi(yi)\right] \leftrightarrow \Phi^{-1}\left[\mathrm{F_{Xi}}(xi)\right] = yi \tag{1}$$

if xi = variable in the original space; yi = variable in the standard normal space; $\mathrm{F_{Xi}}$ = cumulative nonnormal distribution function; $\mathrm{F_{Xi}}^{-1}$ = inverse cumulative nonnormal distribution function; Φ = cumulative standard normal distribution function; and Φ^{-1} = inverse cumulative standard normal distribution function.

The correlation assignment in Equation (2) is also added to this standard normal space script:

$$\left[cyi^{*}\right] = \left[\mathrm{Ch}\right]\left[uyi^{*}\right] \tag{2}$$

if cyi^{*} = set of variables vector in the standard normal space of correlated variables; uyi^{*} = set of variables vector in the standard normal space of uncorrelated variables; and Ch = outcome matrix from the Cholesky decomposition of the equivalent standard normal correlation matrix.

Considered normal and lognormal distributions, the equivalent transformations for representation of variables xi in the original space as a function of variables yi in the standard normal space are further detailed as follows in the next Table 1 as explicit expressions for the equivalent transformations $xi = \mathrm{f}(yi)$ and $\mathrm{f}(xi) = yi$ as previously derived by Equation (1) in compensative probability.

A simplified approach may be considered on the computation of the equivalent standard normal correlation matrix wherein the values of the correlation coefficients between the variables are transformed by empirical relationship. Thus, the transformation F expressed in the next Table 2 is derived by exact relationship and used for the computation of the resultant equivalent standard normal correlation coefficient, when the random variables are normal and lognormal.

A test function as the Rosenbrock which is characterised by one challenging minimum point is very convenient for the purpose of testing, see the following Figure 1.

Table 1. Transformations for representation of variables xi in the original space as a function of variables yi in the standard normal space.

Distributions	$xi = \mathrm{f}(yi)$
Normal	$xi = \mu + \sigma \cdot yi$
Lognormal	$xi = \mathrm{e}^{(\mu l + \sigma l \cdot yi)}$
Distributions	$\mathrm{f}(xi) = yi$
Normal	$\dfrac{xi - \mu}{\sigma} = yi$
Lognormal	$\dfrac{\ln(xi) - \mu l}{\sigma l} = yi$

μ - mean value; σ - standard deviation; μl - log mean value; σl - log standard deviation.

Table 2. Transformation F by exact relationship for representation of the coefficient of correlation between two standard normal variables xi′ and xj′ as $\rho'_{xi'xj'} = F \cdot \rho_{xixj}$.

Variable xi	Variable xj	Transformation F
Normal	Lognormal	$\frac{cv_{xj}}{\sqrt{\left(\ln\left(1+cv_{xj}^2\right)\right)}}$

cv - coefficient of variation.

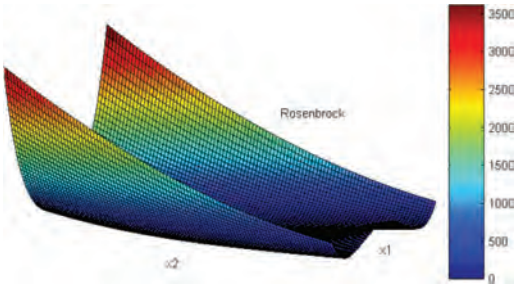

Figure 1. Rosenbrock test function overview if $x_1 \in [-3,+3]$ and $x_2 \in [-3,+3]$.

In fact, a considerable number of suboptimisation algorithms may be considered for the purpose but both local and global engines may fail under certain circumstances. In particular, conjugate gradient and quasi newton optimisation algorithms in a multistart approach are successful on the search for the minimum point of the Rosenbrock test function.

3 DESIGN EXAMPLE

The design example is referred to the strip spread foundation on a relatively homogeneous soil shown in Figure 2, wherein groundwater level is away. Considered the vertical noneccentric loading problem and the calculation model for bearing capacity, the performance function may be described by the simplified Equation (3):

$$M = f\left(B, D, \gamma_s, c_f, \varphi_f, \gamma_f, P, Q\right) \tag{3}$$

if B is the foundation width; D is the soil height above the foundation base; γ_s is the unit weight of the soil above the foundation base; c_f is the cohesion of the foundation soil; φ_f is the friction angle of the foundation soil; γ_f is the unit weight of the foundation soil; P is the dead load; and Q is the live load.

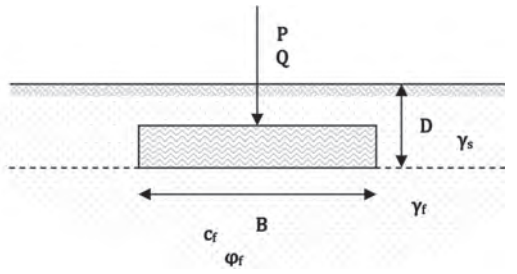

Figure 2. Strip spread foundation.

Table 3 summarises the description of basic input variables, with different types of distributions. The considered correlation coefficients between the

basic input variables are either presented in Table 4. The strip spread foundation is designed by the Eurocode 7 methodology, Design Approach DA.2*.

4 RESULTS AND DISCUSSION

A cautious estimate of the 95% reliable mean value for a known coefficient of variation is considered for each geotechnical characteristic value. The summary description of reliability estimates in interval scenario is further provided in Table 5 for the cases cohesion and friction angle interval scenario, wherein results are obtained from 5e6 simulations or sampling points, Monte Carlo simulation (MCS) considered. The generalised extreme value distribution is selected after a study with Kolmogorov Smirnov and Anderson Darling and Chi Squared goodness of fit tests. The shear strength parameters of the foundation soil are separately implemented as intervals and then combined with other uncertain parameters in the form of random variables under dependence. The optimisation-based probability box structures for the cases cohesion and friction angle interval scenario are drawn in the next Figure 3 and Figure 4 by using conjugate gradient and quasi newton optimisation algorithms in a multistart approach.

The 3.8 target reliability index is considered on the determination of the cohesion and friction angle values which satisfy the safety on every inter-

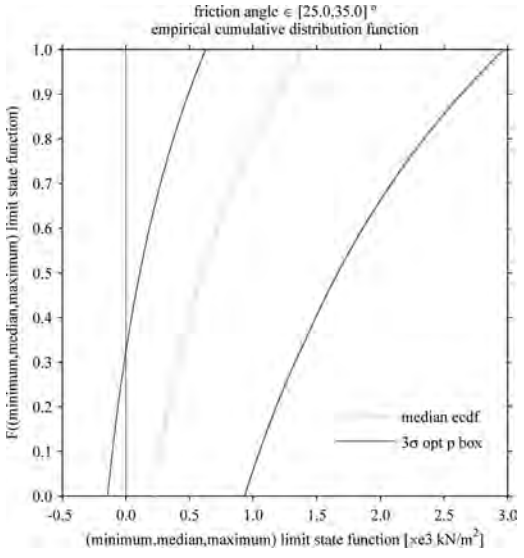

Figure 4. Optimisation-based probability box structure for the case friction angle interval scenario.

val scenario by simulation and distribution fitting. A boundless immeasurable reliability is further noticed on both cases. A comparative analysis of results from both methodologies shows appreciable differences whenever the cohesion values are approaching 15.0 kN/m^2 and the friction angle values are approaching 27.5º, noted that for the correspondent levels of reliability the Monte Carlo simulation failure probability error is estimated higher than 10%. Moreover, it is clearly shown that small variations in the friction angle input are very influential in that the median and the imprecise lower bound of probability correspond to a boundless immeasurable reliability, considered that satisfactory levels of reliability estimates are separately attained for a cohesion of about 12.0 kN/m^2 and for a friction angle of about 26.0º.

Regarding the graphs on Figure 3 and Figure 4, appropriate representation of the minimum and maximum branches comprehends respectively a number of 351 or 201 discretisation points uniformly distributed on the interval [0.0,35.0] kN/m^2 or [25.0,35.0]º. The stairstep median trend is comparatively drawn from a moderate number of discretisation points uniformly distributed on the intervals. The optimisation-based probability box structures are constructed comparatively to the median empirical cumulative distribution function, noted that the empirical cumulative distribution functions corresponding to the collection of minimum and maximum values are sketched at a central credibility level 3σ. From observation of Figure 3 and Figure 4, it is noted that the linear and nonlinear trends evinced by the graphs express the influence of the parameters cohesion and friction angle on the calculation model for bearing capacity. The position of the median trend, which separates the fifty percent chance cases, is further sketched on the safe side. Regarding the limit state, the probability of no failure across the cohesion and friction angle interval scenario at a central credibility level 3σ is respectively circa 50% or 70%, see the probability level for a positive outcome on the minimum branch of the graphs.

The limit state charts to safety assessment are represented on Figure 5 and Figure 6, considered respectively and separately the cases cohesion and friction angle interval scenario, in a sensitivity analysis wherein the random variables are bounded on different levels of probability. Distinct levels of credibility are used to sketch the lines which express the limit state bounds. It is possible to search for a credibility level which ensures no failure regardless of the parameter value on the horizontal axis, see safe level for arrow in Figure 6 against unsafe level for arrow in Figure 5. Conversely, it is possible to find the threshold parameter which ensures no failure for a given credibility level and then to proceed with proper ground investigation and testing or improvement, see in both charts the circles crossing the zero limit state boundary and the 0.9900 credibility level line. In decision making, this valuable approach may be extended by numerical analysis for high dimensional cases with several indecision variables in simultaneous, see Figure 7 and Figure 8.

According to the results on Table 5 and considered the cases cohesion and friction angle interval scenario, the threshold values which satisfy the 3.8 target reliability index are about 12.0 kN/m^2 and 26.0º, respectively. Following the vagueness of the indecision interval, this imprecise approach is interpreted altogether with a complementary limit state imprecise interval analysis for sensitivity, validation and decision. Thereby, it is concluded that satisfactory levels of reliability estimates are attained by the probability level of 0.9900 sketched on the limit state charts to safety assessment. On this framework, Figure 7 and Figure 8 display respectively the limit state three-dimensional joint view to safety assessment for a 0.9900 and a 0.9990 probability level. A three-dimensional representation of the zero limit state reference surface is crossed in one corner by the limit state lower bound surface constructed from a joint assumption of the values of the interval variables cohesion and friction angle. Considered the Figure 7, unsafe coordinates are limited to a cohesion parameter under a value between 7.0 kN/m^2 and 10.5 kN/m^2 or to a friction angle parameter under a value between 29.0º and 30.0º, considered the two worst combination

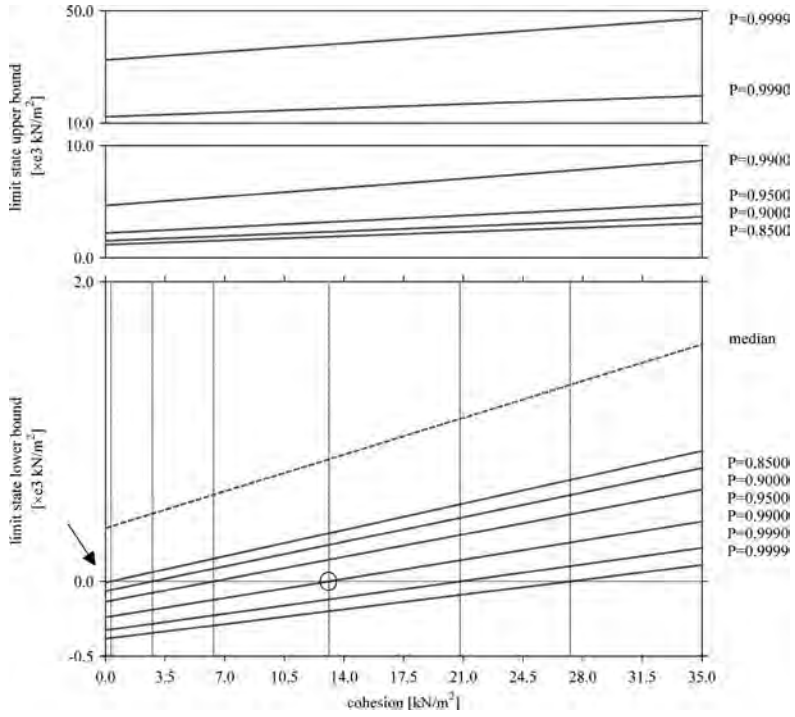

Figure 5. Limit state chart to safety assessment for the case cohesion interval scenario.

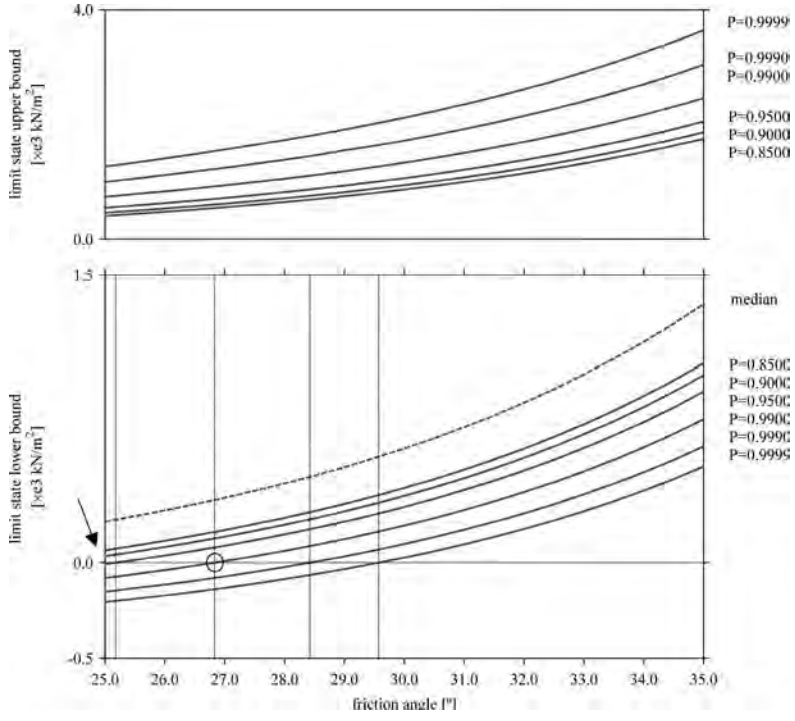

Figure 6. Limit state chart to safety assessment for the case friction angle interval scenario.

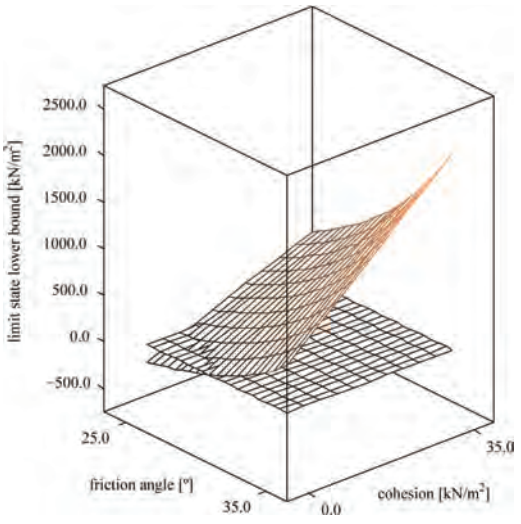

Figure 7. Limit state three-dimensional joint view to safety assessment for a 0.9900 probability level.

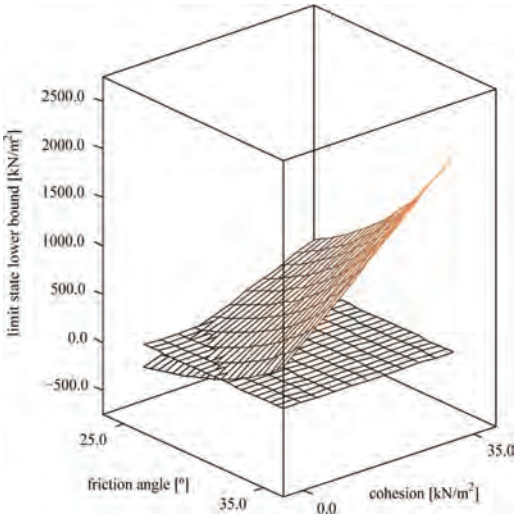

Figure 8. Limit state three-dimensional joint view to safety assessment for a 0.9990 probability level.

cases corresponding to a friction angle of 25.0º or to a cohesion of 0.0 kN/m^2, respectively. Considered the Figure 8, unsafe coordinates are limited to a cohesion parameter under a value between 10.5 kN/m^2 and 14.0 kN/m^2 or to a friction angle parameter under a value between 30.0º and 31.0º, considered the two worst combination cases corresponding to a friction angle of 25.0º or to a cohesion of 0.0 kN/m^2, respectively.

Unrealistic model assumptions are evinced by the limit state charts to safety assessment when higher levels of probability are considered, see the case cohesion interval scenario wherein the limit state upper bounds are obtained from unrealistic coordinates. Therefore, a critical evaluation from the interval scenario may influence the safety-based decision in ground investigation and testing or improvement. In addition, the interval uncertainty comprehends a probabilistic meaning for every combinatory possibility, see the case cohesion interval scenario wherein nonsatisfactory levels of reliability estimates are attained in a significant part of the cohesion interval. Another important issue is the position of the median trend which separates the fifty percent chance cases, here sketched on the safe side, noted that the linear and nonlinear trends evinced by the charts express the influence of the shear strength parameters on the calculation model for bearing capacity.

In the multivariate case the considered probability level prescribes a credible region in the hyperspace, then the imprecise interval analysis complies with a mixed set of probabilistic and nonprobabilistic interval models wherein different bounding measures may be applied in order to find the limit state lower and upper bounds in different scenarios. The proposed step by step optimisation algorithm for minimisation and maximisation further considers any important dependence relationships and whenever interval variables are involved proper constraints are required, see the case friction angle interval scenario. In fact, dependence is an important feature on the geotechnical engineering practice wherein design parameters encompass a physical meaning.

The summary description of reliability estimates in probabilistic scenario are finally provided in the next Table 6, wherein three methods are compared: the first order reliability method (FORM) and the second order reliability method (SORM), or the Monte Carlo simulation (MCS), the latter from counting among 5e6 trials. Regardless of the type of function and within acceptable margin of error, the global behaviour is approachable in every case.

Table 6. Summary description of model results for the reliability index and respective relative errors.

Reliability index β_{FORM}	Reliability index β_{SORM}	Reliability index β_{MCS}	β_{FORM} and β_{MCS} relative error (%)	β_{SORM} and β_{MCS} relative error (%)
3.3716	3.4392	3.4388	–1.9542	0.0102

MCS results from 1e6 simulations.

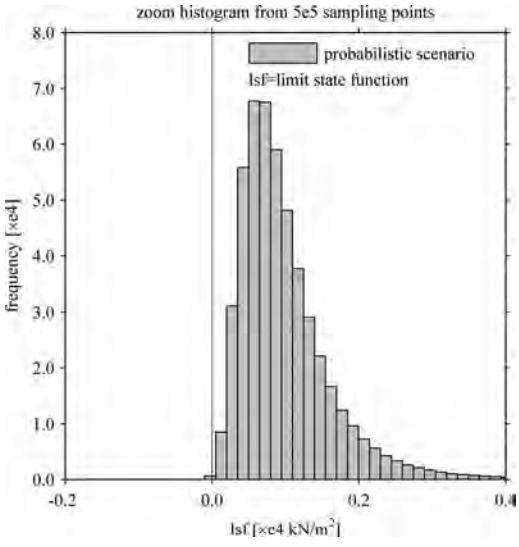

Figure 9. Limit state function histogram in probabilistic scenario.

A limit state function histogram in probabilistic scenario is further presented in the following Figure 9. The behaviour of the nonlinear bearing capacity model is then illustrated noted that the limit state function shows a nonnormal distribution under the probabilistic scenario characterised by the uncertain parameters and dependencies formerly described. Thorough observation reveals the presence of a small amount of data on the left of the zero limit state boundary, unsafe side. Thereby, failure may be considered a quite rare event among the considered 5e5 trials on nonsymmetric right skewed arrangement and with no single center.

5 CONCLUSION

The capabilities of nontraditional models for engineering computation under uncertainty have been under continuous review. Practical experience suggests that important dependence relationships should be considered on the proposed step by step optimisation algorithm for minimisation and maximisation. For demonstration, results are provided on the analysis of a strip spread foundation designed by the Eurocode 7 methodology, and precise versus imprecise probabilistic approaches are discussed. The limit state imprecise probabilistic analysis is interpreted altogether with a limit state imprecise interval analysis for bearing capacity. This sensitivity analysis may reveal unrealistic model assumptions and may provide meaningful results for safety-based decision in ground investigation and testing or improvement. Thus, the limit state charts to safety assessment are separately sketched for the cases cohesion and friction angle interval scenario wherein the random variables are bounded on different levels of probability.

The extension for high dimensional cases is as well considered through a limit state three-dimensional joint view to safety assessment, considered simultaneously the interval variables cohesion and friction angle. In the multivariate case the considered probability level prescribes a credible region in the hyperspace, then the imprecise interval analysis complies with a mixed set of probabilistic and nonprobabilistic interval models wherein different bounding measures may be applied in order to find the limit state lower and upper bounds in different scenarios. Thereby, the Eurocode 7 partial factor design is discussed on the basis of distinct levels of credibility. On this particular case study it is clearly shown that small variations in the friction angle input are very influential in that the median and the imprecise lower bound of probability correspond to a boundless immeasurable reliability. This conclusion is noticeable as well from the limit state chart to safety assessment for the case friction angle interval scenario.

Discussion on evaluation of probability bounds applied to the Eurocode 7

Sónia H. Marques
Doctor in Geotechnics and Senior Professional Civil Engineer of the Portuguese Institution of Engineers, Portugal

ABSTRACT: The underlying idea on the imprecise probability theory consists in modelling an imprecise probability distribution by a set of candidate probability distributions which are derived from the available data. The family is represented through a probability bounding approach applied to specify the lower and upper bounds of the imprecise probability distribution. A number of set-based uncertainty models derived from the probability bounding approach have been considered, namely the probability box structure. Designed from different approaches, probability boxes may differ meaningly from each other. A parametric approach may involve distributions with interval parameters or an envelope of competing probabilistic models. From search amid the number of candidate cumulative distribution functions the envelope of competing probabilistic models is expressed by a probability box function. In this way, a procedure for construction of a probability box structure by optimisation is advanced. Different dependencies may lead to quantitatively varied results so that a single scalar measure of a correlation coefficient may not be able to capture the complexity of the dependence model. Thus, the effects of correlation on the probability box structure may be comparatively considered. The technology is demonstrated on a synthetic exercise and on a design example referred to a strip spread foundation designed by the Eurocode 7.

1 INTRODUCTION

A probability bounding approach is hereafter applied to specify the lower and upper bounds of one imprecise probability distribution, see the review of Vicig & Seidenfeld (2012). By principle, variational correlation measures are insufficient to explore the possible nonlinear dependencies between variables in the form of a general relationship. In fact, the standard correlation concept is associated to a directional variation of paired random variables in that the word correlation is often reserved to be used only with random variables. In this way, a procedure for construction of a probability box structure by optimisation is advanced. In particular, the proposed procedure is aimed to consider how interval variables contained in a set between two endpoints may be related to other random variables characterised by a probability distribution. Regarding a sensitivity analysis, the effects of correlation on the probability box structure are comparatively demonstrated on a synthetic exercise, see the challenge problems in Oberkampf *et al.* (2004), and on a design example referred to a strip spread foundation designed by the Eurocode 7 (EN 1997-1 2004).

Considered that the parameter a follows a uniform distribution on the interval [0.1,1.0] and the parameter b follows a uniform distribution on the interval [0.0,1.0], Figure 1 represents comparatively the Kendall correlation pattern at 0.7 correlation coefficient for Archimedean parameterised copula families as Clayton or Frank or Gumbel, defined directly rather than being defined constructively from multivariate distributions. Considered the Pearson correlation pattern at 0.9 correlation coefficient, the equivalent Kendall rank correlation coefficient of 0.7 is determined at first to find the correspondent copula parameter α to launch the experiments accordingly by using a statistical toolbox. Afterwards, the Kendall correlation pattern at 0.7 correlation coefficient may be compared to the Pearson correlation pattern at 0.9 correlation coefficient, for the purpose see Figure 2. These approaches represent only a measure of the strength of the linear relationship between the two variables. It is further noted that the search for minimum and maximum values may reveal differences when compared the correlatedness and uncorrelatedness scenarios, particularly in the case of a higher correlation coefficient wherein the designed correlation pattern may be displayed as sharp at the endpoints of the intervals.

2 OPTIMISATION-BASED SYNTHETIC EXERCISE

The step by step optimisation algorithm is supported by transformations derived in compensative probability to express the performance function in the standard normal space of uncorrelated random and interval variables. Afterwards, the pair

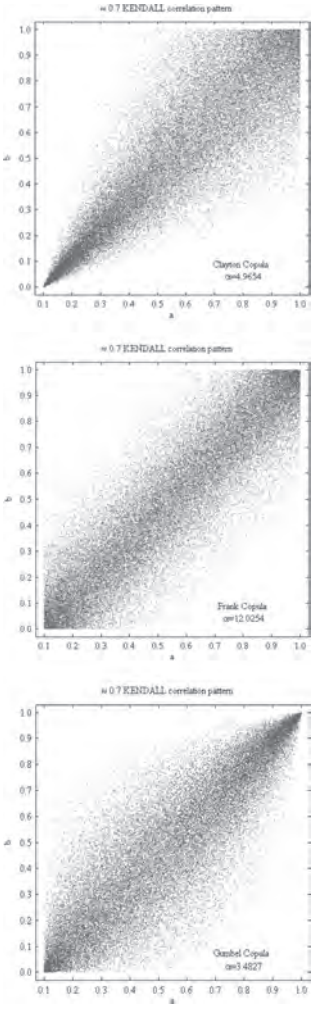

Figure 1. Kendall correlation pattern at 0.7 correlation coefficient, Clayton Copula and Frank Copula and Gumbel Copula.

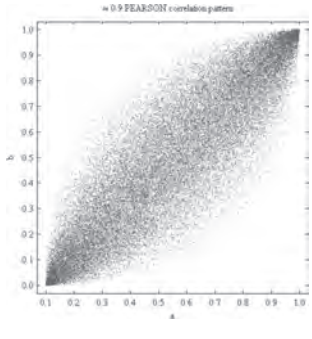

Figure 2. Pearson correlation pattern at 0.9 correlation coefficient.

minimum-maximum is estimated at a given central credibility level for every parametric combination across the indecision interval on the construction of the optimisation-based probability box structure:

[Step 1] Express the distributions and the statistics of basic input variables;
[Step 2] Express the equivalent standard normal correlation matrix;
[Step 3] Express the outcome matrix from the Cholesky decomposition of the equivalent standard normal correlation matrix;
[Step 4] Express the set of random and interval variables vector in the standard normal space of uncorrelated random and interval variables;
[Step 5] Express the performance function and the limit state in the standard normal space of uncorrelated random and interval variables;
[Step 6] Express the set of constraints and whenever required the set of guess values for initialisation of the suboptimisation algorithm;
[Step 7] Select the suboptimisation algorithm properly and run the iterative process in a multistart approach;
[Step 8] Estimate the pair minimum-maximum and the corresponding coordinates in the standard normal space of uncorrelated as well as in the original space of correlated random and interval variables.

The performance function in the standard normal space of uncorrelated random and interval variables is expressed by the following equivalent transformations $xi = f(yi)$ and $f(xi) = yi$ derived by Equation (1) in compensative probability:

$$xi = F_{Xi}^{-1}\left[\Phi(yi)\right] \leftrightarrow \Phi^{-1}\left[F_{Xi}(xi)\right] = yi \tag{1}$$

if xi = variable in the original space; yi = variable in the standard normal space; F_{Xi} = cumulative nonnormal distribution function; F_{Xi}^{-1} = inverse cumulative nonnormal distribution function; Φ = cumulative standard normal distribution function; and Φ^{-1} = inverse cumulative standard normal distribution function.

The correlation assignment in Equation (2) is also added to this standard normal space script:

$$[cyi^*] = [\mathrm{Ch}][uyi^*] \tag{2}$$

if cyi^* = set of variables vector in the standard normal space of correlated variables; uyi^* = set of variables vector in the standard normal space of uncorrelated variables; and ch = outcome matrix

from the Cholesky decomposition of the equivalent standard normal correlation matrix.

A considerable number of suboptimisation algorithms may be considered for the purpose but both local and global engines may fail under certain circumstances. A test function as the Peaks which is characterised by six minimum-maximum points is very convenient for the purpose of testing. In particular, conjugate gradient and quasi newton optimisation algorithms in a multistart approach are successful on the search for the six minimum-maximum points of the Peaks test function.

For demonstration, the proposed procedure is then applied on the synthetic exercise expressed by Equation (3) by using conjugate gradient and quasi newton optimisation algorithms in a multistart approach:

$$y = (a + b)^a \tag{3}$$

where the parameter a belongs to the interval [0.1,1.0] and the parameter b follows a uniform distribution on the interval [0.0,1.0].

Different degrees of correlation are considered to evince the effect of the parameter b on the interval for the parameter a. A sequence of transformations is exemplified next for the optimisation procedure by the group of Equations (5) and (7), respectively developed for the case minimisation to a 0.1 and 0.9 correlation coefficient at central credibility level 5σ and a = 1, wherein the group of Equations (4) and (6) presents the corresponding equivalent standard normal correlation matrix R and the outcome matrix from the Cholesky decomposition of the equivalent standard normal correlation matrix Ch:

Given

$$R = \begin{vmatrix} 1.0 & 0.1 \\ 0.1 & 1.0 \end{vmatrix} \quad \text{and} \quad Ch = \begin{vmatrix} 1.0000 & 0.0000 \\ 0.1000 & 0.9950 \end{vmatrix} \tag{4}$$

$$L(a,b) = (a + b)^a$$

$$L(ya,yb) = \left(F_U^{-1}\left[\Phi(1.0000 \cdot ya + 0.0000 \cdot yb)\right] + F_U^{-1}\left[\Phi(0.1000 \cdot ya + 0.9950 \cdot yb)\right]\right)^{F_U^{-1}\left[\Phi(1.0000 \cdot ya + 0.0000 \cdot yb)\right]}$$

$$-5 \le ya \le 5$$
$$-5 \le yb \le 5$$
$$a = F_U^{-1}\left[\Phi(1.0000 \cdot ya + 0.0000 \cdot yb)\right] = 1$$

$$M = \text{Minimise}(L, ya, yb)$$

$$ya = 5$$
$$yb = -5$$
$$a = F_U^{-1}\left[\Phi(1.0000 \cdot ya + 0.0000 \cdot yb)\right] = 1$$
$$b = F_U^{-1}\left[\Phi(0.1000 \cdot ya + 0.9950 \cdot yb)\right] = 3.8206e-6$$

$$L(ya,yb) = L(a,b) = 1.0000 \tag{5}$$

Given

$$R = \begin{vmatrix} 1.0 & 0.9 \\ 0.9 & 1.0 \end{vmatrix} \quad \text{and} \quad Ch = \begin{vmatrix} 1.0000 & 0.0000 \\ 0.9000 & 0.4359 \end{vmatrix} \tag{6}$$

$$L(a,b) = (a + b)^a$$

$$L(ya,yb) = \left(F_U^{-1}\left[\Phi(1.0000 \cdot ya + 0.0000 \cdot yb)\right] + F_U^{-1}\left[\Phi(0.9000 \cdot ya + 0.4359 \cdot yb)\right]\right)^{F_U^{-1}\left[\Phi(1.0000 \cdot ya + 0.0000 \cdot yb)\right]}$$

$$-5 \le ya \le 5$$
$$-5 \le yb \le 5$$
$$a = F_U^{-1}\left[\Phi(1.0000 \cdot ya + 0.0000 \cdot yb)\right] = 1$$

$$M = \text{Minimise}(L, ya, yb)$$

$$ya = 5$$
$$yb = -5$$
$$a = F_U^{-1}\left[\Phi(1.0000 \cdot ya + 0.0000 \cdot yb)\right] = 1$$
$$b = F_U^{-1}\left[\Phi(0.9000 \cdot ya + 0.4359 \cdot yb)\right] = 0.9898$$

$$L(ya,yb) = L(a,b) = 1.9898 \tag{7}$$

if ya = corresponding parameter a coordinates in the standard normal space; yb = corresponding parameter b coordinates in the standard normal space; F_U^{-1} = inverser cumulative uniform distribution function; and Φ = cumulative standard normal distribution function; noted σ as a unitary standard deviation in the standard normal space.

The following graphs are then designed at 0.1 correlation coefficient and at 0.9 correlation coefficient. Figure 3 and Figure 5 present the minimum and mean and maximum trends across the interval [0.1,1.0] for parameter a. Figure 4 and Figure 6 present the corresponding optimisation-based probability box structure. For appropriate representation of every sketched line, it is selected a number of 181 discretisation points uniformly distributed on the interval [0.1,1.0] for parameter a.

The optimisation-based probability box structure is constructed comparatively to the mean empirical cumulative distribution function, noted that the adjacent empirical functions corresponding to the collection of minimum and maximum values are sketched at a central credibility level 5σ. From observation of Figure 3 and Figure 5 it is noted that the position of the lowest minimum occurs on the inner part of the interval [0.1,1.0] for parameter a, with the position of the highest maximum on the coordinate 1.0. From observation of Figure 4 and Figure 6 it is noted that the gradual

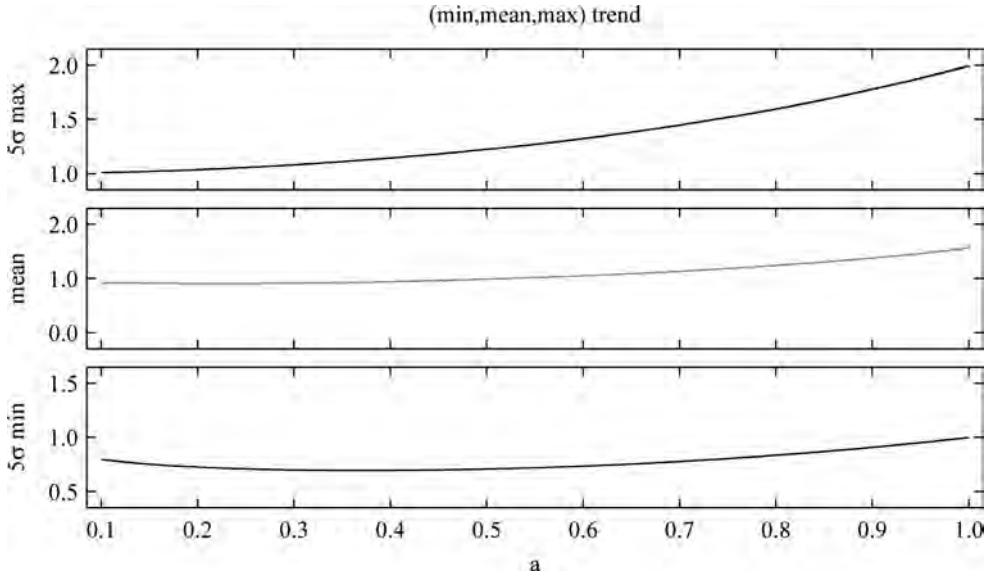

Figure 3. Trends for the synthetic exercise at 0.1 correlation coefficient.

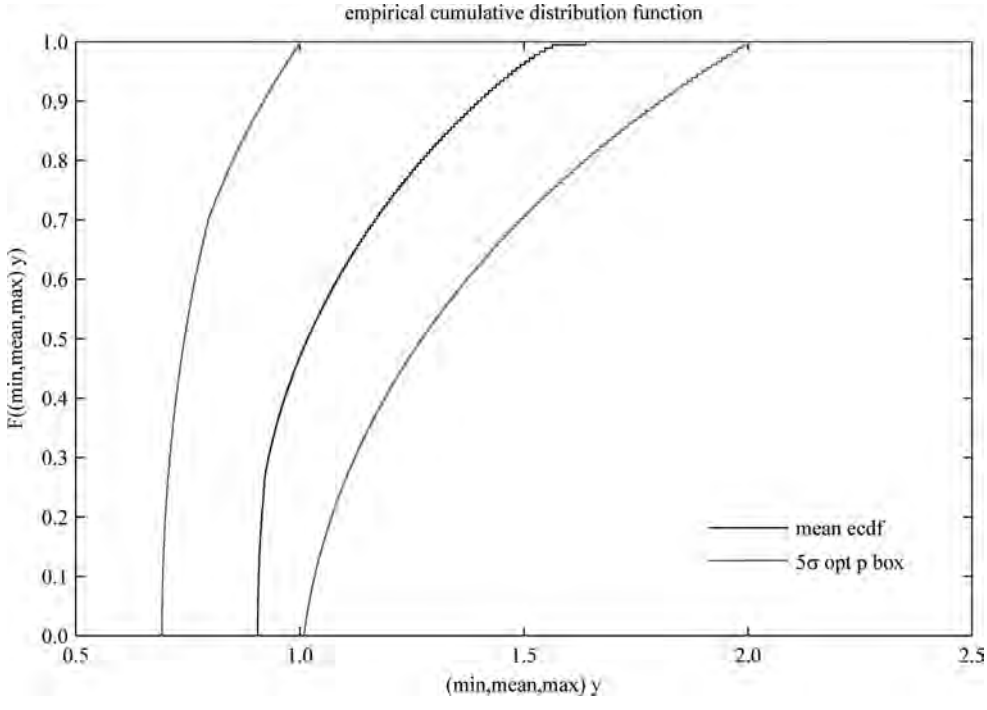

Figure 4. Optimisation-based probability box structure for the synthetic exercise at 0.1 correlation coefficient.

convergence of the major probability lines occurs whenever the correlation coefficient increases, with exception to the zone near the zero probability level on the minimum branch of the optimisation-based probability box structure at 0.9 correlation coefficient. This particular feature is observable because the lowest minimum occurs in the inner part of the interval [0.1,1.0] for parameter a.

3 DESIGN EXAMPLE

The design example is referred to the strip spread foundation on a relatively homogeneous soil shown in Figure 7, wherein groundwater level is away. Considered the vertical noneccentric loading problem and the calculation model for bearing capacity, the performance function

may be described by the simplified Equation (8):

$$M = f\left(B, D, \gamma_s, c_f, \varphi_f, \gamma_f, P, Q\right) \quad (8)$$

if B is the foundation width; D is the soil height above the foundation base; γ_s is the unit weight of the soil above the foundation base; c_f is the cohesion of the foundation soil; φ_f is the friction angle of the foundation soil; γ_f is the unit weight of the foundation soil; P is the dead load; and Q is the live load.

Table 1 summarises the description of basic input variables, with different types of distributions. The considered correlation coefficients between the basic input variables are either presented in Table 2.

The strip spread foundation is designed by the Eurocode 7 methodology, Design Approach DA.2*, wherein partial factors are coupled with characteristic values.

A cautious estimate of the 95% reliable mean value for a known coefficient of variation is considered for each geotechnical parameter regarding the occurrence of a limit state. Scenarios wherein the parameters cohesion and friction angle of the foundation soil are separately implemented as intervals are further considered. The proposed procedures are then applied on the design example. The optimisation-based probability box structure is drawn by using conjugate gradient and quasi newton optimisation algorithms in a multistart approach for the case cohesion interval scenario and for the case friction angle interval scenario, represented respectively in Figure 8 and Figure 9. Considered the case cohesion interval scenario, for appropriate representation of the minimum and maximum branches, it is selected a number of 351 discretisation points uniformly distributed on the interval [0.0,35.0] kN/m^2. Considered the case friction angle interval scenario, for appropriate representation of the minimum and maximum branches, it is selected a number of 201 discretisation points uniformly distributed on the interval [25.0,35.0] °.

The optimisation-based probability box structure is constructed comparatively to the median empirical cumulative distribution function, noted that the adjacent empirical functions corresponding to the collection of minimum and maximum values are sketched at a central credibility level 3σ. The median trend is comparatively drawn from a moderate number of discretisation points uniformly distributed on the interval. From observation of Figure 8 and Figure 9 it is noted that the linear and nonlinear trends evinced by the graphs express the influence of the parameters cohesion and friction angle of the foundation soil on the calculation model for bearing capacity. The position of the median trend, which separates the fifty percent chance cases, is further sketched on the safe

side. Regarding the limit state, the probability of no failure across the cohesion and friction angle interval scenario at a central credibility level 3σ may be determined, see the probability level for a positive outcome on the minimum branch.

4 CONCLUSION

A procedure for construction of a probability box structure by optimisation is advanced. Different dependencies may lead to quantitatively varied results and as the degree of correlation may be unknown, a single scalar measure of a correlation coefficient may not be able to capture the complexity of the dependence model. Thus, the effects of correlation on the probability box structure are comparatively demonstrated on a synthetic exercise and on a design example referred to a strip spread foundation designed by the Eurocode 7. The optimisation-based probability box structure opens a new path in the framework of engineering limit state design under dependence in order to consider the failure analysis on a number of different central credibility levels.

Reliability assessment model of technical object in aspect of catastrophic damage in the form of jamming—an outline

M. Zieja
Air Force Institute of Technology, Warsaw, Poland

M. Jasztal, S. Stępień & M. Ważny
Military University of Technology, Warsaw, Poland

ABSTRACT: This elaboration is an attempt to present a reliability assessment model of a technical object in the aspect of a catastrophic damage. As the technical object a mechanical device was adopted, in which, between operating elements a jamming may occur and as a diagnostic parameter—the operating time of device t. Determining the distribution of device operating time until jamming appeared was based on the Yule's process modified by Gercbach and Kordoński. Due to the adopted simplifications in recording of the above-mentioned model, the process of defining final equations was identified. This process, in a discrete system, depends on the system of equations typical for the accrual process of the diagnostic parameter. By performing a transformation of these equations the formula was determined for reliability of the technical object and density function of the object operating time until the catastrophic damage is found in the form of jamming.

1 INTRODUCTION

A characteristic feature of mechanical devices is the occurrence of movable mating elements creating a system of kinematic pairs. Depending on the intensity of using the device and the conditions in which work of the technical object is being performed, it might lead to wear and, in consequence, e.g. to jamming.

Due to device operation, the clearances between mating elements or resultants in kinematic sequences are changed and deviations are created from normal values, which harmfully affect the automatics operation. The values of deviations of clearances from normal values trigger a change in operating conditions of the technical object, what has a substantial impact on their operation reliability. Sometimes, interferences in automatics of operation of the technical object due to the change in operating conditions along with the increased value of clearances contribute to the formation of jamming, that is a kind of the catastrophic damage (Baranowski & Małachowski 2015, Idziaszek & Grzesik 2014, Tomaszek et al. 2016)

By making an analysis of the device technical condition an essential issue is the choice of a parameter, which will be leading (forecasting) in the assessment under consideration. It, therefore, appears to be appropriate to adopt that the parameter pursuant to which the possibility of occurrence of the catastrophic damage (jamming) is evaluated, will be a number of device completed working cycles. With the increase in the number of completed cycles, the device experiences wearing processes (destructive), which exert a considerable influence on the quality of the device's usage conditions (Dhillon 1999, Tomaszek et al 2013, Tomaszek et al. 2011, Ważny 2009).

2 DETERMINING THE DISTRIBUTION OF THE NUMBER OF THE DEVICE COMPLETED WORKING CYCLES UNTIL DAMAGE APPEARS (JAMMING)

For the diagnostic parameter (forecasting) according to which we will determine the change in technical condition of a device (wearing) the number of cycles completed by the device was assumed. This parameter is a speed function of completing the working cycles by the device and will be defined by equation (1):

$$z = v \cdot t \tag{1}$$

where v = speed of working cycles completed by the device; and t = device operating time.

In the function of the number of cycles completed by the device, the effects of destructive processes continue to increase in the form of wearing and clearances in kinematic chains. As there are more effects related to wearing of components, the chance that the device will jam also increase. Therefore, it might be concluded that with the increase of working cycles completed by the device, there is a change of its technical condition and increases a chance of the occurrence of a damage in the form of jamming. This suggests the possibility of using certain models to describe the risk of the occurrence of a damage in the form of jamming.

To determine the distribution of the number of completed cycles until jamming is found the Yule's process was applied by modifying it. The outline of this modification is provided in work (Gercbach & Kordoński 1968) without a detailed way of acquiring final results. Utilizing the results mentioned in this work (Gercbach & Kordoński 1968) needs supplementing the way they are presented with indirect operations enabling to derive final equations.

To define regularities of this model it is convenient to use discrete values of diagnostic parameter. Way of discretization is shown in Fig. 1 where E_k = discrete values of a diagnostic parameter defined as parameter value states; $\lambda\Delta t$ = probability of transition from E_k to E_{k+1} in a time interval with the length of Δt; λ = intensity of parameter's state changing described as

$$\lambda = \frac{P}{\Delta t}, \tag{2}$$

where P = probability of completion of one working cycle in a time interval with the length of Δt; $q_k(t)$ = probability of interrupting the development of the process of increasing a diagnostic parameter, depending on the process state; μ = increment of intensity of jamming occurrence along with the increase of device working cycle; μ_o = intensity of jamming for initial state (for t = 0); h = average value of the increment of a diagnostic parameter in time Δt; and t = device operating time.

Providing that $P_k(t)$ signifies the probability that for device operating time equaling t a diagnostic parameter takes the value $E_k (k = 0,1,2,\ldots)$. For the adopted arrangements, using the postulates of the Poisson process, a system of equations characterizing the accrual process of a diagnostic parameter may be obtained (DeLurgio 1998, Pham 2006, Werbińska & Zając 2015, Zio 2009).

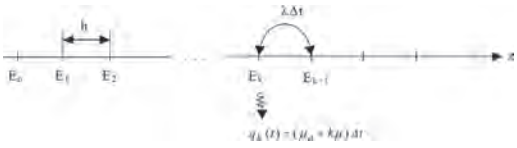

Figure 1. Way of discretization of a diagnostic parameter.

For k = 0:

$$P_0(t+\Delta t) = (1-\lambda\Delta t)(1-\mu_0\Delta t)P_0(t)$$
$$P_0(t+\Delta t) = (1-\mu_0\Delta t - \lambda\Delta t + \lambda\mu_0\Delta t^2)P_0(t).$$

After omitting higher order negligibles the formula takes the following form:

$$P_0(t+\Delta t) = \left(1-(\lambda+\mu_0)\Delta t\right)P_0(t) \tag{3}$$

For k = 1, 2, …

$$P_k(t+\Delta t) = (1-\lambda\Delta t)\left(1-(\mu_0+k\mu)\Delta t\right)P_k(t) + \\ + \lambda\Delta t\left(1-(\mu_0+k\mu)\Delta t\right)P_{k-1}(t);$$
$$P_k(t+\Delta t) = \left(\begin{array}{l} 1-(\mu_0+k\mu)\Delta t - \\ \lambda\Delta t + \lambda\Delta t(\mu_0+k\mu)\Delta t \end{array}\right)P_k(t) + \\ +\left(\lambda\Delta t - \lambda\Delta t(\mu_0+k\mu)\Delta t\right)P_{k-1}(t).$$

Again by omitting higher order negligibles the above-mentioned formula takes the following form:

$$P_k(t+\Delta t) = \left(1-(\lambda+\mu_0+k\mu)\Delta t\right)P_k(t) + \lambda\Delta t\ P_{k-1}(t). \tag{4}$$

Thus, we obtain the following system of equations:

$$\left.\begin{array}{l} P_0(t+\Delta t) = \left(1-(\mu_0+\lambda)\Delta t\right)P_0(t) + O(\Delta t) \\ P_k(t+\Delta t) = \left(1-(\mu_0+k\mu+\lambda)\Delta t\right)P_k(t) + \\ +\lambda\Delta t\ P_{k-1}(t) + O(\Delta t), \quad \text{for k} = 1, 2, \ldots \end{array}\right\}. \tag{5}$$

From system of equations (5) after transformation and movement to the limit from $\Delta t \to 0$ the following system of equations is received:

$$\left.\begin{array}{l} P_0'(t) = -(\mu_0+\lambda)P_0(t) \\ P_k'(t) = -(\mu_0+k\mu+\lambda)P_k(t) + \lambda\ P_{k-1}(t), \\ \qquad \text{for k} = 1, 2, \ldots \end{array}\right\}. \tag{6}$$

The initial condition for all of these equations may be written in the following form:

$$P_i(0) = \begin{cases} 1 & for \quad i = 0 \\ 0 & for \quad i \neq 0 \end{cases}. \tag{7}$$

System of equations (6) is solved by the use of a recursive method.

Solution for $k = 0$:

$$P_0'(t) = -(\mu_0 + \lambda) P_0(t),$$
$$\int_0^t \frac{P_0'(t)}{P_0(t)} dt = -\int_0^t (\mu_0 + \lambda) dt.$$

Therefore,

$$P_0(t) = -C_0 e^{-(\mu_0+\lambda)t}. \quad (8)$$

For $t = 0$, $P_0(0) = 1$ thus, $C_0 = 1$.

Solution for k = 1, 2, 3… can be determined in the following way. A differential equation takes the form:

$$P_k'(t) = -(\mu_0 + k\mu + \lambda) P_k(t) + \lambda P_{k-1}(t) \quad (9)$$

In this case, we predict the solution in the form of:

$$P_k(t) = C_k(t)\ e^{-(\mu_0+\lambda)t}. \quad (10)$$

A derivative of relationship (10) assumes the following form:

$$P_k'(t) = C_k'(t) e^{-(\mu_o+\lambda)t} + C_k(t)\left(-(\lambda + \mu_o)\right) e^{-(\mu_o+\lambda)t}. \quad (11)$$

Substituting the above equation for equation (9) the following formula was obtained:

$$C_k'(t)\ e^{-(\mu_o+\lambda)t} - (\lambda + \mu_o) C_k(t)\, e^{-(\mu_o+\lambda)t} = -(\mu_o + k\mu + \lambda) \underbrace{P_k(t)}_{C_k(t)\ e^{-(\mu_o+\lambda)t}} + \lambda \underbrace{P_{k-1}(t)}_{C_{k-1}(t)\ e^{-(\mu_o+\lambda)t}}.$$

Thus, we obtain an equation:

$$C_k'(t) + k\mu C_k(t) = \lambda C_{k-1}(t) \quad (12)$$

Equation (12) for *k=1* will be as follows:

$$C_1'(t) + \mu C_1(t) = \lambda. \quad (13)$$

Differential equation (13) takes the following general form:

$$y' + P(x)y = Q(x).$$

The solution of which is the following equation:

$$y = e^{-\int_0^t P dx} \left(\int_0^t Q\, e^{\int_0^t P dx} dx \right). \quad (14)$$

Using formula (14) the solution of formula (13) may be written in the following form:

$$C_1(t) = e^{-\int_0^t \mu dt} \left(\int_0^t \lambda\, e^{\int_0^t \mu dt} dt \right) = e^{-\mu t} \left(\int_0^t \lambda\, e^{\mu t}\, dt \right)$$
$$= e^{-\mu t}\ \lambda \frac{1}{\mu} e^{\mu t} \Big|_0^t = e^{-\mu t} \frac{\lambda}{\mu} \left(e^{\mu t} - 1 \right) = \frac{\lambda}{\mu} - \frac{\lambda}{\mu} e^{-\mu t}. \quad (15)$$

For *k = 2* equation (13) assumes the form:

$$C_2'(t) + 2\mu C_2(t) = \lambda \left(\frac{\lambda}{\mu} - \frac{\lambda}{\mu}\ e^{-\mu t} \right). \quad (16)$$

Solution of equation (16):

$$\begin{aligned} C_2(t) &= e^{-\int_0^t 2\mu t} \int_0^t \left(\frac{\lambda^2}{\mu} - \frac{\lambda^2}{\mu}\ e^{-\mu t} \right) e^{\int_0^t 2\mu dt} dt \\ &= e^{-2\mu t} \left(\frac{\lambda^2}{\mu} \frac{1}{2\mu} e^{2\mu t} - \frac{\lambda^2}{\mu} \frac{1}{\mu} e^{\mu t} \right) \Big|_0^t \\ &= e^{-2\mu t} \left(\frac{\lambda^2}{2\mu^2} e^{2\mu t} - \frac{\lambda^2}{2\mu^2} - \frac{\lambda^2}{\mu^2} e^{\mu t} + \frac{\lambda^2}{\mu^2} \right) \\ &= e^{-2\mu t} \left(\frac{\lambda^2}{2\mu^2} e^{2\mu t} + \frac{2\lambda^2 - \lambda^2}{2\mu^2} - \frac{\lambda^2}{\mu^2} e^{\mu t} \right) \\ &= \frac{\lambda^2}{2\mu^2} + \frac{\lambda^2}{2\mu^2} e^{-2\mu t} - \frac{\lambda^2}{\mu^2} e^{-\mu t} \\ &= \frac{\lambda^2}{2\mu^2} \left(1 + e^{-2\mu t} \right) - \frac{\lambda^2}{\mu^2} e^{-\mu t}. \end{aligned} \quad (17)$$

Equation describing function $C_2(t)$ was converted to the form, which suggests the general form of this function:

$$C_2(t) = \frac{\lambda^2}{2\mu^2} + \frac{\lambda^2}{2\mu^2} e^{-2\mu t} - \frac{\lambda^2}{\mu^2} e^{-\mu t} \Big| \cdot 2$$
$$2C_2(t) = \frac{\lambda^2}{\mu^2} - \frac{2\lambda^2}{\mu^2} e^{-\mu t} + \frac{\lambda^2}{\mu^2} e^{-2\mu t}.$$

Thus:

$$C_2(t) = \left(\frac{\lambda}{\mu} - \frac{\lambda}{\mu}\ e^{-\mu t} \right)^2 \cdot \frac{1}{2}. \quad (18)$$

Form of equation (18) allows to predict the general form of this function. This equation assumes the following form:

$$C_k(t) = \frac{1}{k!} \left(\frac{\lambda}{\mu} - \frac{\lambda}{\mu}\ e^{-\mu t} \right)^k. \quad (19)$$

Applying (19) the solution of equation (9) may be written. This solution adopts the following form:

$$P_k(t) = \frac{1}{k!}\left(\frac{\lambda}{\mu} - \frac{\lambda}{\mu}\ e^{-\mu t}\right)^k e^{-(\mu_0+\lambda)t}, \tag{20}$$

for $k = 1, 2, 3 \ldots$

Using equation (8) and (20) it is possible to determine reliability of the device. Therefore:

$$\begin{aligned} R(t) &= \sum_{k=0}^{\infty} P_k(t) \\ R(t) &= \sum_{k=0}^{\infty} \frac{1}{k!}\left(\frac{\lambda}{\mu} - \frac{\lambda}{\mu}\ e^{-\mu t}\right)^k e^{-(\mu_0+\lambda)t}. \end{aligned} \tag{21}$$

It should be noted that the following equation is true:

$$\sum_{k=0}^{\infty} \frac{1}{k!}\left(\frac{\lambda}{\mu} - \frac{\lambda}{\mu}\ e^{-\mu t}\right)^k = e^{\frac{\lambda}{\mu} - \frac{\lambda}{\mu} e^{-\mu t}}. \tag{22}$$

Using equation (22) the formula for reliability takes the following form:

$$R(t) = e^{\frac{\lambda}{\mu} - \frac{\lambda}{\mu} e^{-\mu t}} \cdot e^{-(\mu_0+\lambda)t}.$$

Thus,

$$R(t) = e^{\frac{\lambda}{\mu}\left(1 - e^{-\mu t}\right) - (\mu_0+\lambda)t}. \tag{23}$$

Based on the above-mentioned equation the probability of jamming of the device for the number of completed cycles in time t will equal:

$$Q(t) = 1 - e^{\frac{\lambda}{\mu}\left(1 - e^{-\mu t}\right) - (\mu_0+\lambda)t}. \tag{24}$$

Distribution of the number of working cycles completed by the device until its jamming will be as follows:

$$f(t) = \frac{d}{dt} Q(t).$$

Thus,

$$f(t) = \left(\mu_0 + \lambda\left(1 - e^{-\mu t}\right)\right) e^{\frac{\lambda}{\mu}\left(1 - e^{-\mu t}\right) - (\mu_0+\lambda)t}. \tag{25}$$

The form of relation (25) presents the density function of working cycles completed by the device until catastrophic damage is found in the form of jamming. This distribution can be used to establish the risk of the occurrence of a catastrophic failure in the form of jamming.

3 CALCULATION EXAMPLE

The remarks as regards establishing distribution parameters λ, μ, μ_o shall also be given. The parameter λ will be evaluated by using the number of working cycles completed by the device. Calculation formula of parameter λ will be as follows (Ważny 2015):

$$\lambda^* = \frac{1}{\Delta t^*} \tag{26}$$

where Δt^* = the duration of one device working cycle.

For determining μ_0^* *i* μ^* data are used from observation of the device operating process due to which we obtain for N of devices the list of the number of cycles completed by the device until jamming appears. Hence, we acquire t_1, t_2,…, t_N. These data are used to build a histogram. The value μ_0^* is the ordinate of the histogram in point $t = 0$. Estimation value shall be established from the following expression:

$$\frac{1}{\lambda^*}\left(\frac{n(t)}{N} - 1\right) + t = \frac{1}{\mu^*}\left(1 - e^{-\mu^* t}\right) \tag{27}$$

where $n(t)$ = the number of efficient devices in time $t < t_N$; and t = device operating time (agreed value).

The left side of the equation for an agreed value t is changeable. A value μ^* is the value, which guarantees that the right side of the equation is equal to the left side of the equation in equation (27). For the purpose of estimating a jamming intensity of the device $\gamma(t)$ the following equation shall be used:

$$\gamma(t) = \frac{f(t)}{R(t)}. \tag{28}$$

Replacing equation (25) and (23) with the formula (28), equation (29) was obtained:

$$\gamma(t) = \left(\mu_0 + \lambda\left(1 - e^{-\mu t}\right)\right). \tag{29}$$

As it follows from equation (29) the probability of device's jamming increases with the increase of the number of working cycles completed by the device.

By attempting to perform the number verification of the presented model one adopted technical data characterizing a hypothetical technical object.

Table 1. Calculation results.

z	Δt^*	λ^*	$n(t)$	N	μ_0^*	μ^*
850	0,071	14,197	36	36	0	$1*10^{-9,5}$

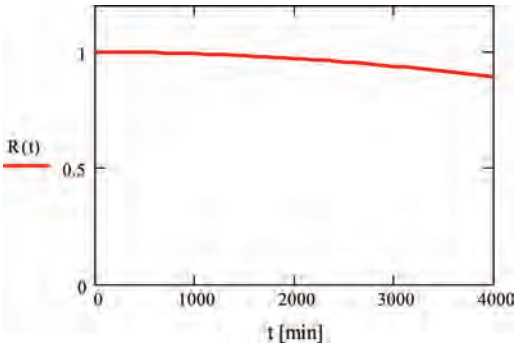

Figure 2. Graphic form of reliability function $R(t)$.

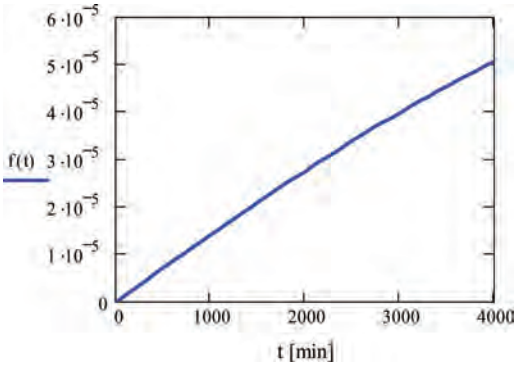

Figure 3. Graphic form of density function $f(t)$.

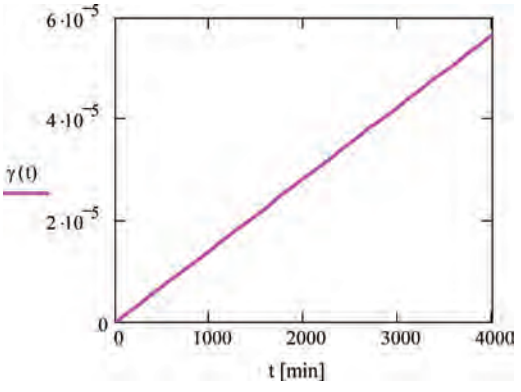

Figure 4. Graphic form of jamming intensity function $\gamma(t)$.

Input data used for calculations and obtained results were summarized in Table 1 where z is the number of working cycles completed by the device.

For the above data the characteristics $R(t)$, $f(t)$ and $\gamma(t)$ were established.

4 FINAL REMARKS

In a diagnostic parameter function there is an accrual process of the impacts of destructive processes such as surface wear, corrosion and other factors, what in consequence contributes to accruing of negative effects leading to the occurrence of the catastrophic damage, among others in the form of jamming, crack and other similar events of the assemblies of technical objects (devices).

The presented method of the assessment of device operation reliability in the aspect of the formation of the catastrophic damage in the form of jamming appears to be justified and correct. The presented calculation example enabled to perform number verification of a developed model and showed the application nature of the established method. Applying parameters determined on the basis of the described method it is possible to present the characteristics of technical properties of the object under consideration. In addition, the developed model can also be applied to estimate the reliability of other technical objects in the aspect of occurring sudden damage originating from relaxation stimuli.

Extensions of the I&AB method for the reliability assessment of the spent fuel pool of EPR

M. Bouissou
EDF Lab Saclay, Palaiseau, France

ABSTRACT: The I&AB (Initiator and All Barriers) method was first introduced at ESREL 2016, as an efficient means to calculate, thanks to closed form formulae, the reliability of a very large repairable system with dependencies among components. The mathematical support of I&AB is continuous time Markov chains, and therefore it cannot be used for modeling the spent fuel pool of a nuclear power plant, because for this system, there are two kinds of *deterministic delays* that must be taken into account: grace times (for example, after the total loss of cooling of the pool, it takes exactly 14 hours for the water to start boiling), and deterministic failures due to the limited capacity of water tanks. In the present paper, we extend the I&AB method to account for deterministic delays. We explain how we could apply this method in the case of the fuel pool of the EPR (European Pressurized Reactor) starting from a model in the form of a BDMP (Boolean Logic Driven Markov Process), and how results and computation times compare to a Monte Carlo simulation of the same BDMP.

1 INTRODUCTION

The standard PSA method (based on fault tree linking) is not well suited for the reliability assessment of the spent fuel pool of a nuclear power plant, for several reasons. Firstly, the dynamics of the phenomena to be modeled are relatively slow because of the large amount of water available in the pool itself and in the safety systems. It is thus not sufficient to look at what can happen in only 24 hours after an initiator. Secondly, the fact that components are repairable, and the existence of multiple standby redundancies cannot be ignored.

EDF has developed several tools for creating and quantifying dynamic models, better suited for this kind of system study. In particular, BDMPs (Boolean logic Driven Markov Processes) are a powerful modeling tool for the dependability analysis of dynamic systems (Bouissou & Bon 2003). For more than ten years, they have been used for assessing the reliability, availability, and safety of complex reconfigurable systems. BDMPs have a graphical representation close to fault trees, yet they specify (potentially very large) CTMCs (Continuous Time Markov Chains). A BDMP model with the same detail level as fault trees of a standard PSA would not be quantifiable by analytical methods, even with classical approximations. On the other hand, it would require too large computation times with Monte Carlo simulation, because the probability of reaching a too low level in the spent fuel pool is very small.

For these reasons, we have developed a new approximate method for the quantification of very large BDMPs, and more generally any model able to generate minimal products containing one initiating event and the failures of the barriers activated after it in order to avoid the undesirable event. This is why the main foreseen application domain is nuclear PSA, all the more so as existing PSA models will be very easy to adapt to I&AB, merely by adding repair rates to component data. In a PSA context, I&AB can be used to take repairs into account instead of postulating that 24 hours after an initiating event, either the undesirable event is unavoidable, or the system is in a safe state. The I&AB (Initiator and all barriers) main principles were published in a paper at ESREL 2016 (Bouissou & Hernu 2016). In the present paper, we give all analytical formulae of I&AB and of its extension in the case of grace times and deterministic failures. We also give some numerical application examples, comparing the I&AB approximation to "exact" calculations performed on a dynamic model via Monte Carlo simulation.

2 THE INITIAL I&AB METHOD (2016)

2.1 *Hypothesis on the system and definitions*

Suppose we want to calculate the reliability of a repairable system with standby redundancies; it may be a good approximation to take into account only one level of dependences between

the components. In other words, one is capable to distinguish failures of "normal" components (they are called "initiating events") and failures of components in standby (that function only in case of failures of normal components). But one cannot discriminate between a component of "primary standby" (that assures the functioning of the system after a failure of the corresponding normal component) and a component of "secondary standby" (that operates only after a failure of the primary standby component).

The I&AB method relies on the two following approximations:

A0: When an initiating event occurs, all standby components are supposed to start functioning (or maybe refuse to start) immediately after the initiating event; then, they may fail and be repaired independently from each other until the initiating event is repaired.

A1: Once an initiating event is repaired, the system cannot anymore fail, whatever happens.

We suppose that the real system is described by a CTMC where the initial, "perfect" state is the state into which the system always returns, until it is absorbed by a failure state. Then its unreliability can be estimated from the following formula (Bouissou & Bon 1992):

$$\bar{R}(t) \le 1 - \exp(-\Lambda p t) \tag{1}$$

where Λ is the frequency of initiating events (sum of rates of all transitions exiting the initial state) and p is the probability that the initiating events lead to an accident before the system goes back to the perfect state.

In I&AB, in order to estimate p we use the "Minimal Content of (failure) Sequences" (MCS) of the Markov chain, as it was defined in (Bouissou 2006). The formal definition of a MCS is given ibid, but it can be defined informally as the result of a Boolean reduction of the following fault tree: a single OR gate with one son per failure sequence, each son being presented as an AND gate over the events appearing in the sequence. Initiating events must be distinguished from other events, so that for example, the MCS of a system made of 2 components Y and Z in active redundancy is {Y_init, Z} {Z_init, Y} and not simply {Y, Z}.

For real, complex systems, the MCS can be obtained in (at least) two ways: by building a PSA type model made of event trees and fault trees, and calculating its minimal cut sets, or by building a BDMP and applying the steps described in (Bouissou & Hernu 2016) to transform it into a standard fault tree whose minimal cut sets are the MCS of the Markov chain specified by the BDMP. In the remainder of the paper, we will therefore suppose that we have the MCS of the studied system at hand, and we will call its elements "minimal products".

2.2 *I&AB general formulae*

Let us suppose that there are n initiating events that can lead out the system from its perfect state. Then, according to (1), the system unreliability at time t can be found from

$$\bar{R}(t) \le 1 - \exp\left(-t \sum_{ie=1}^{n} \lambda_{ie} p_{ie}\right) \tag{2}$$

where λ_{ie} is the failure rate of initiating event *ie* and p_{ie} includes probabilities for all k minimal products corresponding to it.

In calculations we distinguish two time intervals. The first interval is the mission time figuring in (2). The second time interval is *infinite* and starts once an initiating event takes place. The probability that all components in a minimal product c fail within time interval $[0,\infty]$ is simply the unreliability of a parallel system made of these components $\overline{R_c}(\infty)$; then we can use the following upper bound for p_{ie}, that will be a good approximation when all failure probabilities are small:

$$p_{ie} \le \sum_{c=1}^{k} \overline{R_c}(\infty) \tag{3}$$

Using the Murchland approximation, we obtain:

$$p_{ie} \le \sum_{c=1}^{k} \mathrm{E}\left(N_c(\infty)\right) \tag{4}$$

where $N_c(\infty)$ is the number of failures of the minimal product c on an infinite horizon. What keeps p_{ie} small is the fact that in the initial state considered for c, the initiating event is realized with probability 1, but once repaired, it never fails again, contrary to other elements of the product. (this is the approximation *A1*).

In order to calculate $\mathrm{E}\left(N_c(t)\right)$ we need to give first a few definitions. We will utilize the following reliability characteristics:

- Unavailability $Q(t)$ – the probability that a component is in a failure state at time t;
- Unconditional failure intensity $W(t)$: $W(t)\Delta t$ is the mean number of failures of a component between t and $t + \Delta t$.

For markovian basic events, depending on their type, these quantities are given by the following expressions:

- Initiating event (the repair is definitive)

$$Q(t) = \exp(-\mu t)$$

$$W(t) = 0$$

– Failure in operation (it can fail several times)

$$Q(t) = \frac{\lambda}{\lambda+\mu}\left[1-\exp\left(-(\lambda+\mu)t\right)\right]$$
$$W(t) = \lambda\left(1-Q(t)\right)$$

– Failure on demand (the repair is definitive)

$$Q(t) = \gamma\exp(-\mu t)$$
$$W(t) = 0$$

Because of the lack of space, we will not recall here the demonstration given in (Bouissou & Hernu 2016) that leads to the following formula, written for a minimal product c containing l failures on demand and m failures in function.

$$E\left(N_c(t)\right) = \prod_{i=1}^{l}\gamma_{c,i} \times \int_0^t \exp\left(-\mu_{c,ie}x\right) f(x)\,dx \qquad (5)$$

with

$$f(x) = \exp\left(-x\sum_{j=1}^{l}\mu_{c,j}\right)\sum_{i=1}^{m} W_{c,i}(x)\prod_{\substack{j=1\\ j\neq i}}^{m} Q_{c,j}(x).$$

Equation (5) assumes that a minimal product contains at least one basic event with a failure in operation. However, sometimes minimal products are only composed of basic events corresponding to failures on demand (plus one initiating event, as usually). In such a case, we suppose that these events happen at $t = 0$ and the unreliability for minimal product c is given by:

$$\overline{R_c}(\infty) = \Pr\left(\text{top} = \text{true at } t=0\right) = \prod_{i=1}^{l}\gamma_{c,i}. \qquad (6)$$

2.3 *I&AB formulae in the markovian case*

The general equation (5) yields a closed form formula in the purely markovian case, where all components have constant failure and repair rates.

In order to simplify notations, we will omit the index c in the remainder of this section: we will implicitly give formulas for a single minimal product.

Taking an infinite time horizon and replacing $W_i(x)$ by its expression given in section 2.2 for a failure in operation, equation (5) becomes:

$$E\left(N(\infty)\right) = \prod_{i=1}^{l}\gamma_i \times \int_0^{\infty} \exp\left(-\mu_{ie}x\right) f(x)\,dx \qquad (7)$$

with

$$\begin{aligned} f(x) &= \exp\left(-x\sum_{j=1}^{l}\mu_j\right)\sum_{i=1}^{m}\lambda_i\left(1-Q_i(x)\right) \\ &\quad\times\prod_{\substack{j=1\\ j\neq i}}^{m} Q_j(x) \\ &= \exp\left(-x\sum_{j=1}^{l}\mu_j\right) \\ &\quad\sum_{i=1}^{m}\lambda_i\left[\prod_{\substack{j=1\\ j\neq i}}^{m} Q_j(x) - \prod_{j=1}^{m} Q_j(x)\right]. \end{aligned}$$

Here we need to introduce new notations in order to simplify upcoming formulas. Let:

$$\mu = \mu_{ie} + \sum_{j=1}^{l}\mu_j$$
$$r_i = \lambda_i + \mu_i$$

Hence, replacing the functions Q_j by their definitions and using these new notations, we obtain:

$$\begin{aligned} E\left(N(\infty)\right) &= \prod_{i=1}^{l}\gamma_i \sum_{i=1}^{m}\lambda_i \\ &\times\left(\prod_{\substack{j=1\\ j\neq i}}^{m}\frac{\lambda_j}{r_j}\int_0^{\infty} e^{-\mu x}\prod_{\substack{j=1\\ j\neq i}}^{m}\left(1-e^{-r_j x}\right)dx\right. \\ &\left.-\prod_{j=1}^{m}\frac{\lambda_j}{r_j}\int_0^{\infty} e^{-\mu x}\prod_{j=1}^{m}\left(1-e^{-r_j x}\right)dx\right). \end{aligned} \qquad (8)$$

Each integrand includes a product of functions, which can be represented in the following way:

$$\begin{aligned} \prod_{j=1}^{m}\left(1-e^{-r_j x}\right) &= 1-\sum_{i=1}^{m}e^{-r_i x}+\sum_{i=1}^{m}e^{-r_i x}\sum_{j>i}^{m}e^{-r_j x} \\ &-\sum_{i=1}^{m}e^{-r_i x}\sum_{j>i}^{m}e^{-r_j x}\sum_{k>j}^{m}e^{-r_k x}+\ldots+(-1)^m \\ &\times\exp\left(-\sum_{i=1}^{m}r_i x\right). \end{aligned} \qquad (9)$$

Hence, after the integration from 0 to infinity, we obtain an alternating series, every term of which, in its turn, is a sum of fractions. For instance, the second integral results in:

$$\begin{aligned} &\int_0^{\infty} e^{-\mu x}\prod_{j=1}^{m}\left(1-e^{-r_j x}\right)dx = \\ &\frac{1}{\mu}-\sum_{i=1}^{m}\frac{1}{\mu+r_i}+\sum_{i=1}^{m}\sum_{j>i}^{m}\frac{1}{\mu+r_i+r_j} \\ &-\sum_{i=1}^{m}\sum_{j>i}^{m}\sum_{k>j}^{m}\frac{1}{\mu+r_i+r_j+r_k}+\ldots\ldots \\ &+(-1)^m\left(\mu+\sum_{i=1}^{m}r_i\right)^{-1}. \end{aligned} \qquad (10)$$

The first integral is calculated in a similar way, the only difference is that one should exclude current element i from the product.

These analytical formulae (8) and (10) seem very cumbersome; however, they permit to considerably reduce the processing time (in comparison with a

numerical integration) while ensuring an excellent accuracy.

3 I&AB EXTENSIONS

3.1 *Taking grace times into account*

In this section, the focus is on systems such that, after the loss of all components subject to random failures in a minimal product, the undesirable event is delayed by some physical process that guarantees a deterministic grace time. The spent fuel pool is a good example: after the complete loss of the cooling system, the water will heat until it boils, but this process is deterministic and it would give an excessively conservative evaluation to replace the grace time by a random delay, exponentially distributed in order to stay in the markovian framework.

We first suppose that we need to quantify minimal products containing failures of components (with the same hypotheses as in § 2.3) and a single deterministic grace time. Let X_c be the failure time of the set A_c of markovian elements of the minimal product c, Y_c the time needed to repair at least one of the markovian components, starting from the state where they are all failed, and T_c the grace time. For sake of simplicity, we suppose that after a given occurrence of the initiator, the basic event corresponding to the grace time behaves like a Heaviside function: it becomes true at $X_c + T_c$ and stays true forever (it is "not repairable"). The probability p_{ie} to go from the state where the system is just after the initiator *ie* to the failure state can be estimated as:

$$p_{ie} \approx \sum_{c=1}^{k} E\left(N_c(\infty)\right) \cdot \Pr\left(Y_c > T_c\right). \tag{11}$$

The total repair rate when all markovian components are failed is the sum of their repair rates. Hence

$$\Pr\left(Y_c > T_c\right) = \exp\left(-T_c \sum_{i \in A_c} \mu_i\right). \tag{12}$$

As for $E\left(N_c(\infty)\right)$, it can be computed using the formulae of §2.3.

To conclude this section, let us mention that the grace delay may depend on the minimal product, and that a minimal product can contain two or more grace delays: in this case, only the *last one* must be taken into account (cf. §4.1.2 for more details about this choice).

3.2 *Taking deterministic failures into account*

If, after a non-recovered loss of cooling, the water starts to boil in the fuel pool, there is a possibility to add water coming from tanks. However, the capacity of tanks is limited and after a given time the water flow is interrupted: this is what we call a deterministic failure. After a given initiator, such failures can be considered as non-repairable: it is impossible to replenish the tanks in a short amount of time (the same applies to batteries). However, in a dynamic model, they can be associated to a repair (with a small repair rate, see discussion on that topic in §4.1.2) in order to allow the model to return to its initial state. In order to be consistent with general assumptions of I&AB, we will suppose that the "timers" associated to deterministic failures start just after the initiating event; this is obviously conservative, as in fact they start after some failures. This assumption has an immediate consequence: if there are two or more deterministic failures in a minimal product, the one associated to the greatest delay suffices to prevent the minimal product from becoming true until it happens. So, without loss of generality, we will consider in this section that we want to quantify a minimal product containing l failures on demand, m failures in function, and one deterministic failure.

We define the unavailability Q and unconditional failure intensity W, needed in equation (5), for this type of basic event. Q is a Heaviside function and W a Dirac distribution:

$$Q(t) = \bar{R}(t) = \mathrm{H}(t_0) = \begin{cases} 0, & t < t_0 \\ 1, & t \geq t_0 \end{cases}$$

$$W(t) = \delta(t - t_0).$$

With these notations, equation (5) can be written as follows (with an infinite time horizon, and omitting the minimal product index c):

$$E\left(N(\infty)\right) = \prod_{i=1}^{l} \gamma_i \times \int_0^{\infty} \exp\left(-\mu_{ie} x - \sum_{i=1}^{l} \mu_i x\right) \times \sum_{i=1}^{m+1} W_i(x) \prod_{\substack{j=1 \\ j \neq i}}^{m+1} Q_j(x)\, dx \tag{13}$$

Taking, as in §2.3,

$\mu = \mu_{ie} + \sum_{j=1}^{l} \mu_j$ and

$r_i = \lambda_i + \mu_i$

$$E\left(N(\infty)\right) = \prod_{i=1}^{l} \gamma_i \times \int_0^{\infty} \exp(-\mu x) \sum_{i=1}^{m} W_i(x) \times \left(\prod_{\substack{j=1 \\ j \neq i}}^{m} Q_j(x) \times \mathrm{H}(t_0) \right) dx + \int_0^{\infty} \exp(-\mu x) \times \delta(x - t_0) \prod_{j=1}^{m} Q_j(x)\, dx$$

Finally,

$$E\left(N(\infty)\right) = \prod_{i=1}^{l} \gamma_i \times \int_{t_0}^{\infty} \exp(-\mu x) \sum_{i=1}^{m} W_i(x) \times \prod_{j\neq i}^{m} Q_j(x)\,dx + \exp(-\mu t_0) \prod_{j=1}^{m} Q_j(t_0) \quad (14)$$

The second term (the integral) of equation (13) can be written, using the same notations as in §2.3:

$$\sum_{i=1}^{m} \lambda_i \left(\prod_{j\neq i}^{m} \frac{\lambda_j}{r_j} \int_{t_0}^{\infty} e^{-\mu x} \prod_{j\neq i}^{m} \left(1 - e^{-r_j x}\right) dx - \prod_{j=1}^{m} \frac{\lambda_j}{r_j} \int_{t_0}^{\infty} e^{-\mu x} \prod_{j=1}^{m} \left(1 - e^{-r_j x}\right) dx \right). \quad (15)$$

After integration from t_0 to infinity, we obtain for the second integral the following alternate sum:

$$\int_{t_0}^{\infty} e^{-\mu x} \prod_{j=1}^{m} \left(1 - e^{-r_j x}\right) dx = \frac{\exp(-\mu t_0)}{\mu} - \sum_{i=1}^{m} \frac{\exp\left(-(\mu + r_i) t_0\right)}{\mu + r_i} + \sum_{i=1}^{m} \sum_{j>i}^{m} \frac{\exp\left(-(\mu + r_i + r_j) t_0\right)}{\mu + r_i + r_j} - \sum_{i=1}^{m} \sum_{j>i}^{m} \sum_{k>j}^{m} \frac{\exp\left(-(\mu + r_i + r_j + r_k) t_0\right)}{\mu + r_i + r_j + r_k} + \cdots\cdots + (-1)^m \left(\mu + \sum_{i=1}^{m} r_i\right)^{-1} \exp\left(-\left(\mu + \sum_{i=1}^{m} r_i\right) t_0\right).$$

Of course, taking $t_0 = 0$, we obtain again the formula (10) given in §2.3.

All these formulae are so complicated that it is necessary to carefully validate their implementation in a program. The next section has two purposes: give what we believe is the result of I&AB (we cannot guarantee that our Python implementation is totally bug free) and see how I&AB approximations compare to more precise calculations made by Monte Carlo simulation (the only possible method because of deterministic times) on a truly dynamic model.

4 ACCURACY TESTS OF I&AB EXTENSIONS

The small examples of this section were designed just to make comparisons between I&AB and "exact" calculations performed with Monte Carlo simulation. In practice the models were input graphically as BDMPs in KB3 (see Figure 1 for an example), then processed both by I&AB and by the Monte Carlo simulator YAMS. An overview of EDF tools including KB3 and YAMS is given in (Bouissou 2005).

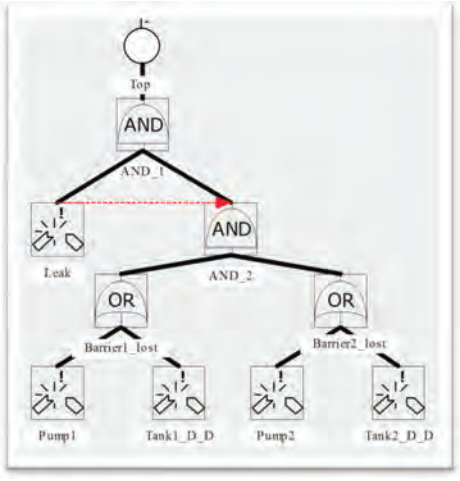

Figure 1. BDMP modeling a system with bounded capacities.

Table 1. I&AB accuracy on various simple test cases. Columns 2 and 3 are the estimations of the unreliability at 10000 hours computed by I&AB and Monte Carlo simulation (the last column is the width half of the 90% confidence interval of the YAMS result).

Test case	I&AB	YAMS	Conf. interval
4.1.1 a	$5.25\ 10^{-3}$	$5.05\ 10^{-3}$	$5.21\ 10^{-5}$
4.1.1 b	$1.17\ 10^{-3}$	$1.12\ 10^{-3}$	$5.50\ 10^{-5}$
4.1.1 c	$5.85\ 10^{-5}$	$5.72\ 10^{-5}$	$3.93\ 10^{-6}$
4.1.2 a	$7.08\ 10^{-3}$	$2.60\ 10^{-3}$	$2.64\ 10^{-4}$
4.1.2 b	$1.73\ 10^{-2}$	$3.90\ 10^{-3}$	$3.24\ 10^{-4}$
4.1.2 c	$2.89\ 10^{-3}$	$6.95\ 10^{-4}$	$4.33\ 10^{-5}$
4.1.2 d	$9.55\ 10^{-3}$	$1.03\ 10^{-3}$	$5.27\ 10^{-5}$
4.1.2 e	$3.54\ 10^{-4}$	$3.80\ 10^{-5}$	$1.01\ 10^{-5}$
4.1.2 f	$3.89\ 10^{-3}$	$1.00\ 10^{-4}$	$1.64\ 10^{-5}$
4.2.1 a	$1.87\ 10^{-1}$	$1.67\ 10^{-1}$	$8.67\ 10^{-4}$
4.2.1 b	$6.21\ 10^{-3}$	$5.44\ 10^{-3}$	$1.71\ 10^{-4}$
4.2.1 c	$1.65\ 10^{-3}$	$1.67\ 10^{-3}$	$9.50\ 10^{-5}$
4.2.2 a	$1.87\ 10^{-1}$	$1.42\ 10^{-2}$	$2.75\ 10^{-4}$
4.2.2 b	$1.87\ 10^{-1}$	$1.56\ 10^{-2}$	$2.88\ 10^{-4}$
4.2.2 c	$6.21\ 10^{-3}$	$9.86\ 10^{-4}$	$7.30\ 10^{-5}$
4.2.2 d	$6.21\ 10^{-3}$	$1.14\ 10^{-3}$	$7.86\ 10^{-5}$
4.2.2 e	$1.65\ 10^{-3}$	$8.28\ 10^{-4}$	$4.73\ 10^{-5}$
4.2.2 f	$1.65\ 10^{-3}$	$8.62\ 10^{-4}$	$4.83\ 10^{-5}$

In all calculations, failures are associated to a failure rate of 10^{-3}/h and repair rate of $2\ 10^{-2}$/h. The grace times and delays of deterministic failures are indicated in § 4.1 and 4.2. Table 1 gives a synthesis of all comparisons. The numbers in the first column correspond to the numbers of sections below that explain the test cases. All calculations with I&AB require a negligible time, whereas some of

the Monte Carlo simulations require a few minutes for sufficient precision.

Below are the descriptions of the test cases and comments on the results.

4.1 *Grace times*

4.1.1 *Single grace time*

The minimal product to quantify is {Initiator, A, B, grace_time}. In the dynamic model, there are only two sequences: Initiator, A, B, grace_time and Initiator, B, A, grace_time (A and B are in active redundancy). The grace time is successively taken equal to 25 h (line 4.1.1.a of Table 1), 50 h (line b), 100 h (line c).

In this case, I&AB works quite well, and it is not surprising, given the fact that the dynamic model corresponds exactly to the simplifying assumptions made in § 2.1.

4.1.2 *Two grace times*

The minimal product to quantify is {Initiator, A, grace_time_1, B, grace_time_2}. In the dynamic model, there is only one sequence: Initiator, A, grace_time_1, B, grace_time_2. The grace time is fractioned, and the component B can fail only after the failure of A and the end of grace_time_1. The two grace times (in hours) are successively taken equal to (5, 20) (line 4.1.2a of Table 1), (20, 5) (line b), (15, 35) (line c), (35, 15) (line d), (30, 70) (line e), (70, 30) (line f). Note that in the dynamic model, the basic event grace_time_1 is considered as repairable (with repair rate equal to 1/250 h), so that after an initiating event, the system can return to its initial state provided it does not reach the undesirable event; the value chosen for the repair rate is not sensitive as long as the mean time to repair components is much smaller than the mean time to repair the grace time: in such a case, after a given occurrence of the initiator, the grace time can be considered as "not repairable" just like in I&AB. In the simulation model, the order of the two grace times makes a difference if they are not equal. In I&AB, it is also the case because only the last grace delay is taken into account. We have also tested the idea of taking the sum of the two grace delays like a single one in I&AB: it yields results much closer to those of the dynamic model, but this approximation can produce optimistic results in some cases (for case f the result is $5.85\ 10^{-5}$). Intuitively, this is due to the fact that in the dynamic model only the last grace delay is competing with *all* repairs of the markovian elements of the cut set. Cf. also §5.

4.2 *Deterministic failures*

4.2.1 *Barriers in active redundancy*

Let us consider a little hydraulic system modeled by the BDMP below:

When the initiator Leak occurs, the two barriers (each one composed of a pump and a tank) are activated. The undesirable event occurs if, before the repair of the leak, the two pumping systems are lost, either because of a random failure of the pump, or because the tank is empty. The failure and repair rates for random events are as described at the beginning of §4, except that the repair rate of the Leak is 0.1/h in order to get small enough probabilities.

The results given in Table 1 correspond to the following values for the times after which Tank1 and Tank2 are empty: (40, 30) (line 4.2.1a), (80, 60) (line b), (150, 100) (line c). Note that the order of the two numbers is not important here, because of the symmetry of the two barriers. I&AB performs quite well on this example, where the minimal product containing the two deterministic failures is dominant. In the dynamic model as well as in I&AB, the amount of water in the biggest tank is the most influent parameter.

4.2.2 *Barrier 2 activated on failure of barrier 1*

In this case, in the dynamic model, the functioning times of the two tanks add up, unless a failure of pump1 forces to start barrier2 before depletion of tank1. It is therefore not surprising that I&AB is more conservative in this case than when the two barriers are in active redundancy. The BDMP corresponding to this case is not shown, because it is the BDMP of Figure 1 with just *one* additional trigger (red dotted line), going from gate Barrier1_lost to gate Barrier2_lost. There is no need to re-run the calculations with I&AB, since for this method, this case gives the same results as the previous one (active redundancy of barriers). But here, the capacities of the two tanks are not exchangeable in the dynamic model, this is why we ran YAMS with the following couples of values for deterministic delays: (40, 30) (line 4.2.2a), (30, 40) (line b), (80, 60) (line c), (60, 80) (line d), (150, 100) (line e), (100, 150) (line f). The unreliability increases a bit when the greatest delay is the last one. Going from line a to f, the results of I&AB range from extremely conservative (by a factor 10) to acceptably conservative (by a factor 2). On the other hand, using the sum of the delays instead of the greatest cannot be recommended because it could lead to optimistic results.

5 DIFFERENCES BETWEEN GRACE TIMES AND DETERMINISTIC DELAYS

In a dynamic model like a BDMP, both grace times and deterministic delays are represented as leaves

associated to a deterministic time to failure. So the difference between those two concepts is not obvious. In essence, the difference between a grace delay and a deterministic failure is that:

- Once the grace delay has started, whatever happens on the system can only postpone (case of a repair) the undesirable event, or leave it unchanged (case of a failure);
- In the case of a deterministic failure, whatever happens on the system can only make the undesirable event happen sooner (case of a failure), or leave it unchanged (case of a repair).

The I&AB theory makes a very clear distinction between the two concepts, because it considers that the grace time starts when all other components of the cut set have failed, whereas the timer of a deterministic failure starts just after the initiator. An intermediate grace time such as in the example of §4.1.2 corresponds to none of these cases, this is why in I&AB it should be simply ignored. It is the user's responsibility to mark leaves as grace delays, deterministic failures or "to be ignored" in the BDMP before transforming it into input data for I&AB.

On a large model, it is probable that the few minimal products with a too conservative quantification will be "hidden in the crowd" and that the global result will not be much affected.

6 APPLICATION TO THE SPENT FUEL POOL

To perform all our tests so far, we have used the implementation of I&AB that we described in (Bouissou & Hernu 2016). It is not the most efficient because it separates the search for minimal products from their quantification, therefore preventing the use of a probability threshold to discard at an early stage in the calculations most minimal products, as it is done by the MOCUS algorithm (Fussell & Vesely 1972). In spite of this limitation, we have been able to demonstrate impressive performances of I&AB in the spent fuel pool application.

We have built a model relative to the spent fuel pool of the European Pressurized Reactor and its support systems. Although less detailed than a classical PSA model, the BDMP we have built takes into account all dependances due to standby redundancies, common cause failures, sharing of electrical supplies… The model takes into account both the grace time of 14 hours before boiling of the water and deterministic failures of tanks used to replace evaporated water.

This BDMP (326 leaves, 77191 minimal products of order up to 6) could be processed by I&AB in a few minutes on a laptop. This model happened to be also quantifiable by YAMS: the Monte Carlo simulation gave a failure probability smaller than the result of I&AB by a factor around 2, but the calculation took 25 minutes to reach a 10% precision with 95% of confidence on the same machine.

Besides, with Monte Carlo simulation, it is very hard to get qualitative results: for that particular model, there is only one dominant sequence and all other sequences are much less probable: it would require many hours of simulation to get results comparable to the, say, 10 most probable minimal products that are easily identified by the I&AB method.

8 CONCLUSION

I&AB is an analytical method for the reliability calculation of large repairable systems with dependences between components. Two kinds of models can serve as input for this method: BDMPs or standard nuclear PSA models complying with the fault tree linking method. Both of them can be transformed into a set of minimal products that are the basis of the calculation. I&AB as it was described in (Bouissou & Hernu 2016) cannot readily be used for the fuel pool case, because for this system, there are two kinds of deterministic delays that must be taken into account: grace times, and deterministic failures due to the limited capacity of water tanks.

In the present paper, we have given two theoretical contributions: the analytical formulae of the I&AB method (so far, they were only available in the French patent file FR3044787) and their extension in the case of deterministic delays. In addition, we have shown on several examples that the extended method can yield reasonably conservative results, in times incomparably shorter than Monte Carlo simulation.

Thanks to a partnership between EDF and Lloyd's Register, I&AB will soon be available for the large community of users of the RiskSpectrum PSA tool. This could revolutionize PSA praxis in upcoming years.

ACKNOWLEDGEMENT

This paper is based on work done in collaboration with Olga Hernu, the co-author of the I&AB method and patent file (Bouissou & Hernu 2016).

Structure function in analysis of multi-state system availability

M. Kvassay, V. Levashenko, J. Rabcan, P. Rusnak & E. Zaitseva
University of Zilina, Zilina, Slovakia

ABSTRACT: Mathematical representation of investigated system is important step of reliability analysis. There are two principal representations of considered system. The first one is known as Binary-State System (BSS), and it permits considering only two states in system/components performance—functioning and failed. Very often, this is not sufficient to adequate mathematical description of system behavior. Therefore, other types of mathematical representation are used. Multi-State System (MSS) is one of most prospective mathematical representations. This representation allows defining more than two states in describing behavior of the system and its components. A MSS can be described by structure function, which defines unambiguous correlation between all possible combinations of states of the system components and the system state. Typical disadvantages of MSS are large dimension and impossibility to form structure function based on uncertain data. We propose to consider application of mathematical methods of Multiple-Valued Logic (MVL) to form the MSS structure function. MVL is natural extension of Boolean algebra in MSS reliability assessment. This logic has been used for analysis of logic functions with more than two values. New method for structure function forming based on uncertain data and application of MVL methods is proposed. Multi-Valued Decision Diagrams (MDDs) are used for structure function representation, in particular. A MDD is useful data structure for representation of MVL function of large dimension. The method presented in this paper takes into account two disadvantages of MSS representation by structure function.

1 INTRODUCTION

System availability analysis can be implemented based on a mathematical representation of investigated system. The construction of the mathematical representation of the system has some factors that cause the final form of this representation. The first of them is definition of the number of availability levels (states) (Natvig 2011; Zaitseva & Levashenko 2017). The second factor is related to the mathematical method that is used for qualitative or quantitative analysis (Lisnianski & Levitin 2003; Zaitseva & Levashenko 2017). The third factor is caused by initial data uncertainty: the different mathematical representations are used for completely specified initial data and for uncertain initial data (Aven 2010).

According to these factors, mathematical representations for evaluation of system availability are divided as *Binary-State System* (BSS) and *Multi-State System* (MSS). A BSS allows representing the initial system as mathematical model with two possible states that are complete failure and perfect working. A MSS permits considering more than only two states in system behavior. In this paper, the MSS is considered for mathematical representation of the investigated system because it allows us to describe system behavior in more details. Both BSS and MSS can be used in analysis of systems for which the initial data is completely specified or uncertain. Four groups of methods are used for MSS analysis (Lisnianski & Levitin, 2003): stochastic processes, universal generating function, Monte Carlo simulation, and extensions of Boolean methods. The methods based on extensions of Boolean methods was historically the first in the MSS reliability evaluation (Murchland 1975), and they are based on the representation of investigated system in a form of the structure function.

The structure function defines dependency of system state on states of system components. There are many mathematical approaches in the reliability engineering for the structure function analysis. The most frequently used are fault trees (Kabir 2017), reliability block diagrams (Distefano & Puliafito 2009), and minimal cut/paths sets (Kvassay et al 2015a). Very often methods of Boolean algebra as *Binary Decision Diagram* (BDD) (Zaitseva et al 2015), Boolean function minimization (Di Maio et al 2016) and Logical Differential Calculus (Schneeweiss 2009) are used in the structure function analysis of BSSs. The similar methods have been developed for MSSs based on mathematical background of Boolean Logic (Xing & Amari 2015) and *Multiple-Valued Logic* (MVL) (Zaitseva & Levashenko 2017). For example, Multi-Valued Decision diagrams (MDDs) as generalization of BDDs are considered in (Xing & Dai 2008,

Zaitseva & Levashenko 2008) for analysis of MSSs. The methods for finding minimal cut/path sets of a MSS are proposed in (Kvassay et al. 2015b). Logical Differential Calculus for MSS importance analysis is considered in (Kvassay et al. 2017).

These investigations show the efficiency of MVL mathematical method use in MSS reliability analysis. However, methods based on structure function have some restrictions in analysis of MSSs, and they do not allow investigating systems for which initial data is incompletely specified. The structure function is constructed based on completely specified data as a rule. Therefore, MVL methods are combined with other methods to construct and analyze structure function of a MSS. One of possible methods has been proposed in (Zaitseva & Levahsenko 2016), and it allows us to construct the MSS structure function using Fuzzy Decision Tree (FDT). The FDT is inducted based on incompletely specified and uncertain data. The FDT permits creating a decision table that agrees with the structure function of the MSS. However, the table is not an optimal representation of MSS structure function because this function has large dimension as a rule. More suitable representation of the structure function of a MSS is MDD.

In this paper, we consider the MSS structure function mathematical representation based on completely specified data (section 2) and incompletely specified data (section 3). The MDD allows us to represent the completely specified structure function of a MSS. The complexity of the MDD depends on the ordering of variables of the structure function in this form. The FDT can be used in case of incompletely specified and uncertain data. The algorithm for induction of FDT for representation of the MSS structure function has been proposed in (Zaitseva & Levashenko 2016). However, this algorithm does not take into account specifics for ordering of variables in a MDD. Therefore, we propose use of other types of FDT that is ordered FDT (Levashenko et al 2007). A new algorithm for transformation of the ordered FDT into MDD is considered in section 4. The evaluation of accuracy of the FDT use in construction of a MDD representing the MSS structure function and efficiency of the ordering of variables in MDD are shown in section 5.

2 MATHEMATICAL REPRESENTATION OF SYSTEM BASED ON COMPLETELY SPECIFIED DATA

2.1 *Structure function*

A system of n components in the stationary state is considered in this paper. This system has M performance levels and is interpreted as a MSS. We suppose that this system is repairable and repairs end in the state as-good-as-new (for the individual components). This assumption allows defining MSS structure function as a time-independent function.

The structure function of MSS defines correlation of the MSS performance levels and its components states (Zaitseva & Levashenko 2017):

$$\phi(\boldsymbol{x}) = \phi(x_1,\ldots, x_n): \{0, \ldots, m_1 - 1\} \times \ldots \times \{0,\ldots, m_n - 1\} \rightarrow \{0,\ldots, M-1\}, \quad (1)$$

where $\phi(\boldsymbol{x})$ defines system performance levels from complete failure ($\phi(\boldsymbol{x}) = 0$) to perfect functioning ($\phi(\boldsymbol{x}) = M$ -1); $\boldsymbol{x} = (x_1,\ldots, x_n)$ is a state vector; x_i is the i-th component state that changes from failure ($x_i = 0$) to perfect functioning ($x_i = m_i$ -1).

Every system component is characterized by the probabilities of its states:

$$p_{i,s} = \Pr\{x_i = s\},\ s = 0,\ \ldots,\ m_i - 1. \quad (2)$$

The probabilities of the MSS performance levels, availabilities and unavailability of the system based on the structure function (1) are defined as (Kvassay et al. 2015b; Lisnianski & Levitin 2003):

$$P_j = \Pr\{\phi(\boldsymbol{x}) = j\},\ j = 0,\ 1,\ \ldots,\ M - 1, \quad (3)$$
$$A_h = \Pr\{\phi(\boldsymbol{x}) \geq h\},\ h = 1,\ \ldots,\ M - 1, \quad (4)$$
$$U = \Pr\{\phi(\boldsymbol{x}) = 0\}. \quad (5)$$

The MSS structure function (1) according to (Zaitseva & Levashenko 2017) is interpreted as MVL function that allows using MVL mathematical methods for MSS analysis. There are some descriptions of MVL function that can be applied for the MSS structure function representation. Two of most well-known are truth table (Zaitseva & Levashenko 2017) and *Multi-Valued Decision Diagram* (MDD) (Xing & Dai 2008).

For example, let us to consider the truth table of the simple service system analysed in (Kvassay et al 2015b) that consists of 3 components ($n = 3$): 2 service points (components 1 and 2) and the service system infrastructure (component 3). This system has 3 performance levels ($M = 3$): 0 – non-operational, 1 – partially operational, 2 – fully operational. Components 1 and 2 have 2 states ($m_1 = m_2 = 2$): functional (state 1) and dysfunctional (state 0). The third component has 3 states ($m_3 = 3$): failure (it is 0), partly working (it is 1) and perfect working (it is 2). The structure function of this system is shown in Table 1.

The basic measures (3)–(5) of this system are calculated by the truth table (Table 1) as:

$$P_2 = p_{1,1} \cdot p_{2,1} \cdot (p_{3,1} + p_{3,2}) + p_{1,1} \cdot p_{2,0} \cdot p_{3,2}, \quad (6)$$
$$P_1 = (p_{1,0} \cdot p_{2,1} + p_{1,1} \cdot p_{2,0}) \cdot p_{3,1} + p_{1,0} \cdot (p_{2,1} + p_{2,0}) \cdot p_{3,2}, \quad (7)$$

Table 1. The structure function of the simple service system.

Components states		x_3		
x_1	x_2	0	1	2
0	0	0	0	1
0	1	0	1	1
1	0	0	1	2
1	1	0	2	2

$$A_2 = p_{1,1} \cdot p_{2,1} \cdot (p_{3,1} + p_{3,2}) + p_{1,1} \cdot p_{2,0} \cdot p_{3,2}, \quad (8)$$

$$A_1 = (p_{1,0} \cdot p_{2,1} + p_{1,1} \cdot p_{2,0} + p_{1,1} \cdot p_{2,1}) \cdot p_{3,1} + p_{3,2}, \quad (9)$$

$$U = p_{3,0} + p_{1,0} \cdot p_{2,0} \cdot p_{3,1}. \quad (10)$$

The truth table of the MSS structure function has dimension $\prod_{i=1}^{n} m_i$. This dimension extremely grows with the increasing number of the function variables, i.e. with the number of system components. In MVL, another representation is used for function of large dimension. It is a MDD (Miller & Drechsler 2002).

2.2 *Multi-valued decision diagram*

A MDD is a graphical presentation of MVL function (Miller & Drechsler 2002). This form for the MSS structure function representation has been proposed in (Xing & Dai 2008, Zaitseva & Levashenko 2008). A MDD has been modified into Multi-state Multi-valued Decision Diagram (MMDD) in (Xing & Dai 2008). A MMDD has been proposed for the MSS in which the number of system performance levels is not equal to the number of component states, and each component in the system may have different number of states. The structure function of this MSS is defined according to (1). A MMDD analyzes the system states with success rather than all system states. In (Zaitseva & Levashenko 2017) the theoretical aspects of MVL mathematical approaches application for a MSS with the structure function (1) have been considered. These results allow us to use MDD to represent a MSS in which the system and each component may have different number of states.

A MDD is specified same as a BDD, except the nodes become more complex. This is due to the Shannon expansion for MVL-functions and this expansion is defined as (Miller & Drechsler, 2002):

$$\phi(\boldsymbol{x}) = 0 \cdot \phi(0_i, \boldsymbol{x}) + 1 \cdot \phi(1_i, \boldsymbol{x}) + \ldots + (m-1) \cdot \phi((m-1)_i, \boldsymbol{x}). \quad (11)$$

The Shannon expansion (11) is the basis for using MDD and a definition of manipulations over them. The format for MDD manipulation

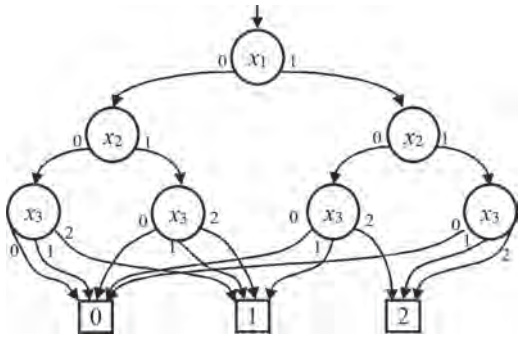

Figure 1. The MDD for the structure function of the simple service system (Table 1).

is defined as expression *case*(a, b_0, b_1, ..., b_{m-1}) = b_a (Miller & Drechsler 2002).

A MDD is a directed acyclic graph representing MVL function based on the Shannon expansion (11). This graph has M terminal nodes, labelled from 0 to (M – 1), representing M states of MSS. Each non-terminal node is labelled with a structure function variable x_i and has m_i outgoing edges. The non-terminal node outgoing edges are interpreted as component states.

For example, the MDD for the representation of the simple service system defined by Table 1 is shown in Figure 1. This MDD is uniquely described by procedures *case* and *if-then-else* as:

If $x_1 = 0$ *then*
    If $x_2 = 0$ *then case* (x_3, 0, 0, 1)
        else case (x_3, 0, 1, 1)
else
    if $x_2 = 0$ *then case* (x_3, 0, 1, 2)
        else case (x_3, 0, 2, 2)

The probabilistic interpretation of the MDD and rules for MSS measure calculation are based on the canonical Shannon expansion (11). The probabilistic interpretation of the MSS assumes that every edge from the i-th node labeled as s_j agrees the i-th component state probability $p_{i,s}$. Rules for the MSS evaluation according to (3) – (5) based on MDD are presented in details in (Zaitseva & Levashenko 2008). A calculation of these measures based on the MDD consists of analysis of paths from the root node to the terminal node "j", $j = 0, \ldots, M-1$. For example, the system availability A_2 based on the MDD in Figure 1 is defined by 3 paths from the root node labeled x_1 to terminal node 2:

$$A_2 = p_{1,1} \cdot p_{2,0} \cdot p_{3,2} + p_{1,1} \cdot p_{2,1} \cdot p_{3,1} + p_{1,1} \cdot p_{2,1} \cdot p_{3,2} = p_{1,1} \cdot p_{2,1} \cdot (p_{3,1} + p_{3,2}) + p_{1,1} \cdot p_{2,0} \cdot p_{3,2}.$$

This agrees with the availability A_2 (8) calculated by the truth table.

The truth table and the MDD are typically used for representation of completely specified function (Stankovic et al 2012). There are investigations to develop methods of the MDD construction for incompletely specified function. Most of these investigations have been provided in logic design (Popel & Drechsler 2003). The unspecified values of function in logic design can be interpreted arbitrarily (Stankovic et al 2012). The unspecified values of the structure function in reliability engineering appear if they cannot be measured or observed, but they must exist. Therefore, these values cannot be ignored (Aven 2010, Zaitseva et al 2017). These specifics require development of new methods and algorithms for representation of incompletely specified structure function because methods for MDD construction proposed in logic design cannot be used. One of possible approach has been proposed in (Zaitseva & Levashenko 2016, Zaitseva et al 2017). It is based on use of decision trees.

3 MATHEMATICAL REPRESENTATION OF SYSTEM BASED ON INCOMPLETELY SPECIFIED DATA

3.1 *Initial data*

According to the approach for the MSS structure function construction based on incompletely specified data in (Zaitseva & Levashenko 2016, Zaitseva et al 2017) this function is interpreted as classification procedure: all system state vectors $(x_1,\ldots, x_n)$ are divided into M classes. This classification is illustrated by MDD too. For example, the MDD of a simple service system in Figure 1 divides all state vectors into 3 classes.

The interpretation of the MSS structure function as classifier allows us to use methods for induction of classifiers based on incompletely specified data. Such methods are well known in Data Mining. One of them is induction of a decision tree. For example, the decision tree can be inducted by algorithm ID3/C4.5 developed by Quinlan (1987). This algorithm can be used for incompletely specified data that has crisp values. But initial data for reliability analysis is collected as expert data often. This data is latent or uncertain. There are different factors that cause uncertainty of data collected for reliability analysis (Aven 2010, Ley 2011). In this paper two of them are considered. The first is incompleteness of data. The second is ambiguity and vagueness of initial data.

The incomplete data is collected if it is impossible to indicate some values of the system components states or system performance levels. For example, it can be very expensive, or it needs unacceptable long time, or it is dangerous for the environment.

The ambiguity and vagueness of initial data are caused by methods for the data collection: measurement and/or expert's knowledge. The measurement can be inaccurate and with an error, that depends on accuracy of measuring device. Therefore, these data can be defined and used with some likelihood. In case of data collected based on expert's knowledge, data cannot be indicated exact because experts can have different opinions on one situation. The fuzzy logic makes it possible to define the structure function in a more flexible form.

The mathematical representation of a MSS in this case is interpreted as a classification problem for uncertain and incompletely specified data that can be decided with the application of FDT (Zaitseva & Levashenko 2016, Zaitseva et al 2017).

3.2 *Fuzzy Decision Tree*

A FDT is one of possible types of decision trees. A FDT allows taking into account not only unspecified values of system states but also uncertain values of components states. It is a formalism for expressing mapping of input attributes on output attribute/attributes, consisting of an analysis of attribute nodes linked to two or more sub-trees and leaves or decision nodes labeled with a class (in our case it is the system performance level) (Olaru & Whenkel 2003). A FDT defines the correlation between n input attributes $\{\mathrm{A}_1,\ldots, \mathrm{A}_n\}$ and an output attribute B. The important step in the use of FDT for the MSS mathematical representation is definition of the correlation between terminologies (formalisms) of FDT induction and MSS structure function.

In (Zaitseva & Levashenko 2016) the state vector $\boldsymbol{x} = (x_1, \ldots, x_n)$ is interpreted as the set of input attributes $\mathbf{A} = \{\mathrm{A}_1, \ldots, \mathrm{A}_n\}$, and value of the structure function $\phi(\boldsymbol{x})$ as the output attribute B for FDT induction. Each input attribute (component state) A_i $(1 \le i \le n)$ is measured by a group of values ranging from 0 to $m_i - 1$, which agree with the values of states of the i-th component: $\{\mathrm{A}_{i,0}, \ldots, \mathrm{A}_{i,mi-1}\}$. Every value $A_{i,j}$ of fuzzy attribute A_i can be considered as a fuzzy set. These sets create the domain of a fuzzy attribute and their count is considered as a domain size. Each value of each instance is described by membership function $\mu_{A_{i,j}}(e) \in [0,1]$, where $\sum_{j=1}^{m_i} \mu_{A_{i,j}}(e) = 1$ and e represents an instance. These restrictions on representation of initial data are caused by the strategy for FDT induction for mathematical representation of the MSS. A FDT assumes that the input set $\mathbf{A} = \{\mathrm{A}_1,\ldots, \mathrm{A}_n\}$ is classified as one of the values of output attribute B. Value B_w of output attribute B agrees with one of the system performance levels and is defined as M values ranging from 0 to $M - 1$ $(w = 0,\ldots, M - 1)$.

For example, let us suppose that we have incompletely specified data with some likelihood about the simple service system (section 2.1). The data is represented in form of Table 2 (Zaitseva et al 2017). This data can be used for the system structure function construction based on likelihood of values (Table 3). But this structure function is incompletely specified (3 values are absent). Therefore, special methods or algorithms have to be used to "reconstruct" this MSS structure function. The method for structure function construction based on uncertain and incomplete data by FDT has been proposed in (Zaitseva & Levashenko 2016).

This method for structure function construction based on uncertain and incomplete data by FDT includes three steps (Zaitseva & Levashenko 2016):

- collection of data into the repository according to requests of FDT induction;
- representation of the system model in the form of a FDT that classifies components states according to the system performance levels;
- construction of the structure function as a decision table that is created by inducted FDT.

According to this method, the structure function is formed as a truth table that indicated the system performance level for each possible combination of components states. In this paper, we propose to transform inducted FDT into MDD for MSS mathematical representation, which is more acceptable for description of a MSS of large dimension. In particular, we propose to use the ordered FDT introduced in (Levashenko et al 2007) for the MDD creating.

Table 2. Uncertain data for the simple service system.

Components states							Performance levels		
x_1		x_2		x_3					
0	1	0	1	0	1	2	0	2	2
0.9	0.1	1	0	0.8	0.2	0	1	0	0
1	0	0.9	0.1	0.1	0.9	0	1	0	0
0.9	0.1	0.1	0.9	0.1	0.8	0.1	0	1	0
1	0	0	1	0	0.1	0.9	0	1	0
0.1	0.9	1	0	0.9	0.1	0	1	0	0
0	1	1	0	0.1	0.8	0.1	0	1	0
0.1	0.9	0	1	1	0	0	1	0	0
0.1	0.9	0	1	0.1	0.9	0	0	0	1
0.2	0.8	0.1	0.9	0	0.1	0.9	0	0	1

Components states		x_3		
x_1	x_2	0	1	2
0	0	0	0	*
0	1	*	1	1
1	0	0	1	2
1	1	*	2	2

4 MULTI-VALUED DECISION DIAGRAM CONSTRUCTION BY FUZZY DECISION TREE

A FDT can have different properties. One of possible FDTs types is ordered FDT. This FDT has the same attributes at one level. It permits to use the predefined order of attributes in analysis of new samples. In this paper, the ordered FDT is used for the construction of the MDD based on uncertain data. The proposed algorithm includes three steps and differs from the method proposed in (Zaitseva & Levashenko 2016) only by the last step:

- collection of data into the repository according to requests of FDT induction;
- representation of the system model in the form of the ordered FDT that classifies components states according to the system performance levels;
- construction of the MDD by inducted FDT.

4.1 *Data collection and Fuzzy Decision Tree induction*

Collection of data in the form of a repository is provided by the monitoring of values of system component states and system performance level. This repository can be presented in the form of a table where the columns agree with the input and output attributes. This table is composed of $n + 1$ columns associated with n input attributes and 1 output attribute. The i-th column, for $i = 1,\ldots, n + 1$, is divided into m_i sub-columns. The j_i-th sub-column, for $j_i = 1, \ldots, m_i$, agrees with the j-th value of the attribute represented by the i-th column. Each row of the repository corresponds to one instance of collected data.

For example, the data about the service system in Table 2 satisfies the given conditions and can be interpreted as the repository.

There are different algorithms for FDT induction. The ordered FDT has been introduced by Levashenko et al (2007). In that paper, the algorithm for induction of ordered FDT based on cumulative information estimation of attributes for the selection of next node in tree's induction has been proposed.

The ordered FDT is inducted based on data in the repository by application of the cumulative

information estimates $I(B;A_{i_1},\ldots,A_{i_{q-1}},A_{i_q})$ where $A_{i_1},\ldots,A_{i_{q-1}}$ are input attributes that were used at previous levels of FDT. FDT induction is based on determination of expanded attribute where A_{i_q} are input attributes which have been used at previous levels of FDT. The selection criterion of expanded attributes A_{i_q} is defined as (Levashenko et al 2007):

$$i_q = argmax \cdot \left(\frac{\mathbf{I}\left(B;A_{i_1},\ldots,A_{i_{q-1}},A_{i_q}\right)}{Cost\left(A_{i_q}\right)\times \mathbf{H}\left(A_{i_q}\right)} \right), , \qquad (12)$$

where $Cost(A_{i_q})$ is an integrated measure that covers financial and temporal costs required to define the value of the A_{i_q} for an instance, and this value is defined a priori; $H(A_{i_q})$ is a cumulative entropy of input attribute A_{i_q}.

The cumulative mutual information in output attribute B about the attribute A_{i_q} and the sequence of attributes $A_{i_1},\ldots,A_{i_{q-1}}$ reflects the influence of attribute A_{i_q} on the output attribute B when sequence $A_{i_1},\ldots,A_{i_{q-1}}$ is known. Maximum value i_q in (12) facilitates the selection of expanded attribute A_{i_q}. This attribute will be associated with a node of the ordered FDT.

Two tuning thresholds α and β are in the algorithm for induction of the ordered FDT (Levashenko et al 2007). A tree branch stops to expand when either the frequency of the branch is below α or when more than β percent of instances left in the branch have the same class label. These values are key parameters needed to decide whether we have already arrived at a leaf node or whether the branch should be expanded further. Decreasing the parameter α and increasing the parameter β allow us to build large FDTs. On one hand, large FDTs describe datasets in more detail. On the other hand, these FDTs are very sensitive to noise in the dataset. We empirically select parameters near $\alpha = 0.10$ and $\beta = 0.80$.

The algorithm for the ordered FDT induction based on cumulative information estimates (12) is considered in (Levashenko et al 2007) in details. According to this algorithm we inducted the ordered FDT based on data in Table 2 for the mathematical representation of the simple service system (Figure 2).

The ordered FDT in Figure 2 allows us to form the decision table for all possible combinations of component states (all state vectors). For example, for state vector $x = (0\ 0\ 0)$ in Figure 2, the value of the output attribute is 0. This value is defined by the path from root node to leaf node $A_{3,0}$ with the confidence of 0.880 without analysis of other attributes. The values for other state vectors are computed in the similar way. All calculated values of the output attribute are equal to system states in Table 1.

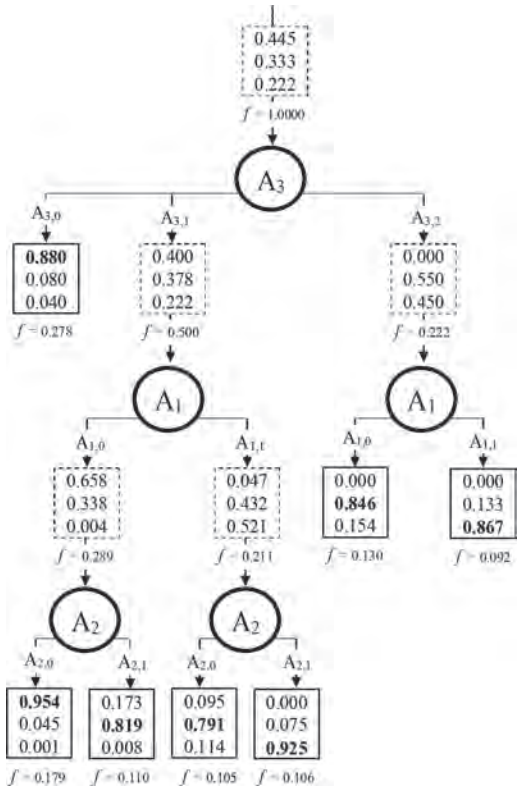

Figure 2. FDT of the simple service system (Table 2).

Therefore the ordered FDT allows represent the structure function uniquely. At the same time, there are many methods and algorithms for the MSS evaluation based on a MDD. The calculation of availability and other measures for the system reliability evaluation are considered in (Mo et al 2017, Xing &Dai 2008, Zaitseva & Levashenko 2008, Zaitseva et al 2013). So, let us consider the transformation of ordered FDT into MDD.

4.2 *Construction of multi-valued decision diagram from Fuzzy Decision Tree*

The important problem in MDD construction is the ordering of the variables: the complexity of MDD depends on the variables order in MDD (Miller & Drechsler 2002). This problem for MDD is being actively investigated and some methods have been proposed for approximate decisions for the optimal ordering of variables in MDD (Stankovic et al 2012, Popel & Drechsler 2003). At the same time the ordered FDT induction supposes the optimal (or quasi optimal) ordering of nodes. Therefore, the ordered FDT can be transformed into MDD with the optimal ordering of variables.

The algorithm for the transformation of the ordered FDT into the MDD includes three steps:

- the transformation of the ordered FDT into decision tree by the defuzzification of the ordered FDT nodes.
- the merger of the same leaf nodes;
- the tree's attributes substitution by appropriate variables.

Let us illustrate these steps by an example of the MDD construction for the service system (Table 2) based on the ordered FDT of this system (Figure 2). According to the proposed algorithm, the first step is defuzzification of the ordered FDT. It can be implemented by construction of decision tree based on maximal values of thresholds α and β. The decision tree for the investigated system is shown in Figure 3.

The second step is the merger of the same leaves that is illustrated in Figure 4. The result of the last step, which is substitution of tree's attributes by appropriate variables, is shown in Figure 5 as MDD of the structure function of the simple service system.

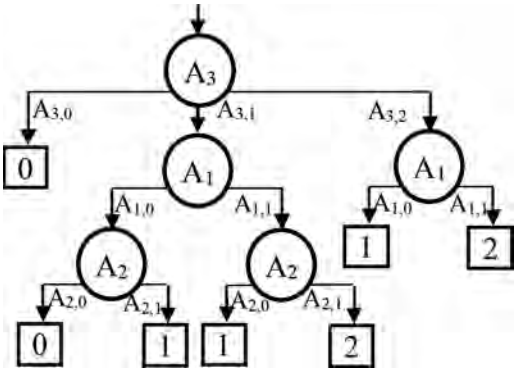

Figure 3. The decision tree of the simple service system formed from the ordered FDT in Fig. 2.

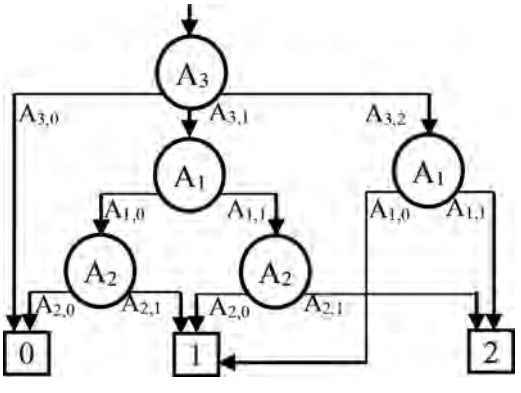

Figure 4. The merger of equal leaf nodes of decision tree in Fig. 3.

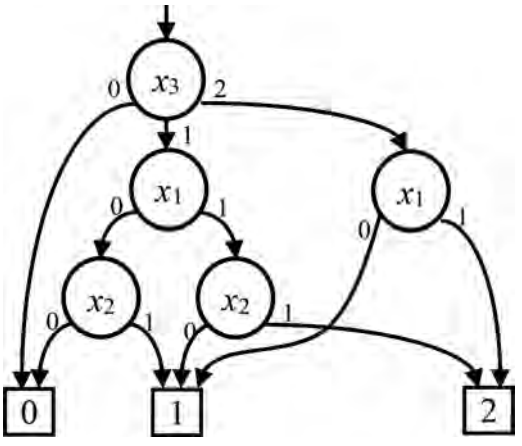

Figure 5. The MDD for the structure function of the simple service system.

The comparison of MDDs in Figure 1 and Figure 5 shows that the MDD constructed based on the ordered FDT has 5 non-terminal nodes and MDD constructed based on the truth table consists of 7 non-terminal nodes. This simple example illustrates that the MDD can be constructed for MSS by incompletely specified data and that the constructed MDD has better ordering of variables than the MDD constructed in section 2.2.

5 EVALUATION

In this section, the efficiency of the algorithm for the construction of the MDD of the MSS structure function based on uncertain data is considered. We use structure functions of three systems analyzed in (Zaitseva et al 2017): outline of an offshore electrical power generation system (Natvig 2011); army battle plan (Boedigheimer & Kapur 1994); a computer system with a memory subsystem subject to competing failure isolation and propagation effect (Xing & Levitin 2011). Basic characteristics of these systems are shown in Table 4. Two types of investigation were implemented.

The first of them is the influence of incompleteness of data on the accuracy of the MSS representation. For this investigation, all integer values representing components states and performance levels of the system were transformed to values with possibilities (Zaitseva et al 2017). We indicated known value with the possibility 1.00 and other values with possibilities 0.00 for components states and performance levels. To model incom-

Numbers of components	5	5	4

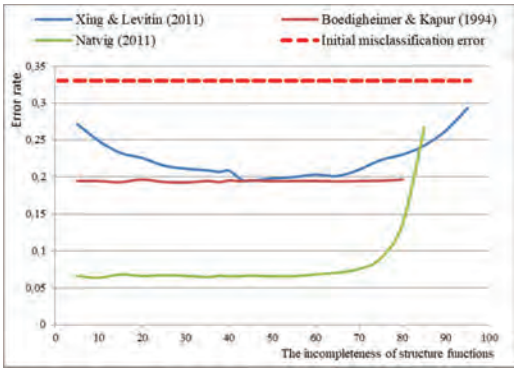

Figure 6. The error rate for the construction of the structure function for three systems.

pleteness of data, the structure functions of the MSSs were randomly transformed into incompletely specified by random deleting some values of the functions. The proportion of deleted values was changed from 5% to 90%. The transformed functions were interpreted as incompletely specified and restored by the ordered FDTs. A restored structure function and initial complete specified function were compared, and the error rate was calculated as a ratio of erroneous values of the structure function to the dimension of unspecified part of the function. The experiments were done for every structure function. The average values for all functions with specified range of deleted values were computed. Error rate for investigated system is less than initial misclassification error (maximal error rate) that is indicated by red line in Figure 6). The evaluation showed that the error increases significantly if the unspecified part is less than 10% or most than 85% for these systems (Figure 6).

The second type of the evaluation was analysis of MDD, in particular, the number of non-terminal nodes of MDDs that are constructed based on different approaches. In particular, we compared the MDD without special ordering of variables of structure function, the MDD formed based on FDT (this algorithm has been considered in (Zaitseva et al 2017) and MDD constructed by ordered FDT. This analysis was implemented for 16 structure functions of coherent systems (number of performance levels $M = 2$ and number

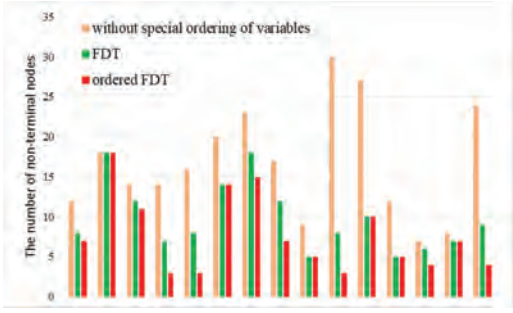

Figure 7. The efficiency of MDD constructed based on the truth table and FDT.

of variables $n = 5$). The evaluation of these MDDs showed that the MDDs created based on ordered FDT have less number of non-terminal nodes (Figure 7).

6 CONCLUSION

The main contribution of this paper is in development of the new algorithm for the construction of the structure function based on incompletely specified and ambiguous data in form of the MDD. It directly supports MSS reliability estimation and can cope with uncertain data for the analysis of system reliability/availability.

The analysis of the error rate of the proposed algorithm for the construction of the structure function based on ordered FDT showed that the method has good efficiency, which is similar to efficiency of the method for construction of structure function based on unordered FDT (Zaitseva et al 2017). This method is acceptable for incomplete data and the incompleteness of initial data can be indicated from 10% to 85%. The structure function constructed based on the proposed method has less error rate than maximal error rate in interval of the incompleteness.

ABSTRACT: Safety and risk analyses rely on models. These models have several important characteristics. They are event-oriented. The system under study changes of state when events, such as failure, hazard, repair and so on, occur. They are probabilistic. The exact moment of the occurrence of a failure is in essence unpredictable. They are discrete. States are represented by means of variables that take their values into finite, usually very small, domains. The most widely used modeling formalisms such as Fault Trees, Block Diagrams and Event Trees rely on Boolean algebra. There are cases however where binary states are not sufficient. For instance, it is sometimes necessary to represent the level of degradation of a component, the quality of a signal, and so on. This kind of models can be easily represented with AltaRica 3.0 – a high level modeling language dedicated to safety analyses. AltaRica 3.0 is at the core of the OpenAltaRica project which aim is to develop a complete set of assessment tools for the language, including among others compilers to Fault Trees and Markov Chains, stochastic and stepwise simulators. In this article we study how the notion of prime implicants can be extended to finite domain calculus. We discuss the efficient implementation of finite domain calculus and show how these results can be applied to simplify Fault Trees, automatically generated from AltaRica 3.0 models. This simplification in its turn significantly improves the efficiency of the assessment of the automatically generated Fault Trees.

1 INTRODUCTION

Risk analysis relies on models. These models have several important characteristics:

- They are event-oriented. The system under study changes of state when events, such as failure, hazard, repair and so on, occur.
- They are probabilistic. The exact moment of the occurrence of a failure is in essence unpredictable.
- They are discrete. States are represented by means of variables that take their values into finite, usually very small, domains.

The last characteristic is pragmatic: given the difficulty to design models and computational complexity of the calculation of indicators, discrete abstractions are a necessary tradeoff. Hence the role of Boolean algebra in Reliability, Availability, Maintainability, Safety engineering. The most widely used modeling formalisms such as Fault Trees, Block Diagrams and Event Trees rely on Boolean algebra. There are cases however where binary states are not sufficient. For instance, it is sometimes necessary to represent the level of degradation of a component, the quality of a signal, and so on. This kind of models can be easily represented with AltaRica 3.0 – a high level modeling language dedicated to safety analyses (Prosvirnova, Batteux, Brameret, Cherfi, Friedlhuber, Roussel, & Rauzy 2013). AltaRica 3.0 is at the core of the OpenAltaRica project[1] which aim is to develop a complete set of assessment tools for the language, including among others compilers to Fault Trees (Prosvirnova & Rauzy 2015) and Markov Chains (Brameret, Rauzy, & Roussel 2015), stochastic and stepwise simulators (Aupetit, Batteux, Rauzy, & Roussel 2015).

In this article we study how the notion of prime implicants can be extended to finite domain cal-

[1]See https://www.openaltarica.fr.

culus and how to encode it efficiently. The contribution of this article is thus multiple. First, we present how the notion of prime implicants can be extended to finite domain calculus. Second, we discuss the efficient implementation of finite domain calculus. Finally we show how these results can be applied to simplify Fault Trees, automatically generated from AltaRica 3.0 models.

The remainder of this article is organized as follows. Section 2 describes a motivating example. Section 3 presents a theoretical work about finite domain calculus and discusses its implementation. Section 4 shows the application of the finite domain calculus to the simplification of Fault Trees automatically generated from AltaRica 3.0 models. Section 5 presents some experimental results using the motivating example. Section 6 concludes this article.

2 MOTIVATING EXAMPLE

Consider a parametric block diagram use case (see Figure 1) with three parameters:

- s the number of blocks in series;
- p the number of parallel blocks;
- q the level of recursivity (depth).

These relatively simple but large safety models can be easily represented in AltaRica 3.0 and handled simply and efficiently by means of the Fault Tree compilation tool chain.

Note that without loosing the efficiency of the assessment, in AltaRica 3.0, it is possible to represent multi-state blocks, e.g. consider the quality of data with the values `ok`, `lost` or `erroneous`, or the level of degradation with the values `ok`, `degraded` or `failed`.

This use case is both representative of a class of industrial models and parametric to show the scalability of the approach. We shall use it throughout the article to illustrate the advances in the simplification of Fault Trees.

3 FINITE DOMAIN CALCULUS

3.1 *Definitions*

Let $\Xi = \{X_1, X_2, ..., X_n\}$ be a finite set of variables. Each Xi takes its values into a finite domain (a finite set of constants) denoted as $dom(X_i)$. The set of well formed formulas over Ξ is the smallest set such that:

- The two Boolean constants 0 (false) and 1 (true) are formulas.
- If X is a variable and c is a constant then $X = c$ is a formula. Such a formula $X = c$ is called a **literal** and makes only sense if $c \in dom(X)$.
- If f and g are formulas, then so are $f + g$ (disjunction), $f * g$ (conjunction), and $-f$ (negation).

We assume that the negation (–) has a higher priority than the conjunction (*), which has a higher priority than the disjunction (+).

A **product** is a set of literals interpreted as the conjunction of its elements. A product is said **fundamental** if it does not contain two literals built over the same variable. We shall consider only fundamental products. The empty product is denoted **1**.

A **minterm** is a product that contains a literal for each variable of Ξ. As we shall see, minterms play a fundamental role in the finite domain calculus for they are the atoms of the underlying Boolean algebra.

A **sum of products** is a set of products interpreted as the disjunction of its elements. The empty sum of products is denoted **0**.

A **variable assignment** of Ξ is a function $\sigma: \Xi \rightarrow dom(X_1) \times dom(X_2) \times ... \times dom(X_n)$, that associates to each variable X_i its value from $dom(X_i)$, $i = 1, ..., n$.

Let f and g be formulas and σ be a variable assignment over Ξ. The value of $\sigma(f)$ is calculated recursively as follows:

- $\sigma(1) = 1$, $\sigma(0) = 0$;
- $\sigma(X = c) = 1$ if $\sigma(X) = c$ and 0 otherwise;
- $\sigma(f + g) = max(\sigma(f), \sigma(g))$, $\sigma(f * g) = min(\sigma(f), \sigma(g))$, $\sigma(-f) = 1 - \sigma(f)$.

The variable assignment σ **satisfies** the formula f, if $\sigma(f) = 1$, otherwise is **falsifies** it.

There is a one to one correspondence between minterms and variable assignments: the minterm p corresponds to the variable assignment σ if for each variable $X \in \Xi$, $X = c \in p$ if and only if $\sigma(X) = c$.

3.2 *Implication, equivalence, properties*

Let $\Xi = \{X_1, ..., X_n\}$ be a finite set of finite domain variables. Let f and g be two formulas built over Ξ. f **implies** g, which is denoted as $f \Rightarrow g$, if any vari-

able assignment that satisfies f satisfies g as well. f is **equivalent** to g, which we denote as $f \Leftrightarrow g$, if both $f \Rightarrow g$ and $g \Rightarrow f$.

The usual properties of Boolean algebras hold for the finite domain calculus:

Neutral element: $f + 0 \Leftrightarrow 0 + f \Leftrightarrow f$ and $f * 1 \Leftrightarrow 1 * f \Leftrightarrow f$

Absorbing element: $f + 1 \Leftrightarrow 1 + f \Leftrightarrow 1$ and $f * 0 \Leftrightarrow 0 * f \Leftrightarrow 0$

Idempotence: $f + f \Leftrightarrow f$ and $f * f \Leftrightarrow f$

Commutativity: $f + g \Leftrightarrow g + f$ and $f * g \Leftrightarrow g * f$

Associativity: $f + (g + h) \Leftrightarrow (f + g) + h$ and $f * (g * h) \Leftrightarrow (f * g) * h$

Distributivity: $f + (g * h) \Leftrightarrow f * g + f * h$ and $f * (g + h) \Leftrightarrow (f + g) * (f + h)$

Double negation: $- - f \Leftrightarrow f$

de Morgan's law: $-(f + g) \Leftrightarrow -f * -g$ and $-(f * g) \Leftrightarrow -f * -g$

3.3 *Negation*

The real difference between the propositional and finite domain calculi stands in the negation.

Let Ξ be a finite set of variables, let X be a variable from Ξ, and finally let c be a constant of $dom(X)$. Then, $-(X = c) \Leftrightarrow \Sigma_{d \in dom(X),\, d \neq c}(X = d)$

Theorem 1 (Elimination of negations).: *For any formula of the finite domain calculus, there exists an equivalent formula involving no negation.*

Note that any formula is equivalent to the sum of minterms that satisfies it, which is a first way to demonstrate the theorem. A more syntactic proof consists in pushing negations down to literals, thanks to de Morgan's law, and then to transform negative literals as shown above.

3.4 *Subsumption, resolution*

Let p and q be two products built over Ξ. We say that p **subsumes** q if $q \Rightarrow p$, i.e. if and only if any literal of p is also a literal of q. If p subsumes q, then $p + q \Leftrightarrow p$.

Let X be a variable of Ξ, let $dom(X) = \{c_1, c_2, ..., c_k\}$ and let $p_1, ..., p_k$ be k products in which X does not show up. Let r be the product $p_1 * p_2 * ... * p_k$. Then the following implication holds: $(X = c_1) * p_1 + ... + (X = c_k) * p_k \Rightarrow r$.

The product r is called the **resolvent** of the products $(X = c_1) * p_1, ..., (X = c_k) * p_k$.

In the case, where there is a product p_j such that $p_j = r$, then the following equivalent holds:

$$(X = c_1) * p_1 + ... + (X = c_k) * p_k \Leftrightarrow (X = c_1) * p_1 + ... + (X = c_j) * p_j + ... + (X = c_k) * p_k + r$$

3.5 *Shannon normal form*

Let X be a variable of Ξ, let c be a constant of $dom(X)$ and finally let f be a formula built over Ξ. There exist two formulas f_1 and f_0 in which the atom $(X = c)$ does not show up such that:

$$f \Leftrightarrow (X = c) * f_1 + f_0$$

The above representation is called the pivotal **decomposition** of f with the respect to X and c.

Assume we are given an (arbitrary) order $<$ over the variables of Ξ and over the constants of the do-main of the variables of Ξ. The set of formulas in **Shannon Normal Form** is defined inductively as follows:

- The two constants 0 and 1 are in Shannon Normal Form.
- If f and g are two formulas in Shannon Normal Form, X is a variable and c is a constant of $dom(X)$, the formula $(X = c) * f + g$ is in Shannon Normal Form if
  - X does not show up in f, and
  - for all literal $(Y = d)$ showing up in g, either $X < Y$ or $X = Y$ and $c < d$.

3.6 *Representation theorem*

Let Ξ be a finite set of finite domain variables. Let X be a variable of Ξ, let c be a constant of $dom(X)$ and finally let $f = (X = c) * f_1 + f_0$ be a formula in Shannon Normal Form built over Ξ.

In the above representation we can assume without a loss of generality that:

- $f_1 \neq 0$ as $(X = c) * 0 + f_0 \Leftrightarrow f_0$
- $f_0 \neq 1$ as $(X = c) * f_1 + 1 \Leftrightarrow 1$

From now, we shall assume that these two **simplification rules** are systematically applied.

Theorem 2 (Representation).: *For any formula of the finite domain calculus, there exists at least one equivalent formula in Shannon Normal Form.*

In general, this equivalent formula is not unique. We shall see that two of the formulas that represent a given sum of products are of special interest: the first one can be interpreted as sum of disjoint products, the other one as the set of prime implicants. These two formulas are extremum in a sense we shall explain.

A formula in Shannon Normal Form can be interpreted as a sum of products. Namely,

- SumOfProducts [0] = 0;
- SumOfProducts[1] = 1;
- SumOfProducts[$(X = c) * f + g$] = $\{(X = c) * p; p \in SumOf\ Products[f]\} \cup SumOf\ Products[g]$

Theorem 3 (Sums-of-Products).: *Shannon Normal Formulas one-to-one correspond with Sums-of-Products (for a given order of variables and constants).*

3.7 *Factors and cofactors*

The **factor** and **cofactor** of a formula f with respect to a variable X, denoted respectively as $f|X$ and

$f \sim X$, are syntactic operations that select respectively the products of f that contain X and the products of f that do not contain X. The **factor** $f|X$ is defined recursively as follows:

- $0[X = 0$ and $1|X = 1$
- $[(X = c) * f + g]|X = (X = c) * f + [g|X]$
- $[(Y = c) * f + g]|X = 0$ if $X < Y$
- $[(Y = c) * f + g]|X = (Y = c) * [f|X] + [g|X]$ if $X > Y$

The **cofactor** $f \sim X$ is defined recursively as follows:

- $0 \sim X = 0$ and $1 \sim X = 1$
- $[(X = c) * f + g] \sim X = g \sim X$
- $[(Y = c) * f + g] \sim X = g$ if $X < Y$
- $[(Y = c) * f + g] \sim X = (Y = c) * [f \sim X] + [g \sim X]$ if $X > Y$

3.8 *Logical operations*

Let Ξ be a finite set of finite domain variables. Let X and Y be two variables of Ξ with $X < Y$. Let c, d and e be three constants such that $c, d \in dom(X)$ with $c < d$, and $e \in dom(Y)$. Finally let $f = (X = c) * f_1 + f_0$, $g = (X = c) * g_1 + g_0$, $h = (X = d) * h_1 + h_0$ and $I = (Y = e) * I_1 + I_0$ be four formulas built over Ξ in Shannon Normal Form. The following equivalences hold and they are used as recursive equations to perform logical operations on formulae in Shannon Normal Form:

- $f + g \Leftrightarrow (X = c) * [f_1 + g_1] + [f_0 + g_0]$
- $f + h \Leftrightarrow (X = c) * f_1 + [f_0 + h]$
- $f + I \Leftrightarrow (X = c) * f_1 + [f_0 + I]$
- $f * g \Leftrightarrow (X = c) * [f_1 * g_1 + f_1 * g_0 \sim X + f_0 \sim X * g_1] + [f_0 * g_0]$
- $f * h \Leftrightarrow (X = c) * [f_1 * h_1 + f_1 * g_0 \sim X] + [f_0 * g]$
- $f * I \Leftrightarrow (X = c) * f_1 + [f_0 * I]$
- $-f \Leftrightarrow [\sum_{d \in Dom(X), d \neq c} (X = d) * -g] + [-f * -g]$

3.9 *Subsumption*

As we shall see, it is of interest to remove from a formula f all the products that are subsumed by a product of a formula g. This operation, denoted $f \div g$, can be defined by means of the following recursive equations. Let Ξ be a finite set of finite domain variables. Let X and Y be two variables of Ξ ($X < Y$), let c, d and e be three constants such that $c, d \in dom(X)$, $c < d$, and $e \in dom(Y)$. Then:

- $f \div 0 = f$, $f \div 1 = 0$, $0 \div g = 0$ and $1 \div g = 1$
- $[(X = c) * f_1 + f_0] \div [(X = c) * g_1 + g_0] = (X = c) * [(f_1 \div g_1) \div g_0] + f_0 \div g_0$
- $[(X = c) * f_1 + f_0] \div [(X = d) * g_1 + g_0] = (X = c) * [f_1 \div g_0)] + f_0 \div g_0$
- $[(X = c) * f_1 + f_0] \div [(Y = e) * g_1 + g_0] = (X = c)[f_1 \div [(Y = e) * g_1 + g_0]] + f_0 \div [(Y = e) * g_1 + g_0]$
- $[(X = d) * f_1 + f_0] \div [(X = c) * g_1 + g_0] = (X = c)[f_1 \div g_0] + f_0 \div g_0$
- $[(Y = e) * f_1 + f_0] \div [(X = c) * g_1 + g_0] = [(Y = e) * f_1 + f_0] \div g_0$

3.10 *Prime implicants*

Let Ξ be a finite set of finite domain variables with an order over variables and constants. Let f and p be respectively a formula and a product built over Ξ.

- p is an **implicant** of f if $p \Rightarrow f$.
- p is a **prime implicant** of f if it is an implicant of f and no strict sub-product (subsuming product) of p is.

The set of prime implicants of f is denoted $PI[f]$.

Theorem 4 (Decomposition of Prime Implicants).: *Let f be a formula in Shannon Normal Form. Then $f = (X = c_1) * f_1 + ((X = c_2) * f_2 + ... + ((X = c_k) * f_k + f_0)) .. .)$ for some constants $c_1,..., c_k$ from $dom(X)$ and some formulas $f_1,..., f_k, f_0$ in Shannon Normal Form in which X does not occur.*

Let $h = (f_1 * f_2 * ... * f_k) + f_0$. Then, the set of prime implicants of f denoted by $PI[f]$ are calculated as follows:

$$PI[f] = \{(X = c_1) * p; p \in PI[f_i] \div PI[h]\}$$
$$...$$
$$\cup \{(X = c_k) * p; p \in PI[f_k] \div PI[h]\}$$
$$\cup \{PI[h]\}$$

The decomposition theorem gives an algorithm to calculate for any formula f in Shannon Normal Form an equivalent formula h such that:

$$g = SumOf\ Products[h] = PI[f]$$

Because all possible resolutions and subsumptions have been performed, g can be considered as the **most simplified form** of f.

At the opposite, we may want to transform f into an equivalent **sum of disjoint products** so to be able to calculate the exact probability of f. Disjoining products encoded by f is performed by the dual operation of calculating resolvents.

Let $f = (X = c_1) * f_1 + ((X = c_2) * f_2 + ... + ((X = c_k) * f_k + f_0)) .. .)$. Assume that $dom(X) = \{c_1,..., c_k\}$ (if some constant c_i of $dom(X)$ is missing we can always add the term $(X = c_i) * 0$). Then, f is equivalent to the following formula:

$$g = (X = c_1) * [f + f_0] + ((X = c_2) * [f_2 + f_0] + ... + ((X = c_k) * [f_k + f_0)] + 0) .. .).$$

By applying this transformation recursively, we get a sum of disjoint products, which is also **unique**, for a given order on variables and constants.

3.11 *Diagrammatic representation*

The idea is to represent sums of products in Shannon Normal Form by means of a variant of Bryant's **Binary Decision Diagrams** (Bryant 1992). The idea is therefore to represent formulas in Shannon Normal Form by means of Directed Acyclic Graphs with two types of nodes:

- Leaves, that are labeled with either 0 or 1.
- Internal nodes, that are labeled with a variable X and a constant c of $dom(X)$ and that have two out-edges called the 1-outedge and the 0-outedge. Such a node represents the formula $(X = c) * f + g$, where f and g are the formulas represented respectively by the node pointed by the 1-outedge and the node pointed by the 0- outedge.

The **Shannon Diagram** representing a formula is always built **bottom-up**. Nodes are maintained into a **unique** table (and accessed by means of a **hash**table). In this way, for any formula f, there is at most one node representing f in the table. Checking the equivalence of two formulas is thus performed in constant time once their Shannon Diagrams are built.

4 APPLICATION

One of the possible applications of the finite domain calculus presented above is the simplification of Fault Trees automatically generated from AltaRica 3.0 models. AltaRica 3.0 is an event-based high level modeling language dedicated to Safety Analyses (Prosvirnova, Batteux, Brameret, Cherfi, Friedlhuber, Roussel, & Rauzy 2013). Its semantics is based on Guarded Transitions Systems (Rauzy 2008).

4.1 *Guarded transitions systems*

A Guarded Transitions System (GTS) G is a quintuple $\langle V, E, T, A, \iota \rangle$, where:

- $V = S \cup F$ F is a set of variables, divided into two disjoint sets: a set S of state variables and a set F of flow variables.
- E is a set of events.
- T is a set of transitions. A transition is a triple $t = \langle e, G, P \rangle$, where e is an event from E, G is a Boolean expression built over variables from V and called the guard of the transition, and P is an instruction built over V and called the action or the post-condition of the transition.
- A is an assertion (i.e. an instruction built over V).
- ι is the initial (or default) assignment of variables of V.

A GTS $G = \langle V, E, T, A, \iota \rangle$ is an implicit representation of a labeled Kripke structure, i.e. a graph $\Gamma = (\Sigma, \Theta)$, where

- the set of nodes Σ represent the variable assignments (of V), and
- Θ is the set of edges labeled by the events from E.

Instructions of GTS are defined recursively as follows:

- "*skip*" is an empty instruction.
- If v is a variable and Exp an expression, then "v: = Exp" is an instruction (called "assignment").
- If C is a Boolean expression, I is an instruction, then " if C then I" is an instruction (called "conditional assignment").
- If I_1 and I_2 are two instructions, then so is "I_1; I_2" (called "parallel composition").

We shall consider two types of instructions. The "Actions" which are instructions in which left members of assignments are only state variables. The "Assertions" which are instructions in which left members of assignments are only flow variables.

Let denote by $\tau = Propagate(A, \iota, \sigma)$ a variable assignment obtained after applying the assertion A to the variable assignment σ., i.e. the calculation of flow variables value. $Propagate(A, \iota, \sigma)$ computes the values of flow variables using the instructions of the as sertion A and the values of state variables in σ. At the end if there are flow variables without any value, they are set to their initial values in ι and the assertion A is applyed to check that all the assignments are satisfied.

4.2 *Compilation to fault trees*

The compilation of AltaRica 3.0 models to Fault Trees works (Prosvirnova & Rauzy 2015) in 5 steps (see Figure 2):

1. The AltaRica 3.0 model is flattened into a GTS.

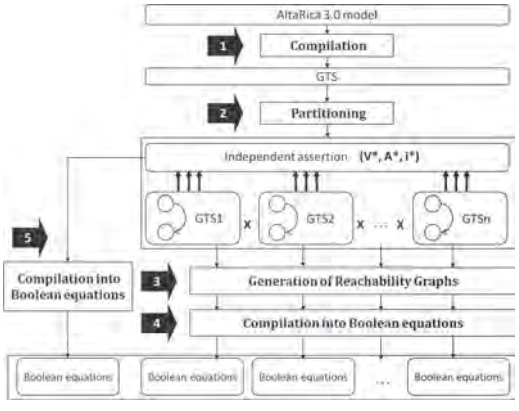

Figure 2. Compilation of AltaRica 3.0 models to Fault Trees.

2. The obtained GTS is partitioned into independent GTSs plus an independent assertion.
3. Reachability graphs of each independent GTS are calculated.
4. Each reachability graph is separately compiled into Boolean equations.
5. The independent assertion is compiled into Boolean equations.

The independent assertion $\langle V^*, A^*, \iota^* \rangle$ (the 5th step of the algorithm) is transformed into a set of Boolean formulas in the following way. For each pair (f, d), where $f \in V^*$ is a flow variable and $d \in dom(f)$ is its value, a formula $\phi_{(f,d)}$ is constructed according to the instructions in the assertion A^* and Boolean formulas $\{\phi_{(u,c)}, u \in U, c \in dom(u)\}$ obtained from the compilation of the independent GTSs.

In order to compile the assertion into Boolean formulas efficiently, one need to separate it into independent parts. The dependency relation between variables in the assertion A^* defines a dependency graph. This graph may contain cycles. The strongly connected components of this graph divide variables of A^* into sets and enable to decompose the assertion A^* into blocks of instructions A_i ($i = 1, ..., m$), where m is the number of strongly connected components: $A^* = A_1^*; A_2^*; \ldots; A_m^*$

Each block of instructions A_i^* is compiled into Boolean formulas recursively. Let denote by

- V_i^* – a set of variables labeling the vertices of the strongly connected component number i.
- A_i^* – an instruction that calculates the values of variables from V_i^*.
- ι_i^* – an initial assignment of variables from V_i^*.
- W_i^* – a set of variables such that variables from V_i^* depend on them in A_i^*.

For all variable v in V_{*_i} the formula $\phi(v, c)$ (where $c \in dom(v)$) is built as follows:

- Let $\Sigma = \underset{w \in W_i^*}{\times} dom(w)$ be the Cartesian product of the domains of variables from W_i^*.
- Let $\sigma \in \Sigma$ be an assignment of variables from W_i^*.
- Let ϕ_σ be a product built over W_i^* (as defined in Section 3.1) calculated as follows:

$\phi_\sigma = \prod_{w \in W_i^*} (w = \sigma(w))$

- Let τ be a partial variable assignment, $\tau: V_i^* \bigcup W_i^* \to \mathcal{C}$, such that:

$\forall w \in W_i^* \tau(w) = \sigma(w)$

- The partial variable assignment τ can be completed by propagating the assertion A_i^*:

$\tau = Propagate(A_i^*, \iota_i^*, \tau)$

- Then for each couple (v, c), with $v \in V_i^*$, such that $\tau(v) = c$, the formula associated with (v, c) is updated as follows

$\phi_{(v,\chi)} \leftarrow \phi_{(v,\chi)} + \phi_\sigma$

At the end of the algorithm, for all variables $v \in V^*$ and their values, we obtain a formula $\phi_{(v,c)}$ built over a finite set of finite domain variables W^*, such that v depends on them in the assertion A^*. We use the diagrammic representation as defined in Section 3.11 to represent these formulas.

As we have seen in Section 3.10, $\phi_{(v,c)} \Leftrightarrow PI[\phi_{(v,c)}]$ and it is the most simplified form of $\phi_{(v,c)}$.

For each variable $v \in V^*$ and its value $c \in dom(v)$, we compute $PI[\phi_{(v,c)}]$ and use this form, which greatly simplifies the generated Fault Tree.

4.3 *Example*

Consider the parametric block diagram use case presented in Section 2. Figure 3 illustrates how each basic block of these diagrams can be represented in AltaRica 3.0.

The variable *State* represents the internal state of a basic block and takes its value in the domain *BLOCKSTATE* = {*ok*, *ko*}. A domain is an enumeration having any finite number of values. The event *failure* represents the internal failure of a basic block. It is possible to associate different probability distributions to the events of basic blocks (e.g. exponential, constant, Weibull). The value of the parameters can also be changed. The behavior of a basic block is represented by a state machine given Figure 3. The variable *Out* is a flow variable, which represents the output of a basic block. The assertion of a basic block is an instruction, which calculates the value of this variable *Out* according to the value of the state variable *State*.

Figure 4 shows how two blocks in series can be modeled in AltaRica 3.0. The assertion of the whole model is

*B*1.*Out*: = *B*1.*State*;

*B*2.*Out*: = *B*2.State;

Out: = if (*B*1.*Out* = = *ok*) *and* (*B*2. *Out* = = *ok*) then *ok* else *ko*;

The compilation into Fault Trees is performed as follows.

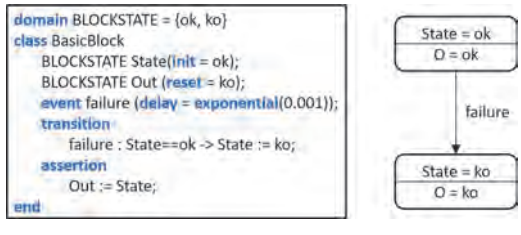

Figure 3. AltaRica 3.0 model of a basic block.

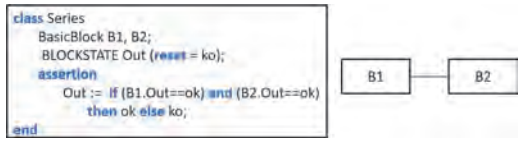

Figure 4. AltaRica 3.0 model of two blocks in series.

First, local reachability graphs are compiled:

$\phi(B1.State,ok) = true$

$\phi(B2.State,ok) = true$

$\phi(B1.State,ko) = B1.failure$

$\phi(B1.State,ko) = B2.failure$

Second, local assertions are compiled:

$\phi(B1.Out,ok) = (B1.State = ok)$

$\phi(B2.Out,ok) = (B2.State = ok)$

$\phi(B1.Out,ko) = (B1.State = ko)$

$\phi(B2.Out,ko) = (B2.State = ko)$

Third, the global assertion is compiled

$\phi(Out,ok) = (B1.Out = ok) * (B2.Out = ok)$

$\phi(Out,ko) = ((B1.Out = ok) * (B2.Out = ko)$
$+(B1.Out = ko) * (B2.Out = ok)$
$+(B1.Out = ko) * (B2.Out = ko))$

Figure 5 represents the last formula by means of a variant of Binary Decision Diagram (as presented in Section 3.11). It can be simpified using the algorithm presented in Section 3.10 as follows:

$dom(B1.Out) = dom(B2.Out) = \{ko, ok\}$

$f = (B1.Out = ko)$
$* [(B2.Out = ko) * 1 + [(B2.Out = ok) * 1 + 0]]$
$+[(B1.Out = ok) * [(B2.Out = ko) * 1 + 0] + 0]$

$f_1 = (B2.Out = ko) * 1 + [(B2.Out = ok) * 1 + 0]$

$f_2 = (B2.Out = ko) * 1 + 0$

$f_0 = 0$

$h = f_1 * f_2 + f_0 = (B2.Out = ko) * 1 + 0$

$PI[h] = (B2.Out = ko) * 1 + 0$

$PI[f_1] = 1$

$PI[f_2] = (B2.Out = ko) * 1 + 0$

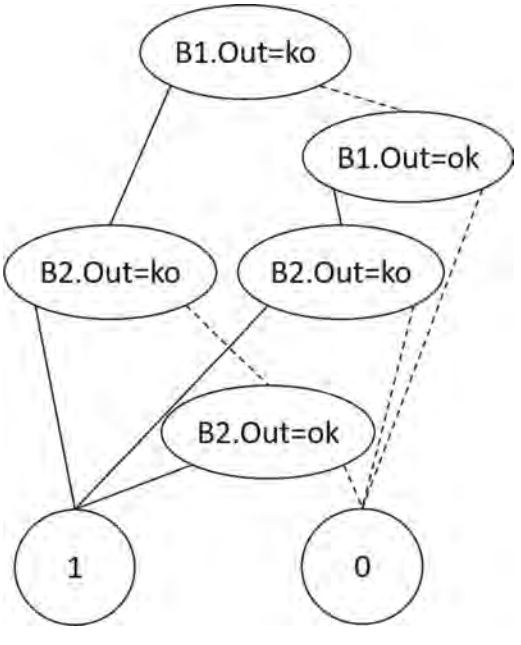

Figure 5. Diagrammatic representation of $((B1.Out = ok) * (B2.Out = ko) + (B1.Out = ko) * (B2.Out = ok) + (B1.Out = ko) * (B2.Out = ko))$.

$PI[f_1] \div PI[h] = 1$

$PI[f2] \div PI[h] = 0$

$PI[f] = (B1.Out = ko) * 1$
$+[(B2.Out = ko) * 1 + 0]$

which reads as $(B1.Out = ko) + (B2.Out = ko)$. It is the most simplified form of $\phi_{(Out,ko)}$.

5 EXPERIMENTS

The Fault Tree compiler of the the OpenAltaRica platform produces Fault Trees from AltaRica 3.0 models. More precisely, according to one or several Boolean observers, representing safety cases of the modeled system, the Fault Tree compiler generates Fault Trees in Open-PSA model exchange format (Hibti, Friedlhuber, & Rauzy 2012) with these Boolean observers as top events. The produced Fault Trees can be then assessed by XFTA (Rauzy 2012) to compute Minimal Cut Sets, probabilities of the top events, and so on.

We have implemented the algorithm presented in Section 4 and integrated it in the original version of the Fault Tree compiler. This algorithm greatly simplifies the generated Fault Trees, compared to those generated by the original version.

We have performed experiments with different values for the three parameters s, p and q of the motivating example pictured Figure 1.

In Table 1 we present the results obtained with the original version of the Fault Tree compiler and with the new one.

The first column is the number of the considered cases. The five next columns, from the second column to the sixth column, present the number of components contained in each sub-parts. We start with n_1 parallel blocks, in each block there are n_2 sub-blocks in series, into each sub-block there are n_3 parallel subblocks, and so on. For example, the first case means 3 parallel blocks, with 3 sub-blocks in series, each one containing 3 parallel sub-blocks; whereas the fifth case means 2 blocks in series, with 4 parallel subblocks, each block containing 4 sub-blocks in series, with 4 parallel sub-blocks into each one. The seventh column represents the total number of basic blocks in the AltaRica 3.0 model. Finally, the eighth and ninth columns represent the number of intermediate events in the Fault Trees generated by the original version of the Fault Tree compiler (ninth column) and the new one (eighth column).

The main observation is about the benefit of the number of generated gates with the new version of the Fault Tree compiler in comparison to the original one. In average, this benefit is of 56.9%. It means that in average with the new algorithm, the number of generated gates is less than 56.9% compared to the number of generated gates with

Table 1. Parametric block diagram use case—fault tree compilation.

Case	n_1	n_2	n_3	n_4	n_5	Number of blocks	Number of gates (new)	Number of gates (original)
1*st*	3	3	3	0	0	27	243	525
2*nd*	3	3	3	3	0	81	720	1158
3*rd*	4	4	4	0	0	64	537	1276
4*th*	4	4	4	4	0	256	2133	5114
5*th*	0	2	4	4	4	128	1135	3236
6*th*	0	3	3	3	2	54	558	1264
7*th*	0	3	3	3	0	27	243	596
8*th*	0	3	3	3	3	81	768	1914
9*th*	0	4	4	4	0	64	549	1562

the original one. The minimal value is 37.8% in the second case; and the maximum value is 64.9% in the fifth case.

The benefit obtained with the new version of the algorithm implemented in the Fault Tree compiler is important.

6 CONCLUSION

Boolean models are widely used for probabilistic safety analysis. There are cases however where binary states are not sufficient. For instance, it is sometimes of interest to represent the level of degradation of a component, the quality of signal, and so on. This kind of models can be easily represented with AltaRica 3.0, a high level modeling language dedicated to safety analyses. AltaRica 3.0 comes with several efficient assessment tools, amongst them a Fault Tree compiler.

In this article we presented how the notion of prime implicants can be extended to finite domain calculus. We discussed how the finite domain calculus can be efficiently encoded using a variant of Binary Decision Diagrams. We shown, using a parametric block diagram use case, how these results can be applied to simplify Fault Trees automatically generated from AltaRica 3.0 models. The number of generated intermediate events is on average divided by two, which greatly improves Fault Trees readability and the efficiency of their assessment.

ABSTRACT: AltaRica 3.0 is an event-based, object-oriented modeling language dedicated to (probabilistic) safety analyses of complex systems. It makes it possible to design models at higher level than done with formalisms traditionally used for safety analyses (fault trees, Markov Chains, stochastic Petri nets, etc.), without increasing the complexity of calculations of risk indicators. Several assessment tools have been developed for AltaRica 3.0, including a stepwise simulator. This tool is of a great help for the design and the validation of AltaRica 3.0 models. It is the analog for modeling of debuggers for programming.

In this article, we show how the AltaRica 3.0 stepwise simulator has been greatly enhanced by the introduction of an abstract notion of time. The key mathematical property is that abstract and concrete simulation are bisimilar: any concrete (timed, stochastic) execution can be simulated by an abstract execution and reciprocally any abstract execution corresponds to at least one concrete execution. This important result paves the way to the design of efficient model-checking algorithms, e.g. generators of sequences of events leading to a failure state.

1 INTRODUCTION

AltaRica 3.0 is an event-based, object-oriented modeling language dedicated to (probabilistic) safety analyses of complex systems (Prosvirnova, Batteux, Brameret, Cherfi, Friedlhuber, Roussel, & Rauzy 2013). It makes it possible to design models at higher level than done with formalisms traditionally used for safety analyses (fault trees, Markov Chains, stochastic Petri nets, etc.), without increasing the complexity of calculations of risk indicators.

The semantics of AltaRica 3.0 is defined in terms of stochastic guarded transition systems (Rauzy 2008). AltaRica 3.0 executions are similar to those of other discrete event modeling formulisms: each time a transition gets fireable, it is scheduled and possibly fired after a certain real-valued delay, see e.g. (Cassandras & Lafortune 2008, Zimmermann 1976) for introductions to (stochastic) discrete event systems. Events labeling transitions may be either deterministic or stochastic. In the later case, AltaRica 3.0 provides both built-in distributions (exponential, Weibull, . . .) and empirical distributions.

Several assessment tools have been developed for AltaRica 3.0, see e.g. (Prosvirnova & Rauzy 2015, Brameret, Rauzy, & Roussel 2015, Aupetit, Batteux, Rauzy, & Roussel 2015), including a stepwise simulator. This tool is of a great help for the design and the validation of AltaRica 3.0 models. It makes it possible to perform interactive step by step simulations, i.e. to go forth and back in sequences of events, enabling in this way to track modeling errors, unexpected behaviors and so on. With that respect, stepwise simulators play a similar role for discrete event modeling as debuggers like GDB or DDD for programming, see e.g. (Matloff & Salzman 2008) for an introduction to the latter.

In this article, we introduce the notion of abstract executions of AltaRica 3.0 models. This notion is implemented into the new version of the AltaRica 3.0 stepwise simulator. The previous version of this tool did not consider the time at all. The reason was that it would have been much

too tedious for the analyst to enter by hand the delay associated with a stochastic transition each time this transition gets fireable. Moreover, infinitely many real-valued delays can be chosen, letting the analyst pondering which one is the most suitable for her or his purpose. However, ignoring delays had a major drawback: the stepwise simulator allowed the firing of sequences of events with no counterpart in stochastic simulation and more generally that did not obey the timed semantics of AltaRica 3.0.

The idea is therefore to abstract away the time in stepwise simulation: each transition is now associated with a time interval. Firing a transition may modify the time intervals associated with already scheduled transitions. This idea is by no means new: it enters into the general framework of Cousot's abstract interpretation (Cousot & Cousot 1977). The problem at stake was to make it work for the particular case of stochastic discrete event simulations. The key mathematical property here is that abstract and (concrete, in the sense of the semantics of AltaRica 3.0) simulations are bisimilar, see e.g. (Milner 1989) for an introduction to this important notion: any (concrete) execution can be simulated by an abstract execution and reciprocally any abstract execution corresponds to at least one (concrete) execution. In a word, abstract executions are in agreement with AltaRica 3.0 semantics.

This important result paves the way to the design of efficient model-checking algorithms, see e.g. (Clarke, Grumberg, & Peled 2000) for an introduction. In particular, it makes it possible the design of generators of sequences of events leading to a failure state.

The remainder of this article is organized as follows. Section 2 presents an illustrative example. Section 3 recalls fundamental notions about timed and stochastic guarded transition systems. Section 4 introduces the notion of abstract execution of guarded transition systems. Section 5 concludes this article and gives some perspectives.

2 ILLUSTRATIVE EXAMPLE

As an illustrative example, we shall consider a system made of two identical, periodically tested, components that evolve independently one another.

The behavior of such a component is represented by the state diagram pictured Figure 1.

The component alternates operation and test phases. It is initially working and starts with a first operation phase that lasts a constant time θ. All subsequent operation phases last a constant time π.

The component may fail when in operation, with a failure rate λ.

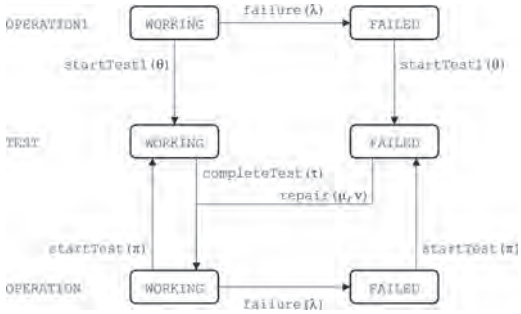

Figure 1. State diagram for a periodically tested component.

Table 1. A possible evolution of component for a periodically tested component.

Transition	Firing date
startTest1	$d_1 = \theta$
completeTest	$d_2 = d_1 + \tau$
failure	$d_3 = d_2 + \delta_1, 0 \ \delta_1 (\pi$
startTest	$d_4 = d_2 + \pi$
repair	$d_5 = d_4 + \delta_2, \mu (\delta_2 (\nu$
startTest	$d_6 = d_5 + \pi$
completeTest	$d_7 = d_6 + \tau$
⋮	⋮

If the component is working when it enters a maintenance phase, this maintenance phase lasts a constant time τ. If, on the contrary, it is failed when it enters a maintenance phase, the duration of its repair is uniformly distributed between two values μ and ν.

Finally, the component is as-good-as-new after a repair.

In the state diagram of Figure 1, transitions failure and repair are thus stochastic while transitions startTest1, startTest and completeTest are deterministic.

Table 1 shows a possible evolution of such a component.

We can assume that θ and π are relatively big compared to τ, μ and ν and that τ is smaller than μ (itself smaller than μ).

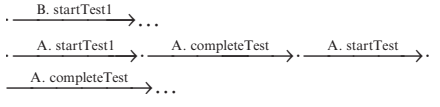
In order not to have the two components A and B out of service due to test or maintenance at the same time, it is reasonable to take different values of θ for A and for B (the values of the other parameters being identical for the two components). For instance, if an operation phase lasts normally six months ($\pi = 4380h$), the component A can be tested after three months (A.$\theta = 2190h$) while the component B is tested after six months (B.$\theta = 4380h$). It this way, tests/maintenances of A and B are shifted

Table 2. Typical values of the parameters.

parameter	A	B
θ	2190	4380
π	4380	4380
τ	0	0
μ	12	12
ν	24	24

by three months which improves the overall availability of the system. Table 2 gives some typical values of the parameters for components A and B that we shall use throughout the article.

With this values of parameters in mind, the reader sees immediately the problem of using a stepwise simulator that does not consider delays associated to transitions. Many executions that would be impossible with a timed semantics become possible with a non-timed semantics, e.g.



On other hand, asking the analyst to introduce interactively delays of stochastic transitions is not a practical solution. Not only it would be tedious, but it would let the analyst facing the choice of suitable delays, which gets quickly puzzling. Hence the need of an abstract notion of time which makes it possible to take into account delays of transitions without asking the analyst to enter them interactively.

To fulfill this need, the idea is to reason in terms of time intervals rather than in terms of dates. To explain how this idea works, we shall first recall the regular semantics of AltaRica in the next section. Then, we shall introduce its abstract semantics (in terms of time intervals) in Section 4.

3 TIMED/STOCHASTIC GUARDED TRANSITIONS SYSTEMS

The semantics of AltaRica 3.0 is defined in terms of stochastic guarded transitions systems (Rauzy 2008), (Batteux, Prosvirnova, & Rauzy 2017). We shall recall here only the notions that are important for the purpose of this article. The reader should refer to the cited articles for in depth presentations.

3.1 *Definition*

A guarded transitions system is a quintuple $S = \langle V, E, T, A, \imath \rangle$, where:

- V is a set of variables. V is the disjoint union of the set S of state variables and the set F of flow variables: $V = S \cup F$. . Each variable v of V takes its value into a finite or infinite set of constants called the domain of v and denoted as $dom(v)$. The global state of the system is thus a variable valuation, i.e. a member of the Cartesian product $\prod_{v \in V} dom(v)$.
- E is a set of events. Each event e of E is associated with a function $delay(e)$ that returns a non-negative real number. $delay(e)$ may be deterministic, in which case it returns always the same value, or stochastic, in which case it returns a value according to a certain cumulative probability distribution.
- T is a set of transitions, i.e. of triples $\langle e, G, P \rangle$, where e is an event of E, G is a Boolean expression built on variables of V (called the guard of the transition) and P is an instruction that modifies the value of state variables (called the action of the transition). For the sake of the clarity, we shall write a transition $\langle e, G, P \rangle$ as $G \xrightarrow{e} P$.
- A is an assertion, i.e. an instruction that modifies the values of flow variables.
- $\imath$ is a valuation of the variables of V, called the initial state.

Example The guarded transitions system encoding the periodically tested components described in the previous section is as follows.

The state of the component is represented by means of two state variables: state that takes its value in {WORKING, FAILED} and phase that takes its value in {OPERATION1, TEST, OPERATION}.

The events are startTest1, startTest, completeTest, failure and repair. They are associated with the delays described in the previous section.

The transitions are as follows.

$$\texttt{state} = \texttt{WORKING} \wedge \texttt{phase} \neq \texttt{TEST} \xrightarrow{\texttt{failure}} \texttt{state} \leftarrow \texttt{FAILED}$$

$$\texttt{phase} = \texttt{OPERATION1} \xrightarrow{\texttt{startTest1}} \texttt{phase} \leftarrow \texttt{TEST}$$

$$\texttt{phase} = \texttt{OPERATION} \xrightarrow{\texttt{startTest}} \texttt{phase} \leftarrow \texttt{TEST}$$

$$\texttt{state} = \texttt{WORKING} \wedge \texttt{phase} = \texttt{TEST} \xrightarrow{\texttt{completeTest}} \texttt{phase} \leftarrow \texttt{OPERATION}$$

$$\texttt{state} = \texttt{FAILED} \wedge \texttt{phase} = \texttt{TEST} \xrightarrow{\texttt{repair}} \texttt{state} \leftarrow \texttt{WORKING}, \texttt{phase} \leftarrow \texttt{OPERATION}$$

Finally, the initial state is defined by the variable valuation: state = WORKING, phase = OPERATION1.

3.2 *Composition*

One of the advantages of guarded transitions systems over some other similar formalisms is that they are highly compositional.

Formally, let $M_1 : \langle V_1, E_1, T_1, A_1, \iota_1 \rangle$ and $M_2 : \langle V_2, E_2, T_2, A_2, \iota_2 \rangle$ be two guarded transitions systems. Then the composition of M_1 and M_2, denoted as $M_1 \otimes M_2$, is simply the guarded transitions system $\langle V, E, T, A, \iota \rangle$ such that $V = V_1 \cup V_2$, $E = E_1 \cup E_2$, $T = T_1 \cup T_2$, $A = A_2 \circ A_1$ and $\iota = \iota_2 \circ \iota_1$.

The above principle extends to any number of guarded transitions systems.

Example To represent the system of the discussed example in the previous section, it suffices to create two copies of the above guarded transitions system and to compose them (which is done automatically by the AltaRica compiler).

In our example, it may be worth to introduce a flow Boolean variable failed to tell when the system is failed. The assertion defining this variable could be as follows.

failed ← A.state = FAILED ∧ B.state = FAILED

3.3 *Semantics*

The semantics of a guarded transitions system $S = \langle V, E, T, A, \iota \rangle$ is defined as the set of its possible executions (sometimes said "concrete" into this article, as opposite to abstract executions introduced into section 4).

To define formally the executions, we need to introduce the notion of schedule. A schedule of a guarded transitions system $S = \langle V, E, T, A, \iota \rangle$ is a function from T to $\mathbb{R} + \cup\{+\infty\}$.

A schedule Γ is compatible with a state σ of the guarded transitions system S and a date d if the following conditions hold for all transitions $t : G \xrightarrow{e} P$ of T.

- $d \le \Gamma(t) < +\infty$ if $G(\sigma) = true$.
- $\Gamma(t) = +\infty$ if $G(\sigma) = false$.

Intuitively, an execution of the guarded transitions system S is a sequence:

$$\langle \sigma_0, d_0, \Gamma_0 \rangle \xrightarrow{t_1} \langle \sigma_1, d_1, \Gamma_1 \rangle \xrightarrow{t_2} \ldots \xrightarrow{t_n} \langle \sigma_n, d_n, \Gamma_n \rangle$$

where $n \ge 0$, the σ_i's are states of S, the d_i's are dates, i.e. non negative real numbers verifying $0 = d_0 \le d_1 \le \ldots \le d_n$, each Γ_i is a schedule compatible with σ_i and d_i and finally the t_i's are transitions of S.

The set of valid executions of the guarded transitions system S is defined recursively as follows.

The empty execution $\langle \iota, 0, \Gamma_0 \rangle$ is a valid execution if the schedule Γ_0 is such that for all transitions $t : G \xrightarrow{e} P$ T:

- $\Gamma_0(t) = delay(e)$ if $G(\iota) = true$.
- $\Gamma_0(t) = +\infty$ if $G(\iota) = false$.

Now, if $\Lambda = \langle \sigma_0, d_0, \Gamma_0 \rangle \xrightarrow{t_1} \ldots \xrightarrow{t_n} \langle \sigma_n, d_n, \Gamma_n \rangle$, $n \ge 0$, is a valid execution, then so is the execution $\Lambda = \xrightarrow{t_{n+1}} \langle \sigma_{n+1}, d_{n+1}, \Gamma_{n+1} \rangle$ if the following conditions hold, assuming $t_{n+1} = G_{n+1} \xrightarrow{e_{n+1}} P_{n+1}$.

- $G_{n+1}(\sigma_n) = true$.
- $\sigma_{n+1} = A(P_{n+1}(\sigma_n))$, i.e. the firing of the transition t_{n+1} is performed in two steps: first, state variables are updated by means of the action P_{n+1} of the transition, then flow variables are updated by means of the assertion A.
- $d_{n+1} = \Gamma_n(t_{n+1})$ and there is no transition t of T such that $\Gamma_n(t) < \Gamma_n(t_{n+1})$.
- Γ_{n+1} is obtained from Γ_n by applying the following rules to all transitions $t : G \xrightarrow{e} P$ of T:
  - If $G(\sigma_{n+1}) = true$, then:
    - If $G(\sigma_n) = true$ and $t \ne t_{n+1}$, then $\Gamma_{n+1}(t) = \Gamma_n(t)$
    - Otherwise, $\Gamma_{n+1}(t) = d_{n+1} + delay(e)$
  - If $G(\sigma_{n+1}) = false$, then: $\Gamma_{n+1}(\tau) = +\infty$

Example Consider again our system of two components.

At time 0, 4 transitions are fireable:

Transition	Firing date
A. startTest1	2190
A. failure	5617
B. startTest1	4380
B. failure	4111

As A.startTest has the earliest firing date, it is fired (at 2190). After its firing, 3 transitions are fireable:

Transition	Firing date
A. completeTest	2190 + 0 = 2190
B. startTest1	4380
B. failure	4111

As A.completeTest has the earliest firing date, it is fired (at 2190). After its firing, 4 transitions are fireable:

Transition	Firing date
A. startTest	2190 + 4380 = 6570
A. failure	2190 + 6020 = 8210
B. startTest1	4380
B. failure	4111

As B.failure has the earliest firing date, it is fired (at 4111). After its firing, 3 transitions are fireable:

Transition	Firing date
A. startTest	6570
A. failure	8210
B. startTest1	4380

As B.startTest1 has the earliest firing date, it is fired (at 4380). After its firing, 3 transitions are fireable:

Transition	Firing date

A. startTest	6570
A. failure	8210
B. repair	4400

As B.repair has the earliest firing date, it is fired (at 4400). After its firing, 4 transitions are fireable:

Transition	Firing date
A. startTest	6570
A. failure	8210
B. startTest	4400 + 4380 = 8780
B. failure	4400 + 5201 = 9601

And so on. . .

This sequence shows how deterministic and stochastic transitions can be intricated. In particular, dates of tests are not decided once for all. They depend on times to failure and to repair of the component.

4 ABSTRACT SEMANTICS

4.1 *Principle*

The first idea to abstract the executions consists in associating an abstract delay *delay*∗ with each event of the model. *delay*∗(*e*) is simply the image of the function *delay*, i.e. an interval of non-negative real numbers.

We have to be a bit careful because some intervals that are the images of distributions are closed while some others are open (to the left and/or to the right) and that we have to consider infinite bounds. A solution consists in working only with closed intervals, but in a non-standard arithmetic built over the set $\overline{\mathbb{R}}^{+} = \mathbb{R}^{+} \cup \{\varepsilon, \infty\}$, , where ε and ∞ are respectively infinitely small and infinitely big numbers verifying: $\varepsilon + \varepsilon = \varepsilon$ and $\infty + x = \infty$ for all $x \in \overline{\mathbb{R}}^{+}$. In this way, the interval $]a, b[$, with $a, b, \in \mathbb{R}^{+}$, can be encoded as $[a + \varepsilon, b - \varepsilon]$. Table 3 gives the abstract delays associated with the most widely used distributions in AltaRica 3.0. Moreover, a transition whose guard is not satisfied in the current state is scheduled in the interval $[\infty, \infty]$.

The second idea is to consider not the date at which transitions are fired, but an interval of time within which they are fired.

Assume that we are building the sequence under study step by step and that the last transition we considered must be fired in the time interval $[l, h]$. Assume moreover that transitions $t_1, t_2, \ldots t_n$ are scheduled in time intervals $[l_1, h_1], [l_2, h_2], \ldots, [l_n, h_n]$. Then, we can make the following remarks.

1. We must have $l \le l_i$ for all $i = 1, \ldots, n$, because the next transition cannot be scheduled in the
2. We must have also $h \le h_i$ for all $i = 1, \ldots, n$, because if $h_i < h$ for some i, it means that the transition t_i must be fired before h_i, therefore the last transition must also be fired before h_i.
3. For the same reason, we can choose t_i as the next transition to be fired only if there is no other transition t_j such that $h_j < l_i$.
4. Again for the same reason, if the transition t_i is fired, it is necessarily fired in the interval $[l_i, h_{min}]$, where h_{min} is the smallest of the h_j's.
5. If the transition t_i is fired and the transition tj is such that $l_j < l_i$, then l_j must be changed to l_i so to obey our first remark.
6. Finally, if the transition t_i is fired and a transition t associated with the interval $[l_t, h_t]$ becomes fireable (t can be the transition t_i itself), then t must be scheduled in the interval $[l_t, h_{min}] + [l_t, h_t] = [l_i + l_t, h_{min} + h_t]$.

We are now able to define formally the abstract semantics of guarded transitions systems (and therefore for AltaRica 3.0).

4.2 *Formal definition*

The abstract semantics of a guarded transitions system $S = \langle V, E, T, A, \iota \rangle$ is defined as the set of its possible abstract executions.

To define formally the abstract executions, we need to introduce the notion of abstract schedule. An abstract schedule of a guarded transitions system $S = \langle V, E, T, \underline{A}, \iota \rangle$ is a function from T to closed intervals over $\overline{\mathbb{R}}^{+}$.

A schedule $\Gamma*$ is compatible with a state σ of the guarded transitions system S and the abstract date $[l, h]$ if the following conditions hold for all transitions $t : G \xrightarrow{e} P$ of T, with $\Gamma*(t) = [l_t, h_t]$.

- $l \le l_t < \infty$ and $h \le h_t$ if $G(\sigma) = true$.
- $l_t = h_t = \infty$ if $G(\sigma) = false$.

An abstract execution of the guarded transitions system S is a sequence:

$$\langle \sigma_0, d_0^*, \Gamma_0^* \rangle \xrightarrow{t_1} \langle \sigma_1, d_1^*, \Gamma_1^* \rangle \xrightarrow{t_2} \ldots \xrightarrow{t_n} \langle \sigma_n, d_n^*, \Gamma_n^* \rangle$$

where $n \ge 0$, the σ_i's are states of S, the d_i^*'s are abstract dates, i.e. time intervals, each Γ_i^* is an abstract schedule compatible with σ_i and d_i^* and finally the t_i's are transitions of S.

The set of valid abstract executions of the guarded transitions system S is defined recursively as follows.

Table 3. Intervals associated with delay functions.

Concrete delay	Abstract delay
Dirac (t)	$[t, t]$
Uniform Deviate (l, h)	$[l, h]$
Exponential (λ)	$[0 + \varepsilon, [$
Weibull (α, β)	$[0 + \varepsilon, [$
Empirical distribution	$[0 + \varepsilon, [$

The empty abstract execution $\langle \sigma_0, [0, 0], \Gamma_0^* \rangle$ is a valid abstract execution if the abstract schedule Γ_0^* is such that for all transitions $t : G \xrightarrow{e} P$ of T:

- $\Gamma_0^*(t) = delay^*(e)$ if $G(t) = true$. .
- $\Gamma_0^*(t) = [\infty, \infty]$ if $G(t) = false$.

If $\Lambda = \langle \sigma_0, [0,0], \Gamma_0^* \rangle \xrightarrow{t_1} \ldots \xrightarrow{t_n} \langle \sigma_n, [l_n, h_n], \Gamma_n^* \rangle$, $n \geq 0$, is a valid abstract execution, then so is the abstract execution, then so is the abstract execution, then so is the abstract execution $\Lambda \xrightarrow{t_{n+1}} \langle \sigma_{n+1}, [l_{n+1}, h_{n+1}], \Gamma_{n+1}^* \rangle$ if the following conditions hold, assuming

$t_{n+1} = G_{n+1} \xrightarrow{e_{n+1}} P_{n+1}$, $\Gamma_n^*(t_{n+1}) = [l^*, h^*]$ and $h_{min} = \min_{[l,h]=\Gamma_n^*(t), t \in T} h$.

- $G_{n+1}(\sigma_n) = true$.
- $\sigma_{n+1} = A(P_{n+1}(\sigma_n))$.
- There is no transition t of T such that $\Gamma_n^*(t) = [l, h]$ and $h < l*$.
- $[l_{n+1}, h_{n+1}] = [l*, h_{min}]$.
- $\Gamma_n^*(t)$ is obtained from Γ_n^* by applying the following rules to all transitions $t : G \xrightarrow{e} P$ of T and $\Gamma_n^*(t) = [l, h]$.
  - If $G(\sigma_{n+1}) = true$, then:
    - If $G(\sigma_n) = true$ and $t \neq t_{n+1}$, then

$$\Gamma_{n+1}^*(t) = [\max(l_{n+1}, l), h]$$

    - Otherwise,

$$\Gamma_{n+1}^*(t) = [l_{n+1}, h_{n+1}] + delay^*(e)$$

  - If $G(\sigma_{n+1}) = false$, then:

$$\Gamma_{n+1}^*(t) = [\infty, \infty]$$

Example We shall consider the abstract version of the execution given in the previous section.

At time 0, 4 transitions are fireable:

Transition	Abstract date
A.startTest1	[2190, 2190]
A.failure	[0 + ε, ∞]
B.startTest1	[4380, 4380]
B.failure	[0 + ε, ∞]

A.startTest1 is fired at the abstract date [2190, 2190]. After its firing, 3 transitions are fireable:

Transition	Abstract date
A.completeTest	[2190, 2190] + [0, 0] = [2190, 2190]
B.startTest1	[4380, 4380]
B.failure	2190, ∞]

A.completeTest is fired at the abstract date [2190; 2190]. After its firing, 4 transitions are fireable:

Transition	Abstract date
A.startTest	[2190, 2190]+[4380, 4380] = [6570, 6570]
A.failure	2190, 2190] + [0 + ε, ∞] = [2190 + ε, ∞]
B.startTest1	[4380, 4380]
B.failure	[2190, ∞]

B.failure is fired at the abstract date [2190 + ε, 4380]. After its firing, 3 transitions are fireable:

Transition	Abstract date
A.startTest	[6570, 6570]
A.failure	[2190 + ε, ∞]
B.startTest1	[4380, 4380]

B.startTest1 is fired at the abstract date [4380, 4380]. After its firing, 3 transitions are fireable:

Transition	Abstract date
A.startTest	6570, 6570]
A.failure	[4380, ∞]
B.repair	[4380, 4380] + [12, 24] = [4392, 4404]

B.repair is fired at the abstract date [4392, 4404]. After its firing, 4 transitions are fireable:

Transition	Abstract date
A.startTest	[6570, 6570]
A.failure	[4392 + ε, ∞]
B.startTest	[4392, 4404] + [4380, 4380] = [8872, 8884]
B.failure	[4392, 4404] + [0 + ε, ∞] = [4392 + ε, ∞]

And so on…

4.3 *Bisimulation*

The key mathematical property is that abstract and concrete executions are bisimilar: any concrete (timed, stochastic) execution can be simulated by an abstract execution and reciprocally any abstract execution corresponds to at least one concrete execution.

Theorem 1. *Let $S = \langle V, E, T, \iota, A \rangle$ be a guarded transitions system. Let $\Lambda = \langle \sigma_0, d_0, \Gamma_0 \rangle \xrightarrow{t_1} \ldots \xrightarrow{t_n} \langle \sigma_n, d_n, \Gamma_n \rangle$, be a (concrete) execution of S. Then it exists an abstract execution $\Lambda_a = \langle \sigma_0, d_0^*, \Gamma_0^* \rangle \xrightarrow{t_1} \langle \sigma_1, d_1^*, \Gamma_1^* \rangle \xrightarrow{t_2} \ldots \xrightarrow{t_n} \langle \sigma_n, d_n^*, \Gamma_n^* \rangle$, such that the following properties hold:*

- $\forall n \geq 0 d_n \in d_n^*$;
- $\forall n \geq 0 \forall t \in T\ \Gamma_n(t) \in \Gamma_n^*(t)$.

Theorem 2. *Let $S = \langle V, E, T, \iota, A \rangle$ be a guarded transitions system. Let $\Lambda_a = \langle \sigma_0, d_0^*, \Gamma_0^* \rangle \xrightarrow{t_1} \langle \sigma_1, d_1^*, \Gamma_1^* \rangle \xrightarrow{t_2} \ldots \xrightarrow{t_n} \langle \sigma_n, d_n^*, \Gamma_n^* \rangle$ be an abstract execution of S. Then Λ_a corresponds to at least one (concrete) execution $\Lambda = \langle \sigma_0, d_0, \Gamma_0 \rangle \xrightarrow{t_1} \ldots \xrightarrow{t_n} \langle \sigma_n, d_n, \Gamma_n \rangle$, such that the following properties hold:*

- $\forall n \geq 0 d_n \in d_n^*$;
- $\forall n \geq 0 \forall t \in T\ \Gamma_n(t) \in \Gamma_n^*(t)$.

Proofs of these two previous theorems are done recursively on the abstract executions or (concrete)

executions. They are out of the scope of this article and are not described.

5 CONCLUSION AND PERSPECTIVES

In this article, we introduce the notion of abstract executions of AltaRica 3.0 models. This notion implemented into the new version of the AltaRica 3.0 stepwise simulator. This notion of abstract executions enables to reconcile both stochastic and stepwise simulations of AltaRica 3.0 models.

We show that abstract and (concrete) simulations are bisimilar: any (concrete) execution can be simulated by an abstract execution and reciprocally any abstract execution corresponds to at least one (concrete) execution.

We illustrate our purpose using a motivating example that mix both stochastic and deterministic transitions.

The introduction of the notion of abstract executions to the stepwise simulator paves the way to the design of efficient model-checking algorithms, and in particular to the design of generators of sequences of events leading to a failure state.

The next step of our work is the application of the presented results for the development of an efficient sequence generator for AltaRica 3.0 models.

Reliability forecasting of components/systems in automobile applications by using two-dimensional stress functions

Abderrahim Krini
Robert Bosch GmbH Engineering of Remanufacturing and Quality, Schwäbisch Gmünd, Germany

Josef Börcsök
Department of Computer Architecture and System Programming, University of Kassel, Kassel, Germany

ABSTRACT: For remanufacturing automobile subsystems, the knowledge of future failure rates of systems produced in serial production is from great importance. Remanufacturing departments especially need information about the number of cores to remanufacture, the condition of those cores as well as the number of replacement system the market requires. On the basis of an already existing model that predicts failure rates using warranty data as input, a bivariate prognosis model is developed, which takes two variables of stress in field into account. By enhancing the existing model a more precise prognosis of future failure rates is expected as well as a better knowledge of the damage. This paper presents all necessary mathematical tools to perform a bivariate lifetime prognosis as well as the implementation in MATLAB.

1 INTRODUCTION

After serial production, automotive suppliers have the obligation to assure post series supply of replacement components and systems. The demanded number of replacement systems influence the production method. When the demand drops, from one point on, the remanufacturing of old systems represents the most economical method. In order to optimize the strategy of after series production, a suitable prognosis is needed. Requirement for this prognosis is a precise prediction of future failure rates in field in order to estimate the number of returning cores as well as the demand for replacement systems. Additionally, an accurate picture of the stress in field, the cores have experienced, is an advantage. It gives information about the costs that should be taken into account for remanufactureing the systems. On the basis of a univariate prognosis model by Pauli and Meyna [1], [2], [3] a bivariate model is developed. This model predicts future failures in field with respect to two different variables that represent the stress in field. Data basis for the model are warranty data. The knowledge of the distribution of stress in field for a car model allows a transformation to predict failure rates as a function of time. The prognosis is carried out by using bivariate stochastic distribution functions. Methods of fitting bivariate functions and comparing the goodness of fit between several distributions are presented. The discussed multivariate prognosis method has to be categorized between univariate prognosis models and prognosis models using neuronal networks.

2 THEORETICAL BACKGROUND

This chapter gives a brief overview of the basic tools the model is based on.

2.1 *Univariate prognosis model as basis for the new model*

As basis for reliability prediction models in general, data can be collected from different data origins: Laboratory testing, testing in field or real field data from the customers. The disadvantage of Laboratory testing and testing in field is the small sample size as well as the incomplete consideration of the variety of stress in field. Therefore, Pauli and Meyna developed an approach to predict the reliability of automobiles as well as automotive subsystems by using warranty data. These data must contain: Time in field until failure and mileage until failure for at least 50 failures. This method will be described briefly. For a better understanding, consider also reading references: [1], [2], [4] and [3].

In order to describe the stress in field, the driven mileage until failure is a suitable variable. Time in field is inappropriate due to varying user behavior [1].

Varying usage of automobiles can be described by the mileage distribution. Considering time in field and mileage (until failure), under the assumption of a linear driving behavior of each driver, one can develop a mileage distribution for a certain time period by using warranty data. Theoretical distribution functions can then be fitted to empirical data:

By cumulating the number of failures that occurred within a certain mileage interval, e.g. 3001 to 4000 km, a failure frequency is obtained. Based on the mileage distribution of the warranty period, it is known that only a share of all components of the sample has reached a certain mileage interval within warranty period. Until all components will have reached this interval, a certain number of additional failures are expected. The so called candidates can be estimated by correcting the observed failures by considering the mileage distribution for each interval.

In order to calculate a time dependent failure probability, it is necessary to fit a theoretical distribution function on the corrected failure frequency. By normalizing the resulting function with respect to the sample size, the mileage dependent failure probability can be obtained. The transformation to a time dependent failure probability is carried out by utilizing the mileage distribution for each date.

2.2 *Bivariate reliability parameters*

Considering the probability of failure as a bivariate function, the lifetime of a component is characterized by two positive continuous random variables X_1 and X_2. The system fails if both variables of stress, x_1 and x_2, exceed X_1 and X_2:

$$F(x_1,x_2) = P(X_1 \le x_1, X_2 \le x_2) \quad \text{for } x_1,x_1 \ge 0 \quad (1)$$

$F(x_1, x_2)$, the failure distribution function, indicates the probability for a component that experienced the stress x_1 and x_2 to be failed.

For $x_1, x_2 \to \infty$ the component fails:

$$\lim_{x_1,x_2\to\infty} F(x_1,x_2) = 1 \quad (2)$$

The derivation of $F(x_1, x_2)$ with respect to x_1 and x_2 gives information about the density of failures at a certain combination of stress:

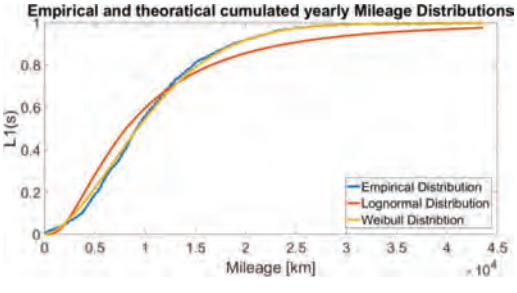

Figure 1. Empirical yearly mileage distribution, fitted lognormal distribution and fitted Weibull distribution.

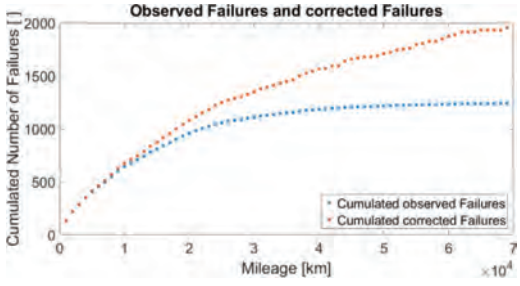

Figure 2. Observed failures and corrected failures.

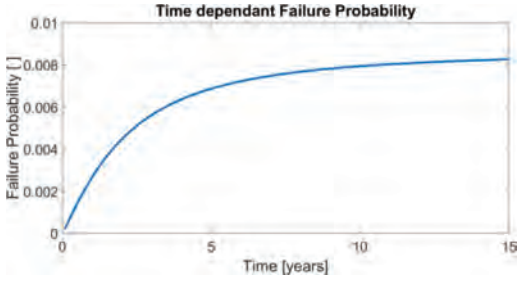

Figure 3. Time dependent failure probability.

$$f(x_1,x_2) = \frac{\partial^2 F}{\partial x_1 \partial x_2} \quad \text{for} \quad x_1,x_2 \ge 0 \quad (3)$$

The reliability R(t) is the complement of F(t). A component survives if one or both variables of stress, x_1 and x_2, remain below the random variables X_1 and X_2 [6][7].

$$\begin{aligned} R(x_1,x_2) &= P(X_1 > x_1, X_2 > x_2) \\ &= 1 - P(X_1 \le x_1, X_2 \le x_2) = 1 - F(x_1,x_2) \end{aligned} \quad (4)$$

By dividing the failure density through the reliability the hazard rate $h(x_1, x_2)$ can be determined. The hazard rate is an important indicator for the reliability of a component.

$$h(x_1,x_2) = \frac{f(x_1,x_2)}{R(x_1,x_2)} \quad (5)$$

Both, the failure distribution function and the reliability function, can be determined by empirical data. All other parameters can be derived. For a better distinction, the empirical functions are marked with a tilde. The sample size of all examined components (n_0), consists of the subsets of failed components (n_a) and surviving components (n_b):

$$n_0 = n_a(x_1,x_2) + n_b(x_1,x_2) \quad (6)$$

The empirical probability of failure is defined as:

$$\tilde{F}(x_1, x_2) = \frac{n_a(x_1, x_2)}{n_0} \tag{7}$$

The complement $\tilde{R}(t)$ is defined as:

$$\tilde{R}(x_1, x_2) = \frac{n_b(x_1, x_2)}{n_0} \tag{8}$$

In equations (7) and (8), the cumulated failures n_a and n_b must be used.

2.3 *Bivariate distribution functions*

For most of the common univariate distribution function, multivariate counterparts exist. Most important fields for application of such functions are financial (insurance) mathematics, meteorology and reliability statistics. In this chapter important bivariate distributions, in the context of reliability of automobile components, are presented.

In general, bivariate distribution functions are a useful tool for a dataset that fits the following criteria:

- The distribution of the events fits the same univariate distributions for each variable.
- The correlation between both variables is neither 0 nor ± 1.

In [5] a distribution function of the **bivariate normal distribution** is defined as follows:

$$f_{x_1x_2}(x_1, x_2) = \frac{1}{2\pi\sigma_1\sigma_2\sqrt{1-\rho^2}} * \exp\left\{ -\frac{1}{2(1-\sigma^2)} \left[\left(\frac{x_1-\mu_1}{\sigma_1}\right)^2 - 2\rho\frac{x_1-\mu_1}{\sigma_1} * \frac{x_2-\mu_2}{\sigma_2} + \left(\frac{x_2-\mu_2}{\sigma_2}\right)^2 \right] \right\} \tag{9}$$

The parameters stand for:

For a given distribution function, the cumulative distributions function can be derived by double integrating the distribution function with respect to both variables [5].

Table 1. Parameters of the bivariate distribution function.

Parameter	Meaning	Domain of definition
μ_1, μ_2	First moment of X_1, X_2	$-\infty\ \mu_i; \mu_2\ \infty$
σ_1^2, σ_2^2	Variance of X_1, X_2	$\sigma_1^2; \sigma_2^2 > 0$
ρ	Correlation coefficient of X_1 and X_2	$-1 < \rho < 1$

$$F_{x_1x_2}(x_1, x_2) = \int_{-\infty}^{x_1}\int_{-\infty}^{x_2} f_{v_1v_2}(v_1, v_2)\, dv_2\, dv_2 \tag{10}$$

Another important distribution for reliability models is the **bivariate lognormal distribution**. In [6] the distribution function is defined as:

$$f(x_1, x_2) = \frac{1}{2\pi x_1 x_2 \sigma_{y_1}\sigma_{y_2}\sqrt{1-\rho^2}} * \exp\left\{ -\frac{1}{2(1-\rho^2)} * \left[\left(\frac{\ln(x_1)-\mu_{y_1}}{\sigma_{y_1}}\right)^2 - 2\rho * \left(\frac{\ln(x_1)-\mu_{y_1}}{\sigma_{y_1}}\right) * \left(\frac{\ln(x_2)-\mu_{y_2}}{\sigma_{y_2}}\right) + \left(\frac{\ln(x_2)-\mu_{y_2}}{\sigma_{y_2}}\right)^2 \right] \right\} \tag{11}$$

One way to estimate the parameters of the distribution is the method of moments. On the basis of empirical failure data, an estimation for the parameters can be calculated using the equations given in (12):

$$\begin{aligned} &\sigma_{y_1}: \text{standard deviation} \\ &\sigma_{y_i} = \left[\log\left(1 + \frac{\sigma_{x_i}^2}{\mu_{x_i}^2} \right) \right]^{1/2} \\ &\mu_{y_1}: \text{first moment } \log(\mu_{x_i}) - \left(\frac{\sigma_{y_i}^2}{2}\right) \\ &\rho: \text{correlation coefficient} \\ &\rho = \frac{E[(Y_1-\mu_{y_1})(Y_2-\mu_{y_2})]}{\sigma_{y_1} * \sigma_{y_2}} \end{aligned} \tag{12}$$

The cumulative distribution function can be derived by applying equation (10).

Especially the reliability of electronic components can often be described by the exponential distribution. In [7] a **bivariate exponential distribution**, developed by Gumbel, is described.

$$F(x_1, x_2) = e^{-(\alpha x_1 + \beta x_2 + \theta\alpha\beta x_1 x_2)} \quad for \quad 0 < \theta < 1 \tag{13}$$

By derivating the cumulative distribution function with respect to both variables, the following distribution function can be obtained:

$$f(x_1, x_2) = \left\{ (1-\theta)\alpha\beta + \theta\alpha^2\beta x_1 + \theta\alpha\beta^2 x_2 + \theta^2\alpha^2\beta^2 x_1 x_2 \right\} F(x_1, x_2) \tag{14}$$

With:

$$E(X_1) = \frac{1}{\alpha}; E(X_2) = \frac{1}{\beta} \tag{15}$$

For the univariate Weibull distribution several bivariate counterparts were developed, for example by Hougaard [8]. Because of the difficult applicability of these functions, in the case of the bivariate Weibull distribution, the developed model works with copula functions. A copula function is a function that consists of marginal distributions as variables but contains additional parameters. For the developed reliability forecast model, three different copula functions fit the need. The goodness of fit with empirical failure data for all three functions is comparable [9].

Gumbel Copula:

$$F(x_1,x_2) = e^{-\left[\left(-\log(F_1(x_1))\right)^{\theta}+\left(-\log(F_2(x_2))\right)^{\theta}\right]^{\frac{1}{\theta}}} \quad \text{for} \quad \theta \geq 1 \tag{16}$$

Clayton Copula:

$$F(x_1,x_2) = \left(F_1(x_1)^{-\theta} + F_2(x_2)^{-\theta} - 1\right)^{-\frac{1}{\theta}} \quad \text{for} \quad \theta > 0 \tag{17}$$

Frank Copula:

$$F(x_1,x_2) = -\frac{1}{\theta} log\left[1 + \frac{\left(e^{-\theta F_1(x_1)} - 1\right)\left(e^{-\theta F_2(x_2)} - 1\right)}{e^{-\theta} - 1}\right] \quad \text{for} \quad \theta \neq 0 \tag{18}$$

$F_1(x_1)$ and $F_2(x_2)$ represent the cumulated marginal Weibull distributions of x_1 and x_2.

2.4 *Fitting of bivariate distribution functions*

The difficulty in dealing with multivariate distribution functions is the estimation of appropriate parameters. Most important methods will be explained briefly.

Method of moments
The method specified here makes use of the mathematical relationship between parameters of the function and characteristic values of the sample data. First step is the expression of the parameters of the function as a formula of moments of the distribution. The value of the moments is then calculated on the basis of the sample data. Important moments are for example mean and variance of a distribution. [5]

Maximum likelihood
A maximum likelihood estimate is the value of a parameter for which the sample data gain the highest possibility. For fitting univariate distributions, maximum likelihood is the predefined method MATLAB uses. [5]

Method of least squares
This method estimates parameters by minimalizing the deviation of the empirical and the theoretical distribution. The deviation is measured by the sum of the squared residuals. Those parameters for which this sum is minimal are chosen. The sum of squared residuals (SSE) serves as an index to compare the goodness of fit of several fitted theoretical distributions. [10] [11]

3 DISTRIBUTION OF STRESS IN FIELD

The above described univariate prognosis model uses the driven mileage as a variable to describe the stress in field. When dealing with ECU's, the finite number of storage processes the non-volatile storage can handle before wearing out, should be considered. Therefore switching cycles[1] are considered as an additional appropriate variable when modelling electronical components.

The sample data used in this paper contains failure data of ECU's in automobile application. The prognosis is carried out on basis of time in field, mileage and switching cycles at the time of failure for each sample. Nevertheless, the model is not limited on electronic components. It can be applied on all automobile systems and subsystems when two appropriate variables are determined to describe stress in field.

Exposure profiles of automobiles vary greatly from customer to costumer. To take this variety into account a distribution of stress in field is formed on the basis of all failures. A linear increase of mileage and switching cycles over time is assumed. An empirical distribution of stress in field, $lz_t(s, z)$, is obtained by considering all failure data, normalized to a certain time period. For example one year:

$$s_1 = s_F * \frac{t_1}{t_F}; \quad z_1 = z_F * \frac{t_1}{t_F} \tag{19}$$

S_1, z_1: mileage, switching cycle during one year
S_F, z_F: mileage, switching cycle until failure
t_1: one year
t_F: time in field until failure

[1]Switching cycle: Turning the ignition key in the off position forces the ECU to write data to the non-volatile memory.

By using all of the above described methods for fitting distributions, a bivariate normal-, lognormal-, exponential-distribution as well as a Weibull copula function can be fitted to the sample data. A brief description of the implemented fitting procedure for each distribution is given in the following:

Bivariate normal distribution
All parameters of the bivariate normal distribution are estimated by the method of moments. Values were calculated using the sample data (Table 1).

Bivariate lognormal distribution
On basis of mean, variance and covariance of the sample, the parameters were estimated, using equations (12).

Bivariate exponential distribution
Parameters α and β can be estimated by the first moments of the sample data, according to (15). Afterwards an estimator for θ is found by the method of least squares.

Bivariate Weibull distribution (Copula)
Both marginal distributions are estimated using maximum likelihood. In MATLAB this operation is carried out by "wblfit". Parameter θ for equations (16), (17) and (18) is then estimated by the method of least squares.

According to goodness of fit, carried out by SSE, the bivariate lognormal distribution and the bivariate Weibull distribution fit the sample data best:

The sum of squared residuals of the bivariate Weibull distribution, with a value of 0,00255, is smaller than the sum of squared residuals of the bivariate lognormal distribution with 0,00291. Therefor the stress in field for further calculations is considered to be a bivariate Weibull distribution with estimated parameters. The cumulative distribution function $LZ_t(s, z)$ is derived by double integrating $lz_t(s, z)$.

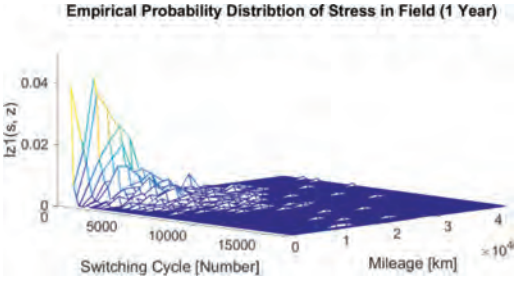

Figure 4. Empirical probability distribution of stress in field during a period of one year.

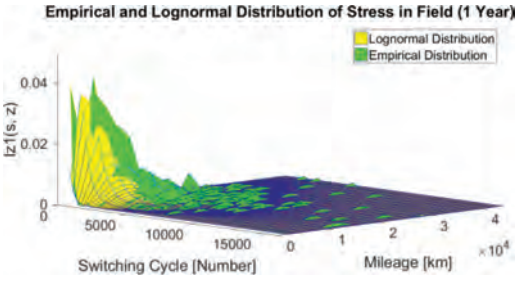

Figure 5. Empirical probability distribution of stress in field during a period of one year and fitted bivariate lognormal distribution.

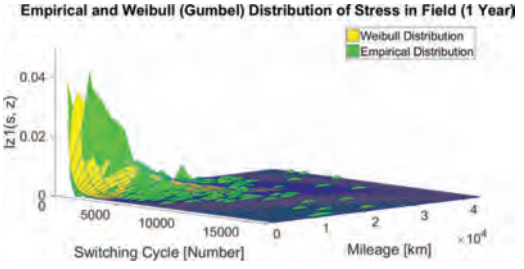

Figure 6. Empirical probability distribution of stress in field during a period of one year and fitted bivariate Weibull distribution (Gumbel copula).

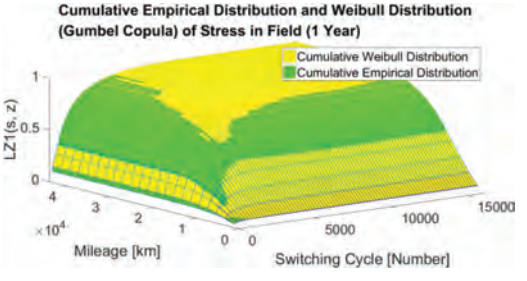

Figure 7. Cumulative empirical probability distribution of stress in field during a period of one year and fitted cumulative, bivariate Weibull distribution (Gumbel copula).

$$LZ_t(s,z) = \int_0^s \int_0^z lz_t(\sigma,\zeta)\, d\zeta\, d\sigma \qquad (20)$$

The cumulative distribution function can be transformed for arbitrary time periods, using the following equation:

$$LZ_t(s,z) = LZ_1\left(s\frac{t_1}{t}, z\frac{t_1}{t}\right) = LZ_G\left(s\frac{t_G}{t}, z\frac{t_G}{t}\right) \qquad (21)$$

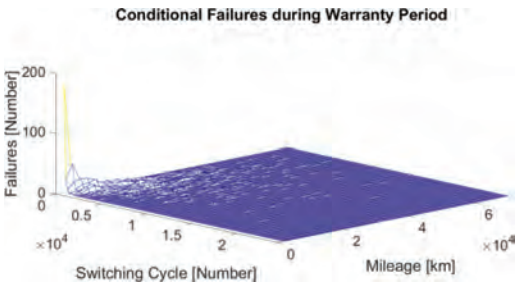

Figure 8. Distribution of the conditional failures during warranty period as a function of the class of stress in field.

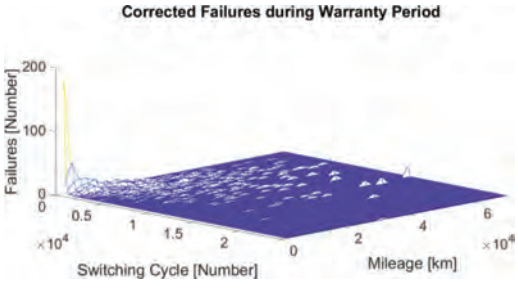

Figure 9. Distribution of the corrected failures during warranty period as a function of the class of stress in field.

LZ_1: cumulative distribution function for the period of one year

LZ_G: cumulative distribution function for the warranty period

t_G: warranty period

4 ESTIMATION OF CANDIDATES

Regarding warranty data, the sample is divided in two subsets: complained components and fully functional components still in field. For every complained component additional information exists:

- Time in field
- Mileage
- Switching cycles

For an efficient further processing in MATLAB, the data set of failed components is to be discretized. For the described application, a class size of 2000 km × 200 switching cycles was chosen. Each class contains $n_a(s, z)$ failures. These failures are called *conditional failures*, because until all components will have reached the considered class, additional failures are expected to occur: the *candidates*.

Considering the distribution of stress in field, the ratio of components that has already reached a certain class of stress during warranty period, can be estimated:

$$P(S \geq s, Z \geq z) = 1 - LZ_G(s,z) \tag{22}$$

The number of corrected failures n_k for each class composes of all conditional failures and all candidates.

$$n_k(s,z) = \frac{n_a(s,z)}{1 - LZ_G(s,z)} \tag{23}$$

5 STRESS DEPENDANT LIFETIME PREDICTION

Fitting an adequate theoretical distribution function to the distribution of corrected failures allows a forecast of the stress dependent lifetime of the regarded component. Procedure of fitting bivariate distributions is similar to the methods described in 3. The corrected failure density is calculated using the following equation:

$$\tilde{f}_k(s,z) = \frac{n_k(s,z)}{n_0} \tag{24}$$

A bivariate exponential, normal and lognormal distribution was fitted as well as a bivariate Weibull (copula) distribution. According to goodness of fit, carried out by SSE, the bivariate lognormal distribution and the bivariate Weibull distribution fit the corrected failure density $\tilde{f}_k(s,z)$ best:

For the calculation of a time dependent lifetime prediction goodness of fit of the theoretical distribution functions has to be compared. According to SSE, the Weibull distribution fits the data best.

SSE lognormal distribution: 33065

SSE Weibull distribution: 16945

For the present data set, the time dependent lifetime prediction is best carried out by a $\tilde{f}_k(s,z)$ represented by the Weibull distribution.

6 TIME DEPENDANT LIFETIME PREDICTION

To transfer the stress dependent lifetime distribution, determined in 5, in a time dependent distribution the distribution of stress in field must be considered:

$$F(t) = \int_0^\infty \int_0^\infty \tilde{f}_k(s,z) * \left(1 - LZ_1\left(\frac{s}{t}, \frac{z}{t}\right)\right) ds\, dz \tag{25}$$

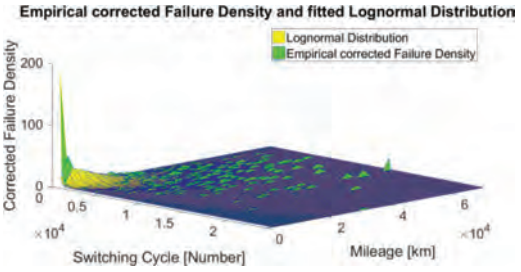

Figure 10. Empirical corrected failure density and the fitted lognormal distribution.

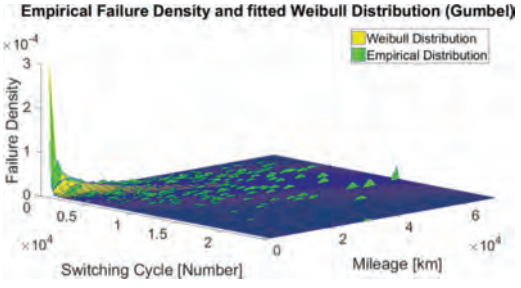

Figure 11. Empirical failure density and fitted Weibull distribution using Gumbel copula.

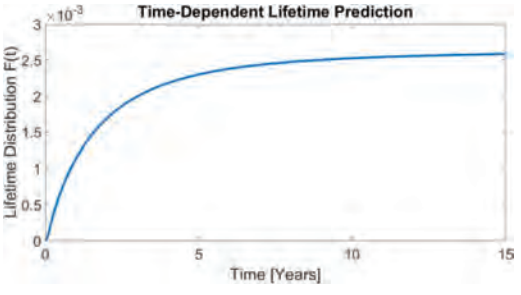

Figure 12. Time-dependent lifetime distribution as the result of a bivariate prognosis model.

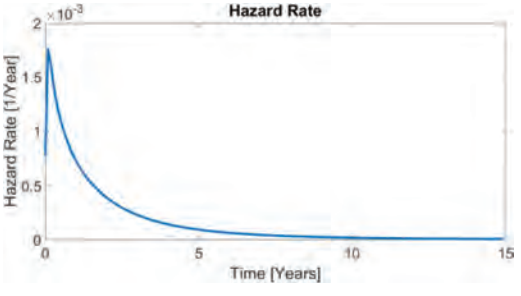

Figure 13. Time-dependent hazard rate.

The result of the bivariate prognosis model is the time-dependent lifetime prediction.

A time-dependent hazard rate can be determined using the following formula:

$$h(t) = \frac{f(t)}{R(t)} = \frac{dF(t)}{dt} * \frac{1}{1-F(t)} \tag{26}$$

The hazard rate shows a typical early failure characteristic.

7 ASSUMPTIONS/LIMITATIONS

Underlying the model a few assumptions concerning the data and the usage behavior were made:

- The warranty database is complete and all failures of the regarded period of time are registered.
- The warranty database contains an appropriate number of samples (Recommendation: Minimum 1 000 failed samples).
- A constant increase of mileage over time is considered for the complete lifetime of the component/the automobile.

The basic limitation of the described model is the ability to only describe one type of failure behavior (e.g. early failures, random failures or wear out failures). In order to describe the full life cycle of a product consider the superposition of three independent predictions.

8 CONCLUSIONS

The previous chapters prove the possibility to create a bivariate reliability forecast model as well as the successful implementation of said model in MATLAB. Comparing the calculated forecast with real field failure data, good accordance was determined. As a result it can be said that a model on basis of bivariate distribution functions with respect to two variables of stress in field can successfully be applied in quality management of automobile systems.

ACKNOWLEDGMENTS

Our thanks go to Christian Lachenmaier who put a great deal of data processing in the topic of bivariate prognosis models, associated with his master studies at Robert Bosch Automotive Steering GmbH.

Newly enhanced computing algorithm to quantify unavailability of maintained multi-component systems

R. Briš & N.T.T. Tran
VŠB—Technical University of Ostrava, Czech Republic

ABSTRACT: In our previous work we developed an analytical algorithm which is able to carry out exact reliability quantification of highly reliable systems with maintenance (both preventive and corrective). A directed Acyclic Graph (AG) was used as a system representation. The unavailability of a node of an AG is in fact given by going over all possible combinations of probabilities of the input edges (such combinations that cause failure of the node). New improvement of the computing methodology will be presented in this paper, which efficiently reduces computing time and complexity. The improvement is based on applicable properties of internal non-terminal nodes. If an internal node has multiple-dimensionality, i.e. a lot of input edges, resulting in an excessive summarizing combinations, the number of combinations can be significantly reduced by multiple application of the pivotal decomposition. The effectiveness of the process will be demonstrated on selective systems.

1 INTRODUCTION

Estimating (un)availability of a highly-reliable multi-component and maintained system is a problem of great interest in different areas such as computer systems, telecommunications, mechanics, aircraft design, power utilities, and many other engineering fields. Increasing demand for system reliability cannot depend on the increasing reliability of components due to technological restrictions. Safety systems of nuclear power stations represent other example of highly reliable complex systems. They have to be reliable enough to comply with still increasing internationally agreed safety criteria and moreover they are mostly so called sleeping systems which start and operate only in the case of big accidents. Their hypothetical failures are not apparent (hidden or latent failures) and thus repairable only at optimally selected inspection times. Wide class of highly reliable fault-tolerant systems, which, through the use of redundancy, have the ability to operate properly in the presence of faults are investigated in (Villén-Altamirano 2014). Any system failure should have a small probability of occurring; that is, it should be a rare event. It is important to estimate such probabilities because when a rare event does occur, its consequences may be catastrophic. For example, network servers play an increasingly important role due to the rapid growth in demand for internet services, and a server breakdown event may cause significant financial losses. As a result, redundancy is usually built in to prevent services from breaking down.

A Monte Carlo simulation method (Marseguerra & Zio 2001) is used for the quantification of reliability when accurate analytic or numerical procedures do not lead to satisfactory computations of system reliability. Since highly reliable systems require many Monte Carlo trials to obtain reasonably precise estimators of the reliability, various variance-reducing techniques (Tanaka, Kumamoto & Inoue 1989), eventually techniques based on reduction of prior information (Baca A. 1993) have been developed. A direct simulation technique has been improved by the application of a parallel algorithm to such an extent that it can be used for real complex systems which can be then modelled and quantitatively estimated from the point of view of reliability without unreal simplified conditions which analytic methods usually expect (Briš 2008). However, if it is necessary to work and quantitatively estimate highly reliable systems, for which unreliability indicators (i.e. system non-functions) move to the order 10^{-5} and higher (i.e.10^{-6} etc.), the simulation technique, whatever improved, can meet the problems of prolonged and inaccurate computations.

In our previous work we developed a new analytical algorithm which is able to carry out exact reliability quantification of highly reliable systems with maintenance (both preventive and corrective). An exponential distribution for the time to a failure is supposed, possibly for the time to restoration. A generalization of the original methodology so as to be used for unavailability quantification of systems with ageing input components with optional lifetime distribution (i.e. where gener-

ally distributed failure and repair times were supposed) is developed in (Bris & Byczanski 2017a). A directed acyclic graph was used as a system representation. The algorithm allows take into account highly reliable and maintained input components. The unavailability of a node of an AG is in fact given by going over all possible combinations of probabilities of the input edges (such combinations that cause failure of the node). For example, having 20 input edges, we have regularly a million combinations to be summarized. This process has two disadvantages: first, computing errors can easily be committed, which were discussed and removed in (Bris & Byczanski 2013), and second, it is hard to be computed systems having big nodes with a lot of input edges.

New improvement of the computing methodology will be presented in this paper, which efficiently reduces CPU-time and computing complexity as well. The improvement is based on applicable properties of internal non-terminal nodes. If an internal node has multiple-dimensionality, i.e. a lot of input edges, resulting in a lot of summarizing combinations, the number of combinations can be significantly reduced by multiple application of the pivotal decomposition. The effectiveness of the process will be demonstrated on selective systems.

2 SYSTEM REPRESENTATION AND UNAVAILABILITY COMPUTATION

2.1 *The directed acyclic graph*

Example of a real system to be analyzed is shown in Figure 1. The system is demonstrated by means of a directed Acyclic Graph (AG), (Bris 2008). A graph is composed of nodes and edges. The highest node (here u1) represents functionality of the whole system (success, failure), internal and terminal nodes represent subsystems and components. All of the nodes are bounded by edges. Direction of the graph is not explicitly marked in Figure 1 it is given by itself—by projection to vertical direction. The graph is acyclic which means that it cannot contain feedback loops.

Terminal nodes, as for example T1 or T2, of the AG are marked by blue squares. They represent stochastic functionality of input system components given by a probability distribution of their time to failure and a maintenance model. From them we can compute a time course of the unavailability function of input components, using methodology of basic renewal theory (Bris 2007).

Internal nodes (non-terminal) are marked by blue triangles. They represent functionality of subsystems. A subsystem is well functioning in a given time point (success) just in the case when the number of well-functioning inferior edges reaches at least the number that is inside of the triangle, see Figure 1. Otherwise it is not-functioning (failure). For example internal node u3 is well-functioning when the number of well-functioning inferior edges is at least 1.

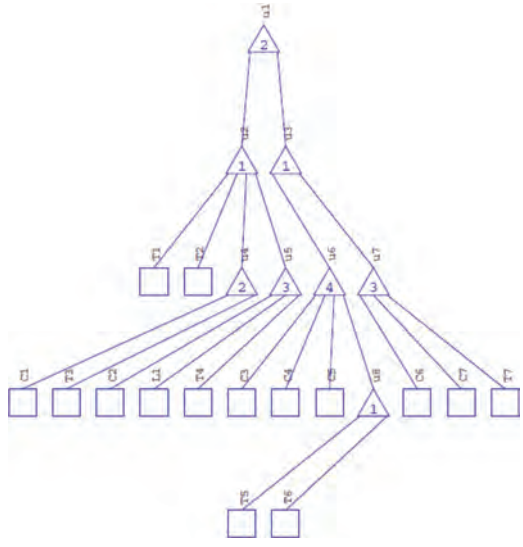

Figure 1. Graph structure of a real system.

The key problem is to estimate the point (or instantaneous) unavailability at any time t, which is the probability that the system is unavailable at time t due to a failure or due to an ongoing repair after the detection of a failure. System may be composed of highly reliable components. In (Bris 2010) we developed new procedure for exact reliability quantification of a highly reliable system. The procedure eliminates all errors made by a computing hardware system when calculations close to error limit are executed.

2.2 *Determination of system unavailability according to a graph structure*

The algorithm will be demonstrated on the system from Fig. 1, which is composed of different terminal nodes. The probability of a non-functional state of the system (represented by the u1 node) can be obtained upwards resulting from unavailability functions of independent terminal nodes.

For instance the unavailability of internal node u7 can be computed as follows:

- numerical expression of the unavailability of inferior terminal nodes, i.e. elements C6, C7 and T7 (having unavailability q_6, q_7 and q_{T7}).
- numerical expression of the unavailability q_{u7} of the internal node u7 which is given by the following sum:

$$q_{u7} = q_6.q_7.q_{T7} + (1-q_6).q_7.q_{T7} + q_6.(1-q_7).q_{T7} + q_6.q_7.(1-q_{T7}) + (1-q_6).(1-q_7).q_{T7} + (1-q_6).q_7.(1-q_{T7}) + q_6.(1-q_7).(1-q_{T7}) \quad (1)$$

In other words we go over all possibilities of non-function state of the node u7 in ascending order of functioning edges. The process is terminated just in the case when the number of well functioning inferior edges reaches 3 (i.e. the number that is inside of the triangle).

The unavailability of a node of an AG is in fact given by going over all possible combinations of probabilities of the input edges (such combinations that cause failure of the node). If a node has a lot of input edges, we can expect computational difficulties. For example, having 20 input edges we have regularly a million combinations to be summarized what results in an unaccepted excessive long computing time.

2.3 *Computational improvement*

In Figs 2–4 we give definitions of following nodes N1-N3, with input edges denoted as 1,2, …k:

We denote unavailability of j^{th} node as $U(Nj)$ and unavailability of i^{th} input edge as $U(i)$. Obviously we can write:

$$U(N1) = U(1).U(N2) + (1- U(1)).\ U(N3) = U(1).\ [U(N2) - U(N3)] + U(N3) \quad (2)$$

This operation we call as pivotal decomposition (applied to first input edge). Expression in square brackets can be simplified (a lot of elements are eliminated applying subtraction) to the following expression:

$$\sum_{\binom{k-1}{m-1}} \ldots \times U(i) \times \ldots \times \left(1 - U(j)\right) \times \ldots \quad (3)$$

indexes i are from {2,3,…k} ↓ number of factors in parentheses is "m–1".

And the last summand in (2) can be simplified by analogy (i.e. recurrently, by the same way as $U(N1)$). In other words the process of pivotal decomposition can be applied to second input edge, etc. By applying this process recurrently we obtain an alternative and time saving formula to compute $U(N1)$.

Example: Let us substitute in Figure 2 for m = 3 and k = 4. Then

$$U(N1) = U(1).\{(1- U(2)).(1- U(3)).U(4) + (1- U(2)).U(3).(1-U(4)) + U(2).(1-U(3)).(1-U(4))\} + U(2).\{(1-U(3)).U(4) + U(3).(1-U(4))\} + U(3).U(4) \quad (4)$$

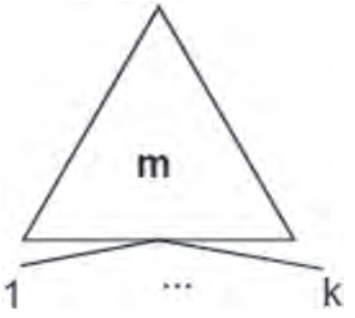

Figure 2. Node 1 (N1).

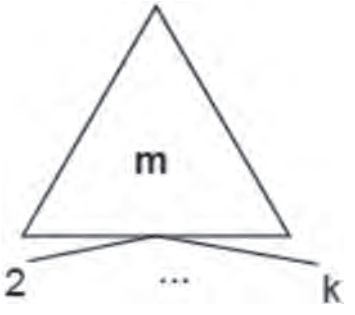

Figure 3. Node 2 (N2).

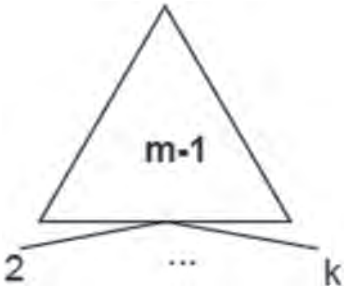

Figure 4. Node 3 (N3).

2.4 *Unavailability models of terminal nodes*

Most of component models (i.e. models of terminal nodes) including maintenance, both preventive and corrective, can be described by the following three models:

Model I with components that cannot be repaired. Final time dependent unavailability coefficient $U(t)$ for this simplest model is given by the distribution function of the time to failure of the component:

$$U(t) = F(t) = \int_0^t f(x)dx, \quad (5)$$

where $F(t)$, $f(t)$ is distribution function and probability density function (*pdf*) of the time to failure.

Model II with repairable components (CM – Corrective Maintenance) for apparent failures, i.e. a model when a possible failure is identified at its occurrence and immediately afterwards it starts a process leading to its restoration. In Model II, two random variables are immediately connected, i.e. the time to failure X, characterized by distribution function $F(t)$ and density $f(t)$, and the repair (or restoration) time Y, characterized by distribution function $G(t)$ and density $g(t)$. In this model we can apply well known relations from renewal theory and alternating renewal processes. In (Briš & Byczanski 2017b) we derived and proofed the following Theorem for time dependent unavailability $U(t)$:

$$U(t) = \int_0^t f(x)\cdot[1-G(t-x)]dx + \int_0^t (f*g)(x)\cdot U(t-x)dx \tag{6}$$

where * means convolution. This Theorem can be considered as a recurrent linear integral equation which helps us to compute $U(t)$.

Model III with repairable components with hidden failures, i.e. a model when a failure is identified only at special deterministically assigned times, appearing with a given period (moments of periodical inspections). In the case of its occurrence at these times an analogical restoration process starts, as in the previous case. Inspections are carried out periodically. Let us denote inspection time points as k_1, k_2, k_3…, then $k_{i+1} - k_i = T_p$ is period of inspections. In (Briš & Byczanski 2017b) we derived numerical formula to calculate the time dependent unavailability coefficient $U(t)$:

$$U(t) = \int_{k_n}^t f(x)dx + \sum_{i=1}^n S_i \cdot \left\{ \int_{k_n-k_i}^{t-k_i} (g*f)(x)dx + [1-G(t-k_i)] \right\} \tag{7}$$

where S_i is the probability that in the inspection time k_i a renew was realized. Numerical formulas to find probabilities S_i are as well derived in (Briš & Byczanski 2017b).

3 RESULTS WITH TESTED SYSTEM FROM REFERENCE

We consider a system model that is a generalization of the Highly Reliable Markovian System (HRMS) often used to represent the evolution of multi-component systems in reliability settings, and which has been studied in (Villén-Altamirano 2014, L'Ecuyer & Tuffin 2011), among others. In the HRMS model, the system has c types of component, with n_i identical components of type i. The system works if at least r_i components of each type i work. Each component is either in a failed state or in an operational state. Specifically we consider a system with 3 types of component, $c = 3$, with n components each. Although formulas (5)–(7) are numerically realized for any probability distributions $f(t)$ and $g(t)$, we assume exponential lifetime and repair times with failure rates $\lambda_1 = 0.01$, $\lambda_2 = 0.015$ and $\lambda_3 = 0.0002$, respectively, and repair rates $\mu = 1$ for all components to be compared with results in above mentioned reference. In other words, all components are of Model II. There are ample repairmen who work simultaneously on all the failed components. The system breaks down as soon as at least one component type had less than 2 operational units ($r = 2$). The redundancy is the same for all 3 types of component. Graph structure of the system for n = 8 is demonstrated in Figure 5. We realized comparison computations for n = 8, 12, 16 and 20.

The concern is to estimate transient measures, such as time dependent system unavailability, including steady state unavailability.

3.1 *Computed results*

The system is to such extent complex that it would be hardly computed by applying original methodology from (Bris 2010). Number of combinations of all input edges each of 3 internal nodes

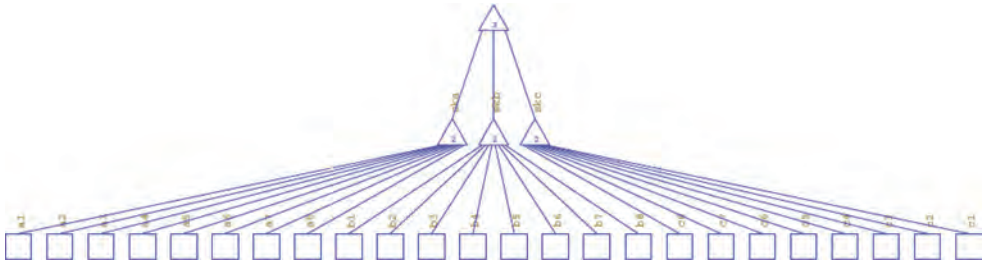

Figure 5. Graph structure of the referenced system for n=8.

is excessive. If computational improvements are realized, see formulas (2)–(4), all computations can be run in CPU-times less than 1 min. In Figs 6–8 we can see dependence of system unavailability on time for n = 8, 16 and 20, ending in steady state unavailability values.

3.2 *Comparisons with referenced results*

Advanced simulation methodology, so called RESTART estimators, to compute unavailability of this system was used in (Villén-Altamirano 2014). Table 1 brings comparison of our obtained numerical results of steady state unavailability with simulation results from the reference, including computing CPU-time.

As can be observed, very low probabilities were accurately estimated with reduced computational effort.

Our improved computational method as well as RESTART estimators can be extended to many other models of highly reliable components, such as non-Markovian models, without much additional effort. In first case computational experiments in (Bris & Byczanski 2017a) comparing exponential and Weibull distributions do not show relevant difference in computational time of both probability distributions. In second case author (Villén-Altamirano 2014) showed that the computational times in the two first system versions (for $n = 8$ and 12) were around 2.5–3 times greater when Raleigh-Erlang distributions were utilized, which was caused for two reasons (i) it is more time consuming to generate random numbers from these distributions than from exponential, and (ii) rescheduling with Erlang distribution is much more time-consuming than with exponential.

Table 1. Steady state unavailability of the referenced system with c = 3, r = 2 and changing n.

	Numerical results		Simulation results (with relative error = 0.1)	
n	U	CPU-time	$\hat{U}$	CPU-time
8	1.284×10^{-12}	< 1(min)	1.31×10^{-12}	0.67 (min)
12	8.74×10^{-20}	< 1(min)	8.76×10^{-20}	2.33 (min)
16	5.49×10^{-27}	< 1(min)	5.38×10^{-27}	3.60 (min)
20	3.258×10^{-34}	< 1(min)	3.19×10^{-34}	9.60 (min)

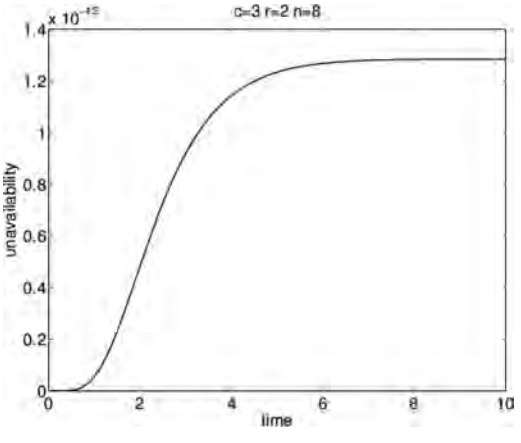

Figure 6. Dependence of system unavailability on time, n = 8.

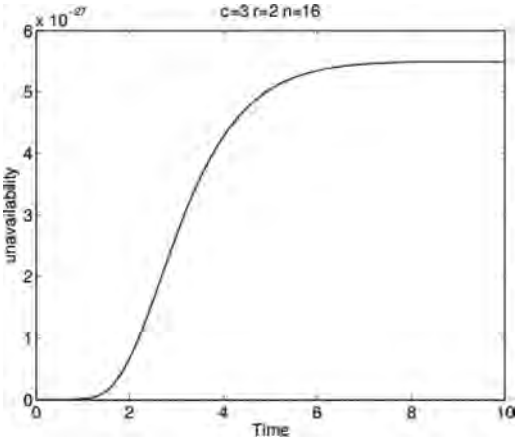

Figure 7. Dependence of system unavailability on time, n = 16.

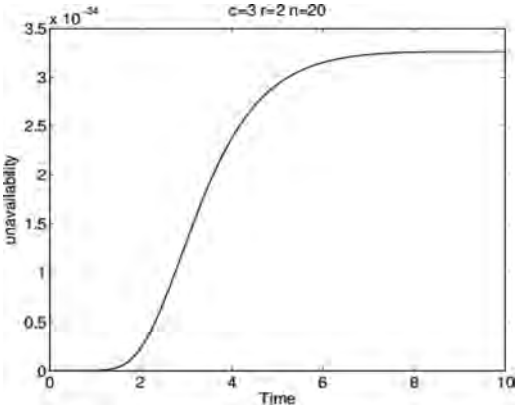

Figure 8. Dependence of system unavailability on time, n = 20.

4 CONCLUSIONS

We demonstrated that the innovative computational method for unavailability quantification is comparable with recent advanced simulation methodology. Even our numerical method gives better computational times particularly when $n \geq 12$.

The innovative methodology for high-performance computing enables exact unavailability quantification of a maintained and highly reliable system containing highly reliable components having optional probability distribution of the time to failure, as well as time to repair, i.e. a complex system with both ageing and non-ageing components can be analyzed. All frequently used component models with both preventive and corrective maintenance may be considered.

The most important advantage of the computing methodology is that it enables the analyst to calculate arbitrary small values of the unavailability function during a mission time exactly. Such small unavailability values as for example values of order 10^{-45} are hardly computed by other methods or software, including advanced simulation RESTART estimators, where computational time increases with increasing number of components.

Having system represented by AG, numerical expression of an unavailability value of one internal node of the AG has a combinatorial character. We have to go over all combinations of input edges leading to a non-functional state of the node. We showed that using pivotal decomposition this computational process can be efficiently improved.

The innovative computing methodology has been numerically realized within the high-performance language MATLAB. All computations above run on Intel (R) Core™ i7-3770 CPU @ 3.4 GHz 3.9 GHz, 8.00 GB RAM.

MLE versus MCMC estimators of the mixture of failure rate model

T.T. Thach & R. Briš
Department of Applied Mathematics, Faculty of Electrical Engineering and Computer Science, VSB–Technical University of Ostrava, Czech Republic

ABSTRACT: In this paper, the parameters and reliability characteristics of the failure distribution of the mixture of failure rates are estimated based on a complete sample using both Markov Chain Monte Carlo (MCMC) method and Maximum Likelihood Estimation (MLE). While MLE is the most frequently used method for parameter estimation, MCMC has recently emerged as a good alternative. The most popular MCMC method, called Metropolis-Hastings algorithm is used to provide complete analysis of the concerned posterior distribution. A simulation study is provided to compare MCMC with MLE, and differences between the estimates obtained by the two approaches are evaluated.

1 INTRODUCTION

Engineering systems, while in operation, are always subject to environmental stresses and shocks which may or may not alter the failure rate function of the system. Suppose p is the unknown probability that the system is able to bear these stresses and its failure model remains unaffected, and q is the probability of the complementary event. In such situations, a failure distribution is generally used to describe mathematically the failure rate on the system. To some extent, the solution to the proposed problem is attempted through the mixture of distributions (Mann et al. 1974, Sinha 1986, Lawless 2002). However, in this regard we are faced with two problems. Firstly, there are many physical causes that individually or collectively cause the failure of the system or device.

At present, it is not possible to differentiate between these physical causes and mathematically account for all of them, and, therefore, the choice of a failure distribution becomes difficult. Secondly, even if a goodness of fit technique is applied to actual observations of time to failure, we face a problem arising due to the non-symmetric nature of the life-time distributions whose behaviour is quite different at the tails where actual observations are sparse in view of the limited sample size (Mann et al. 1974). Obviously, the best one can do is to look out for a concept which is useful for differentiating between different life-time distributions. Failure rate is one such concept in the literature on reliability. After analyzing such physical considerations of the system, we can formulate a mixture of failure rate functions which, in turn, provide the failure time distributions. In view of the above, and due to continuous stresses and shocks on the system, let us suppose that the failure rate function of a system remain unaltered with probability p, and it undergoes a change with probability q. Let the failure rate function of the system in these two situations be in either of the following two states (Sharma et al. 1997):

1.1 *State 1*

Initially it experiences a constant failure rate model and this model may (or may not) change with probability $q(p = 1 - q)$.

1.2 *State 2*

If the stresses and shocks alter the failure rate model of the system with probability q, then it experiences a wear-out failure model.

In comparison with Sharma et al. (1997), this study brings distinctive generalization of the state by implementation of a new parameter, which enables to take into account also more general Weibull model.

In probability theory and statistics, the Weibull distribution is a continuous probability distribution, which is named after the Waloddi Weibull. This is the most commonly used distribution to model times until failure and provides a good description for many types of lifetimes (Rinne 2008, Lawless 2002). The Weibull distribution has two parameters, a shape parameter β and a scale parameter. Only shape parameters $\beta > 1$ correspond to an increasing failure rate, implying that ageing processes can be intensively studied. We will therefore not consider cases with $\beta \leq 1$. Recent studies that adopt a Weibull lifetime distribution include Xia et al. (2015), Zhou et al. (2015), and Xu & Cao (2015).

As a result of flexibility in time to-failure of a very widespread diversity to versatile mechanisms,

the two-parameter Weibull distribution has been recently used quite extensively in reliability and survival analysis particularly when the data are not censored. Much of the attractiveness of the Weibull distribution is due to the wide variety of shapes which can assume by altering its parameters.

Using such a failure rate pattern, the characterization of life-time distribution in the corresponding situation is given. Various inferential properties of this life-time distribution along with the estimation of parameters and reliability characteristics is the subject matter of the present study. Since the estimates based on the operational data can be updated by incorporating past environmental experiences on the random variations in the lifetime parameters (Martz and Waller 1982), therefore, the Bayesian analysis of the parameters and other reliability characteristics is also given.

The remainder of this article is organized as follows. Section 2 introduces the intended mixture of failure rates model including basic characteristics of the corresponding life-time distribution as well. Section 3 brings maximum likelihood estimators for two unknown parameters of the model on one hand and the Metropolis-Hastings algorithm based on MCMC method on the other hand. In addition, Bayesian methodology resulting from special likelihood function of the mixture model is demonstrated bringing formulas for alternative estimators in comparison with MLE. Section 4 shows short illustration how estimation procedures work. Section 5 reports simulation study on special selected situations where both MCMC and MLE are confronted.

2 CHARACTERISTICS OF THE LIFE-TIME DISTRIBUTION

Notations: Let

T: the random variable denoting life-time of the system.
$h(t)$: the failure rate function.
$f(t)$: the probability density function (p.d.f.) of T.
$F(t)$: the cumulative distribution function of T.
$R(t) = \mathbb{P}(T > t)$: the reliability/survival function.
$\mathbb{E}(T) = \int_0^\infty R(t)\,dt$: mean time to failure (MTTF).

2.1 *The mixture of failure rate model*

Let

p: the probability of the event A, that the system is able to bear the stresses and shocks and its failure pattern remains unaltered.

$q = 1 - p$: the probability of the complementary event A^c.

Further, let, the mixture of the failure rate function be

$$h(t) = p\lambda + (1-p)\lambda t^k, \quad \lambda, t > 0, 0 < p < 1 \tag{1}$$

for

1. $p = 1$; represents the failure rate of an exponential distribution.
2. $k = 1$ and $p = 0$; represents the failure rate of the Rayleigh distribution or Weibull distribution with shape parameter 2.
   Note: In our context $\beta = k + 1$
3. $k = 1$; represents the linear ageing process.
4. $0 < k < 1$; represents the concave ageing process.
5. $k > 1$; represents the convex ageing process.

In Weibull reliability analysis it is frequently the case that the value of the shape parameter is known (Martz & Waller 1982). For example, the Raleigh distribution is obtained when $k = 1$. The earliest references to Bayesian estimation of the unknown scale parameter are in Harris & Singpurwalla (1968). Since that time this case has been considered by numerous authors, see Sharma et al. (1997), Canavos (1974), Moore & Bilikam (1978), Tummala & Sathe (1978), Alexander et al. (2009) & Muhammad et al. (2014). This study is free continuation and generalization of the research originally introduced by Sharma et al. (1997).

2.2 *Characteristics of the life-time distribution*

Using the well-known relationship between p.d.f. and failure rate function

$$f(t) = h(t)\exp\left\{-\int_0^t h(x)\,dx\right\}, \quad t > 0 \tag{2}$$

and in view of (1), the p.d.f. of the life-time T is

$$f(t) = h(t)\exp\left\{-\left(p\lambda t + \frac{\lambda(1-p)}{k+1}t^{k+1}\right)\right\} \tag{3}$$

The reliability function is

$$R(t) = \exp\left\{-\left(p\lambda t + \frac{\lambda(1-p)}{k+1}t^{k+1}\right)\right\}, \quad t > 0. \tag{4}$$

The MTTF is given by

$$\begin{aligned} MTTF = \mathbb{E}(T) &= \int_0^\infty R(t)\,dt \\ &= \int_0^\infty \exp\left\{-\left(p\lambda t + \frac{\lambda(1-p)}{k+1}t^{k+1}\right)\right\}dt \end{aligned} \tag{5}$$

This integral can be obtained by using some suitable numerical methods.

3 ESTIMATION OF PARAMETERS AND RELIABILITY CHARACTERISTICS

Let $D: t_1,\ldots,t_n$ be the random failure times of n items under test whose failure time distribution is as given in (3). Then the likelihood function is

$$L(D \mid \lambda, p) = \lambda^n \left[\prod_{i=1}^{n}\left(p + (1-p)t_i^k\right)\right] \times \exp\left\{-\lambda \sum_{i=1}^{n}\left(pt_i + \frac{1-p}{k+1}t_i^{k+1}\right)\right\}. \quad (6)$$

3.1 *Maximum likelihood estimation*

The log-likelihood function can be written as

$$\log L(D \mid \lambda, p) = \sum_{i=1}^{n}\log\left(p + (1-p)t_i^k\right) + n\log\lambda - \lambda\sum_{i=1}^{n}\left(pt_i + \frac{1-p}{k+1}t_i^{k+1}\right). \quad (7)$$

From (7), we derive the likelihood equations for the two parameters p and λ, by taking the partial derivatives with regard to each of the parameters and equating them to zero

$$\frac{\partial log\, L}{\partial \lambda} = \frac{n}{\lambda} - \sum_{i=1}^{n}\left(pt_i + \frac{1-p}{k+1}t_i^{k+1}\right) \quad (8)$$

$$\frac{\partial log\, L}{\partial p} = \sum_{i=1}^{n}\frac{1-t_i^k}{p+(1-p)t_i^k} - \lambda\sum_{i=1}^{n}\left(t_i - \frac{1}{k+1}t_i^{k+1}\right) \quad (9)$$

We get

$$\hat{\lambda} = \frac{n}{\sum_{i=1}^{n}\left(pt_i + \frac{1-p}{k+1}t_i^{k+1}\right)} \quad (10)$$

and

$$\sum_{i=1}^{n}\left(\frac{1}{p + \frac{t_i^k}{1-t_i^k}}\right) - \frac{n\sum_{i=1}^{n}t_i\left(1+k-t_i^k\right)}{(k+1)\sum_{i=1}^{n}\left(pt_i + \frac{1-p}{k+1}t_i^{k+1}\right)} = 0. \quad (11)$$

Equation (11) may be solve for $\hat{p}$ by Newton-Raphson or other suitable iterative methods and this value is substituted in (10) to obtain $\hat{\lambda}$. By using the invariance property of MLE's,

1. The MLE for $R(t)$, say $\hat{R}(t)$, will be

$$\hat{R}(t) = \exp\left\{-\hat{\lambda}\left(\hat{p}t + \frac{1-\hat{p}}{k+1}t^{k+1}\right)\right\}. \quad (12)$$

2. The MLE for $h(t)$, say $\hat{h}(t)$, will be

$$\hat{h}(t) = \hat{\lambda}\left(\hat{p} + (1-\hat{p})t^k\right). \quad (13)$$

3. The MLE for MTTF will be

$$\hat{MTTF} = MTTF\left(\hat{p}, \hat{\lambda}\right), \quad (14)$$

which can be obtained by installing into (5) and integrating.

3.2 *The Metropolis-Hastings algorithm*

The Metropolis-Hastings algorithm is the most popular MCMC method (Hastings 1970, Metropolis et al. 1953). According to Navarro & Perfors, the basic problem is that MCMC provides a method for sampling from some generic distribution $p(x)$, say target distribution. The idea is that in many cases, we know how to write out the equation for the target distribution $p(x)$, but we do not know how to generate a random number from this target distribution. This is the situation where MCMC is very useful. In fact, for the Metropolis-Hastings algorithm we do not even need to know how to calculate $p(x)$ completely.

The basic idea behind MCMC is to define a Markov chain over possible x values, in such a way that the stationary distribution of Markov chain is in fact $p(x)$. That is, what we are going to do is to use a Markov chain to generate a sequence of x values, denoted ($x_0, x_1, x_2,$), in such a way that as $n \to \infty$, we can guarantee that $x_n \sim p(x)$. There are many different ways of setting up a Markov chain that has this property, one of which is the Metropolis-Hastings algorithm.

Here is how Metropolis-Hastings algorithm works. Suppose that the current state of the Markov chain is x_n, and we want to generate x_{n+1}. In the Metropolis-Hastings algorithm, the generation of x_{n+1} is a twostage process. The first stage is to generate a candidate, which we will denote x^*. The value of x^* is generated from the proposal distribution, denoted $q(x^* \mid x_n)$, which depends on the current state of the Markov chain, x_n. There is a few minor technical constraints on what we can use as a proposal distribution.

The second stage is the accept-reject step. Firstly, what we need to do is calculate the acceptance probability $A(x_n \to x^*)$, which is given by:

$$A(x_n \to x^*) = min\left(1, \frac{p(x^*)}{p(x_n)} \times \frac{q(x_n \mid x^*)}{q(x^* \mid x_n)}\right) \tag{15}$$

There are two things to pay attention to here. Firstly, notice that the ratio $\frac{p(x^*)}{p(x_n)}$ does not depend on the normalizing constant for the target distribution $p(x)$. The second thing to pay attention to is the behavior of the other term, $\frac{q(x_n|x^*)}{q(x^*|x_n)}$. What this term does is correct for any biases that the proposal distribution might induce. In this expression, the denominator $q(x^* \mid x_n)$ describes the probability of generating a x^* as the candidate given that the current state is x_n (i.e., what actually happened), whereas the numerator describes the probability that the "opposite" event would have occurred: that is, if the current state had actually been x^*, what is the probability that you would have generated x_n as the candidate value? If the proposal distribution is symmetric, then these two probabilities will turn out to be equal, $\frac{q(x_n|x^*)}{q(x^*|x_n)} = 1$. This special case of the Metropolis-Hastings algorithm is called the Metropolis algorithm.

Having proposed the candidate x^* and calculated the acceptance probability, $A(x_n \to x^*)$, we now either decide to "accept" the candidate (in which case we set $x_{n+1} = x^*$) or we decide to "reject" the candidate (in which case we set $x_{n+1} = x_n$). To make this decision, we generate a (uniformly distributed) random number between 0 and 1, denoted u. Then:

$$x_{n+1} = \begin{cases} x^* & \text{if } u \le A(x_n \to x^*) \\ x_n & \text{if } u > A(x_n \to x^*) \end{cases} \tag{16}$$

3.3 *Bayesian estimation*

For our mixture model, the Bayesian model is constructed by specifying a prior distribution for p and λ, and then multiplying with the likelihood function to obtain the posterior distribution. Given a set of data $D: t_1 \ldots, t_n$, the likelihood function is

$$\log L(D \mid \lambda, p) = \sum_{i=1}^{n} \log\left(p + (1-p)t_i^k\right) + n \log \lambda - \lambda \sum_{i=1}^{n} \left(pt_i + \frac{1-p}{k+1} t_i^{k+1}\right) \tag{17}$$

Denote the prior distribution of p and λ as $\pi(p,\lambda)$, the posterior distribution of p and λ given $D: t_1 \ldots, t_n$ is given by

$$\pi(p, \lambda \mid D) = \frac{L(D \mid p, \lambda)\pi(p, \lambda)}{\int_0^\infty \int_0^1 L(D \mid p, \lambda)\pi(p, \lambda)\, dp\, d\lambda} \tag{18}$$

Because the denominator in (18) is a normalizing constant, Bayes' theorem is often expressed as:

$$\pi(p, \lambda \mid D) \propto L(D \mid p, \lambda)\pi(\lambda, p) \tag{19}$$

Here the prior distribution is given beforehand, usually based on prior information of the parameters, such as that from historical data, previous experiences, expert suggestions, even wholly subjective suppositions, or simply from the point of mathematical conveniences.

The proposed priors for parameters p and λ may be taken as

$$\pi(p) = \frac{1}{B(a,b)} p^{a-1}(1-p)^{b-1}, \quad a, b > 0. \tag{20}$$

$$\pi(\lambda) = \frac{\alpha^\beta}{\Gamma(\beta)} \lambda^{\beta-1} e^{-\alpha\lambda} \quad \alpha > 0, \beta > 0. \tag{21}$$

For these two parameters, we assume independent priors. Then the joint prior distribution for p and λ will be

$$\pi(p, \lambda) = \frac{\alpha^\beta}{B(a,b)\Gamma(\beta)} p^{a-1}(1-p)^{b-1} \lambda^{\beta-1} e^{-\alpha\lambda} \tag{22}$$

In view of the prior in (22), the posterior distribution of p and λ given $D: t_1 \ldots, t_n$ is given by

$$\pi(p, \lambda \mid D) \propto \lambda^{n+\beta-1} \left[\prod_{i=1}^{n} \left(p + (1-p)t_i^k\right)\right] \times e^{-\lambda\left(\alpha + \sum_{i=1}^{n}\left(pt_i + \frac{1-p}{k+1} t_i^{k+1}\right)\right)} p^{a-1}(1-p)^{b-1} \tag{23}$$

Then, under the square error loss function, the Bayes estimate of p, λ, failure rate function $h(t)$ and reliability function $R(t)$ are given by

$$p^* = \mathbb{E}(p \mid D) \tag{24}$$

$$\lambda^* = \mathbb{E}(\lambda \mid D) \tag{25}$$

$$h^*(t) = \mathbb{E}(h(t) \mid D) \tag{26}$$

$$R^*(t) = \mathbb{E}(R(t) \mid D) \tag{27}$$

In our study, we use adaptive Metropolis-Hastings sampling (Chivers 2012) to generate sample $\theta_i = (p_i, \lambda_i), i = 1, \ldots, n$ from the posterior distribution $\pi(p, \lambda \mid D)$. Then, Monte Carlo integration estimates p^*, λ^*, $h^*(t)$ and $R^*(t)$ by calculating the means:

$$p^* = \mathbb{E}(p \mid D) \approx \frac{1}{n} \sum_{i=1}^{n} p_i \tag{28}$$

$$\lambda^* = \mathbb{E}(\lambda \mid D) \approx \frac{1}{n} \sum_{i=1}^{n} \lambda_i \tag{29}$$

$$h^*(t) = \mathbb{E}(h(t) \mid D) \approx \frac{1}{n}\sum_{i=1}^{n} h(t; p_i, \lambda_i) \tag{30}$$

$$R^*(t) = \mathbb{E}(R(t) \mid D) \approx \frac{1}{n}\sum_{i=1}^{n} R(t; p_i, \lambda_i) \tag{31}$$

4 ILLUSTRATIVE EXAMPLE

In this section, we present an example to illustrate the estimation procedures discussed in this paper. We consider data given in Table 1, which were used as an illustrative example in our previous study (Bris & Thach 2016). The data set was generated in case $p = \frac{1}{3}$, $\lambda = 0.2$ and $n = 30$ and the parameter k is considered to be fixed to one. In this study, we use both MLE and MCMC method to estimate the parameters and reliability characteristics. In order to obtain MCMC estimators, prior parameters are arbitrarily taken as $a = b = 2$ and $\alpha = 0.1$, $\beta = 1$ and we ran the Metropolis-Hastings algorithm to construct Markov chain of length 50,000 with burn-in of 1000 and reduced the autocorrelation by retaining only every 5 iterations of the chain and obtain 9801 samples. Table 2 shows our MCMC point estimates and two-sided 90% of Bayes credible interval for p and λ, and Table 3 shows our MLE point

estimates and two-sided 90% bootstrap confident interval BCa (bias corrected and accelerated) for p and λ. Figures 1–2 show posterior distributions and trace plots of each parameter of the Bayesian model obtained by Metropolis-Hastings algorithm, and Figures 3–4 show time courses of reliability function and failure rate function obtained by both MLE and MCMC method. On the basic of these results, we may conclude that MCMC is better than MLE.

5 SIMULATION STUDY

A Monte Carlo simulation study is conducted to compare the performance of MLE and MCMC estimators for the parameters of mixture failure rate. For each of the following choice of parameters, we simulate 1000 sets of data with sample size $n = 20$, 50, 100 and 200, respectively, and based on each set of data we computed the MLE and MCMC estimator for the model parameters. In order to obtain MCMC estimators, prior parameters are taken as in section 4, and we ran the Metropolis-Hastings algorithm to construct Markov chain of length 20,000 with burn-in of 1000 and reduced autocorrelation by retaining only every 5 iterations of the chain and obtain 3801 samples. Note that as discussed earlier, when $p = 1$, the hazard rate function $h(t)$ represents the failure rate of an exponential distribution, while when $p = 0$, it represents the failure rate of the Rayleigh distribution or Weibull distribution with shape parameter 2.

1. $p = 0.3$ and $\lambda = 0.2$
2. $p = 0.5$ and $\lambda = 0.2$
3. $p = 0.7$ and $\lambda = 0.2$

The Tables 4–6 list the results of the simulation study. Denote $\hat{\theta}$ as the MLE and θ^* as the MCMC

	MCMC	–0.0779	0.0165	–0.0099	0.0008
200	MLE	–0.0115	0.0067	0.0001	0.0005
	MCMC	–0.0393	0.0076	–0.0055	0.0004

of θ. Bias is calculated as the mean of 1000 estimates minus the true value, and MSE is the mean square error, the mean of the squared differences between 1000 estimators and true value. And Figures 5–10 show the bias and MSE obtained in Tables 4–6.

From the comparison of estimates, we observe the following:

- For estimation of p and λ, although for some cases the biases of MLE are smaller than those of MCMC, MCMC has overwhelming advantage over MLE in the index of MSE. Therefore MCMC is more stable than MLE, in spite of the fact that when sample size is large (say, larger

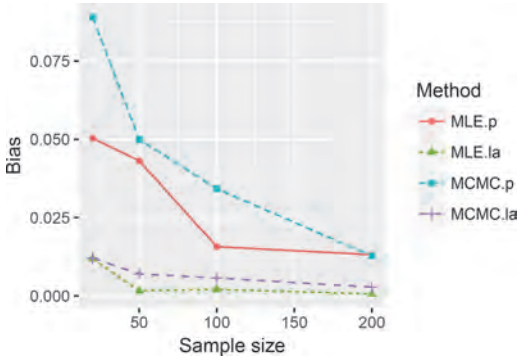

Figure 5. Comparison of bias of $\hat{\theta}$ and θ^* for $\theta = (0.3, 0.2)$.

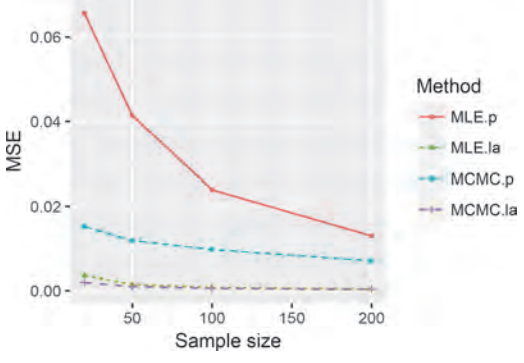

Figure 6. Comparison of MSE of $\hat{\theta}$ and θ^* for $\theta = (0.3, 0.2)$.

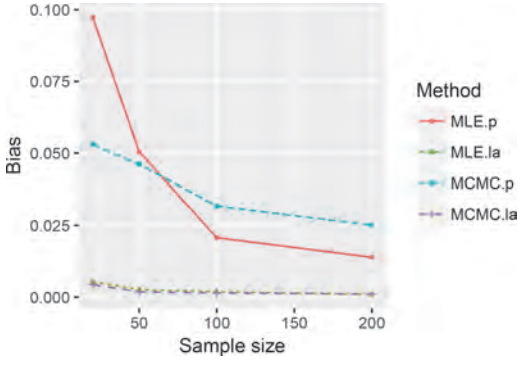

Figure 7. Comparison of bias of $\hat{\theta}$ and θ^* for $\theta = (0.5, 0.2)$.

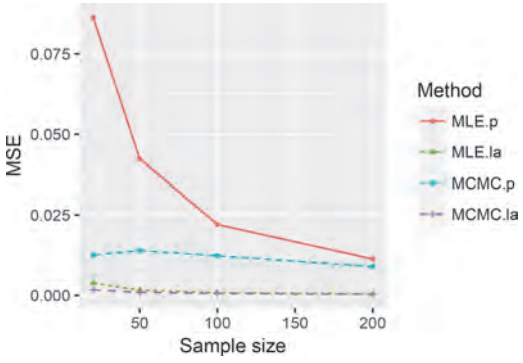

Figure 8. Comparison of MSE of $\hat{\theta}$ and θ^* for $\theta = (0.5, 0.2)$.

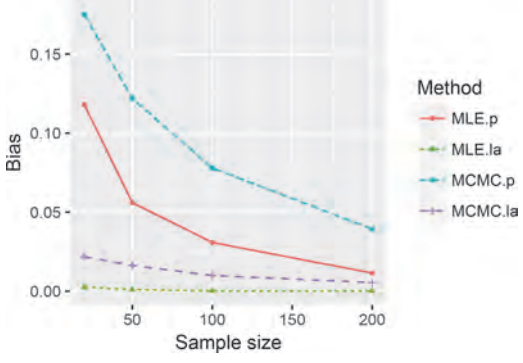

Figure 9. Comparison of bias of $\hat{\theta}$ and θ^* for $\theta = (0.7, 0.2)$.

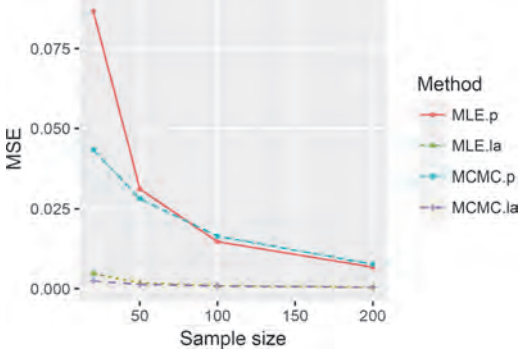

Figure 10. Comparison of MSE of $\hat{\theta}$ and θ^* for $\theta = (0.7, 0.2)$.

than 100), MLE has less bias than MCMC. In general MCMC is better than MLE.

- When the sample size is small (say, less than 100), MCMC behaves better than MLE with regard to the indexes, bias, and MSE. The advantage of MCMC over MLE is especially remarkable in the estimation of parameter λ.

6 CONCLUSION

Based on the simulation results, we may conclude that under square error loss function, the MCMC method can show better result than MLE method to estimate the parameters and reliability characteristics of the failure distribution of the mixture failure rate. We suggest the use of MCMC instead of MLE for point estimation when sample size is not very large. Even when sample size is large, MCMC is still more stable than MLE.

Probabilistic safety assessment and state prediction of cranes based on fuzzy theory

G. Shen, X.J. Zhang, X.L. Tang & S.T. Wang
Beijing Materials Handling Research Institute, Beijing, China

G. Shen & D. Xiang
Tsinghua University, Beijing, China

ABSTRACT: Crane is the supporting equipment in the construction of engineering projects, thus ensuring its safe operation has become an important work. The critical load-bearing part, steel structure, in case of failure can affect reliable operation of the whole crane. Therefore, steel structure is chosen as the study object. First of all, we construct the testing system and data-integration platform to collect running data. Then, the article focuses on establishing the index system of safety assessment, determining the weight of each index based on the Analytic Hierarchy Process (AHP), and obtaining the membership matrix by utilizing the Fuzzy Theory. On this basis, we evaluate the safety level of its current state, and further express the possibility of each safety level occurring by probability form. Finally, we introduce the parameter, transition probability between different safety states, and build the model predicting future safety state of steel structure.

1 INTRODUCTION

1.1 *Research background*

Crane plays an indispensable role in the construction of engineering projects, and has been widely used in the pillar industry, such as machinery manufacturing industry, transportation and logistics industry, water conservancy and hydropower engineering, and nuclear power construction. In recent years, crane is developing rapidly in the direction of large scale and specialization, for adapting to the increasingly enlargement of basic industry and infrastructure.

Under actual operation conditions, the complex alternating load is frequently applied to cranes, which makes its safety to be the significant index in the process of design, manufacture and maintenance. Therefore, we know the crane's safety is of great importance. In case of failure, the economic loss produced tends to be extremely disastrous. Accordingly, carrying out the study on safety assessment and safety state prediction has become the critical breakthrough in solving the problem.

1.2 *Research reviews*

The latest research developments indicate that testing technology (Tian et al. 2009) and assessment method (Yang 2005) have been the focus in the field of crane's safety assessment.

In the aspect of testing technology, remote monitoring (Szpytko 1998, Li & Liu 2012) and spot inspection (Zhang 2017) are widely used in this field, and also become the research focus. Especially in the era of Internet of Things and Big Data, real-time monitoring of actual operation and timely capture of overload, emergency braking and other safety conditions can improve the safety and production efficiency of cranes. However, the current inspection of cranes is still based on the traditional way, which depends on spot experience and simple instrument inspection (Li & Yin 2011). Obviously, the current inspection level is relatively low, and the inspection content is narrow. It is just limited to the standard inspection and no inspection items are carried out according to the new market demand, such as safety level assessment and future state prediction. Moreover, many monitoring systems mainly focus on reflecting the real-time running parameters (Cen et al. 2015), and the in-depth analysis of these parameters is not enough. Thus, it is difficult to assess the current safety state and failure possibility of cranes (Wang et al. 2013, Makovskii 1994).

In terms of assessment method, the current research work mostly includes two aspects, the assessment of current safety state (Yang et al. 2009, Bucas et al. 2014) and the prediction of future safety state (Wu et al. 2010), and the latter is also called life prediction. At present, the assessment of

crane's safety state is mainly based on Grey Theory Method, Combination Weighting Method, Unascertained Measurement Theory, Fisher Discriminant Method, Support Vector Machine, Fuzzy Theory Method and Artificial Neural Network (Fan et al. 2011). In these methods, the application of Fuzzy Theory Method is the most extensive. On the other hand, scholars have conducted in-depth and systematic research by theoretical and experimental methods for life prediction (Zhou et al. 2012), and put forward several life prediction models for the whole crane or steel structure. However, due to the complexity and randomness of environment and loading conditions, these classical methods based on deterministic equations have being developing towards the direction of probability statistics.

On account of the insufficient research above, we accurately grasp the new market demand of safety assessment, and further carry out the research on index system of safety assessment, probabilistic safety assessment method, and future state prediction method for crane's steel structure. The research results will help to ensure the reliable operation of cranes for a long time and bring enormous economic benefits. Besides, these results can also promote the technological progress of hoisting machinery industry and enhance the international competitiveness of cranes, which have the long-term social benefits.

In this paper, the method, Analytic Hierarchy Process (AHP), has been used to assessing the safety level of cranes. AHP actually represents the decision process, namely at first resolving the total assessment target into several layers and then carrying out qualitative and quantitative analysis. The specific procedures mainly include: establishing the index system, defining the assessment level, constructing the judgment matrix, calculating the weight vector, checking the consistency, determining the membership and assessing the safety level, as shown in section 2 and section 3.

2 INDEX SYSTEM OF SAFETY ASSESSMENT

2.1 *Establishing the index system*

According to BS 7121-1:2006, GB 6067-1:2010 and GB/T 21920:2008, the influence factors have been sorted out and index system of safety assessment for cranes has been established, which includes three aspects, such as target layer, standard layer and index layer, as shown in Figure 1.

The target layer, namely the final result layer, refers to the safety assessment level of cranes, which is represented by the parameter *F*.

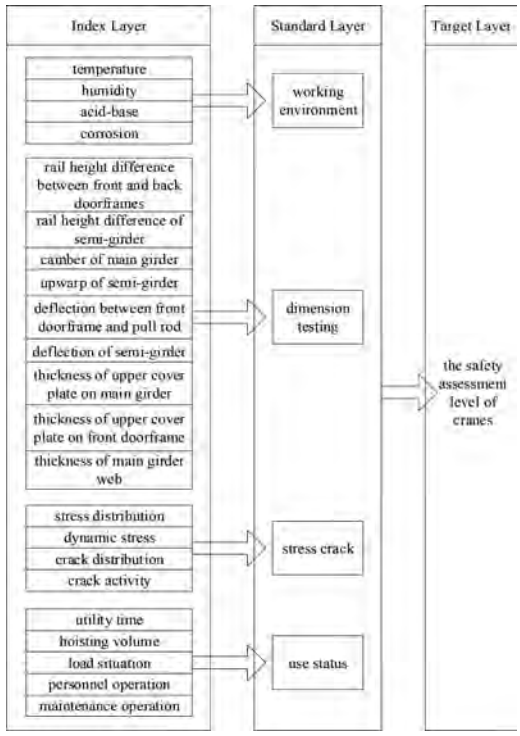

Figure 1. Index system of safety assessment for crane's steel structure.

The standard layer is sorted based on four aspects, including working environment, dimension testing, stress crack and use status. Namely, $V = [V_1\ V_2\ V_3\ V_4]$ = [working environment, dimension testing, stress crack, use status].

The index layer is the specific expansion of the factors in standard layer. For the working environment, $V_1 = [M_{11}\ M_{12}\ M_{13}\ M_{14}]$, where M_{11} represents the temperature; M_{12} represents the humidity; M_{13} represents the acid-base property; M_{14} represents the corrosion degree, respectively. For the dimension testing, $V_2 = [M_{21}\ M_{22}\ M_{23}\ M_{24}\ M_{25}\ M_{26}\ M_{27}\ M_{28}\ M_{29}]$, where M_{21} represents the rail height difference between front and back doorframes; M_{22} represents the rail height difference of semi-girder; M_{23} represents the camber of main girder; M_{24} represents the upwarp of semi-girder; M_{25} represents the deflection between front doorframe and pull rod; M_{26} represents the deflection of semi-girder; M_{27} represents the thickness of upper cover plate on main girder; M_{28} represents the thickness of upper cover plate on front doorframe; M_{29} represents the thickness of main girder web, respectively. For the stress crack, $V_3 = [M_{31}\ M_{32}\ M_{33}\ M_{34}]$, where M_{31} represents the stress distribution; M_{32} represents the dynamic stress; M_{33} represents the

crack distribution; M_{34} represents the crack activity, respectively. For the use status, $V_4 = [M_{41}\ M_{42}\ M_{43}\ M_{44}\ M_{45}]$, where M_{41} represents the utility time; M_{42} represents the hoisting volume; M_{43} represents the load situation; M_{44} represents the personnel operation; M_{45} represents the maintenance operation, respectively.

The index system above is established on the basis of AHP, which takes into account not only the technical elements such as dimension testing and stress crack, but also the non-technical elements such as working environment and use status. The method and index system are mainly used to assess cranes' comprehensive safety performance in the middle and later stages of service. Moreover, for the other mechanical products similar to cranes, the safety assessment can also be carried out by adjusting for the factors in the index system correspondingly.

2.2 *Constructing the testing system*

Under actual service conditions, the working environment of cranes exists uncertain factors, and heavy alternating load often acts on crane's steel structure at the same time. Therefore, collecting the real-time running data and testing data has become the basis of carrying out safety assessment research.

Based on the index system of safety assessment established in Figure 1, we construct the testing system with multiple modules, such as corrosion morphology testing module, dimension deformation testing module, stress distribution testing module, dynamic stress testing module, crack distribution testing module and crack activity testing module. Specifically, the advanced sensor technology has been applied on crane's steel structure to collect testing parameters, including corrosion parameter, deformation parameter, stress-strain parameter, crack parameter, crack growth parameter and so on. On this basis, the data-integration software platform is built to gather all the testing data, which are exactly the basic data source for assessing safety level of crane's steel structure.

3 SAFETY ASSESSMENT OF CURRENT STATE

3.1 *Definition of assessment level*

According to statistical data and previous experience, the assessment level of safety state has been classified in consideration of the severity of crane's failure accidents. There exists five kinds of safety level listed in descending order. It can be expressed as follows: $U = [U_1\ U_2\ U_3\ U_4\ U_5]$, where U_1 represents the excellent level; U_2 represents the good level; U_3 represents the available level; U_4 represents the require-repair level; U_5 represents the discard level, respectively.

3.2 *Weight of factors in standard layer*

The 1–9 scale method has been proposed to quantify the relative importance between working environment, dimension testing, stress crack, and use status, as shown in Table 1.

According to the scale method in Table 1, the judgment matrix can be constructed as follows.

$$N = \left(a_{ij}\right)_{n\cdot n} \tag{1}$$

where the element a_{ij} in matrix N indicates the relative importance between every two factors.

For the factor F in target layer, the matrix N reflecting the relative importance between working environment V_1, dimension testing V_2, stress crack V_3 and use status V_4 in standard layer, has been constructed and specifically expressed as follows.

$$N = \begin{bmatrix} 1 & 1/5 & 1/7 & 1/3 \\ 5 & 1 & 1/5 & 3 \\ 7 & 5 & 1 & 5 \\ 3 & 1/3 & 1/5 & 1 \end{bmatrix} \tag{2}$$

The maximum eigenvalue and eigenvector of matrix N have been calculated by MATLAB. The eigenvector exactly reflects the relative importance of factors in standard layer, which is also called the allocation of weight coefficient. The expression of eigenvector after normalization is given as follows.

$$A = (0.0521\ \ 0.2195\ \ 0.6194\ \ 0.1090) \tag{3}$$

In order to verify whether the allocation of weight coefficient is reasonable, it is necessary

Table 1. 1–9 scale method.

Scale value	Explanation
1	The two factors are of the equal importance
3	One is a little more important than the other
5	One is more important than the other
7	One is more important than the other intensely
9	One is more important than the other extremely
2,4,6,8	The intermediate values of adjacent scales above

to carry out the consistency check of judgment matrix N. The consistency ratio is defined as the parameter CR.

$$CR = \frac{CI}{RI} \tag{4}$$

$$CI = \frac{\lambda_{\max} - n}{n-1} \tag{5}$$

where $\lambda_{\max}$ represents the maximum eigenvalue; n represents the matrix dimension; RI represents the mean random consistency index.

When the consistency ratio satisfies the condition $CR < 0.1$, it is considered that the allocation of weight coefficient is reasonable. Otherwise, we should adjust the elements' value in judgment matrix N, and redistribute the weight coefficient.

Based on equations 4–5, the calculating result shows that $CR = 0.09 < 0.1$, which indicates the elements' value of matrix N and the weight coefficient distribution of eigenvector A are both reasonable and effective.

3.3 *Weight of factors in index layer*

For the factor V_1, the judgment matrix reflecting the relative importance between temperature M_{11}, humidity M_{12}, acid-base property M_{13} and corrosion degree M_{14} in index layer, has been constructed based on 1–9 scale method. The specific expression is shown as follows.

$$N_1 = \begin{bmatrix} 1 & 1/5 & 1/4 & 1/7 \\ 5 & 1 & 3 & 1/3 \\ 4 & 1/3 & 1 & 1/5 \\ 7 & 3 & 5 & 1 \end{bmatrix} \tag{6}$$

The maximum eigenvalue and eigenvector of matrix N_1 have been calculated by MATLAB. The expression of eigenvector after normalization is given as follows.

$$A_1 = (0.0516 \;\; 0.2605 \;\; 0.1276 \;\; 0.5604) \tag{7}$$

In aspect of the consistency check, the calculating result shows that $CR_1 = 0.067 < 0.1$, which indicates the elements' value of matrix N_1 and the weight coefficient distribution of eigenvector A_1 are both reasonable and effective.

For the factor V_2, the judgment matrix reflecting the relative importance between M_{21}, M_{22}, M_{23}, M_{24}, M_{25}, M_{26}, M_{27}, M_{28}, and M_{29} in index layer, has been constructed based on 1–9 scale method. The specific expression is shown as follows.

$$N_2 = \begin{bmatrix} 1 & 1/2 & 2 & 2 & 2 & 3 & 2 & 3 & 2 \\ 2 & 1 & 3 & 3 & 2 & 3 & 2 & 4 & 2 \\ 1/2 & 1/3 & 1 & 3 & 2 & 2 & 1/2 & 1 & 1/2 \\ 1/2 & 1/3 & 1/3 & 1 & 1/3 & 1/2 & 1/3 & 2 & 1/3 \\ 1/2 & 1/2 & 1/2 & 3 & 1 & 3 & 2 & 3 & 2 \\ 1/3 & 1/3 & 1/2 & 2 & 1/3 & 1 & 1/3 & 2 & 1/3 \\ 1/2 & 1/2 & 2 & 3 & 1/2 & 3 & 1 & 4 & 2 \\ 1/3 & 1/4 & 1 & 1/2 & 1/3 & 1/2 & 1/4 & 1 & 1/3 \\ 1/2 & 1/2 & 2 & 3 & 1/2 & 3 & 1/2 & 3 & 1 \end{bmatrix} \tag{8}$$

The maximum eigenvalue and eigenvector of matrix N_2 have been calculated by MATLAB. The expression of eigenvector after normalization is given as follows.

$$A_2 = (0.1660 \;\; 0.2136 \;\; 0.0969 \;\; 0.0488 \;\; 0.1338 \ldots \\ \ldots 0.0555 \;\; 0.1326 \;\; 0.0427 \;\; 0.1100) \tag{9}$$

In aspect of the consistency check, the calculating result shows that $CR_2 = 0.061 < 0.1$, which indicates the elements' value of matrix N_2 and the weight coefficient distribution of eigenvector A_2 are both reasonable and effective.

For the factor V_3, the judgment matrix reflecting the relative importance between M_{31}, M_{32}, M_{33}, and M_{34} in index layer, has been constructed based on 1–9 scale method. The specific expression is shown as follows.

$$N_3 = \begin{bmatrix} 1 & 1/3 & 1/6 & 1/7 \\ 3 & 1 & 1/4 & 1/5 \\ 6 & 4 & 1 & 1/3 \\ 7 & 5 & 3 & 1 \end{bmatrix} \tag{10}$$

The maximum eigenvalue and eigenvector of matrix N_3 have been calculated by MATLAB. The expression of eigenvector after normalization is given as follows.

$$A_3 = (0.0513 \;\; 0.1061 \;\; 0.2890 \;\; 0.5536) \tag{11}$$

In aspect of the consistency check, the calculating result shows that $CR_3 = 0.065 < 0.1$, which indicates the elements' value of matrix N_3 and the weight coefficient distribution of eigenvector A_3 are both reasonable and effective.

For the factor V_4, the judgment matrix reflecting the relative importance between M_{41}, M_{42}, M_{43}, M_{44} and M_{45} in index layer, has been constructed based on 1–9 scale method. The specific expression is shown as follows.

$$N_4 = \begin{bmatrix} 1 & 1/3 & 3 & 7 & 5 \\ 3 & 1 & 5 & 8 & 6 \\ 1/3 & 1/5 & 1 & 4 & 2 \\ 1/7 & 1/8 & 1/4 & 1 & 1/3 \\ 1/5 & 1/6 & 1/2 & 3 & 1 \end{bmatrix} \quad (12)$$

The maximum eigenvalue and eigenvector of matrix N_4 have been calculated by MATLAB. The expression of eigenvector after normalization is given as follows.

$$A_4 = (0.2705 \quad 0.5045 \quad 0.1153 \quad 0.0368 \quad 0.0729) \quad (13)$$

In aspect of the consistency check, the calculating result shows that $CR_4 = 0.045 < 0.1$, which indicates the elements' value of matrix N_4 and the weight coefficient distribution of eigenvector A_4 are both reasonable and effective.

3.4 *Obtaining the membership matrix*

According to the assessment level of safety state defined in section 3.1, the fuzzy subset for factors in index layer needs to be constructed. Namely, $D = [D_1\ D_2\ D_3\ D_4\ D_5]$ = [excellent, good, medium, poor, extremely poor], where D_1 represents the excellent state; D_2 represents the good state; D_3 represents the medium state; D_4 represents the poor state; D_5 represents the extremely poor state, respectively. Then, we analyze quantitatively the degree of each factor being subordinate to fuzzy subset D, and further obtain the membership matrix.

For working environment V_1, the membership matrix has been obtained as follows.

$$R_1 = \begin{bmatrix} 0.1 & 0.1 & 0.2 & 0.3 & 0.3 \\ 0.1 & 0.1 & 0.2 & 0.3 & 0.3 \\ 0.1 & 0.1 & 0.1 & 0.4 & 0.3 \\ 0 & 0 & 0 & 0 & 1 \end{bmatrix} \quad (14)$$

The first row vector represents the membership degree of temperature factor M_{11} being subordinate to fuzzy subset D. As the temperature of cranes is changing during service, the membership degree corresponding to each state D_1-D_5 is the result of probability statistics. Through referring to the weather data, poor weather appears more frequently, and the membership vector of temperature M_{11} is [0.1 0.1 0.2 0.3 0.3]. In the same way, for the other two factors humidity M_{12} and acid-base property M_{13}, we can also obtain the membership vector based on previous data, as shown by the second row vector and the third row vector.

The fourth row vector represents the membership degree of corrosion factor M_{14} being subordinate to fuzzy subset D. It is remarkable that the membership vector is a definite value rather than the form of probability distribution because the corrosion degree is uniquely determined by the on-site testing results. According to the testing data, the degree of corrosion has reached state D_5, namely the extremely poor state. Therefore, the membership vector of M_{14} is [0 0 0 0 1].

For dimension testing V_2, the membership matrix has been obtained as follows.

$$R_2 = \begin{bmatrix} 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 \\ 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 \end{bmatrix} \quad (15)$$

The first row vector represents the membership degree of factor M_{21} being subordinate to fuzzy subset D. We have collected six groups of testing data, which are respectively 7 mm, 10 mm, 14 mm, 6 mm, 3 mm and 7 mm. The results indicate that M_{21} has reached state D_4, namely the poor state, so the membership vector is [0 0 0 1 0].

The second row vector represents the membership degree of factor M_{22} being subordinate to fuzzy subset D. We have collected thirteen groups of testing data, which are respectively 32 mm, 9 mm, 18 mm, 13 mm, 6 mm, 4 mm, 12 mm, 1 mm, 3 mm, 25 mm, 1 mm, 23 mm and 25 mm. The results indicate that M_{22} has reached state D_3, namely the medium state, so the membership vector is [0 0 1 0 0].

The third row vector represents the membership degree of factor M_{23} being subordinate to fuzzy subset D. We have collected two groups of testing data, which are respectively 8 mm and 5 mm. The results indicate that M_{23} has reached state D_3, namely the medium state, so the membership vector is [0 0 1 0 0].

The fourth row vector represents the membership degree of factor M_{24} being subordinate to fuzzy subset D. We have collected two groups of testing data, which are respectively 76 mm and 133 mm. The results indicate that M_{24} has reached state D_5, namely the extremely poor state, so the membership vector is [0 0 0 0 1].

The fifth row vector represents the membership degree of factor M_{25} being subordinate to fuzzy subset D. The testing value of M_{25}, deflection

between front doorframe and pull rod, is 29 mm, which has reached state D_2, namely the good state, so the membership vector is [0 1 0 0 0].

The sixth row vector represents the membership degree of factor M_{26} being subordinate to fuzzy subset D. The testing value of M_{26}, deflection of semi-girder, is 100 mm, which has reached state D_4, namely the poor state, so the membership vector is [0 0 0 1 0].

The seventh row vector represents the membership degree of factor M_{27} being subordinate to fuzzy subset D. We have collected three groups of testing data, which are respectively 25.8 mm, 25.9 mm and 25.9 mm. The results indicate that M_{27} has reached state D_3, namely the medium state, so the membership vector is [0 0 1 0 0].

The eighth row vector represents the membership degree of factor M_{28} being subordinate to fuzzy subset D. We have collected three groups of testing data, which are respectively 14.5 mm, 14.6 mm and 14.5 mm. The results indicate that M_{28} has reached state D_3, namely the medium state, so the membership vector is [0 0 1 0 0].

The ninth row vector represents the membership degree of factor M_{29} being subordinate to fuzzy subset D. We have collected three groups of testing data, which are respectively 11.8 mm, 11.9 mm and 11.9 mm. The results indicate that M_{29} has reached state D_3, namely the medium state, so the membership vector is [0 0 1 0 0].

For stress crack V_3, the membership matrix has been obtained as follows.

$$R_3 = \begin{bmatrix} 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 \end{bmatrix} \tag{16}$$

For use status V_4, the membership matrix has been obtained as follows.

$$R_4 = \begin{bmatrix} 0 & 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 & 1 \\ 0.1 & 0.2 & 0.3 & 0.2 & 0.2 \\ 0.1 & 0.1 & 0.1 & 0.4 & 0.3 \\ 0 & 0.1 & 0.1 & 0.2 & 0.6 \end{bmatrix} \tag{17}$$

It should be noted that the membership degree of factors M_{31}-M_{34}, M_{41}-M_{45} being subordinate to fuzzy subset D can be determined in the same way by the on-site test and data analysis, so we won't repeat it.

3.5 *Assessing the safety level*

Based on equation 7 and equation 14 above, the assessing vector of working environment V_1 has been calculated. The expression of this vector B_1 after normalization is given as follows.

$$\begin{aligned} B_1 &= A_1 R_1 \\ &= (0.0440 \;\; 0.0440 \;\; 0.0752 \;\; 0.1447 \;\; 0.6922) \end{aligned} \tag{18}$$

Based on equation 9 and equation 15 above, the assessing vector of dimension testing V_2 has been calculated. The expression of this vector B_2 after normalization is given as follows.

$$B_2 = A_2 R_2 = (0 \;\; 0.1338 \;\; 0.5958 \;\; 0.2216 \;\; 0.0488) \tag{19}$$

Based on equation 11 and equation 16 above, the assessing vector of stress crack V_3 has been calculated. The expression of this vector B_3 after normalization is given as follows.

$$B_3 = A_3 R_3 = (0 \;\; 0 \;\; 0.4464 \;\; 0.5536 \;\; 0) \tag{20}$$

Based on equation 13 and equation 17 above, the assessing vector of use status V_4 has been calculated. The expression of this vector B_4 after normalization is given as follows.

$$\begin{aligned} B_4 &= A_4 R_4 \\ &= (0.0152 \;\; 0.0340 \;\; 0.0456 \;\; 0.0524 \;\; 0.8528) \end{aligned} \tag{21}$$

The following work is to integrate these assessing vectors, including B_1, B_2, B_3, and B_4, and then we can obtain the fuzzy relation matrix B of final index F in target layer, as shown in the following equation.

$$B = \begin{pmatrix} B_1 \\ B_2 \\ B_3 \\ B_4 \end{pmatrix} \tag{22}$$

Based on equation 3 and equation 22 above, the assessing vector of final target F has been calculated. The expression of this vector C after normalization is given as follows.

$$C = AB = (0.0039 \;\; 0.0354 \;\; 0.4161 \;\; 0.4048 \;\; 0.1397) \tag{23}$$

Equation 23 indicates that each safety level U_1-U_5 has the possibility of occurrence based on the current testing data, and the vector C exactly represents the probability distribution as shown in Figure 2.

In Figure 2, the first column represents the probability of excellent level occurring, and the

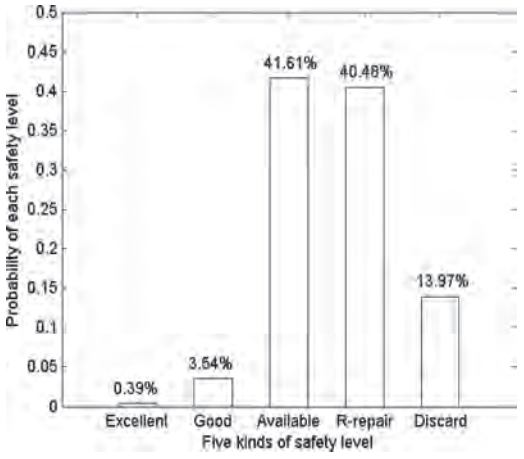

Figure 2. The probability distribution of current safety state.

value is 0.39%. The second column represents the probability of good level occurring, and the value is 3.54%. The third column represents the probability of available level occurring, and the value is 41.61%. The fourth column represents the probability of require-repair level occurring, and the value is 40.48%. The fifth column represents the probability of discard level occurring, and the value is 13.97%.

Next, the final score of current state are calculated considering the weighting coefficient, as shown in the following expression.

$$G = C \cdot S^T \tag{24}$$

where S represents the vector of weighting coefficient; G represents the final score of current state.

Based on equation 23 and equation 24, the safety score G is 60.99. Then, combining with the partition of safety state as shown in Table 2, the service state of crane's steel structure can be ultimately evaluated.

From Table 2, although the score 60.99 corresponds to the require-repair level, it is also near the discard level. Therefore, from the conservative perspective, the conclusion has been drawn that this crane should be discarded in the short term.

The above contents have described the process of analyzing cranes' safety state based on AHP and Fuzzy Theory. Then, we invite the experts in this field to discuss the assessment results obtained. Experts consider that the method is reasonable and the factors listed in index system are comprehensive, which correspond to the actual situation of cranes. To sum up, the assessment effect is very good. Similar to its application on cranes, the method can be further applied to assessing other critical mechanical products such as automobiles, wind turbines, nuclear power equipment, so as to provide important support for obtaining the current service state timely.

Table 2. Partition of safety state.

Safety score	Safety state
90–100	excellent level
80–89	good level
70–79	available level
60–69	require-repair level
< 60	discard level

4 SAFETY PREDICTION OF FUTURE STATE

4.1 *Transition probability between different safety states*

There exists five kinds of safety states for the factor F in target layer, namely $U = [U_1\ U_2\ U_3\ U_4\ U_5]$ = [excellent, good, available, require-repair, discard]. We introduce the parameter, transition probability p_{ij} (i,j = 1,2,3,4,5), to characterize the possibility of safety state i developing to safety state j, as shown in the following equation.

$$p_{ij} = p(U_i \to U_j) \tag{25}$$

It is necessary to point out that when the time interval of state developing is one year, p_{ij} is known as one-step transition probability. Therefore, parameter p_{ij} represents the transition probability of safety state developing from this year to the next year.

For crane's steel structure, the assessing result is a vector rather than a numerical value, which indicates that the assessing result includes several safety states and each state has the possibility of occurrence. In section 3.5, the assessing vector C of this year has been calculated and characterized by the form of probability distribution. On this basis, predicting the assessing vector C' of the next year has become the focus, and the transition probability matrix P can be expressed as follows.

$$P = \begin{bmatrix} p_{11} & p_{12} & p_{13} & p_{14} & p_{15} \\ p_{21} & p_{22} & p_{23} & p_{24} & p_{25} \\ p_{31} & p_{32} & p_{33} & p_{34} & p_{35} \\ p_{41} & p_{42} & p_{43} & p_{44} & p_{45} \\ p_{51} & p_{52} & p_{53} & p_{54} & p_{55} \end{bmatrix} \tag{26}$$

Based on equation 23 and equation 26 above, the assessing vector of future safety state can be obtained as follows.

$$C' = C \times P \tag{27}$$

$$\begin{aligned}&\left(c'_{U1} \quad c'_{U2} \quad c'_{U3} \quad c'_{U4} \quad c'_{U5}\right)\\&=\left(c_{U1} \quad c_{U2} \quad c_{U3} \quad c_{U4} \quad c_{U5}\right)\\&\times\begin{bmatrix}p_{11} & p_{12} & p_{13} & p_{14} & p_{15}\\p_{21} & p_{22} & p_{23} & p_{24} & p_{25}\\p_{31} & p_{32} & p_{33} & p_{34} & p_{35}\\p_{41} & p_{42} & p_{43} & p_{44} & p_{45}\\p_{51} & p_{52} & p_{53} & p_{54} & p_{55}\end{bmatrix}\end{aligned} \tag{28}$$

where c_{U1} represents the probability of excellent level occurring in this year; c_{U2} represents the probability of good level occurring in this year; c_{U3} represents the probability of available level occurring in this year; c_{U4} represents the probability of require-repair level occurring in this year; c_{U5} represents the probability of discard level occurring in this year; c'_{U1} represents the probability of excellent level occurring in the next year; c'_{U2} represents the probability of good level occurring in the next year; c'_{U3} represents the probability of available level occurring in the next year; c'_{U4} represents the probability of require-repair level occurring in the next year; c'_{U5} represents the probability of discard level occurring in the next year.

4.2 *Solving the transition probability matrix P*

Based on equation 27, the corresponding equations can be obtained.

$$C^{2011} = C^{2010} \cdot P \tag{29}$$

$$C^{2012} = C^{2011} \cdot P \tag{30}$$

$$C^{2013} = C^{2012} \cdot P \tag{31}$$

$$C^{2014} = C^{2013} \cdot P \tag{32}$$

$$C^{2015} = C^{2014} \cdot P \tag{33}$$

After expanding these equations above, we can solve the transition probability matrix P as follows.

$$P = K^{-1} \times L \tag{34}$$

$$K=\begin{pmatrix}C^{2010}\\C^{2011}\\C^{2012}\\C^{2013}\\C^{2014}\end{pmatrix},\quad L=\begin{pmatrix}C^{2011}\\C^{2012}\\C^{2013}\\C^{2014}\\C^{2015}\end{pmatrix} \tag{35}$$

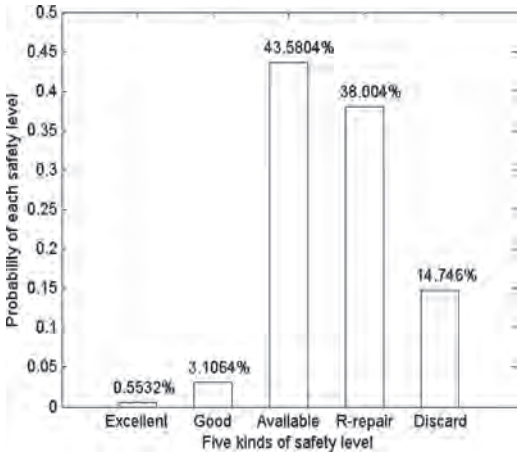

Figure 3. The predicting probability distribution of future safety state.

4.3 *Predicting the future safety state*

For the assessing vectors of the past years, C^{2010}, C^{2011}, C^{2012}, C^{2013}, C^{2014} and C^{2015} have been obtained based on the running data tested once a year. Accordingly, the matrix P can be solved and the assessing vector in 2016 can be predicted as follows.

$$\begin{aligned}C^{2016} &= (c_{U1}^{2016} \quad c_{U2}^{2016} \quad c_{U3}^{2016} \quad c_{U4}^{2016} \quad c_{U5}^{2016})\\&= (0.0055 \quad 0.0311 \quad 0.4358 \quad 0.3800 \quad 0.1475)\end{aligned} \tag{36}$$

The assessing vector in equation 36 exactly represents the prediction of probability distribution, as shown in Figure 3.

Contrasting and analyzing the assessing results between the testing result and the predicting result have been carried out. Equation 23 and Figure 2 represent the safety state in 2016 based on on-spot testing, while equation 36 and Figure 3 represent the safety state in 2016 based on predicting model. In general, the possible safety states in the later stage of service are the last three states. The comparison results show that the percent error of available level is 4.7354%, the percent error of require-repair level is 6.1166%, and the percent error of discard level is 5.5548%. All these three percent error are below 10%, so the prediction of probabilistic safety assessment has high accuracy.

5 CONCLUSIONS

The key load-bearing part, steel structure, in case of failure can affect reliable operation of the whole crane, therefore carrying out the study on safety assessment and safety state prediction has become

the critical breakthrough in solving the problem. Considering the complexity and diversity of influence factors, we adopt the method, Analytic Hierarchy Process (AHP), to assess the safety level of cranes. The final results have indicated that the application of AHP on safety assessment is effective. After our research work, the following conclusions have been drawn.

1. The index system of safety assessment including target layer, standard layer and index layer has been established, which almost covers the factors affecting crane's safety. On this basis, constructing the testing system with multiple modules, and collecting the real-time running data have been carried out.
2. Based on fuzzy theory, we obtain the weight vector of each factor and membership matrix of each factor, and then depict the probability distribution diagram of current safety state. Further more, the safety score 60.99 is calculated, which indicates that the current safety state has nearly reached the discard level, and therefore this crane should be discarded in the short term.
3. To predict the safety state of cranes, we introduce the parameter *p*, transition probability between different states, and further build the model that can obtain the future safety state based on testing data of previous years. Moreover, the prediction of probabilistic safety assessment has high accuracy through comparative analysis.

Optimal prognostic maintenance policy for railway track systems using rolling contact fatigue data

F. Dinmohammadi
School of Engineering and Built Environment, Glasgow Caledonian University, Glasgow, UK
School of Engineering and Physical Sciences, Heriot-Watt University, Edinburgh, UK

ABSTRACT: Railway tracks are one of the most important assets in rail transport that are subject to very high stresses and have to be made of very high-quality steel alloy. The dominant form of track degradation is Rolling Contact Fatigue (RCF) which occurs mainly due to cyclic loading. If RCF is not controlled by maintenance operations, it will result in intensive correction works, service disruption, and even train derailment. In order to reduce such negative consequences and improve the quality of transport services, the railway organizations are moving towards using prognostic analytics approaches for the optimisation of maintenance and repair actions. In this paper, we investigate a cost-optimal prognostic maintenance policy for a railway track system by incorporating RCF data. The mechanism of RCF is analyzed by means of Finite Element Analysis (FEA) and the fatigue propagation behavior is described by the Paris-Erdogan power law function. The length of the cracks over time is also modelled by a stochastic gamma process and its parameters are estimated using the Maximum Likelihood Estimation (MLE) method. An optimization model is proposed to determine fixed time interval and/or Million Gross Tons (MGT) achieving the best possible balance between non-destructive tests and emergency maintenance. The proposed model is applied to support the maintenance decision-making for a conventional rail track system 60E1 in steel grade R350HT. The results show that the use of the proposed prognostic maintenance allows a significant reduction of the costs compared to the strategy when maintenance is conducted on an as-needed basis.

1 INTRODUCTION

Britain's railway system is one the most reliable, comfortable and safest rail networks in the world. Nevertheless, the country's rail network is still confronted with serious problems arising from the failures of infrastructure assets that require costly and time-consuming maintenance work. The rail infrastructure includes those assets that are fixed such as tunnels, bridges, permanent way, tracks, stations, signaling equipment, etc. The key components of a rail infrastructure system are illustrated in Figure 1.

Conducting regular Maintenance and Renewal (M&R) is essential for railway infrastructure to ensure network availability and reliability, passenger safety and comfort, and also energy efficiency. Currently, the maintenance of the railway infrastructure assets is preventive in nature and includes repair or renewal of some certain components at regular time intervals or pre-determined Million Gross Tons (MGT). However, it has been reported in many case studies that a significant portion of maintenance resources (e.g., budget, time, manpower) is wasted due to insufficiency or inefficiency of current programs.

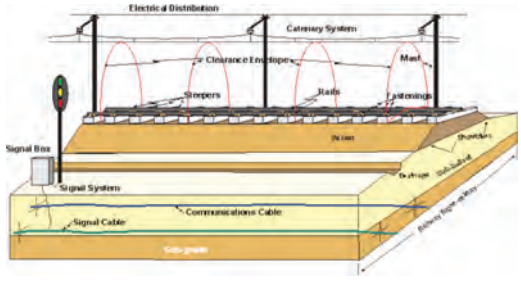

Figure 1. Railway infrastructure components.

To increase the cost-effectiveness of maintenance operations while achieving higher levels of reliability and service quality, several rail transport organisations across the Europe, such as Network Rail in the UK, Administrador de Infraestructuras Ferroviarias (ADIF) in Spain, ProRail in the Netherlands, Trafikverket in Sweden, and Österreichische Bundesbahnen (ÖBB) in Austria, etc. are moving towards using *prognostic analytics* approaches for the optimisation of maintenance programmes within the railway transport network (Dinmohammadi, 2018). However, a survey of the literature

shows that there are few studies examining the problem of optimised prognostic maintenance regimes for railway transport infrastructure assets.

Generally, railway infrastructure defects occur due to a number of specific causes that have been classified by many researchers. Olofsson and Nilsson (2002) divided the defects of steel tracks into two types of surface-initiated and subsurface-initiated cracks. Cannon *et al.* (2003) classified the steel track defects into three main groups: (i) defects originating from rail manufacture, (ii) defects originating from damage caused by inappropriate handling, installation and use, and (iii) defects caused by the exhaustion of the rail's inherent resistance to Rolling Contact Fatigue (RCF).

The RCF process in rail tracks is very complex as it depends on various factors such as age, traffic density, axle load, material properties, track geometry, curvature, speed, and accumulated MGT (Kumar, 2008). If RCF is not controlled by maintenance operations, it will result in intensive correction works, service disruption, and even train derailment. In order to analyse and control the rate of RCF growth, Non-Destructive Testing (NDT) is extensively used by railway operators. NDT includes an extensive range of inspection techniques such as ultrasonic, acoustic, eddy current, thermography, etc. that provide information about the presence of defect, its location, size and depth. The steel rail track has to undergo an emergency repair when the size or depth of crack exceeds a "warning" level. We assume that the costs for an NDT inspection and an emergency repair task are respectively C_I and C_r, where $C_r > C_I > 0$. The main problem encountered in this policy is to determine the optimal time interval (T), or MGT level (U), or number of fatigue cycles (N) for maintenance tasks such that the railroad availability is maximized and/or total inspection and repair cost is minimized.

In this paper, we formulate an optimal prognostic maintenance policy for steel rail tracks subjected to progressive RCF phenomenon. The mechanism of RCF is analyzed by means of Finite Element Analysis (FEA) and the fatigue propagation behavior is described by the Paris-Erdogan power law function. The length of the cracks over time is also modelled by a stochastic gamma process and its parameters are estimated using the Maximum Likelihood Estimation (MLE) method. The explicit expression of the long-run expected cost function per unit time is derived and the existence and uniqueness of the optimal solution are shown for the infinite-horizon case. The performance of the proposed prognostic policy in terms of cost is evaluated and compared to the case when only emergency repairs are considered.

The rest of this paper is organized as follows. The formulation of the optimization model and the properties of the optimal solution are discussed in Section 2. In Section 3, the model is applied to a real-life case study. Section 4 concludes this study.

2 MODEL FORMULATION

The aim of this model is to determine an optimal time interval or MGT level or number of fatigue cycles for the maintenance of steel railway tracks in case that they are subject to risk of progressive RCF. The RCF process typically involves three following phases: (i) initiation, (ii) propagation (or growth), and (iii) the failure. The step-by-step procedure on how to implement the model is presented below:

1. Suppose that the RCF processes initiate in the interval [0, t) following a Non-Homogeneous Poisson Process (NHPP), $\{N(t); t \geq 0\}$ with intensity function $m(t)$ and mean value function $M(t)$, i.e,

$$M(t) = \int_0^t m(x)dx, t \geq 0, \tag{1}$$

where t is the age of the track system and $M(t)$ is a non-decreasing function of t with $M(t) = 0$. Then, the probability that exactly j (= 0, 1, 2, …) RCF processes occur in the interval [0, t), $P_j(t)$ is given by

$$P_j(t) = P\{N(t) = j\} = e^{-M(t)} \times \frac{[M(t)]^j}{j!} \tag{2}$$

Let $T_j (j = 0, 1, 2, \ldots)$ denote the initiation time of the j^{th} RCF process in track system, where $T_0 = 0$. Then, the cumulative distribution function of the random variable T_j is given by

$$F_j(t) = P\{T_j \leq t\} = \sum_{i=j}^{\infty} p_i(t),\ j = 1,2,\ldots. \tag{3}$$

2. Propagation is the second phase of the RCF process which may be accelerated by adverse environmental conditions. Many models have been developed to study how RCF process in steel rail tracks propagate. For instance, Ringsberg (2001) proposed a crack growth model for railway tracks in which the crack propagation life is divided into three stages: (i) shear stress driven initiation at the surface; (ii) transient crack growth behavior; and (iii) subsequent tensile and/or shear driven crack growth (see Figure 2).

In this paper, the RCF propagation is modelled using a stochastic *gamma* process, which represents the evolution of RCF length/size/depth in time. The gamma process is a stochastic process with independent non-negative increments having a gamma

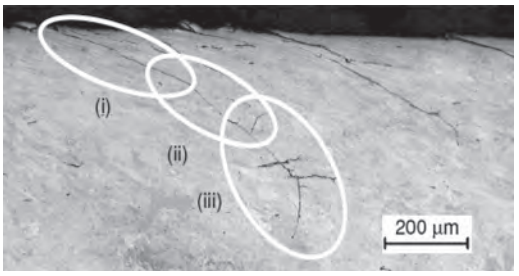

Figure 2. Crack propagation phenomenon in railway tracks (Ringsberg and Bergkvist, 2003).

distribution with identical scale parameter. The gamma process has been widely studied for different maintenance applications by several authors (see van Noortwijk (2009) for a thorough review on the use of gamma process in maintenance modeling). Also, it has been observed that the gamma process is satisfactorily fitted to data of different gradual degradation phenomena (such as wear and crack propagation) in railway industry (Meier-Hirmer *et al.*, 2005). Moreover, the existence of an explicit probability distribution function of gamma process permits feasible mathematical developments.

Let $X_j(t)$ be the length/size/depth of the j^{th} RCF process after t units of time from initiation. We assume that $X_j(t)$ has a homogeneous gamma process with shape and scale parameters given by αt and β respectively. Then, for $t > 0$, the density and the cumulative distribution function of the increment of the length/size/depth of the j^{th} RCF process is given by (Park and Padgett, 2008):

$$g_{\alpha t,\beta}(x) = \frac{\beta^{\alpha t}}{\Gamma(\alpha t)} x^{\alpha t-1} e^{-\beta x},\ x \geq 0, \tag{4}$$

and

$$G_{\alpha t,\beta}(x) = \frac{\gamma(\alpha t, \beta x)}{\Gamma(\alpha t)},\ x \geq 0;\ \alpha, \beta > 0, \tag{5}$$

where $\Gamma(\cdot)$ [$\gamma(.,.)$] denotes the gamma [incomplete gamma] function, i.e.,

$$\Gamma(\upsilon) = \int_0^\infty z^{\upsilon-1} e^{-z} dz;\ \gamma(\upsilon, u) = \int_u^\infty z^{\upsilon-1} e^{-z} dz,\ \upsilon, u > 0.$$

3. Steel railway track undergoes an emergency repair when the length/size/depth of RCF exceed a warning level D. In the event of a repair, the track segment returns to an "as-good-as-new" condition. Let U_j be the length of the interval between the initiation time of the j^{th} RCF process to the time that it attains the warning threshold D. Thus,

$$U_j = \inf\left\{t \geq 0 : X_j(t) \geq D\right\},\ j = 1,2,\ldots, \tag{6}$$

Then, from Eqs. (4) and (5), the density and the cumulative distribution function of U_j, respectively, are given by

$$g_{Uj}(t) \equiv g_U(t) = \frac{\beta^{\alpha t}}{\Gamma(\alpha t)} D^{\alpha t-1} e^{-\beta D},\ t \geq 0;\ \alpha, \beta > 0, \tag{7}$$

and

$$G_{Uj}(t) \equiv G_U(t) = \frac{\Gamma(\alpha t, \beta D)}{\Gamma(\alpha t)},\ t \geq 0;\ \alpha, \beta > 0. \tag{8}$$

We denote by S_j the time point that the length/size/depth of the j^{th} RCF process exceeds the warning level D. Then,

$$S_j = T_j + U_j,\ j = 1,2,\ldots. \tag{9}$$

Lemma. Let $\mathrm{I_A}(.)$ denote the indicator function that is defined as $\mathrm{I_A}(x) = 1$ for $x \in \mathrm{A}$, and 0 otherwise. Let $\{N_S(t);\ t \geq 0\}$ be the counting process associated with the random variables S_j ($j = 0, 1, 2, \ldots$), that is,

$$N_S(t) = \sum_{j=1}^{\infty} I_{[0,t]}(S_j), \tag{10}$$

Then, having in mind that the convolution of any functions $a(.)$ and $b(.)$ is given by

$$a(x) \bullet b(x) = \int_0^x a(x-t) db(t),$$

$\left\{N_S(t); t \geq 0\right\}$ is an NHPP with intensity function,

$$h(t) = m(t) \bullet g_U(t), \tag{11}$$

where $g_U(t)$ is given by Eq. (7) (Shafiee and Finkelstein, 2015).

Let X_r denote a maintenance cycle defined by the time interval between maintenance actions (either NDT inspection or emergency repair). Under the assumptions of the model, we have

$$X_r = \min(S_{[1]}, T), \tag{12}$$

where $S_{[1]}$ denotes the time that, for the first time, an RCF process exceeds the warning threshold D, i.e.,

$$S_{[1]} = \min\left\{S_j,\ j = 1,2\cdots\right\}, \tag{13}$$

Then, by using lemma, the survival function of $S_{[1]}$ is given by

$$\bar{F}_{S_{[1]}}(t) = P\{S_{[1]} > t\} = P\{N_s(t) = 0\} = \exp\left(-\int_0^t h(x)dx\right), \quad (14)$$

where $h(.)$ is the failure rate function of $S_{[1]}$, and is given by Eq. (11). Then, the expected length of a maintenance cycle $E[X_r]$, is given by

$$E[X_r] = \int_0^T \bar{F}_{S_{[1]}}(t)dt, T > 0. \quad (15)$$

Let $C(t)$ be the *s*-expected cost of operating the system for the time interval [0, t). From the *renewal reward theorem* (see Ross 1970, p. 52), the expected cost rate, denoted by $CR(t)$, is the expected operational cost incurred in a maintenance cycle divided by the expected cycle length, i.e.,

$$CR(T) = \lim_{t\to\infty} \frac{C(t)}{t} = \frac{C_r \times F_{S_{[1]}}(T) + C_I \times \bar{F}_{S_{[1]}}(T)}{\int_0^T \bar{F}_{S_{[1]}}(t)dt}, \quad (16)$$

where $F_{S_{[1]}}(\cdot)\left[\bar{F}_{S_{[1]}}(\cdot)\right]$ is the cumulative distribution [survival] function of $S_{[1]}$. The problem is to find the optimal value of T^* that minimizes the objective function $CR(T)$, given in Eq. (16). Therefore, the proposed optimization model can be formulated as follows:

$$minimise\ CR(T) = \frac{C_I + \int_0^T (C_r - C_I)h(t)\bar{F}_{S_{[1]}}(t)dt}{\int_0^T \bar{F}_{S_{[1]}}(t)dt}. \quad (17)$$

The following theorem solves this problem.

Theorem. If $h(T)$ is strictly increasing in t, and $\lim_{T\to\infty} h(T_{max}) > CR(T_{max})$, there exists an unique and finite minimum $T^* \in (0, T_{max})$ that verifies the following equation:

$$\bar{F}_{S_{[1]}}(T^*) + h(T^*) \times \int_0^{T^*} \bar{F}_{S_{[1]}}(t)dt = \frac{C_r}{C_r - C_I}, \quad (18)$$

whereas, if $h(T)$ is non-decreasing in t, and $(C_r - C_I)h(T_{max}) \le CR(T_{max})$, then $T^* = T_{max}$ (implying maximum preventive replacement interval).

3 SIMULATED CASE STUDY

In this Section, we present an application of the RCF-based maintenance decision-making model to a conventional rail track system 60E1 in steel grade R350HT. 60E1 is a common rail profile developed by the International Union of Railways (UIC) (http://uic.org/). It also has been widely used by Network Rail as the standard for all new high speed rail lines. The rail 60E1 profile was designed by 3D Abaqus simulation software and is shown in Figure 3.

UIC60 rails are made of high-quality steel alloys, resistant to Rolling Contact Fatigue (RCF), wear, plastic deformation and corrosion. Different sizes of UIC60 rails are available and used on railroads. In this study, a standard rail section as shown in Figure 4 was chosen for the analysis.

The material properties of the rail (e.g. mass, density and Young's modulus) were provided by the manufacturer, British Steel (britishsteel.co.uk). We assume that the arrival of RCF cracks on rail track follows a Poisson process with rate $\hat{m} = 0.144$/month (Shafiee *et al.*, 2016). The

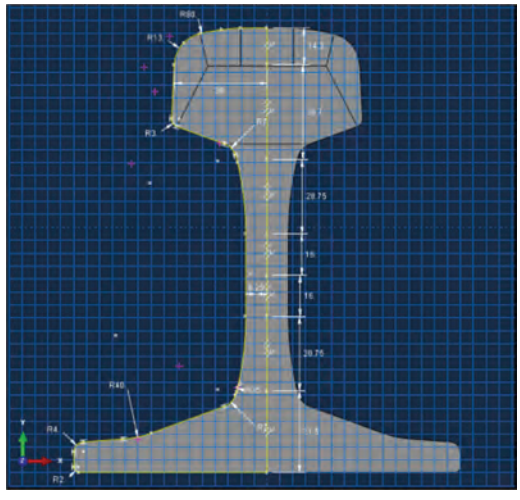

Figure 3. Rail 60E1 profile designed by 3D Abaqus simulation.

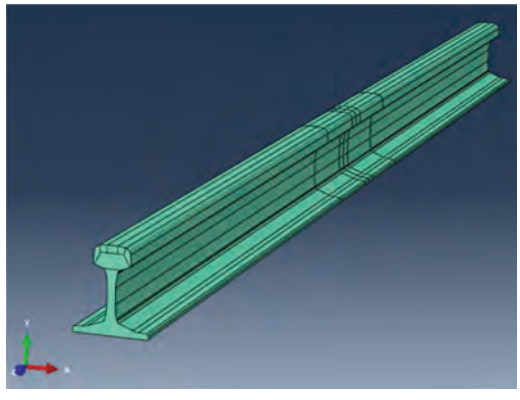

Figure 4. A rail section designed by 3D Abaqus simulation.

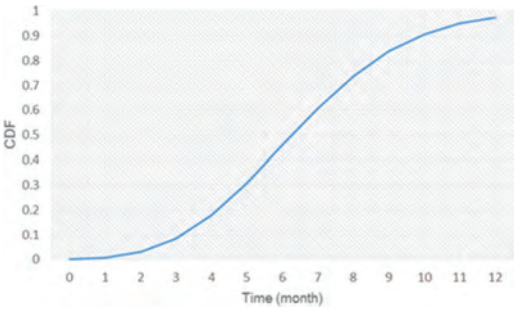

Figure 5. CDF of time-to-initiate a RCF crack.

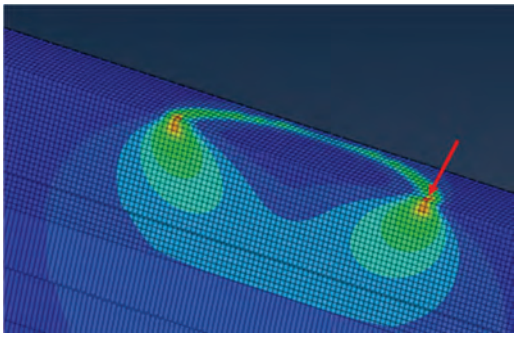

Figure 6. Cross section of contact patch localised on rail track.

Cumulative Distribution Function (CDF) of time-to-initiate a crack is illustrated in Figure 5. The mean-time-to-initiate a crack is estimated 6.94 months.

In order to estimate the rate of degradation propagation, an FEA simulation model was constructed by commercially available software package, Abaqus. The cross section of the contact patch localised on rail track is shown in Figure 6.

Many models have so far been developed *to describe the crack growth* process, e.g. Paris' law (also known as the Paris-Erdogan law). *The Paris' law is a power-function used to predict* crack evolution for structures subject to fatigue stresses. The Paris' law equation is given as follows (Paris and Erdogan, 1963):

$$\frac{da}{dN} = C(\Delta K)^m, \tag{19}$$

where a represents the crack length, N represents the number of load cycles, da/dN is the fatigue crack growth rate per cycle, and C and m are empirical constants (usually referred to as Paris' law parameters) which depend on material properties and operating environment. The range of the stress intensity factor, ΔK represents the difference between the stress intensity factor at maximum and minimum loads for a particular crack length and is calculated as:

$$\Delta K = K_{\max} - K_{\min} = \Delta\sigma Y\sqrt{\pi a}, \tag{20}$$

where $K_{\max}$ and $K_{\min}$ are, respectively, the maximum and minimum stress intensity factors, $\Delta\ \sigma$ is the range of cyclic stress amplitude, and Y is a dimensionless parameter that depends on the crack and loading geometries. The remaining cycles can be found by substituting Eq. (20) into Eq. (19):

$$\frac{da}{dN} = C(\Delta\sigma Y\sqrt{\pi a})^m, \tag{21}$$

For relatively short cracks, Y can be assumed as independent of a and the differential equation can be solved via separation of variables

$$\begin{aligned}\int_0^{N_f} dN &= \int_{a_i}^{a_c} \frac{da}{C(\Delta\sigma Y\sqrt{\pi a})^m} \\ &= \frac{1}{C(\Delta\sigma Y\sqrt{\pi a})} \int_{a_i}^{a_c} a^{-\frac{m}{2}},\end{aligned} \tag{22}$$

and subsequent integration

$$N_f = \frac{2\left(a_c^{1-\frac{m}{2}} - a_i^{1-\frac{m}{2}}\right)}{(2-m)C(\Delta\sigma Y\sqrt{\pi})^m}, \tag{23}$$

where N_f is the remaining number of cycles to fracture, a_c is the critical crack length at which instantaneous fracture will occur, and a_i is the initial crack length at which fatigue crack growth starts for the given stress range $\Delta\sigma$. If Y strongly depends on a, numerical methods might be required to find reasonable solutions. Basically, crack propagation can be divided into three stages: stage I (short cracks), stage II (long cracks) and stage III (final fracture). At stage I, once a fatigue crack is initiated, it propagates along high shear stress planes (45 degrees). When the stress intensity factor K increases as a consequence of crack growth or higher applied loads, slips start to develop in different planes close to the crack tip, initiating stage II. Finally, stage III is related to unstable crack growth as K_{max} approaches K_{IC}. At this stage, crack growth is controlled by static modes of failure and is very sensitive to the microstructure, load ratio, and stress state (plane stress or plane strain loading). The cross-section of a fatigue crack introduced to the model in 100 nm scale is shown in Figure 7.

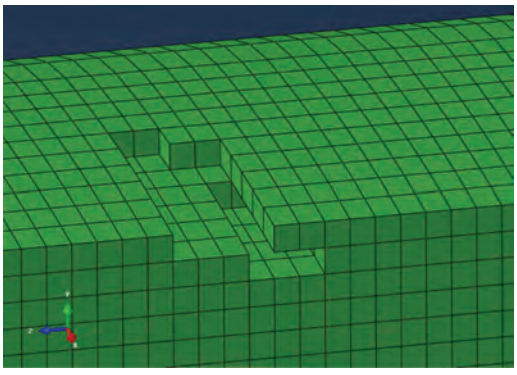

Figure 7. Cross-section of a crack that was introduced to model (scale bar: 100 nm).

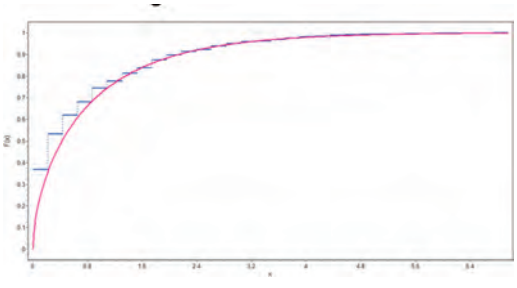

Figure 8. Cumulative distribution function for crack length.

The length of the fatigue cracks in time is modelled using the gamma distribution as presented in Equations (4) and (5). The parameters of the Gamma process are estimated by means of maximum likelihood estimators given in Kahle *et al.* (2016) and are reported as follows:

$\hat{\alpha} = 0.576$ and $\hat{\beta} = 1.50$ (α/β is 0.384 mm per month).

The best-fit models for the cumulative distribution function associated with the length of RCF processes are shown in Figure 8.

Average length of the rail repaired emergently is $L = 8$ meters (Patra, 2009). The cost of 60E1 railway track (including neutralization) per meter is 2,250 Monetary Unit (MU). Average labour cost per hour (including the track worker cost, track welder cost, and inspection personnel cost) is 625 MU. The hourly rate of hiring the welding equipment or service vessels for maintenance, replace or inspection of the railway track is 80 MU. The mean time required to perform a maintenance (either corrective or preventive) is 4 hours. However, the corrective type may cause traffic disruption that incurs an additional cost η to the route operator. The physical lifetime of 60E1 railway track is considered to be equal to six years (72 months). We wrote a MATLAB code for the minimization of the expected cost rate, as given in Eq. (17), to determine the optimal preventive NDT inspection interval T^*. The pictorial representation of the expected cost rate as a function of the inspection interval T for three different cases of (i) $\eta = C_r - C_I = 0$; $\eta = 5{,}000$, and $\eta = 10{,}000$ MU is shown in Figure 9. From Figure 9, it is found that the use of optimal prognostic inspection policy allows a significant reduction of the maintenance cost compared to the strategy when only emergency repair is considered (the corresponding cost is the asymptote of the path, when T tends to T_{max}). The optimal value of T^* and the corresponding expected cost rate, $CR(T^*)$ the expected cost rate for corrective maintenance policy, $CR(T_{max})$, and the percentage reduction of the maintenance cost, r are presented in Table 1.

It can be seen that as the cost parameter η increases, the optimal NDT inspection interval T^* becomes shorter, however the expected cost rate, $CR(T^*)$ increases. Also, when a large additional cost is likely to be incurred by the infrastructure

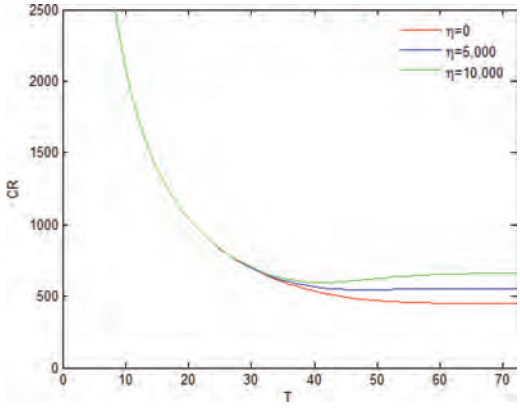

Figure 9. Expected cost rate for different values of η.

Table 1. Results of the optimization model for different values of η.

	Unit	$\eta = 0$	$\eta = 5{,}000$	$\eta = 10{,}000$
T^*	month	72	49	42
$CR(T^*)$	MU / month	448.38	546.40	594.81
$CR(T_{max})$	MU / month	448.38	554.94	661.49
Cost reduction	%	0	1.54	10.08

owner in emergency maintenance case, applying the prognostic inspection policy will be more efficient than corrective repair and has a huge potential to reduce the maintenance cost. For instance, when the cost parameter η is 10,000, the prognostic maintenance policy allows for approximately %10 reduction of the maintenance cost compared to the corrective repair policy.

4 CONCLUSIONS

In this paper, an optimal prognostic Non-Destructive Testing (NDT) and inspection policy is presented for railway track systems subject to progressive Rolling Contact Fatigue (RCF). The RCF phenomenon was modelled by means of Finite Element Analysis (FEA) and the fatigue propagation behavior was described by the Paris-Erdogan power law function. The length/size/depth of the RCF processes over time was formulated by a stochastic gamma process and a preventive inspection was conducted before the length/size/depth of cracks exceeds a "warning" level. This study can be extended in many directions to make it more practical in maintenance management of railway industry. The model can be formulated and analyzed for the case when RCF is only detected if its length/size/depth reaches a detection threshold c (> 0); and, a cost comparison can be made between the proposed prognostic inspection policy and other common strategies such as RCM.

ABSTRACT: Accelerated Degradation Testing (ADT) is used to collect more performance degradation data under accelerated stress levels in a limited time. However, limited sample size or inadequate testing time may lead to the lack of degradation information, which causes inaccuracy of the evaluation of the lifetime. High Accelerated Life Test (HALT), High Accelerated Stress Screen (HASS) are common testing methods, whose information should be considered in evaluation of the lifetime and reliability. In this paper, Methodology for Integration of HALT, HASS and ADT (MIHHA) is proposed as the method with the multi-utilization of HALT, HASS and ADT. One difficulty of MIHHA is how to integrate the information of HALT, HASS and ADT to provide crucial information for product life prediction. We propose an evaluation method of MIHHA which integrated degradation information of HLAT, HASS into ADT evaluation based on Bayesian theory. This method would be a great help to the engineering application of MIHHA.

1 INTRODUCTION

During the past decades, Accelerated Degradation Testing (ADT) has drawn much more attention in both industry and academia, which can collect more performance degradation data under accelerated stress levels in a limited time (Ge et al. 2012). It is convenient to establish model of reliability and life assessment with degradation information through ADT technique. However, sometimes limited sample size or inadequate testing time may lead to the lack of degradation information, which causes inaccuracy of the evaluation of the lifetime and reliability. Usually, Highly Accelerated Life Testing (HALT) and highly Accelerated Stress Screening (HASS) are mainly applied in qualitative method to improve the reliability of products (Liu et al. 2016). But the information of HALT and HASS can make up for the lack of ADT information very well. Based on this, Methodology for Integration of HALT, HASS and ADT (MIHHA) was proposed to coordinate the design of HALT, HASS, ADT, and collect more information under the limited time and samples.

The different between ADT and MIHHA is MIHHA contains information of HALT, HASS. The key issue of MIHHA is how to integrate the information of HALT, HASS into ADT to predict reliability or lifetime of product. As quality and reliability of product improved, there was less failure in HALT and HASS. People pay more attention to the degradation information in HALT and HASS (Gray & Paschkewit, 2016). In this article, we consider to make full use of degradation information of HALT and HASS in evaluation method of MIHHA.

Bayesian inference is an important technique in statistical inference (Box & Tiao 1992). In Bayesian inference of ADT evaluation method, the degradation data of HALT and HASS can be regard as the prior information and degradation data of ADT can be considered as the sample information. The theory of Bayesian can successfully integrate degradation data of HALT, HASS into ADT evaluation method. To solve the problem that there are two sources of prior information come from HALT and HASS, a weighting fusion method is adopted to integrate them into one prior distribution based on correlation function. The technology roadmap of the evaluation method of MIHHA with integrated degradation information of HLAT, HASS is shown in Fig. 1.

In conclusion, this article proposes an evaluation method of MIHHA based on Bayesian inference, which integrated degradation information of HLAT, HASS and ADT. The evaluation method

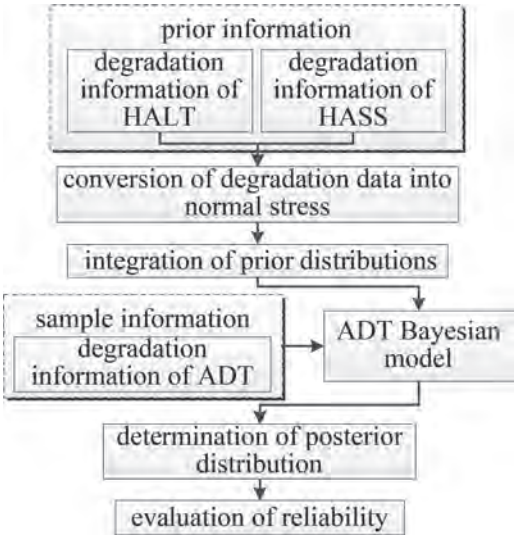

Figure 1. Technology roadmap of the evaluation method of MIHHA.

of MIHHA can make full use of various sources of information and improve the engineering application value of MIHHA.

2 BAYESIAN INFERENCE OF ADT MODEL

ADT Model and the relationship of parameters in Bayesian inference are essential parts of the evaluation method and integration method. In this paper, we describe the degradation paths through Wiener process and give the relationship of ADT model and parameters in Bayesian inference.

2.1 *ADT model based on Wiener process*

Wiener process is used for degradation data analysis widely (Whitmore & Schenkelberg 1997). The degradation model of Wiener process can be expressed as:

$$Y(t) = \sigma B(t) + d(s) \cdot t + y_0 \tag{1}$$

where $Y(t)$ is the performance degradation process of product, $B(t)$ means the standard Brownian motion, denoted as $B(t) \sim N(0,t)$, σ is a constant named diffusion coefficient, which is free from changes caused by stress or time. y_0 represents initial value of product performance. $d(s)$ means the drift coefficient, which represents the degradation rate of product under specific stress level s. Normally we use acceleration model to describe the relationship between $d(s)$ and s (Zou, T.J., et al., 2015). This article defines acceleration model as:

$$\ln d(s) = a + b\varphi(s) \tag{2}$$

where, $\varphi(s)$ is a function of stress s. Known from the property of the Wiener process, the degradation increment Δy during the unit time Δt is subject to a normal distribution with the mean of $d(s) \cdot \Delta t$ and the square deviation of $\sigma^2 \cdot \Delta t$, i.e., $\Delta y \sim N(d(s) \cdot \Delta t, \sigma^2 \cdot \Delta t)$. The probability density function of Δy is:

$$f(\Delta y) = \frac{1}{\sigma\sqrt{2\pi\Delta t}} \exp\left\{ -\frac{\left[\Delta y - d(s) \cdot \Delta t\right]^2}{2\sigma^2 \cdot \Delta t} \right\} \tag{3}$$

The literature (Whitmore & Schenkelberg 1997) suggests that the first passage time of Wiener process to a threshold follows the inverse Gaussian distribution. We assume y_f as the failure threshold of performance degradation. In other word, product failures when $Y(t) - y_f < 0$. Thus, the key of ADT evaluation method turn to the calculation of probability distribution of the first passage time t to the threshold y_f. The probability density function of the inverse Gaussian distribution with the mean $\mu = ((y_f - y_0)/d(s))$ and the shape parameter $\lambda = (y_f - y_0/\sigma)^2$ is:

$$f(t; y_0, y_f) = \frac{y_f - y_0}{\sigma\sqrt{2\pi t^3}} \exp\left\{ -\frac{\left[(y_f - y_0) - d(s) \cdot t \right]^2}{2\sigma^2 t} \right\} \tag{4}$$

The reliability function of degradation process (Lu, J., 1995) is given by:

$$R(t) = \Phi\left[\frac{y_f - y_0 - d(s)t}{\sigma\sqrt{t}} \right] - \exp\left(\frac{2d(s)(y_f - y_0)}{\sigma^2} \right) \cdot \Phi\left[-\frac{y_f - y_0 + d(s)t}{\sigma\sqrt{t}} \right] \tag{5}$$

From the reliability function above, the unknown parameters a,b,σ are the key parameters in ADT evaluation method, which are also known as prior parameters in Bayesian inference. We assume $\boldsymbol{\theta}$ as the prior parameter vector of model, i.e. $\boldsymbol{\theta} = (a,b,\sigma)$. The relationship of ADT model and prior parameters is shown in the Fig. 2.

If prior parameters are obtained, it is easy to accomplish the evaluation of lifetime and reliability (Wang et al. 2016). The crux of evaluation method of MIHHA is how to obtain reasonable valuations of prior parameters through degradation information of HLAT, HASS and ADT.

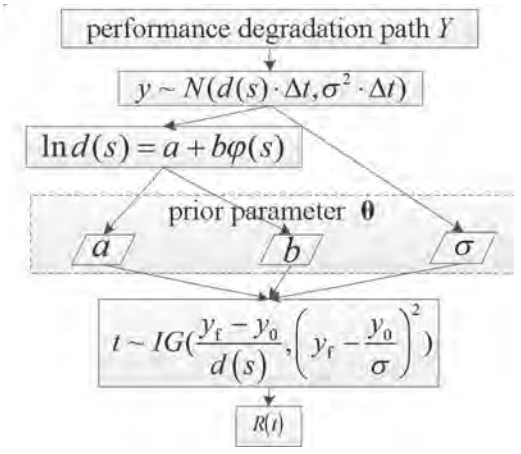

Figure 2. The relationship of ADT model and prior parameters.

2.2 *Bayesian inference of ADT model*

Bayesian inference is an important technique in statistical inference. Normally, we use Bayesian theorem to update the probability for a hypothesis as more evidence or information becomes available (Wang et al. 2016). It is suitable for integrating degradation information of HLAT, HASS and ADT in evaluation method. Bayesian inference is particularly important in the dynamic analysis of a sequence of data. Through Bayesian inference, this article can obtain the posterior distribution of the parameters to evaluate lifetime and reliability of product with degradation information of HALT, HASS and ADT.

In this paper, the observed data x (also known as sample information) can be obtained from degradation data of ADT and degradation data of HLAT, HASS can be regarded as prior information. The posterior distribution is the distribution of the parameters after taking into account the observed data, which combines the observed data and the prior information and forms the core of Bayesian inference. With the observed data x, the Bayesian theory suggests that the posterior distribution of parameters can be expressed as:

$$\pi(\theta \mid x) = \frac{\pi(\theta)\cdot p(x \mid \theta)}{\int_{\Theta} \pi(\theta)\cdot p(x \mid \theta) d\theta} \tag{6}$$

where, Θ is value range of θ. $\pi(\theta)$ is the prior distribution. $p(x|\theta)$ is the distribution of the observed data conditional on its parameters, which is termed the sampling distribution or likelihood function. In this paper, it is expressed as:

$$p(x \mid \theta) = \frac{1}{\sqrt{2\pi\sigma^2\Delta t}} \exp\left\{ -\frac{\left[x - \exp(a + b\cdot\varphi(s))\cdot\Delta t \right]^2}{2\sigma^2\Delta t} \right\} \tag{7}$$

3 INTEGRATION OF PRIOR DISTRIBUTIONS

3.1 *Integrate degradation information from HALT and HASS*

Before the integration, we should make sure that the degradation data from HALT, HASS and ADT meet the following conditions: 1) the degradation data from HALT, HASS and ADT should belong to the same performance parameter. 2) the degradation mechanism of performance degradation data from HALT, HASS and ADT should be the same (Wang et al. 2013).

The degradation data of HLAT, HASS can be regarded as prior information. Thus, we assume $\pi_1(\theta)$ represents the prior distribution obtained from degradation information of HALT and $\pi_2(\theta)$ represents the prior distribution obtained from degradation information of HASS. For there are two prior distributions about parameters, a weighting fusion method is adopted to integrate into one prior distribution. Through using the weight coefficient α_1 and α_2, the prior distribution after integration is expressed as:

$$\pi(\theta) = \alpha_1\pi_1(\theta) + \alpha_2\pi_2(\theta) \tag{8}$$

where, the weight coefficient α_1 and α_2 are constrained by formula as follow:

$$\alpha_1 + \alpha_2 = 1 \tag{9}$$

According to the Bayesian theory, the posterior distribution after integration is expressed as:

$$\pi(\theta \mid x) = \frac{\alpha_1\pi_1(\theta)\, p(x \mid \theta) + \alpha_2\pi_2(\theta)\, p(x \mid \theta)}{\int_{\Theta} \alpha_1\pi_1(\theta)\, p(x \mid \theta) + \alpha_2\pi_2(\theta)\, p(x \mid \theta)\, d\theta} \tag{10}$$

It can be transformed into:

$$\pi(\theta \mid x) = \frac{\alpha_1 m_1(x)}{m(x)}\cdot\pi_1(\theta \mid x) + \frac{\alpha_2 m_2(x)}{m(x)}\cdot\pi_2(\theta \mid x) \tag{11}$$

where, $\pi_1(\boldsymbol{\theta}|x)$ and $\pi_2(\boldsymbol{\theta}|x)$ represent the posterior distribution of HALT and HASS independently.

$m(x)$ is known as the posterior predictive distribution, which is the distribution of a new data point, marginalized over the posterior:

$$m_i(x) = \int_{\Theta} \pi_i(\theta)\, p(x|\theta)\, d\theta \quad i = 1,2 \tag{12}$$

$$m(x) = \alpha_1 m_1(x) + \alpha_2 m_2(x) \tag{13}$$

Here, we assume:

$$\beta_i = \frac{\alpha_i m_i(x)}{m(x)} \tag{14}$$

So we can easily reach the conclusion:

$$\beta_1 + \beta_2 = 1 \tag{15}$$

And, the expression of posterior distribution after integration is transformed into formula (16), which is a weighted equation of posterior distributions with the weight coefficient β_1 and β_2.

$$\pi(\theta|x) = \beta_1 \pi_1(\theta|x) + \beta_2 \pi_2(\theta|x) \tag{16}$$

3.2 *Calculation based on correlation function*

Correlation function is a function that gives the statistical correlation between random variables. Sometimes correlation functions of different random variables are referred to as cross-correlation functions to emphasize that different variables are being considered. Through analyzing the correlation function, the correlativity between posterior distributions and prior distributions can be weighted.

In this paper, we set u_i as the mean of $\pi_i(\theta)$, u_i' as the mean of $\pi_i(\theta'|x)$. According to the formula(16), the mean of posterior distribution $\pi(x|\theta)$ can be descried as:

$$u' = \beta_1 u_1' + \beta_2 u_2' \tag{17}$$

Then we assume three equations as follow to describe the correlativity between prior and posterior distributions.

$$\begin{cases} u' = a_0 + a_1 u_1 + a_2 u_2 \\ u_1' = a_{01}' + a_{11}' u_1 + a_{21}' u_2 \\ u_2' = a_{02}' + a_{12}' u_1 + a_{22}' u_2 \end{cases} \tag{18}$$

There are three unknown coefficients in each equation in formula(18). Through simulation sampling, three groups of random data are obtained. So we can get three group of estimated value of u_i, u_i', u' to solve the equations.

We $v_i'^2$ as the square deviation of $\pi_i(\theta|x)$. The correlation function defined as (Wang et al. 2013):

$$r_i = \frac{d_{1i}' a_1 v_1'^2 + d_{2i}' a_2 v_2'^2}{\sqrt{d_{1i}'^2 v_1'^2 + d_{2i}'^2 v_2'^2} \cdot \sqrt{a_1^2 v_1'^2 + a_2^2 v_2'^2}} \quad i = 1,2 \tag{19}$$

From the formula(19) we can see $0 \le r_i \le 1$. A lager r_i means $\pi_i(\theta|x)$ is more closely associated with $\pi(\theta|x)$, which illustrates that $\pi_i(\theta)$ should have a stronger weight in $\pi(\theta)$. The weight coefficient α_1 and α_2 of prior distributions are obtained by formula (20):

$$\alpha_i = \frac{r_i}{r_1 + r_2} \quad i = 1,2 \tag{20}$$

With the values of α_i, we can easily obtain the posterior distribution $\pi(x|\theta)$ after integration. According to the reliability function of ADT, it is easy to achieve the evaluation of ADT.

4 A SIMULATION EXAMPLE

4.1 *Data simulation*

Accelerated test conditions are typically produced by testing units at higher levels of temperature, voltage, pressure, etc (Nelson 1971). In this paper, we assume the degradation process is mainly affected by high temperature. Arrhenius model is suitable to describe the relationship between the degradation rate and temperature (Alferink 2012), which means $\varphi(s) = 1/(s + 273.15)$. s is Celsius temperature.

In order to verify the effectiveness of the evaluation method of MIHHA, we simulated 240 degradation data points for each of the 6 samples under HALT and 30 degradation data points for each of the 6 samples under HASS. Performance monitor interval, ie.Δt, is one minute. Fig. 3 shows the degradation paths under different high-temperature level in HALT. Fig. 4 shows degradation paths of high temperature at 120°C involving vibration synchronously under different cycle in HASS. Both data of Fig. 3 and Fig. 4 are the prior information in Bayesian inference.

Then, we simulated a 2-day Step Stress ADT (SSADT) with 2880 degradation data points for each of the 6 samples under as observed data or sample information. Fig. 5 shows the degradation paths of SSADT under different stress.

According to the formula (2), we can convert all the degradation data under accelerated stress into the degradation data of 25°C by method of linear regression. The equivalent Δt_i at 25°C are shown in the Table 1. We can obtain the $d(s) \cdot \Delta t$ at 25°C of different samples under HALT, HASS and ADT through $\Delta y / \Delta t_i$.

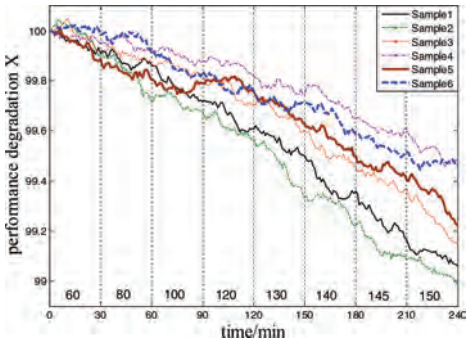

Figure 3. The degradation paths of high-temperature test in HALT.

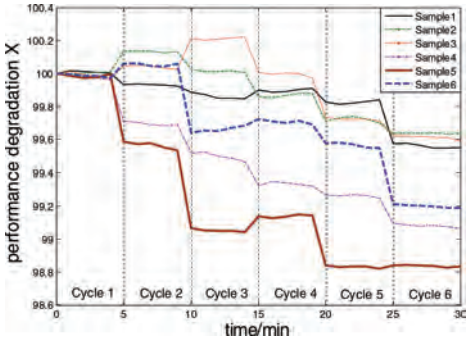

Figure 4. The degradation paths of high temperature vibration synthesis test in HASS.

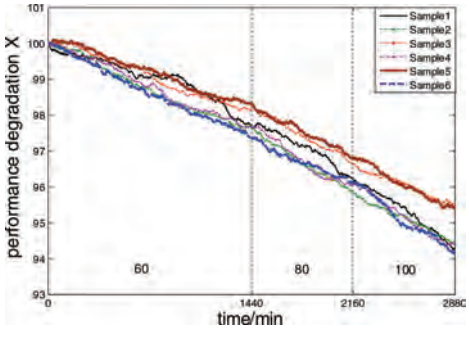

Figure 5. The degradation paths of SSADT.

4.2 *Integration of prior distributions*

As all the data have be converted into the data of 25°C, we can set $d(s) \cdot \Delta t$ as prior parameter replace a and b to reduce the calculation. The prior information is obtained from the distribution data of HALT and HASS as show in the Table 2.

With the help of Matlab, we simulate three groups of random samples from prior distribution

Table 1. Conversion factors of Δt_i

Accelerated stress	Δt/min	Equivalent Δt_i at 25°C/min
60°C	1	1.447711
80°C		1.730614
100°C		2.029593
120°C		2.341943
130°C		2.502343
140°C		2.665169
145°C		2.747404
150°C		2.830144

Table 2. Prior distributions.

Prior parameters	$d(s) \cdot \Delta t$	$\sigma^2 \cdot \Delta t$
HALT	N(0.0014, 0.00041)	N (2.34e-05, 2.61e-06)
HASS	N(0.0098, 0.0047)	N (1.21e-03, 9.19e-04)

$\pi_1(d(s) \cdot \Delta t)$, $\pi_1(\sigma^2 \cdot \Delta t)$, $\pi_2(d(s) \cdot \Delta t)$, $\pi_2(\sigma^2 \cdot \Delta t)$ and posterior distribution $\pi_1(d(s) \cdot \Delta t|x)$, $\pi_1(\sigma^2 \cdot \Delta t|x)$, $\pi_2(d(s) \cdot \Delta t|x)$, $\pi_2(\sigma^2 \cdot \Delta t|x)$ to calculate the value of three unknown coefficient in each equation in formula (18). Final, the posterior distributions after integration are obtained as the formulas shows:

$$\pi\left(d(s) \cdot \Delta t \mid x\right) = 0.9408\pi_1\left(d(s) \cdot \Delta t \mid x\right) + 0.0592\pi_2\left(d(s) \cdot \Delta t \mid x\right) \tag{21}$$

$$\pi\left(\sigma^2 \cdot \Delta t \mid x\right) = 0.9054\pi_1\left(\sigma^2 \cdot \Delta t \mid x\right) + 0.0946\pi_2\left(\sigma^2 \cdot \Delta t \mid x\right) \tag{22}$$

From the formula (21) and formula (22), we can see that there is a heavier weight coefficient of HALT than HASS, which illustrating the degradation information of HALT is more relevant to the observe data of ADT in the simulation example.

4.3 *Evaluation of reliability*

Through the posterior distribution after integration, we can obtain the assessed value of key parameters in reliability function:

$$\hat{\theta} = E\left(\theta \mid x\right) = \xi_1 E_1\left(\theta \mid x\right) + \xi_2 E_2\left(\theta \mid x\right) \tag{23}$$

where, E represents the mean of the posterior distributions.

We assume the initial value of product performance $y_0 = 100$ and the failure threshold of performance degradation $y_f = 50$. The evaluation

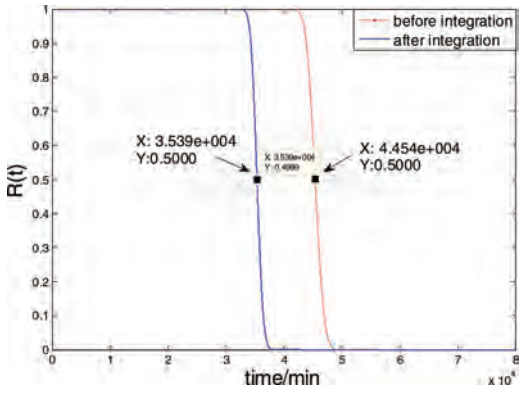

Figure 6. Evaluation of reliability before and after integration.

of reliability can be calculated by formula (5). To compare the different between evaluation results with information of HALT and HASS or not, the results of reliability before and after integration are showed in the Fig. 6.

The red line in Fig. 6 indicates the evaluation of reliability before integration, which is obtained from the information of ADT only. It represents the traditional ADT evaluation method. The blue line means the evaluation of reliability after integration, which integrated the information of HALT, HASS and ADT. It represents the evaluation method of MIHHA. From the Fig. 6 we can take the conclusion that the medium life is diminished after integration. We can hold the opinion that the evaluation result of MIHHA updates the evaluation result of ADT with information of HALT and HASS through Bayesian inference. Thus, the evaluation method of MIHHA contains more information than ADT; it can be a better indicator of reliability level of product.

5 CONCLUSION

Directing against the existing problem that ADT may lack degradation information for limited sample size or inadequate testing time, this article proposes an evaluation method of MIHHA. It solves the key issue of MIHHA that how to integrate HALT, HASS into ADT to predict reliability or lifetime of product. First, an ADT model based on Wiener process is proposed and the prior parameters are given. Then, based on the framework of Bayesian inference, the degradation information of HALT, HASS is regarded as prior information and the degradation information of ADT is considered as observed data. Through the prior information and observed data, we can obtain the posterior distribution which integrated the information of HALT, HASS and ADT. Third, the degradation information of HALT and HASS are integrated into one prior distribution based on weighting fusion method and the correlation function is adopted to calculate the weight coefficient of HALT and HASS, which solving the problem that the prior information comes from two sources. Finally, a simulation example is given to prove the feasibility of the evaluation method of MIHHA.

The evaluation method of MIHHA integrates degradation information of HALT, HASS and ADT. It provides a new path for evaluation method of product which makes full use of the information of HALT and HASS. This method would be a great help to the promotion and application of MIHHA.

Structural damage detection by integrating short time fourier transform, principal component analysis and logistic regression

Anand Kumar Agrawal & G. Chakraborty
Systems, Dynamics and Control Laboratory, Department of Mechanical Engineering, Indian Institute of Technology-Kharagpur, India

ABSTRACT: The aim of this work is to present a novel methodology for damage detection in a structure. In this method, new features based on Short Time Fourier Transform are used, dimensionality reduction was carried out by Principal Component Analysis and the classification was performed using Logistic regression. The efficacy of this method is demonstrated by detecting the presence of damage in a cantilever beam using the features based on transformation of displacement response.

Even though the difference between the displacement waveforms from damaged and the undamaged beam is not clearly perceptible, the difference is clearly visible in the principal components' space. Data belonging to damaged and undamaged classes are linearly separable up to a certain level of noise after which linear separability is lost. A linear decision boundary was obtained corresponding to a particular noise level after the mean normalization and feature scaling of the data. Feasibility of dimensionality reduction is ensured by checking the loss percent in the reduction process. And generalization ability of the classifier has been assessed on some test sets.

1 INTRODUCTION

Structural Health Monitoring (SHM) has been studied as a potential way to improve safety and reliability of various mechanical, aerospace and civil infrastructures. Current SHM techniques process dynamic responses of a structure in order to detect, localize or find out the extent of damage (Farrar & Worden 2013). There are two approaches for SHM i) The Model based and ii) The Data driven approach. In model based approach, the system is modeled based on its physics using a suitable modeling technique. Further the updating of this model is carried out using the field data. During this updating, initial model is tuned in a way that it produces outputs which match well with the real data. Eventually after updating stage a reasonably accurate model of the healthy system is obtained. Now the characteristics of the damage will be indicated in the form of change in parameter values on further updating using data from the monitoring stage. On the other hand in data driven approach instead of using a physics based model, the data obtained from the system is used to develop a statistical model for classification to achieve diagnosis. Major steps involved in the data driven approach are 1) Measurement of dynamic response 2) Feature extraction 3) Dimensionality reduction 4) Classification and 5) Prognosis. They are followed in sequence as shown in Figure 1.

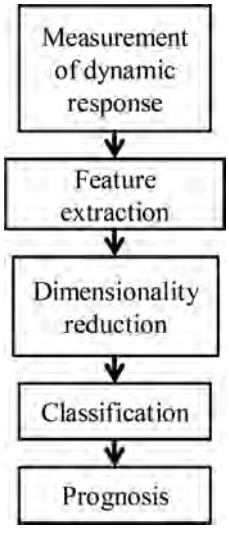

Figure 1. Major steps in SHM.

It is expected that accurate damage detection will require successful feature extraction, dimensionality reduction and signal classification. Appropriate selection of features and classification algorithm for an application depends on the nature of the dataset at hand. No single classification method can be preferred over others to

achieve good generalization. (Duda et al. 2001). Similarly by *Ugly duckling theorem*, no features can be called as best features irrespective of the application (Duda et al. 2001). Consequently many different classification methods and feature sets are explored in the SHM literature to suit a particular application. For example (Zhou et al. 2013) proposed a methodology for damage detection based on integrating data fusion and random forests. They used energy features extracted using wavelet packet transform for training. (He & Yan 2007) suggested a method where the classification was carried out using a wavelet based support vector machine and the feature extraction was done from wavelet energy spectrum constructed using wavelet packet transform. (Satpal et al 2016) have used support vector regression for localization of the damage using displacement values corresponding to first mode shape as the features. Although new methodologies are continually being proposed for damage detection still there are many to be explored. Damage detection accuracy can depend not only on the individual techniques used for feature extraction and classification but also on their various combinations.

The aim of this work is to present a novel methodology for damage detection in a structure. In this method, new features based on Short Time Fourier Transform (STFT) are used, dimensionality reduction is carried out by Principal Component Analysis and the classification is performed using Logistic regression. The efficacy of this method is demonstrated by detecting the presence of damage in a cantilever beam using the features based on transformation of displacement response obtained from a model of the beam.

Even though the difference between the displacement waveforms from damaged and the undamaged beam is not clearly perceptible, the difference is clearly visible in the principal components' space. Data belonging to damaged and undamaged classes are linearly separable up to a certain level of noise after which linear separability is lost. A linear decision boundary has been obtained for a particular noise level after the mean normalization and feature scaling of the data. Feasibility of dimensionality reduction is ensured by checking the loss percent in the reduction process. And generalization ability of the classifier has been assessed on some test sets.

2 METHODOLOGY

In this section the mathematical formulation of each step taken toward damage detection is provided.

2.1 *Data generation*

The purpose of this step is to acquire multiple signals (displacement time history) from a damaged and an undamaged beam. Here damaged and undamaged conditions are two different classes for which the classifier has to be designed. In a data driven approach the data are obtained either by carrying out experiments or with a reliable model. In this case we model the damaged beam based on Euler-Bernoulli hypothesis. The task of producing multiple signals has been accomplished as follows. Firstly the variational formulation of the damaged beam (shown in Figure 2) was done using Hamilton's principle and application of Ritz method to obtain the approximate response/signal. Subsequently the above signal was mixed with noise to obtain multiple signals corresponding to damaged beam with different damage locations. To get multiple signals for undamaged beam the damage size was substituted to be zero and the corresponding signal was mixed with noise. The mathematical formulation of this process is described below.

$$\text{By Hamilton's Principle: } \delta\int_{t_1}^{t_2}\left[K-U+W\right]dt=0 \qquad (1)$$

where, Kinetic energy, $K=\frac{\rho}{2}A\int_{0}^{L_1+\Delta L+L_2}\left(\frac{\partial w}{\partial t}\right)^2 dx-\frac{\rho}{2}b\delta\int_{L_1}^{L_1+\Delta L}\left(\frac{\partial w}{\partial t}\right)^2 dx$ Potential energy, $U=\frac{EI}{2}\int_{0}^{L_1+\Delta L+L_2}\left(\frac{\partial^2 w}{\partial x^2}\right)^2 dx-\frac{E\Delta I}{2}\int_{L_1}^{L_1+\Delta L}\left(\frac{\partial^2 w}{\partial x^2}\right)^2 dx$ Workdone by external forces, $W=f(t)w\left(x=L_1+\Delta L+L_2\right)$ where, ρ = desity, E = Young's modulus, I = moment of inertia

$f(t)$ = exitation force

w = deflection of the centreline of the beam

A = area of cross section

x is the direction along the length with its zero at the fixed end

To get the response using Ritz method we assume

$$w(x,t)=\{H\}^T\{p\}$$

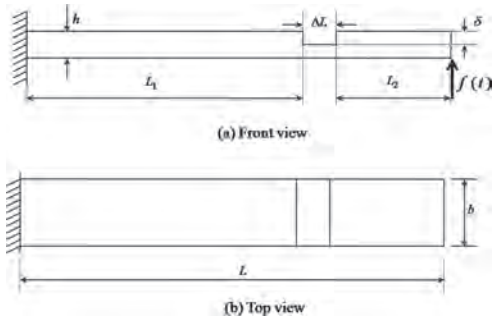

Figure 2. Beam geometry.

where, $\{H\}=\left[H_1(x),H_2(x)...H_N(x)\right]^T$ consisting of N linearly independent admissible functions. Such that $H_i(x)=\left(\frac{x}{L}\right)^2\left(1-\frac{x}{L}\right)^{i-1}, i=1,2,...,N$ & $\{p\}=\left[p_1(t),p_2(t),...p_N(t)\right]^T$ here $p_1(t),p_2(t),...p_N(t)$ are unknown coordinate functions.

The following equation is finally obtained

$$\left[\left[M_1\right]-\left[M_2\right]\right]\{\ddot{p}\}+\left[\left[K_1\right]-\left[K_2\right]\right]\{p\}=f(t)\{H\}_{x=L_1+\Delta L+L_2} \quad (2)$$

where,

$$\left[M_1\right]\triangleq\int_0^{L_1+\Delta L+L_2}\rho A\{H\}\{H\}^T dx,\left[M_2\right]\triangleq\int_{L_1}^{L_1+\Delta L}\rho b\delta\{H\}\{H\}^T dx$$

$$\left[K_1\right]\triangleq\int_0^{L_1+\Delta L+L_2}EI\{H\}''\{H\}''^T dx,\left[K_2\right]\triangleq\int_{L_1}^{L_1+\Delta L}E\Delta I\{H\}''\{H\}''^T dx$$

The above equations are subsequently solved.

The output from the sensor placed at $x = x_0$, is $w(x_0,n)=\{H\}^T_{x=x_0}\{p\}$, which is the required signal when the damage is at a location L_1 from the fixed end as shown in Fig. 2. By changing the location L_1 one can get signals corresponding to different damage locations. But, when these signals are acquired experimentally, the signal is bound to get distorted by noise. To simulate the real experiment the noise is added to the original signal giving multiple signals corresponding to each damage location. Similarly, one can get multiple signals from an undamaged beam as well. The process of mixing noise to the deterministic signal is expressed mathematically as

$$w_{\text{new}}(x_0,n)=\Psi(w(x_0,n),SNR)$$

where, Ψ is a function which adds noise to $w(x_0, n)$ with signal to noise ratio being *SNR*.

2.2 *Feature extraction*

Step 1: The set of time domain signals which one gets from data generation step are first transformed to a time-frequency domain signal by using the discrete Short Time Fourier transform (STFT) as shown in Equation 3.

$$S[m,\xi]=\sum_{n=0}^{N_s-1}w_{\text{new}}(x_0,n)\varphi(n-m)e^{\frac{-j2\pi\xi n}{N_s}} \quad (3)$$

where, $\varphi(n)$ is the window function given as:

$$\varphi(n)=\frac{I_0\left(\pi\alpha\sqrt{1-\left(\frac{2n}{\omega-1}-1\right)^2}\right)}{I_0(\pi\alpha)},\ 0\le n\le\omega$$

where, I_0 is the zeroth-order modified Bessel function of the first kind, ω is the width of the window and α is an arbitrary non negative real number that determines the shape of the window.

Step 2: In this step one forms a matrix [*P*] given in equation (4) using the outputs of the STFT given by Equation (3) in this matrix time increases across the columns of [*P*] and frequency increases down the rows, starting from zero.

First, two vectors namely the frequency and time vectors are defined as following:

$$\{F\}=\left[\xi_1,\xi_2,...\xi_{q_r}\right]^T,\ \left(\xi_i<\xi_{i+1}\right)$$

$$\{T\}=\left[m_1,m_2,...m_{q_c}\right],\ \left(m_i<m_{i+1}\right)$$

The entries of [*P*] denoted by $P(m_i, \xi_j)$ is defined as:

$$P\left(m_i,\xi_j\right)=\varsigma\left|S\left(m_i,\xi_j\right)\right|^2$$

where, $\varsigma=\frac{2}{f_s\sum_{n=1}^{\omega}|\varphi(n)|^2}$ when $\xi_i \neq 0$, Nyquist frequency $\varsigma=\frac{1}{f_s\sum_{n=1}^{\omega}|\varphi(n)|^2}$ otherwise

The time and frequency used in equation (3) are taken from $\{T\}$ and $\{F\}$ respectively. Finally the matrix [*P*] looks like

$$[P]=\begin{bmatrix} P(m_1,\xi_1) & P(m_2,\xi_1) & \cdots & P(m_{q_c},\xi_1)\\ P(m_1,\xi_2) & P(m_2,\xi_2) & \cdots & P(m_{q_c},\xi_2)\\ \vdots & \vdots & \cdots & \vdots\\ P(m_1,\xi_{q_r}) & P(m_2,\xi_r) & \cdots & P(m_{q_c},\xi_{q_r}) \end{bmatrix} \quad (4)$$

This matrix has been computed for each of the signals in the data generation step.

Step 3: Subsequently the eigenvalues of $[P]^T[P]$ are calculated and used as initial features. Therefore the data matrix [*X*] is given as:

$$[X]^T=\left[\{x\}_1\ \ \{x\}_2\ \ \cdots\ \ \{x\}_{n_s}\right] \quad (5)$$

where, $\{x\}_k = \left[f_1, f_2, ..., f_{q_c} \right]^T$ and *f, s* are the eigenvalues corresponding to the matrix $[P]^T [P]$ constructed from k^{th} signal and n_s is the number of signals used in training. In other words the rows of the data matrix [*X*] represent the feature vectors corresponding to each signal used in the training.

2.3 *Dimensionality reduction using principal component analysis*

Principal Component Analysis (PCA) attempts to project the data obtained in the feature extraction step into a lower dimensional vector space maintaining the maximum variance possible. The mathematical procedure to obtain such a transformation is as follows.

Step 1: Given the data matrix: [*X*] the variance-covariance matrix can be calculated as:

$$[S] = \begin{bmatrix} \mathrm{var}(F_1F_1) & \mathrm{cov}(F_1F_2) & \cdots & \mathrm{cov}(F_1F_{q_c}) \\ \mathrm{cov}(F_2F_1) & \mathrm{var}(F_2F_2) & \cdots & \mathrm{cov}(F_2F_{q_c}) \\ \vdots & \vdots & \cdots & \vdots \\ \mathrm{cov}(F_{q_c}F_1) & \mathrm{cov}(F_{q_c}F_2) & \cdots & \mathrm{cov}(F_{q_c}F_{q_c}) \end{bmatrix}$$

where, $F_i = [X_{1i}, X_{2i}, X_{3i}, ...X_{n_s i}]^T$ such that X_{ij} is an element of data matrix at i^{th} row and j^{th} column, $\mathrm{cov}(F_iF_j) = \frac{1}{n_s - 1} \sum_{k=1}^{n_s} (F_{ik} - \mu_i)(F_{jk} - \mu_j)$, and $\mathrm{var}(FF) = \frac{1}{n_s - 1} \sum_{k=1}^{n_s} |(F_{ik} - \mu)|^2$

Step 2: Now eigenvalues and eigenvectors of matrix [*S*] are calculated by solving the eigenvalue problem as given in Equation 6.

$$[S]\{v\}_i = \lambda_i \{v\}_i \tag{6}$$

Step 3: Subsequently λs are arranged in descending order as $\lambda_1 \rangle \lambda_2 \rangle \lambda_3 .... \lambda_{q_c}$

Step 4: For dimensionality reduction the first γ Eigen vectors corresponding to the Eigen values which are arranged in descending order were chosen. These Eigen vectors are stacked into a matrix [T] such that

$$[T] = \left[\{v\}_1 \{v\}_2 \{v\}_3 .... \{v\}_\gamma \right] \quad \& \quad \frac{\sum_{i=1}^{\gamma} \lambda_i}{\sum_{i=1}^{n_c} \lambda_i} \geq 0.99$$

The quantity $\left(1 - \frac{\sum_{i=1}^{\gamma} \lambda_i}{\sum_{i=1}^{n_c} \lambda_i} \right) * 100$ is referred as loss percentage.

Step 5: Finally the new data matrix corresponding to the new vector space can be obtained as:

$$[X]_{\text{reduced}} = [T]^T [X]^T \tag{7}$$

Each column of the new data matrix denotes the projection of a point in $\mathbb{R}^{q_c}$ on to the $\mathbb{R}^{\gamma}$. Hence, one gets all the q_c dimensional vectors converted to γ dimensional vectors where $\gamma < q_c$ The proof that the matrix $[T]^T$ indeed projects the data on to a subspace which maximizes the variance can be found in (Bishop 2006). For visualization of the data, γ must be ≤ 3.

2.4 *Classification using logistic regression*

Reduced dimensional feature vectors obtained after the PCA are first mean normalized and scaled and then augmented with unity to create the augmented feature vectors. These augmented feature vectors along with the corresponding class labels are used as training data. Logistic regression uses a hypothesis function given below (Ng 2012). The unknown parameter vector $\{\theta\}$ in the hypothesis function is estimated by optimizing the cost function given in equation (9) using a MATLAB function 'fminunc'. The value of the hypothesis function calculated for a feature vector can be treated as the probability of it belonging to the damaged beam.

Training set:

$$\left\{ \left(\{\chi\}^{(1)}, y^{(1)} \right), \left(\{\chi\}^{(2)}, y^{(2)} \right), \ldots \left(\{\chi\}^{(n_s)}, y^{(n_s)} \right) \right\}$$

Hypothesis function,

$$h_\theta(\{\chi\}) = \frac{1}{1 + e^{-\{\theta\}^T \{\chi\}}} \tag{8}$$

Cost function J($\{\theta\}$) is given as following:

$$J(\{\theta\}) = -\frac{1}{m} \left[\sum_{i=1}^{m} y^{(i)} \log h_\theta \left(\{\chi\}^{(i)} \right) + \left(1 - y^{(i)} \right) \log \left(1 - h_\theta \left(\{\chi\}^{(i)} \right) \right) \right] \tag{9}$$

where, $\{\chi\}^{(i)} = \begin{Bmatrix} 1 \\ c_i \end{Bmatrix}$

such that $\mathbf{c}_i = \begin{Bmatrix} \frac{PC_1^i - meanPC_1}{\sigma_{pc1}} \\ \frac{PC_2^i - meanPC_2}{\sigma_{pc2}} \end{Bmatrix}$

PC_1^i and PC_2^i are the values of 1st and 2nd principal components corresponding to column of matrix $[X]_{reduced}$, mean PC_1 and mean PC_2 are the means of 1st and 2nd principal components, while

σ_{pc1} and σ_{pc2} are the corresponding standard deviations and $y \in \{0,1\}$ n_s is the number of signals used in training, $\{\theta\}$ is the vector of parameters.

Assessment of the classifier was done by creating a test set following the same procedure as in the case of training data, except that during test set creation the noise added to the signals were altered. The accuracy obtained for various test set is tabulated in Table 2. The classifier thus made from the training data can be used for classifying the signal from the real structure.

3 RESULTS AND DISCUSSION

The method explained in the previous sections is now applied to a cantilever beam of the following specifications.

$$L = 45\ cm,\ b = 5.2\ cm,\ h = 0.5\ cm,\ \delta = 0.2\ cm$$

$$L_1 = (5\ cm,\ 10\ cm,\ 15\ cm,\ 20\ cm,\ 25\ \text{cm},\ 30\ cm)$$

$$\Delta L = 0.2\ cm,\ L_2 = L - \Delta L - L_1,\ E = 200\ GPa$$

$\rho = 7850\ kg/m^3$ where the geometric parameters are shown in Figure 2. For simulation of equation (2) the initial conditions were set to zero and the forcing function was a rectangular pulse of small width as shown in Figure 3. The displacement responses for different damaged and undamaged cases are shown in Figure 4. To verify the correctness of the above results the damage size was substituted to be zero in the mathematical model for the damaged beam and the first four natural frequencies obtained through Fast Fourier Transform (FFT) of the response with the ones obtained by analytical formula and ANSYS were compared. The comparison is shown in Table 1. It is clear from Table 1 that all natural frequencies calculated through FFT of the response match reasonably well with the natural frequencies obtained by the analytical formula. On the other hand when compared with the natural frequencies obtained by ANSYS the match is fairly good for the first two natural frequencies but there is a big difference between the third and fourth natural frequencies. The reason for above mismatch for higher frequencies can be attributed to the following reason. In ANSYS the field problem is solved over the entire domain without making any special assumptions as in Euler and Bernoulli's beam theory. It is known that at high frequencies more realistic assumptions like the inclusion of rotary inertia (Rayleigh beam theory) and shear deformation (Timoshenko beam theory) are to be incorporated (Shames 1985). The predicted results of Euler-Bernoulli beam overestimate the correct values. Looking at the displacement signals corresponding to various damage conditions it is almost impossible to figure out any difference between them. Time frequency plots given in Figure 5 do reveal some differences present between the signals. But after the feature extraction and dimensionality reduction by the STFT and PCA respectively a good separation can be seen in the final 2D feature space (principal components' space) as shown in Figure 6.The loss% during PCA is of the order of 10^{-6} which indicates that the data obtained after the feature extraction step has most variance in the first two principal directions. Another interesting thing can be noted in Figure 6 is that there are seven clusters which are

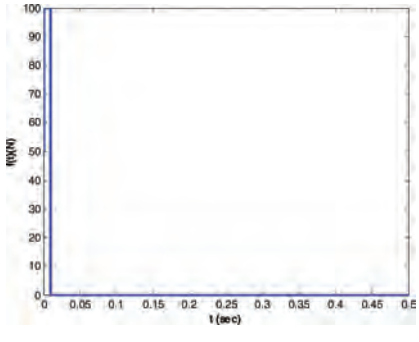

Figure 3. Excitation force.

Table 1. Comparison of natural frequencies.

Natural frequency number	From FFT of the MATLAB response	Analytical	(FEM) ANSYS
1*st*	20 Hz	20.1329 Hz	20.131 Hz
2*nd*	126 Hz	126.17 Hz	126.08 Hz
3*rd*	354 Hz	353.28 Hz	207.21 Hz
4*th*	694 Hz	692 Hz	328.4 Hz

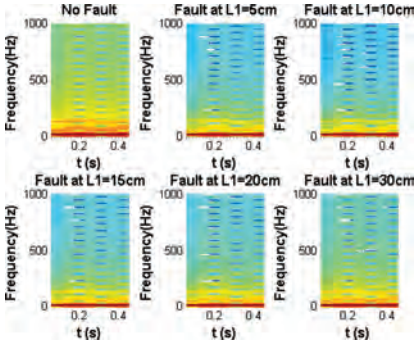

Figure 5. Spectrograms for different damage locations.

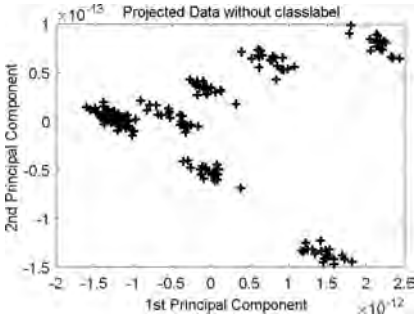

Figure 6. Data obtained after PCA.

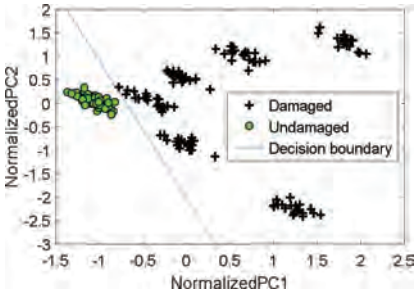

Figure 7. Decision boundary.

indicative of the nature of data set because the data set contains vectors corresponding to the six different damage locations and the undamaged system. Decision boundary obtained using logistic regression for training data obtained by mixing noise of $SNR = 91$ is shown in Figure 7. It can be noticed from Figure 7 that the accuracy obtained on the training set is 100%. Generalization assessment performed by calculating the accuracy achieved on different test sets in given in Table 2. It is clear that the accuracy achieved on test sets created with SNR ≥ 91 is 100% on the other hand the accuracy is 98.89% with the SNR = 90 in the test set. Hence the classifier is working quite well on the data outside the training set.

Table 2. Accuracy achieved for various test sets.

SNR	No. of test points	Accuracy
90	90	98.89%
91	90	100%
92	90	100%

4 CONCLUSION

The proposed structural damage detection methodology is based on integrating techniques used in the field of Signal processing and Machine learning in a novel way, but the combination of the methods and the features proposed are new. New features based on the Short Time Fourier Transform of the response signal have been successfully used to detect the presence of a damage in a beam. As these features are able to discriminate between the damaged and undamaged beams they can also be used with classifiers other than the one presented here. In addition, the method is also capable of capturing the characteristic of the data by creating different clusters in the principal components' space for different damage location indicating the possibility of damage localization as well. The assessment of the classifier showed the accuracy of 100% on the test sets with $SNR \geq 91$ and 98.89% for $SNR = 90$.

Fault diagnosis and remaining useful life prediction of multiple deteriorating components in hybrid dynamical system

Om Prakash, A.K. Samantaray & R. Bhattacharyya
Systems, Dynamics and Control Laboratory, Department of Mechanical Engineering, Indian Institute of Technology, Kharagpur, India

ABSTRACT: A Hybrid Dynamical System (HDS) includes a set of continuous dynamics in which a particular continuous dynamics is activated at a particular set of discrete events, termed as mode of the system. Thus, a different mode triggers a different continuous dynamics. Degradation evolutions of the components of HDS depend on the operating mode of the system. Thus, the existing approaches for continuous systems are not suited for Remaining Useful Life (RUL) prediction for HDS. In addition, a discrete mode fault may be possible besides the parametric faults (abrupt or progressive nature). This article presents an integrated approach to Fault Diagnosis (FD) and RUL prediction of multiple deteriorating components in an HDS. For improving FD scheme, dynamic fault signature matrices are utilized for parametric and discrete mode fault isolation, which minimize the possible suspected faults by using the possible deviation direction of the faults. If the detected fault is progressive in nature, then the FD scheme is further utilized to point out the severity change points of the degradation. Using the knowledge of each severity change points and the deviation direction of progressive fault, constrained parameter estimation method with dynamically updated parameter's bound is proposed for fast degradation states estimation. The estimates of the degradation at different time instances in a respective operating mode are further utilized for mode-dependent degradation model identification and RUL prediction. An online degradation model selection scheme is proposed for degradation model identification in different operating modes. The proposed method is able to identify the degradation model of multiple degrading components in a real time at different operating modes and can be adapted with new information of their degradation states estimated by the constrained parameter estimation during continuous monitoring. The proposed approach is demonstrated through numerical simulation of an example hybrid dynamical system.

1 INTRODUCTION

Nowadays, due to advances in technology and modern control systems, most of the process engineering systems, like drinking water systems, chemical process engineering systems, etc., can be best modeled as hybrid dynamical systems (HDS). Fault diagnosis (FD) and remaining useful life (RUL) prediction of HDS are complicated because the dynamical behaviour of such system is governed by a specific combination of discrete modes (autonomous mode or supervisory controller mode) (Narasimhan & Biswas, 2007; Wang et al. 2013; Borutzky, 2015). These systems show different continuous dynamics in different modes. Most of the existing FD and RUL prediction approaches (Medjaher & Zerhouni, 2009; Jha et al., 2016) are typically developed for continuous dynamical systems and assume the occurrence of single fault with constant rate of degradation throughout the components life cycle. However, many faults may be possible during the continuous operation of a system and RULs of all such faulty components must be provided to the plant engineers for the decision making and maintenance scheduling. Generally, component's degradation is a slow process where the degradation severity level changes in the time units of hours, days, weeks, months, or even years depending on the type of the system, its dynamics and the environmental conditions. These severity change time points for different components may be different, i.e., different components degrade at different rates. The existing approaches may not be easily applied to HDS since the degradation progress in the faulty components depend on system operating mode and the existing approaches may fail to diagnose the actual faulty components due to single fault assumption. Thus, the switching behavior of the system and possibility of occurrence of multiple faults make the FD and RUL prediction tasks very challenging for HDS, especially considering the

fact that some fault symptoms may be masked or compensated by pre-existing fault symptoms. Also, a discrete mode fault may be possible besides the parametric faults (abrupt or progressive nature). Examples of discrete mode faults are valve stuck on/off fault, mode transition failure, control command communication fault, etc. Thus, the existing approaches based on single fault assumption may provide unreliable results and lead to misdiagnosis. Therefore, there is a need for development of more effective and efficient techniques for FD and RUL prediction of HDS and it is also practical to unify both in a common methodology for health monitoring of the system. Also, degradation of a component is usually irreversible and the associated parameter value deviates monotonically in a certain direction (either increasing or decreasing parameter value). This information of parameter deviation direction can be used for improving parameter estimation algorithms through specification of appropriate constraints.

Recently, many works have been published using hybrid bond graph (HBG) technique with applications to modeling, control and FD of HDS (Narasimhan & Biswas, 2007; Wang et al. 2013; Borutzky, 2015; Low et al., 2010; Ghoshal et al., 2012; Levy et al., 2015). But, very limited works (Yu et al., 2015; Daigal et al., 2015) deal with RUL prediction along with FD of HDS. In (Yu et al., 2015; Daigal et al., 2015), HBG technique is utilized for system modelling and FD; however particle filtering/Monte Carlo technique is applied for identification of degradation rate. According to available literatures for HDS, no work is found related to RUL prediction of sequentially occurring multiple faults, where new fault's symptoms may be masked or compensated by the already existing degradations in other components.

In summary, paper proposes an integrated approach for real time RUL prediction of multiple degrading components in an HDS using HBG as a common framework. Constrained parameter estimation (CPE) technique with dynamically updated constraints supported by the information of parameter drift direction is proposed to speed up the degradation pattern identification and RUL prediction. The proposed method accommodates the influences of different operating modes and is adapted with new information of degradation states identified through continuous monitoring.

The remaining article is organized as follows. Section 2, presents the common terminology and methodology used for health monitoring of HDS using HBG approach. Section 3 presents the FD and RUL prediction of multiple deteriorating components. Section 4 shows the efficacy of the proposed method using simulation and Section 5 gives conclusions and perspectives.

2 HBG-BASED DIAGNOSIS METHODOLOGY

2.1 *Hybrid dynamical system*

A benchmark hybrid two-tank example system is shown in Figure 1, which is considered as the application example in this paper. This system includes tanks, valves, pipes, and PI-controlled pump flow (Q_P). Valve V_1 is on-off type and operates at different state (on or off state) according to the supervisory controller command (a_{v1}). Two drainage pipes L_1 and L_2 belong to two autonomous modes transitions (a_1 and a_2, respectively) of the system, which depend on the internal dynamics of the system, i.e. state of liquid level (H_1, H_2) of tanks T_1, T_2, respectively. When the level of liquid in T_1 exceeds the level H_{L1} then the autonomous mode a_1 is switched to its active mode and liquid starts flowing from T_1 to T_2 through pipe L_1. Likewise, when the level of liquid in T_2 exceeds the level H_{L2} then another autonomous mode a_2 is switched to its active mode and the liquid starts flowing from T_2 to atmosphere through pipe L_2. These changing modes complicate the FD and RUL prediction process. For example, performance of an on-off valve V_1 may degrade due fouling (buildup of sediment/lime-scale, etc.). But, the deterioration rate of V_1 is not always constant, as it depends on the liquid flow through this unit. During off command of V_1, there is no buildup of fouling as no liquid flows through this unit. Only in on command of V_1, fouling is possible and may increase at some unknown rate.

Also, two imaginary valves V_{Leak1} and V_{Leak2}, respectively, are modeled to simulate leakage faults in tanks T_1 and T_2. The pump saturation characteristic (Φ_P) and output law of PI-controller (Φ_{PI}) are, respectively, stated as

$$Q_P = \begin{cases} U_{PI}, & \text{if } 0 \le U_{PI} \le f_{max} \\ 0, & \text{if } U_{PI} \le 0 \\ f_{max}, & \text{if } U_{PI} > f_{max} \end{cases} = \Phi_P(U_{PI}) \qquad (1)$$

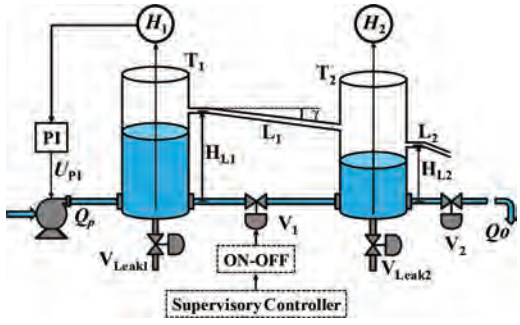

Figure 1. A schematic of hybrid two-tank system.

$$U_{\mathrm{PI}} = K_{\mathrm{P}}(S_{\mathrm{pt}} - \rho.g.H_1(t)) + K_{\mathrm{I}} \int (S_{\mathrm{pt}} - \rho.g.H_1(t))\,\mathrm{d}t = \Phi_{\mathrm{PI}}\left(H_1(t)\right) \tag{2}$$

where U_{PI} is PI-controller output, $f_{\max}$ is the maximum pump flow, S_{pt} is a controller set point, K_{P} is proportional gain and K_{I} is integral gain, g is acceleration due to gravity, ρ is liquid density.

2.2 *Diagnostic Hybrid Bond Graph (DHBG) model*

In bond graph, generalized elements, i.e., *Se*-effort source, *Sf* – flow source, *I* – inertia, *C* – compliance, *R*-resistor, 0 – equal effort junction, 1 – equal flow junction, *TF* – transformer, *GY* – gyrator, *De* – effort detector and *Df* – flow detector, are used to model the multi-physics system in a unified way (Samataray et al., 2008). The diagnostic BG technique is proposed for diagnosis of continuous system as in Samataray et al., 2006, Samataray et al., 2008. This technique is further extended for hybrid system, called DHBG technique (Low et al., 2010), which is well-suited for diagnosis of HDS by means of controlled/switched junctions and by feeding the measurements and mode information to the DHBG model. Also for the uncertain system, the nominal parameters are decoupled from their uncertain parts to account for the parameter uncertainties and modeled in linear fractional transformation (LFT) form by using feedback loops of internal variables, which is called LFT-DHBG model (Djeziri et al., 2007; Merzouki et al., 2012). For example, a LFT-DHBG model of hybrid two-tank system is presented in Figure 2, where the two level sensors (H_1, H_2) are fed to the model and the respective parameter uncertainty is decoupled from its nominal value to account for the uncertainty. In Figure 2, 1 – junctions with subscript a_{v1}, a_1 and a_2 are switched junctions related with discrete modes.

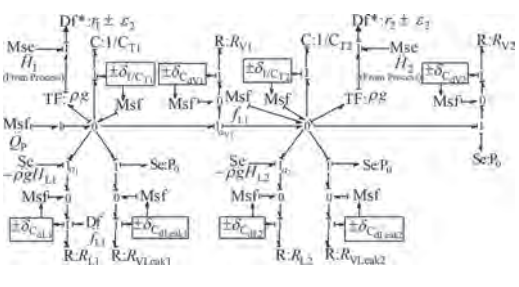

Figure 2. LFT-DHBG model of hybrid two-tank system.

2.3 *ARRs/GARRs and adaptive thresholds*

The analytical redundancy relations (ARRs) or global ARRs (GARRs) represent the conservation equations like continuity or mass balance equations, energy equations, momentum equations, etc. for the system. These relations are true at all times and at any working mode of the system. These relations do not depend on the past history of events. Evaluations of these relations provide the residuals which are ideally zero during fault free operation of system. But, due to measurements and parameters uncertainties, practically, residuals show small non-zero values and hence they are bounded with some time varying thresholds, called adaptive thresholds. The ARRs/GARRs and adaptive thresholds equations can be systematically derived from LFT-DHBG model, whose general form is

$$GARR_{ni}\left(Z,\theta,U,Y\right) \pm (\lambda_i + \lambda_{Si}) = 0 \tag{3}$$

where GARR_{ni}, λ_i and λ_{Si} represent the nominal residual (r_i) ($i = 1, 2, \ldots, n$; n is number of residuals), uncertain part due to parameter uncertainties and small static uncertain part needed to account for measurement errors, respectively. The uncertain parts of residual provide the adaptive threshold as $\varepsilon_i = \pm\mathrm{abs}(\lambda_i + \lambda_{Si})$. Also, $Z = [a_1, a_2, \ldots, a_k, \ldots, a_m]^T$ signifies the switched-junction ideal mode vector of m discrete components, $a_k \in (0, 1)$, $\theta = [\theta_1, \theta_2, \ldots, \theta_j, \ldots, \theta_p]^T$ signifies a known ideal parameter vector of p components, U and Y are the measured input and output variables of the system.

The two imaginary flow detectors (Df^*) in the LFT-DHBG model of hybrid two-tank system (Fig. 2) provide the two GARR_i ($i = 1, 2$) and uncertain parts (λ_i). These GARRs are nothing but represent continuity equations of the system in any mode.

Since absolute values of uncertain parts contribution is added in adaptive threshold, the small λ_{Si} part can be neglected, thus, the GARRs can be written as

$$\begin{aligned}\mathrm{GARR}_1 : {} & Q_{\mathrm{P}} - C_{\mathrm{T1}}\frac{\mathrm{d}}{\mathrm{d}t}\rho g H_1(t) - a_{\mathrm{v1}}C_{\mathrm{dv1}}\sqrt{|\rho g(H_1(t) - H_2(t))|} \\ & .\mathrm{sign}(H_1(t) - H_2(t)) - a_1 C_{\mathrm{dL1}}\rho g(H_1(t) - H_{\mathrm{L1}}) \\ & - C_{\mathrm{dLeak1}}\sqrt{|\rho g H_1(t)|} \pm \lambda_1 = 0,\end{aligned} \tag{4}$$

$$\begin{aligned}\mathrm{GARR}_2 : {} & a_{\mathrm{v1}}C_{\mathrm{dv1}}\sqrt{|\rho g(H_1(t) - H_2(t))|}\ .\mathrm{sign}(H_1(t) \\ & - H_2(t)) - C_{\mathrm{T2}}\frac{\mathrm{d}}{\mathrm{d}t}(\rho g H_2(t)) + a_1 C_{\mathrm{dL1}}\rho g(H_1(t) \\ & - H_{\mathrm{L1}}) - a_2 C_{\mathrm{dL2}}\rho g(H_2(t) - H_{\mathrm{L2}}) \\ & - C_{\mathrm{dv2}}\sqrt{|\rho g H_2(t)|} - C_{\mathrm{dLeak2}}\sqrt{|\rho g H_2(t)|} \pm \lambda_2 = 0\end{aligned} \tag{5}$$

where $C_{Ti} = A_i/g$, A_i is tank cross-section area, and

$$a_i = \begin{cases} 0, \text{ if } H_i(t) \le H_{\mathrm{L}i} \\ 1, \text{ if } H_i(t) > H_{\mathrm{L}i} \end{cases}, \; i = 1, \; 2.$$

Using Equations (1)–(2), two more ARRs, respectively, for actuator and controller (assumed to have no uncertainty) are obtained as

$$\mathrm{ARR}_3\colon Q_{\mathrm{P}} - \Phi_{\mathrm{P}}(U_{\mathrm{PI}}) = 0 \tag{6}$$

$$\mathrm{ARR}_4\colon U_{\mathrm{PI}} - \Phi_{\mathrm{PI}}(H_1(t)) = 0 \tag{7}$$

The uncertain parts λ_i (i = 1, 2) presented in Equations (4) and (5), respectively, are given as

$$\begin{aligned} \lambda_1 = {} & \left|\delta_{\mathrm{C1}} C_{\mathrm{T1}} \frac{\mathrm{d}}{\mathrm{d}t} \rho g H_1(t)\right| + \\ & \left|a_{\mathrm{v1}} \delta_{C_{\mathrm{dv1}}} C_{\mathrm{dv1}} \sqrt{\left|\rho g (H_1(t) - H_2(t))\right|}\right| \\ & + \left|a_1 \delta_{C_{\mathrm{dL1}}} C_{\mathrm{dL1}} \rho g (H_1(t) - H_{\mathrm{L1}})\right| \\ & + \left|\delta_{C_{\mathrm{dLeak1}}} C_{\mathrm{dLeak1}} \sqrt{|\rho g H_1(t)|}\right| \end{aligned} \tag{8}$$

$$\begin{aligned} \lambda_2 = {} & \left|a_{\mathrm{v1}} \delta_{C_{\mathrm{dv1}}} C_{\mathrm{dv1}} \sqrt{\left|\rho g (H_1(t) - H_2(t))\right|}\right| + \\ & \left|\delta_{\mathrm{C2}} C_{\mathrm{T2}} \frac{\mathrm{d}}{\mathrm{d}t} \rho g H_2(t)\right| + \left|a_1 \delta_{C_{\mathrm{dL1}}} C_{\mathrm{dL1}} \rho g (H_1(t) - H_{\mathrm{L1}})\right| + \\ & \left|a_2 \delta_{C_{\mathrm{dL2}}} C_{\mathrm{dL2}} \rho g (H_2(t) - H_{\mathrm{L2}})\right| + \left|\delta_{C_{\mathrm{dv2}}} C_{\mathrm{dv2}} \sqrt{|\rho g H_2(t)|}\right| + \\ & \left|\delta_{C_{\mathrm{dLeak2}}} C_{\mathrm{dLeak2}} \sqrt{\rho g H_2(t)}\right| \end{aligned} \tag{9}$$

2.4 *Fault signature matrix and coherence vector*

For different faults (parametric or mode faults), the GARRs are utilized to create the fault signature matrix (FSM), which depends upon the sensitivities of GARRs to the parameter variations (Low et al., 2010). In this study, global fault sensitivity signature matrix (GFSSM) and mode change sensitivity signature matrix (MCSSM) (Levy et al., 2015) are utilized, which have a power to discriminate between increasing ($\theta_j\uparrow$) and decreasing ($\theta_j\downarrow$) variations in the parameters. These dynamic matrices (see Equations (10) and (11)) are the extended forms of GFSM/MCSM matrices (Low et al., 2010) used for diagnosis of HDS.

$$GFSSM_{ji} = \begin{cases} -\operatorname{sign}(\partial r_i / \partial \theta_j), & \text{if } r_i \text{ is sensitive to } \theta_j\uparrow \\ +\operatorname{sign}(\partial r_i / \partial \theta_j), & \text{if } r_i \text{ is sensitive to } \theta_j\downarrow \\ 0, & \text{otherwise} \end{cases} \tag{10}$$

$$MCSSM_{ki} = \begin{cases} -\operatorname{sign}(\partial r_i / \partial a_k), & \text{if } r_i \text{ is sensitive to } a_k\uparrow \\ +\operatorname{sign}(\partial r_i / \partial a_k), & \text{if } r_i \text{ is sensitive to } a_k\downarrow \\ 0, & \text{otherwise} \end{cases} \tag{11}$$

For example, the signature for the leakage fault in tank T_1, i.e. $C_{\mathrm{dLeak1}}\uparrow$, is as

$$\begin{aligned} \mathrm{GFSSM}^{(C_{\mathrm{dLeak1}}\uparrow)} = {} & \left[-\operatorname{sign}\left(\frac{\partial GARR_1}{\partial C_{\mathrm{dLeak1}}} \right), \right. \\ & \left. -\operatorname{sign}\left(\frac{\partial GARR_2}{\partial C_{\mathrm{dLeak1}}} \right) \right] \\ = {} & \left[+\operatorname{sign}\left(\sqrt{|\rho g H_1(t)|} \right), \; 0 \right] \end{aligned} \tag{12}$$

Likewise, signatures for all faults are derived.

A coherence vector (***CV***) is used to generate the alarm state (0 or 1), whose standard form is given as $\boldsymbol{CV} = [cv_1(t), cv_2(t),..., cv_n(t)]$, where $cv_i(t)$, i = 1, 2,..., n, are generated from decision procedure, $\Theta\left(r_i(\mathrm{t})\right)$. For robust FD, each residual $r_i(t)$ is tested against an adaptive threshold $\varepsilon_i(t)$ as follows:

$$cv_i(t) = \Theta\left(r_i(\mathrm{t})\right) = \begin{cases} 0, \text{ if } -\varepsilon_i(t) \le r_i(t) \le \varepsilon_i(t) \\ +1, \text{ if } r_i(t) \ge \varepsilon_i(t) \\ -1, \text{ otherwise} \end{cases} \tag{13}$$

Here, it is assumed that $\varepsilon_i(t) \simeq \lambda_i(t)$. During monitoring, ***CV*** is derived at every sampled data for generating the alarm state. An alarm state shows 1 if any abnormality is found in the system with $\boldsymbol{CV} \neq [0, 0,\ldots, 0]$. After an alarm, the ***CV*** is matched with the GFSSM/MCSSM for the isolation of real degrading component. If a unique fault signature matches with the obtained ***CV*** the fault is isolated. A detectable and isolable component fault is represented by detectability index $D_{\mathrm{b}} = 1$ and isolatability index, $I_{\mathrm{b}} = 1$, respectively, in the fault signature matrix.

3 FD AND RUL PREDICTION OF MULTIPLE COMPONENTS DEGRADATIONS

A schematic flow diagram of integrated FD with RUL prediction of multiple degrading components occurring in a sequential way is presented in Fig. 3. The GARRs and adaptive thresholds are numerically evaluated at each and every time instance. If any threshold violation occurs for any unknown fault (abrupt/progressive parametric fault or discrete mode fault) then the obtained instantaneous ***CV*** is checked with both MCSSM/GFSSM and generates the initial set of suspected faults (SSF). Inclusion of discrete mode fault in SSF complicates the fault isolation process, since the discrete mode fault in a component shares the same fault signature as the partial parametric fault associated with the same component. First, it is assumed that the threshold violation occurs due to

a discrete mode fault, as discrete mode fault has more severe impact on the system dynamics and its stability. This paper presents a new method to discriminate discrete mode fault from the parametric fault based on magnitude of residual deviation after a fault, which is identified from Equation (14) as

$$D_{a_k}^{\eta} = \left|GARR_i(Z,\ \theta,\ U,\ Y)\right| - \left|\frac{\partial GARR_i}{\partial a_k}\right| \le \varepsilon_i, \quad (14)$$

where $D_{a_k}^{\eta}$ is the difference between absolute value of residual deviation after a fault and sensitivity of residual with respect to suspected discrete parameter a_k in the initial SSF. If any discrete mode fault is found, then the DHBG model is updated with faulty mode for subsequent detection of fault (if monitoring is continued). After updating the DHBG model, all residuals are forced to remain bounded within the updated thresholds even in presence of one or more faults. If it is found that the discrete modes are con-sistent, then it indicates that the threshold violation is due to parametric fault. Then, the discrete mode faults are removed from the initial SSF, and the algorithm is triggered for parametric fault identification only for the suspected parameters which remain in refined SSF. Using the knowledge of deviation directions of suspected parameters obtained from GFSSM, the bounds of the suspected parameters, $\theta_F \in [\theta_{FL},\ \theta_{FU}]$ are created. Bounds are created based on previous known nominal values of the parameters (θ_F) and their possible extreme variations after the fault, derived from the deep knowledge of the system, called technological specifications. For the time varying parameter, the parameter bound is also updated when the true magnitude of varying parameter is obtained after successive estimation of fault at different times in the respective mode. A CPE technique with dynamically updated parameter bounds is proposed by integrating the gradient-projection method with Gauss-Newton method. To further improve the parameter estimation, sensitivity BG technique (Samantaray & Ghoshal, 2007) is utilized which provides the gradient information of the cost function during optimization process. The gradient projection method is more efficient, particularly, when constraints include only bounds on the parameters (Nocedal & Wright, 2006). The objective function is formulated as:

$$\min_{\theta} J(\theta) = \frac{1}{2}\sum_{j=k-q}^{k} \mathbf{r}^{\mathrm{T}}(t_j).\mathbf{W}.\mathbf{r}(t_j)$$
$$\text{subject to}: \ \theta_L \le \theta \le \theta_U \quad (15)$$

where $\mathbf{r}(t_j)$ is the residual vector obtained by evaluating the *GARRs* at time instant t_j, k is the current sample time, $q \ge 0$ is the number of collection of past sampled data during monitoring, and $\mathbf{W} \in \mathbb{R}^{n\times n}$ is a positive semi-definite weighing function and can be considered as unit matrix, θ_L and θ_U are, respectively, the sets of lower and upper parameter bounds on the parameters.

Thus, CPE finally isolates (say $\theta_j\downarrow$ at mode $\boldsymbol{Z}=z^{(i)}$) the actual deteriorating component (θ_j) at k^{th} time instant and gives the first estimate $\theta_j^{\mathrm{E}}(k, z^{(i)})$ (fault magnitude at k^{th} instant). The parameter vector is updated as $\theta = [\theta_1, \theta_2, ..., \theta_j^{\mathrm{E}}(k, z^{(i)}), ..., \theta_P]^T$ and considered as a new nominal parameter vec-

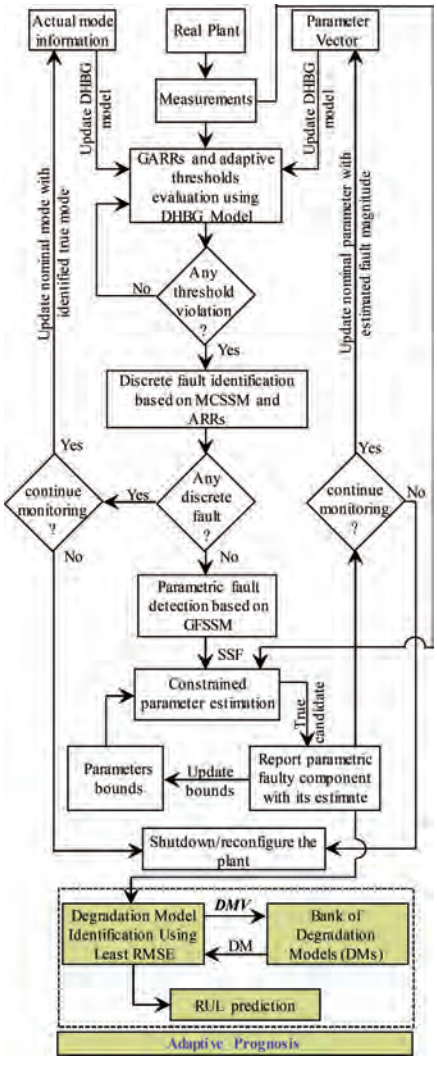

Figure 3. A schematic flow diagram of integrated approach.

tor at k^{th} instant. Also, initial bound $\theta_j \in [\theta_{jL}, \theta_{jU}]$ is updated with fault magnitude at k^{th} instant as $\theta_j \in [\theta_{jL}, \theta_j^f(k, z^{(i)})]$. The evaluation of residuals with updated parameters again forces the residuals to remain lie within the updated thresholds. If the identified degradation is progressive, the parameter $\theta_j(t, z^{(i)})$ varies slowly at mode $z^{(i)}$. Thus, the updated residuals again violate the same thresholds after some more time, and again CPE technique with the updated bound $\theta_j \in [\theta_{jL}, \theta_j^f(k, z^{(i)})]$ gives the second fault estimate $\theta_j^f(k+\Delta, z^{(i)})$ at $(k+\Delta)^{th}$ time instant. Parameter estimation method converges quickly as the search zone is reduced dynamically here. Likewise, more estimated data points are accumulated with dynamically updated bounds of the supervised system at a particular mode $z^{(i)}$. If the j^{th} mode switching occurs at $t^{(j)}$ time instant during sample data accumulation for CPE in the preceding mode $z^{(i)}$ then the fresh sampled data of a fixed time window at new mode $z^{(j)}$ are accumulated and deteriorating parameter, $\theta_j(t, z^{(j)})$ is estimated in this new mode $z^{(j)}$. This way, a set of estimated parameter values (degradation trend) is obtained at different time instants in different operating modes. Depending upon the number of such estimates, an interpolation curve is generated and that curve is extrapolated to obtain the RUL.

3.1 *Degradation model and RUL prediction*

Degradation estimates $D_{\theta_j}^{z^{(i)}} = \left(t_w, \theta_j^f\left(t_w, z^{(i)}\right)\right)$, $w = 1, 2, \ldots, k$, is further used for degradation model (DM) identification at mode $z^{(i)}$. Model fitting should contain sufficient number of estimated data points for precise degradation model identification. The proposed RUL prediction adapts to any new information of deteriorating state of the supervised system. Initially, for RUL prediction, linear DM is used which has good prediction accuracy with less information of data and as the monitoring is continued DM and RUL are adapted with the new facts of deteriorating state of the component or system. The initially predicted RUL provides some indication to the maintenance engineers for decision and maintenance planning. Thus, the selection of DM which depends on the information of estimated data points up to current time t_k at mode $\boldsymbol{Z} = z^{(i)}$ is represented as;

$$M_{\theta_j}^{z^{(i)}}: \begin{cases} \theta_j(t, z^{(i)}) = \mathrm{M}_{\mathrm{LIN}}, & \text{if } w < w_S \\ \theta_j(t, z^{(i)}) = \zeta_1 \mathrm{M}_{\mathrm{LIN}} + \zeta_2 \mathrm{M}_{\mathrm{PL2}} + \zeta_3 \mathrm{M}_{\mathrm{EXP}}, & \text{if } w \geq w_S \end{cases} \tag{16}$$

where w is number of estimated data points up to current time, w_S is sufficient number of estimated data points decided by the user for precise degradation model identification. $\mathrm{M}_{\mathrm{LIN}}$ is linear model, $\mathrm{M}_{\mathrm{PL2}}$ is second order polynomial model and $\mathrm{M}_{\mathrm{EXP}}$ is exponential model. Thus, if $w \geq w_S$, a particular degradation model is selected for data fitting according to the value of degradation model vector $\boldsymbol{DMV} = [\zeta_1, \zeta_2, \zeta_3]$. If $\boldsymbol{DMV} = [1, 0, 0]$ then $\mathrm{M}_{\mathrm{LIN}}$ is selected, if $\boldsymbol{DMV} = [0, 1, 0]$ then $\mathrm{M}_{\mathrm{PL2}}$ is selected and if $\boldsymbol{DMV} = [0, 0, 1]$ then $\mathrm{M}_{\mathrm{EXP}}$ is selected and the model which has least root mean square error (RMSE) to the data fit is selected as a best degradation model at mode $\boldsymbol{Z} = z^{(i)}$. Likewise, other equation models can be plugged into Equation (13).

However, this paper uses these three models only for RUL prediction since these models show the monotonic increasing or decreasing trend and can touch the set failure threshold after extrapolation of the models. It is also suggested that the polynomial models of higher order more than the second order model should be avoided in data fitting unless there is some known physical reason or any past experience of such type of degradation of the component. The RUL prediction with higher order polynomial models may give good interpolation result, but may give bad extrapolation result (Randall, 2011).

RUL is predicted for degrading parameter $\{\theta_j(t, Z), t > 0\}$ by extrapolating the data using the identified model $M_{\theta_j}^{z^{(i)}}$ with the future operating modes ($\boldsymbol{Z}$) of the system known up to the current time (obtained from past experience of the system). Thus, when the extrapolated trend of θ_j reaches a well set failure threshold θ_j^{fl} then the component is declared as end of life (EOL) component at time to failure (TTF) t_{fl}. Thus, the t_{fl} and RUL are defined as

$$t_{fl} = \inf\{t \in \mathbb{R} : \theta_j(t, Z) \geq \theta_j^{fl} \mid \theta_j(t_0, Z) < \theta_j^{fl}\} \tag{17}$$

$$\mathrm{RUL}\left(t, Z\right) = t_{fl} - t_0 \tag{18}$$

Also, the identified mode-dependent DM, $M_{\theta_j}^{z^{(i)}}$, are fed into DHBG model for detection of subsequent faults precisely. In case of multiple degrading components, RUL is predicted for every degrading component and the component with least predicted RUL requires more attention by plant technicians.

4 NUMERICAL SIMULATION

The proposed approach is demonstrated through simulation on two-tank system (Fig. 1). Two faults are injected, first in valve V_1 (mode, a_{v1}, dependent degradation, see Fig. 4) and second in tank T_1 at instances $t_{f1} = 225$ s and $t_{f2} = 1475$s, respectively, as

$$C_{\mathrm{dv1}}(t,Z)=\begin{cases}C_{\mathrm{dv1n}}(Z).a_{\mathrm{v1}}, & \text{if } t < t_{f1}\\ C_{\mathrm{dv1n}}(Z)\left(e^{-r(Z).t_{\mathrm{on}}}\right).a_{\mathrm{v1}}, & \text{if } t \geq t_{f1}\end{cases} \quad (19)$$

$$C_{\mathrm{dLeak1}}(t)=\begin{cases}C_{\mathrm{dLeak1n}}, & \text{if } t < t_{f2}\\ C_{\mathrm{dLeak1n}}+k_{\mathrm{L}}(t-t_{f2}), & \text{if } t \geq t_{f2}\end{cases} \quad (20)$$

where $C_{\mathrm{dv1n}}(\boldsymbol{Z})$ is the nominal discharge coefficient of V_1 at respective mode ($\boldsymbol{Z}$), $r(\boldsymbol{Z}) = 1.0 \times 10^{-4}$ s^{-1} at $\boldsymbol{Z} = \mathrm{z}^{(1)} = a_{\mathrm{v1}} = 1$, and $r(\boldsymbol{Z}) = 0$ s^{-1} at $\boldsymbol{Z} = \mathrm{z}^{(2)} = a_{\mathrm{v1}} = 0$, $t_{\mathrm{on}} = \int_{t_{f1}}^{t} a_{\mathrm{v1}}\mathrm{d}t$, C_{dLeak1n} is the nominal discharge coefficient of V_{Leak1} and $k_{\mathrm{L}} = 1.0 \times 10^{-6}$ kg$^{1/2}$ m$^{1/2}$ s^{-1}.

The system is simulated for a time span of 2400s, with a fixed step size of 0.02 s, by setting all state variables to zero at $t = 0$ s. The nominal parameters of system are $K_{\mathrm{P}} = 1$ ms, $K_{\mathrm{I}} = 5 \times 10^{-2}$ m, $S_{\mathrm{pt}} = 0.5$ m, $f_{\max} = 1$ kg/s, $A_i = 2.16 \times 10^{-2}$ m^2, $C_{\mathrm{dv}i} = 1.593 \times 10^{-2}$ kg$^{1/2}$ m$^{1/2}$, $C_{\mathrm{dL}i} = 1 \times 10^{-3}$ ms, $C_{\mathrm{dLeak}i} = 0$ kg$^{1/2}$ m$^{1/2}$, (i = 1, 2), $H_{\mathrm{L1}} = 0.58$ m, $H_{\mathrm{L2}} = 0.40$ m, $P_{\mathrm{atm}} = 0$ N/m^2, $g = 9.81$ m/s^2, $\rho = 1000$ kg/m^3.

4.1 *Implementation of proposed scheme*

The measurements (Q_{P}, H_1, H_2) and the modes (a_{v1}, a_1, a_2) information obtained from the simulation are used to evaluate the residuals and the adaptive thresholds presented in Equations (4)-(5) and Equations (8)-(9), respectively. Activation of mode (a_1) and no activation of mode a_2 are noticed according to respective prescribed condition. So, $a_2 = 0$ for all the duration of simulation. The response of residuals (r_1, r_2) and adaptive thresholds (ε_1, ε_2), using single fault assumption, is shown in Figure 5.

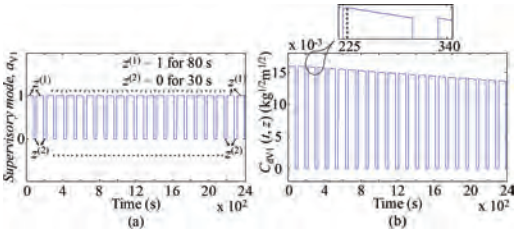

Figure 4. (a) mode, a_{v1} (b) mode-dependent degradation in V_1.

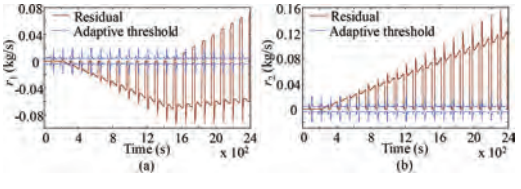

Figure 5. Residuals and thresholds with single fault assumption.

From the simulation results, $H_1 > H_2$ is found during the observation period 0 to 2400s, so the GFSSM and MCSSM are as presented in Table 1. Also, the obtained $\boldsymbol{CV}_{\boldsymbol{S}}$ (subscript $\boldsymbol{s}$ signifies single fault assumption) using previous existing approaches and obtained $\boldsymbol{CV}_{\boldsymbol{M}}$ (subscript $\boldsymbol{M}$ signifies multiple sequential faults assumption) using proposed method just after the both faults are also shown. Note that taking of absolute value of signatures in Table 1 without deviation direction provides the standard GFSM/MCSM. $\boldsymbol{CV}_{\boldsymbol{S}}$, just after 225 s, provides SSF = {a_{v1}, C_{dv1}} if mode $a_1 = 0$; otherwise SSF = {a_{v1}, C_{dv1}, C_{dL1}} if mode $a_1 = 1$ (see Table 1). In any mode, parametric fault (C_{dv1}) is not isolatable as a_{v1}, C_{dv1}, C_{dL1} share a common signature. Also, the inclusion of a_{v1} in SSF complicates the task of FD; so, tracking real mode ($a_{\mathrm{v1}} = 1$) just after the fault is also required. As dynamics of V_1 is dependent on mode a_{v1}, the evaluated residuals (r_1, r_2) at $a_{\mathrm{v1}} = 0$ forces the residuals to enter into the threshold bounds even after detecting this fault (see Fig. 5); and under such situation, FD is not possible unless the system enters into a different working mode ($a_{\mathrm{v1}} = 1$). Also, $\boldsymbol{CV}_{\boldsymbol{S}}$, just after 1475s, provides the same SSF as before. In such cases, the real fault (C_{dLeak1}) is not included in SSF which leads to misdiagnosis. Here, next component degradation (C_{dLeak1}) is concealed by the already known component degradation (C_{dv1}).

The response of residuals (r_1, r_2) and adaptive thresholds (ε_1, ε_2) using proposed modified method, in which LFT-DHBG model is dynamically updated after each fault estimate, is shown in Figure 6. It is observed that using proposed technique with locally updating the model, SSF includes the true faults

Table 1. GFSSM with MCSSM of the system.

Parameter	r_1	r_2	D_b	I_{b}
$C_{\mathrm{dv1}}\uparrow$	a_{v1}	$-a_{\mathrm{v1}}$	a_{v1}	0
$C_{\mathrm{dv1}}\downarrow$	$-a_{\mathrm{v1}}$	a_{v1}	a_{v1}	0
$C_{\mathrm{dv2}}\uparrow$	0	+1	1	0
$C_{\mathrm{dv2}}\downarrow$	0	−1	1	$1-a_2$
$C_{\mathrm{dL1}}\uparrow$	a_1	$-a_1$	a_1	0
$C_{\mathrm{dL1}}\downarrow$	$-a_1$	a_1	a_1	0
$C_{\mathrm{dL2}}\uparrow$	0	a_2	a_2	0
$C_{\mathrm{dL2}}\downarrow$	0	$-a_2$	a_2	0
$C_{\mathrm{dLeak1}}\uparrow$	+1	0	1	1
$C_{\mathrm{dLeak2}}\uparrow$	0	+1	1	0
$a_{\mathrm{v1}}\uparrow$	+1	−1	1	0
$a_{\mathrm{v1}}\downarrow$	−1	+1	1	0
$\boldsymbol{CV}_{\mathrm{S}}$ after 225 s	−1	+1	1	0
$\boldsymbol{CV}_{\mathrm{S}}$ after 1475s	−1	+1	1	0
$\boldsymbol{CV}_{\mathrm{M}}$ after 225 s	−1	+1	1	0
$\boldsymbol{CV}_{\mathrm{M}}$ after 1475s	+1	0	1	1

according to $\boldsymbol{CV_M}$ for the same faults scenario discussed beforehand. The suspected mode fault ($a_{v1}\downarrow$) is tested as per Equation (14) just after threshold violation and it is found that $a_{v1} = 1$ is consistent. Thus, using CPE technique only for the faults remain in the refined SSF, i.e., $C_{dv1}\downarrow$ and $C_{dLeak1}\uparrow$ are isolated as true faults just after 225 s and 1475s, respectively. Also, the predicted RULs for both faults using linear DMs, with less data points of deteriorating parameters ($C_{dv1}\downarrow$ and $C_{dLeak1}\uparrow$), are presented in Figures 7a and 8a, respectively. The horizontal lines in these figures indicate the degradation threshold or end of life of a component. Subsequently, updated RULs estimated with adapted models after getting the sufficient data points are presented in Figures 7b and 8b, respectively. The gradually evolving degradation pattern reconstructed from results of the simulation and parameter identification matches with the expected behavior defined in Equations (19)-(20).

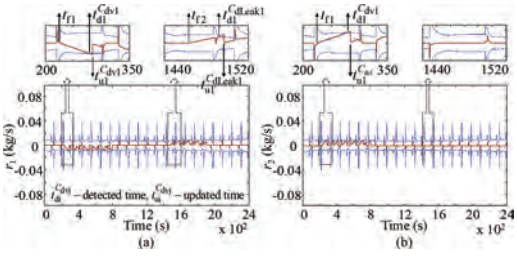

Figure 6. Residuals and thresholds using proposed method.

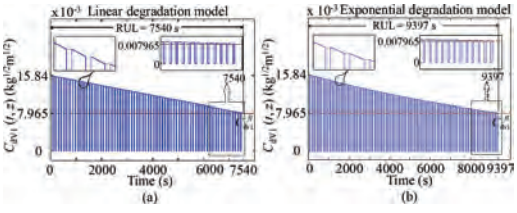

Figure 7. RUL of C_{dv1} using (a) initial linear model (b) identified true model, with a failure threshold $\left(C_{dv1}^{fl}\right)$.

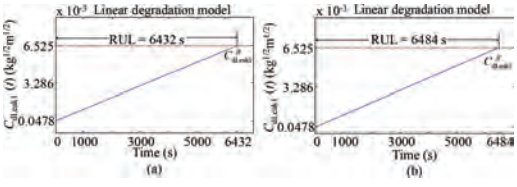

Figure 8. RUL of C_{dLeak1} using (a) initial linear model (b) identified true model, with a failure threshold $\left(C_{dLeak1}^{fl}\right)$.

5 CONCLUSION

The key features of the proposed technique are (1) the use of residual response to identify the minimal set of prognosis candidates for which parameter estimation is triggered, (2) detection of the time points when the parameter estimation needs to be triggered (3) the use of minimization of only inconsistent residuals for the degradation state estimation and the use of sensitivity of ARRs during estimation (4) successive ARRs updation with the degradation estimates in order to force the residuals to lie within the respective adaptive thresholds and thereby detect the further degradation and predict the degradation trends of multiple degrading components, and (5) RUL prediction is coupled with the operation mode of the system and adapts to any new state of health information on the system's components. The implementation of proposed CPE technique with SBG approach, dynamic model updation and use of GFSSM/MCSSM improve the FD and RUL prediction. The problem of misdiagnosis with multiple sequential faults is also discussed. However, the proposed work demonstrated through simulation and the predicted RULs are also deterministic in nature. In future, the proposed technique will be applied to some real experiment, and uncertainties and confidence limit will be taken into account for the prediction of the RULs. Also, in the current work, failure threshold for each component is selected arbitrarily just for demonstration. However, setting failure threshold for multi-component system based on system level performance limits is also a crucial design factor in prognosis, which can be considered as a future research problem.

ABSTRACT: This paper discusses novel technologies for energy efficiency and predictive maintenance using hardware accelerated energy disaggregation. The disaggregation process involves the use of custom designed smart sensors that collect and treat aggregated information on the current and voltage waveforms. The treated data are further on transmitted to the cloud where they are stored and processed to enable the extraction of advanced information on individual device consumption patterns and health status. This information can be extremely useful for the management of electric devices in residential or commercial sites as well as for predictive maintenance in industrial sites. The paper reviews the underlying methodologies, and presents preliminary work and results from data collection in the offices of a software company. The presented work involves the installation of measurement devices and the development of complementary hardware and software. This is part of the ongoing 4-year project PREDIVIS (PREdictive, Disaggregation Intelligent VIS (meaning "power" in Latin)).

1 INTRODUCTION

Nowadays, the ever-growing power demand of industries and households combined with the goals for carbon dioxide emission reduction, have led the communities to take action, by implementing conservation and energy efficiency programs. The first step in energy reduction actions is the rollout of smart meters to monitor energy consumption and the smart grid technologies to distribute the available energy more efficiently, combined with the wide adoption of renewable energy sources.

The energy consumption and carbon emissions are regulated by frameworks and directives, mainly focused on actions by industries in order to minimize their impact on climate change. In most cases these actions are costly and inefficient, and often industries are incapable of adapting new equipment and carbon dioxide emission reduction techniques which leads to increased taxes and fines when goals are not achieved.

Monitoring of energy consumption at appliance level is essential for predicting energy needs and monitoring appliance operation in a household, a building or an industrial system. Energy disaggregation refers to using data analytics and signal processing, to identify specific patterns and to break down electricity consumption to individual appliances. This is usually done in a non-intrusive manner by monitoring the utility connection meter, and has been a field of significant research work for over twenty years. Non-Intrusive Load Monitoring (NILM) is a process where the aggregated electricity consumption is metered at the Grid-consumer connection point, and by analyzing the changes in voltage and current wavelengths tries to identify which appliances are being used at a certain time. Still, NILM technology's main goal is to provide insights into energy consumption at appliance level, mainly to support energy efficiency actions with economic and environmental impact. There are novel techniques using various approaches of NILM for a great number of

applications, like safety on industrial environments, device health monitoring and predictive maintenance and demand response applications.

Equipment monitoring on industrial sites is a necessity and most of the time, a costly and complex process. Various industries, monitor their machinery and equipment to prevent malfunctions, minimize danger, service and repair costs, and to increase the overall operating time. NILM techniques could be a cheap alternative to equipment monitoring systems which are costly and require huge and complex installations. Monitoring equipment is vulnerable to failures due to its numerous sensors and measurement devices that are being deployed. NILM is not widely used in industrial and commercial environments because of the complexity of these environments: the great number of similar devices, power factor correction and load balancing equipment, as well as the huge number of harmonics in loads make this process really challenging.

2 TECHNICAL PROBLEM DESCRIPTION

Let a system of N devices. Devices can be of different types (let K denote the number of possible types, e.g., washing machine, PC, monitor, refrigerator, etc.). For each type $k = 1, 2, \ldots, K$ of device $n = 1, 2, \ldots, N$ there is a set S_k of possible operation states. The assumption here is that there is a mapping between the state of a certain device and its electrical footprint on an aggregated time series. Consequently, the sequence of operational states leaves a string of unique fingerprints on the time series of energy consumption measurements.

The usual case is that for each time segment, only the total energy consumption is measured and not the individual consumptions of each device. The device fingerprints are therefore mixed up. The disaggregation exercise consists of analyzing the system data in order to unravel the strands of each device, and enable further analysis of the device operation. The disaggregation process is accompanied by information on the operational pattern of each device type, for instance, continuous operation or interrupted, expected duration of each operational state etc.

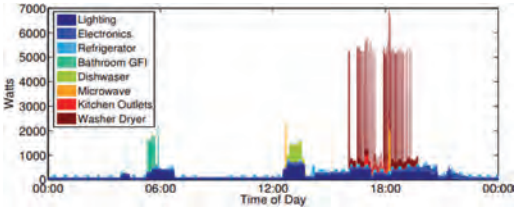

Figure 1. Example of a household total energy consumption from the REDD[1] dataset.

Looking more closely at the device types, it is also possible to extract and make use of more advanced information. Indeed, different device types usually generate slightly different harmonic distortions. The harmonic distortions can be identified if the resolution of the time series is sufficiently high.

3 STATE-OF-THE ART ON ENERGY DISAGGREGATION

Over the past 20 years, there have been many different approaches to addressing the problem of energy disaggregation and the subsequent monitoring of device health.

Since Hart [1] first introduced the concept of Non-Intrusive Appliance Load Monitoring (NIALM) in 1992, numerous techniques have been developed to address the problem. Initial approach was focused on examining a device as a state machine, trying to identify the states and disaggregate the device from the aggregated load. The method could perform well for large loads and devices with a finite number of states that are not always on, with discrete power changes between states.

Since then, other works [5, 6, 7] have proposed different techniques for electrical signature analysis to address the classification problem, with promising results. Such methods include, Support Vector Machines (SVM), Bayesian methods, k-Nearest Neighbors etc. The most common techniques used are Hidden Markov Models and Artificial Neural Networks using supervised, semi-supervised and unsupervised methods [8–12].

Regarding energy disaggregation, the non-intrusive approaches (NILM) promise adequate accuracy with lower installation costs and complexity compared to smart plug-based [2, 12] approaches. NILM methods using steady-state and transient load signatures are further classified according to data time series' measurement frequency. High-frequency [13] methods require custom hardware (high-frequency meters ~10^6 Hz/s) and employ an array of machine learning and pattern recognition methods. Low-frequency methods [14] (1 sec up to 1 hour) apply similar data processing techniques, but are not sufficiently tested to guarantee commercial-grade accuracy. NILM is so far mainly focused on households and small-scale buildings, so there is also the issue of its scalability to commercial buildings or even entire neighborhoods in order to extract useful information for demand response applications, as well as for grid and device health.

The models employed range from least square estimation to Hidden Markov models. Some approaches use Fast Fourier Transform and other transformations to reduce hardware, bandwidth

and storage cost. Research in this field focuses on finding the algorithm that increases the accuracy of energy disaggregation in each application case. More recently, new approaches with semi-/un-supervised algorithms are being studied [15]. An emerging research trend is to use IoT based architectures for data capturing and on-board [16] analytics on appliance level to provide energy efficiency solutions. By using IoT devices dedicated to energy monitoring and data manipulation, researchers aim to extract more information by analyzing the electrical characteristics of the appliances in the deployed sites.

At the moment, there is no universal Machine Learning (ML) algorithm that will fit multiple application cases. The specification of the ML algorithms varies with the constraints of each application case. A list of well performing algorithms in different application cases should include Artificial Neural Networks, SVM + kernels, Decision Tree, Random Forests etc. Marking a turning point in the history of Artificial Intelligence, Deep Neural Networks (DNN) are now widely used, e.g., for face recognition on smartphone cameras. Research in this field is ongoing in response to the evolving market interest for improved DNNs. It includes development of new hardware architectures implementing DNNs to improve on the current CPUs and GPUs [17]. Neuromorphic chips have reduced energy consumption and enhanced DNN capabilities in processing the vast volumes of information generated by the IoT [18].

Analyzing data from multiple sensors can provide critical information on each current state of the monitored devices and enable predictions of behavior in the future. The sensors can measure a variety of device/environmental attributes, such as the temperature [19]. Likewise, electrical consumption data, when added to other available device data, can provide significant input to predictive maintenance, and also minimize the data volume that needs to be processed and stored. Approaches to predictive maintenance through electrical consumption data has been made on specific cases.

4 PROPOSED APPROACH

4.1 *Description of solution*

Project PREDIVIS aims to develop novel tools for energy disaggregation and monitoring of device operation status, based on real-time pattern recognition/matchmaking of complex energy load data time-series, using hardware acceleration techniques. The proposed approach requires the design, development and implementation of complex algorithms on a reprogrammable Field Programmable Gate Array (FPGA), in order to create a network of distributed agents that performs the majority of the data analysis in real-time, and transmits events, instead of raw data, to a main server.

This project is trying to address the problem of energy Disaggregation on household and commercial/industrial environments. Due to the difference in complexity of the above mentioned two cases that this project is trying to address, we will need to utilize different approaches, algorithms and also fine-tune the sampling frequency needed per case to acquire sufficient data for the disaggregation process. A system like that depends on the specifications of each deployment site, e.g., different sites have different number of devices with different characteristics that might lead us in using completely different data acquisition rate. Typically, a NILM system design involves three main components: Data Acquisition and Storage, Analysis and Classification.

Most of the previous projects were using private generated/produced or open datasets to train models and validate the results and the algorithm efficiency. Previous works are using data collection methods at either High frequency (1 to 10^3 kHz) or Low frequency (10^{-6} to 10^{-3} kHz). The sampling rate may differ from one sample per 15 minutes or more, to a couple of millions per second. This project focuses on High frequency methods using a sampling rate between 8 kHz and 64 kHz to be able to extract more features from the available data to assist the classification process. Sampling rate determines the information that can be extracted from the sampled signals. Consider for example an electrical installation with fundamental power frequency of 5×10^{-2} kHz. Sampling the wavelength with higher sampling rate (8 kHz) fulfilling the Nyquist-Shannon theorem, enables our system to capture up to the 160-th harmonic. By analyzing the different harmonic distortions, we can identify and differentiate the device from the aggregated workload.

Using high frequency sampling rates requires large storage space to store the acquired data and huge bandwidth to transfer the data over the internet to a central powerful unit for further analysis. To minimize storage and bandwidth, some applications are using compression technics or on-site devices to analyze the data. These hardware devices require a great amount of power in order to perform the analysis and usually they are very expensive.

Project PREDIVIS will use a novel technique implementing on site disaggregation to limit bandwidth and storage needed (Figure 2). Using dedicated hardware implemented in FPGA devices will help in decreasing not only the overall bandwidth and storage but also the power consumption needed for the data analysis. Based on the installation,

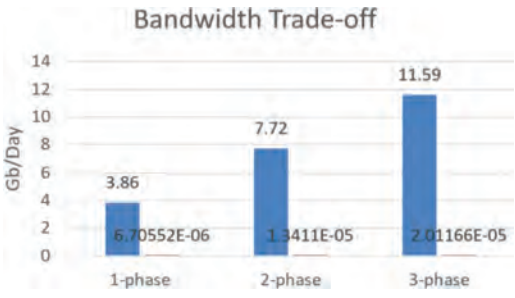

Figure 2. Bandwidth trade-off between raw data transfer and event reporting architecture.

which can be one-, two- or three- phase, the number of electric power transmission data to be used for the disaggregation, will increase proportionally. Note, however, that, the detected events will be more or less the same for each case, despite the number of phases.

For data storage, PREDIVIS will use a small local memory capable of storing the device signatures and a couple of hours of data stream. Aside from the local storage, data like on/off events, total energy consumption and total amount of operation time, anomalies on appliance electric characteristics etc., will be sent to a cloud infrastructure and will be saved in a No-SQL database. Each agent will have the ability to retrain when specific conditions are applied. The system will use adaptive learning techniques to adapt better on new and existing installations by sharing knowledge on already known devices between the employed agents through the central cloud system.

In terms of data analysis, various techniques will be used to extract information from the available data in order to identify:

- Event transitions, when a device is turned on or off. Event-based approaches detect only major changes and anomalies on the energy load time series.
- State transitions, when the device swifts from one state to another (e.g. from full operation to standby and vice versa). State-based approaches also detect the different states of device workload.

4.2 *Description of project*

Project PREDIVIS consists of three main components:

- Agents, which are custom hardware components for data collection, data analysis and load monitoring
- Cloud-based platform for data visualization, storage and NILM assisting mechanisms

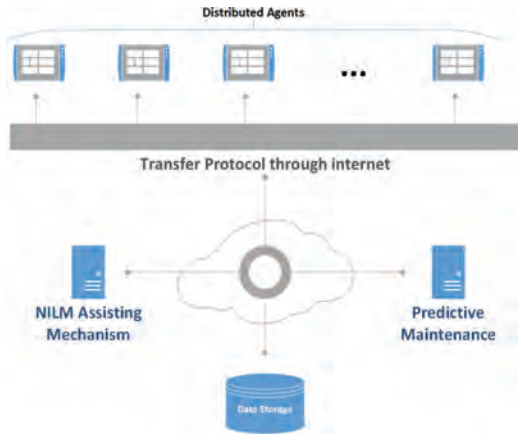

Figure 3. PREDIVIS architecture diagram.

- NILM and Predictive maintenance algorithm suite

The Agents mentioned above are custom hardware implementations using FPGA devices and different Intellectual Property (IP) blocks (e.g., ADC, DSP etc.) to address data collection and analysis on the deployment site. Hardware acceleration of NILM algorithms will help us take the computational load off the cloud infrastructure and minimize the bandwidth needed, as mentioned earlier. Each deployment site is unique, having a different number of N devices with different K states, making the case of using a universal algorithm/approach very challenging. Each device will be able to perform better on its deployment site through adaptive learning techniques, with the assistance of the Central platform and information gathered by other deployed agents with similar site characteristics or identical device types.

The Cloud-based platform will provide data visualization and display information through a friendly User Interface (UI) helping the user get insights on the energy consumption. Acting as a central point for reporting, the platform will complement distributed agents by collecting and analyzing information from each one of them about the deployment site and the site's devices, and will help distributing knowledge between them.

The Cloud platform will also host a NILM suite with several algorithms for analyzing real-time data to determine which algorithm/method is more suitable for that particular site's appliance mix, condition etc. Finally, the predictive maintenance suite will analyze the data and anomalies detected by the agent to help reduce hazardous machinery errors, downtimes and failures.

The consortium of this project comprises the following complementary partners:

- the System Reliability and Industrial Safety Laboratory, National Center for Scientific Research "Demokritos" as a research partner supporting NILM and predictive maintenance analysis.
- Plegma Labs S.A as Enterprise partner in IoT technologies supporting the cloud infrastructure, and the data storage and management.
- the Department of Information and Communication Systems Engineering, University of the Aegean, as a research partner supporting hardware development and data acquisition processes.

Figure 4 depicts the three main stages of this project. The project will run for 4 years and the work is currently at stage one.

4.3 *PREDIVIS technologies breakdown*

The project is a combination of the aforementioned techniques, ranging from hardware blocks to advanced software features. In a nutshell, this project will try to implement hardware designs for data collection using Analog to Digital conversion and Digital Signal Processing techniques, combined with embedded Artificial Intelligence functions and methods. The ability to reprogram over the air an FPGA device, can help each device adapt better to new or pre-installed environments. The software portion of this project includes:

a. the Cloud-based high-level software for data transport and storage,
b. the intelligent adaptive NILM algorithm suite to reprogram and calibrate DNN on agents, and
c. the Predictive maintenance analytics suite combined with statistical models and machine learning algorithms, to predict future failures and stimulate faults.

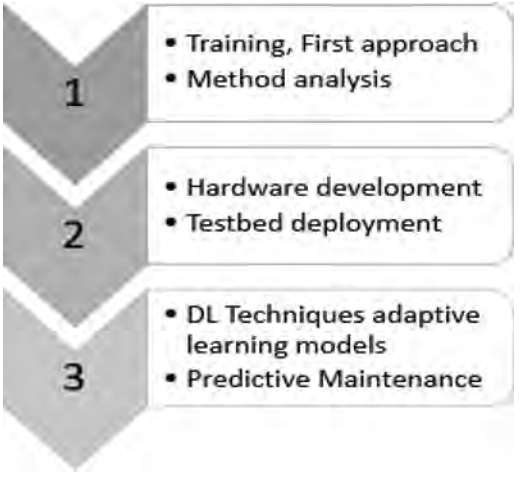

Figure 4. PREDIVIS project stages.

5 GENERATION OF DATA SETS

In order to develop and test different energy disaggregation methods and optimize the efficiency of PREDIVIS project, a variety of datasets will be used. These involve open High Frequency public datasets as well as privately generated data. Some of the public sets that we intend to use are the REDD [2] (2011), the Blued [3] (2012), and the UK-DALE [4] (2015). These datasets relate mainly to residential applications.

The private datasets will contain data from office sites and from industrial sites. Regarding the former, a set of measuring devices is currently installed at offices of a typical software SME. Figure 3 shows the layout of the company offices. The site is connected to the electricity grid through a three-phase power supply. Note that, three-phase data have entirely different characteristics compared to single or two-phase data and this will be considered during the analysis stages.

The installed measuring devices collect data logs from the main power circuitry connector, as well as from individual devices. The main power data involve the aggregated electric current and voltage waveforms, and these are measured at both low and high-frequency rates. The electric power of individual devices is monitored using one smart plug per device.

Seventeen (17) different entities are monitored, ranging from lighting to air-condition units. These include multiple devices of the same appliance type, for example 9 monitors and 3 laptops.

5.1 *Monitoring devices setup*

This section presents the employed technical equipment towards the generation of the dataset described above.

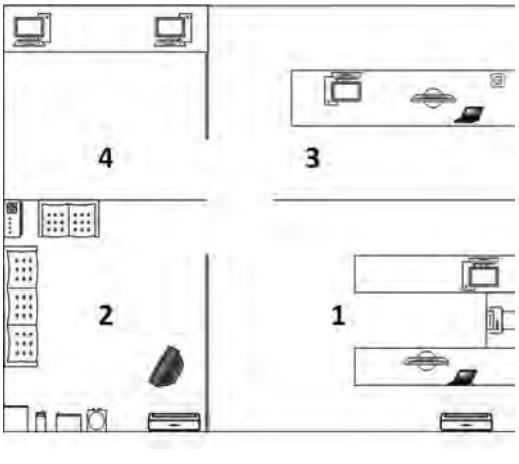

Figure 5. Plegma labs headquarters installation.

For the main power supply, the authors developed a custom implementation using (a) a set of voltage and electric current converters for the measurements, (b) an Analog to Digital Converter (ADC) and (c) an ARM based single board computer for data treatment. In particular:

a. The current sensors used for this project are current transformers with 1:1800 turn ratio with rated input of 100 Amperes to 50 milliamperes output. For the voltage sensing, in-house implemented voltage transformers have been used.
b. The employed ADS is the ADS 131E08 by Texas Instruments, which is capable of sampling simultaneously eight different channels. The number of available channels allows the measuring of electric current and voltage for each of the three phases, leaving two channels free for additional analog sensors (e.g. for temperature, humidity, luminosity etc.). The sampling frequency can range from 1 kHz up to 64 kHz. For the needs of the PREDIVIS project, data are collected at the maximum resolution. In the future, the analysis will indicate whether lower are sufficient (to reduce the sensor consumption) without losing on the quality of results.
c. The arm single board computer is a Raspberry Pi 3 by Raspberry Pi Foundation which receives data from the ADC through serial peripheral interface (SPI) communication.

In order to verify the data collected through the above custom implementation, a widely used industrial grade energy meter/analyzer is also connected to the system. The selected device is the BFM136 produced by SATEC ltd (see Table 1).

For the recording of individual devices' data, a Z-wave based system is implemented. The system uses two different types of smart-pugs, namely the Wall Plug by Fibaro and the Smart Switch 6 by Aeotec. Each plug is monitored continuously at the interval of 5 seconds or less, using a Z-wave USB adapter. The adapter is the Z-Stick S2 by Aeotec (see Table 1).

The two sets of measuring devices are accompanied by appropriate software components developed by the authors. These include:

Table 1. Devices used in the case study.

Metering device	Number
BFM136	1
100 A High Accuracy Current Sensors	3
ADS136E08 with RPi	1
100 A:50 mA Current Sensors	3
Voltage Sensors	3
Fibaro Wall Plug	4
Aeotec Smart Switch 6	13

a. a No-SQL database to store the data locally. The chosen format for the recorded data is in the form of time—voltage—current triplets. These follow a key-value format, with UNIX timestamp for the time.
b. a custom interface is herein implemented to collect and transmit the data and visualize the current and voltage waveforms. The data are sent over the internet to Plegma's cloud infrastructure.

All the devices reported in Table 2 are measured through the smart-plug installation. The two main monitoring devices are currently polled in 3 second (BFM136) intervals, as well as with frequency of 8 kHz (custom implementation). The main monitoring devices are measuring the three-phase installation as follows:

Table 2. Measuring devices and entities.

Entity	Measuring device	Room No
Main	BFM136 & ADS with RPi	Electricity board
Water cooler	Fibaro Wall plug	2
Microwave	Fibaro Wall plug	2
Coffee maker	Fibaro Wall plug	2
Refrigerator	Fibaro Wall plug	2
Work station 1 desktop with 2 monitors	Aeotec Smart Switch 6	1
Work station 2 laptop with 1 monitor	Aeotec Smart Switch 6	4
Work station 3 1 desktop with 2 monitors	Aeotec Smart Switch 6	3
Work station 4 1 high load desktop with 2 monitors	Aeotec Smart Switch 6	4
1 Monitor	Aeotec Smart Switch 6	3
1 Laptop	Aeotec Smart Switch 6	3
1 TV monitor	Aeotec Smart Switch 6	2
1 Router	Aeotec Smart Switch 6	2
1 Printer	Aeotec Smart Switch 6	1
Guest plug 1	Aeotec Smart Switch 6	1 or 3
Guest plug 2	Aeotec Smart Switch 6	1 or 3
2 Air-condition Units	Aeotec Smart Switch 6	1, 2

- Phase 1 lights for rooms 1, 2, 3 and 4,
- Phase 2 sockets of rooms 1 and 2,
- Phase 3 sockets of rooms 3 and 4.

5.2 *Future steps*

Due to the differentiation of the two cases this project is trying to address, it is necessary to be able to simulate different events and scenarios to test its efficiency. The two cases are divided in two major categories residential and industrial/commercial. In order to test the efficiency of the utilized algorithm on specific cases and validate our data different devices will be simulated on variable working states.

The collected data allow us to test different approaches of NILM, based on either high or low frequency data. This project is trying also to address the problem of device health monitoring, and predictive maintenance. In order to have sufficient data for the third phase of the project where a Predictive Maintenance suite will be implemented, we will tamper some specific days of the data from the devices, with different methods (e.g. leaving the fridge door open, turning devices on and off, modifying thermal loads etc.).

Additional data will be generated to see how the disaggregation mechanisms work, to test their ability to distinguish the anomalies produced and match them to the device or entity appropriately. More similar sites will follow so that the final dataset has adequate variety to allow the development of widely applicable algorithms and tools.

6 CONCLUSIONS

In this paper, we reviewed the fundamentals of NILM systems and the energy disaggregation problem. A novel technique is proposed to address this problem that will be applicable to the energy efficiency and predictive maintenance.

Recent works indicate that energy disaggregation is an active field, and there are a lot of different approaches to address it. Even, however, the most advanced methods have not achieved adequate results to be reliable for deployment on a large scale. The problem, therefore, is still open and the potential benefits of disaggregation, in terms of its ability to support end-users and utilities, cannot be fully exploited.

The project PREDIVIS presented here proposes a novel approach with custom hardware implementation of measuring devices. The combination of software and hardware modules can address the problem of data bandwidth and storage size. Adequate information on predictive maintenance can be obtained by combining electric consumption data with other monitoring data.

The availability of relevant and reliable data is crucial for the development of the disaggregation tools. For this reason, the project starts with the generation of datasets for residential, commercial and industrial energy use patterns. The collected residential and commercial data will be combined with publicly available datasets. For commercial and industrial environments, the lack of public datasets makes it a more challenging process.

Once the datasets are fixed, the main work involves the development of energy disaggregation algorithms, the design of data collection and smart on-site devices for hardware accelerated analysis. With continuous monitoring it is possible to produce useful information about the device and machinery health. Monitoring the full cycle of operation could support energy efficiency and predictive maintenance applications, by detecting abnormalities, predicting total operating time of components etc. The current approach could thus detect early-stage device malfunction in industrial sites, supported by energy consumption evidence as well as other sensor data (e.g. temperature). The project considers, at a later stage, the development of decision support systems for industrial, commercial and large residential sites. The success of non-intrusive electric load monitoring on predictive maintenance could provide a much cheaper alternative as compared to complex and expensive monitoring equipment.

A diagnosis method for diesel engine wear fault based on grey rough set and SOM neural network

Silin Qian, Shenghan Zhou, Wenbing Chang & Yiyong Xiao
School of Reliability and Systems Engineering, Beihang University, Beijing, China

Fajie Wei
School of Economics and Management, Beihang University, Beijing, China

ABSTRACT: The paper aims to establish a model to identify wear fault of marine diesel engine based on grey rough set and Self-Organizing Map (SOM) network with oil monitoring data analysis. The empirical data indicates the wear fault takes great proportion in fault types of diesel engine. Through oil monitoring, the change of parameters of lubricating oil and the information of wear particle can be obtained to analyze status of components. Firstly, the paper constructs the two-dimensional fault decision table. Subsequently, the grey relational analysis and rough set theory are used to reduce the fault decision table horizontally and longitudinally. Next, the fault diagnosis model is established by SOM network. Finally, the proposed model is validated by empirical research. The result suggests that the proposed model is feasible in wear fault diagnosis problem. Moreover, compared with the traditional SOM neural network, the model has less error and better diagnosis effect.

1 INTRODUCTION

Marine diesel engine as the heart of the marine power plant, its safety and reliability is vital. However, due to the abominable work condition and the complexity of marine diesel engine structure, the fault of diesel engine is relatively frequent. In addition, there are many kinds of faults in diesel engines, and the proportion of faults caused by abnormal wear is the highest, which is about 37.5% (Jones et al. 2000). Therefore, monitoring of the running status in real time and timely recognition of the wear condition with marine diesel engine can effectively improve the reliability and economy of the operation of the ship (Xiang 2009).

During the operation of the marine diesel engine, the oil is circulated in various parts of the equipment. Through the oil monitoring, we can learn the changes of lubricating oil indexes and the wear particles of each friction pair. Further, the diesel engine wear state can be qualitatively and quantitatively identified. Spectral analysis and ferrography analysis, which are able to detect concentration of elements and identify the fundamental parameters of ferromagnetic wear particles in lubricating oil, is one of oil monitoring technologies and widely used for diagnosing wear-out fault of diesel engine (Gao et al. 2013).

Due to the complexity of the factors that affect the oil and the result of fault diagnosis is greatly influenced by the oil sampling period and oil change, the traditional "three-line value" method based on statistics is no longer applicable. Therefore, the best way is to excavate the nonlinear relationship behind the data as much as possible through data learning. The development of artificial intelligence algorithm provides more choices for fault diagnosis research (Li et al. 2017). Among them, Self-Organizing Mapping (SOM) network has good self-organization, self-adaptability and robustness. Due to the unsupervised learning method, the SOM network does not need to specify the category of the input vector. It is a kind of recognition network based on small sample training, which is different from the traditional neural network that requires a large number of training samples to ensure the accuracy of classification (Wen 2016). Therefore, SOM networks are widely used in pattern recognition and classification.

However, when inputting a large amount of complex data, the SOM network often suffers from slow convergence and low classification accuracy due to the complexity of the network. The rough set theory can identify and extract the hidden and valuable key data in input information, and remove redundant and invalid data. Yi et al. (2014) used rough set theory to simplify decision rules and removes redundant information, and proposed a fault diagnosis model for the lube oil system of gas turbine based on rough set and SOM neural network. Zhao et al. (2016) designed a neural network

fault diagnosis model based on rough set theory. Although these researches use the rough set theory to reduce the attribute of fault decision table, that is, the two-dimensional decision table is reduced by the longitudinal dimension. However, the other dimension of the two-dimensional decision table is ignored-the data of the horizontal dimension. Therefore, the traditional reduction of input data is not complete, but there are still some irrelevant and redundant data. These data will still be excessive learning in the SOM network, affecting the classification accuracy of the model.

Therefore, this paper makes a two-dimensional reduction of the fault decision table; first, the data reduction of the horizontal dimension is carried out by grey relational analysis, and then the rough set theory is used to reduce the redundant attributes of the longitudinal dimension in the fault decision table. Finally, a diesel engine wear fault diagnosis model based on Grey rough set and SOM neural network is established.

2 TWO DIMENSION REDUCTION OF FAULT DECISION TABLE

For the marine diesel engine, the fault diagnosis process caused by abnormal wear is actually a decision-making process. The basis of decision making can be a predetermined decision table which represents the experience knowledge of managers. It can also be a cumulative decision table which is abstracted and generated according to the summary of historical failure events (Gao et al. 2013). A common fault decision table is shown in Table 1.

Each column in the table represents an attribute, and each row represents an object. $a_1 \ldots a_n$ represent the conditional attributes, and D represent the decision attributes. In practice, there are many fault reporting events and oil monitoring information of diesel engine. Therefore, there are more condition attributes, and the objects in the horizontal dimension also have some irrelevant and redundant data.

Thus, in this paper, two-dimension reduction of two dimensional fault decision table is introduced. Indeed, the data reduction of the horizontal dimension in the fault decision table is carried out by grey relational analysis, and then the rough set theory is used to reduce the redundant attributes of the longitudinal dimension.

Table 1. Diagrammatic sketch of fault decision table.

U	a_1	…	a_k	…	a_n	D
X_1	1	…	2	…	1	0
…	…	…	…	…	…	…
X_i	2	…	1	…	2	1
…	…	…	…	…	…	…
X_m	1	…	1	…	1	0

2.1 *Grey relational analysis method*

Grey system theory is one of the important methods and techniques for studying uncertain systems. And grey relational analysis is a very active branch in the grey system theory, which basic idea is to divide the factors as sequence curve, and then through the similarity degree of geometric shapes to obtain the correlation degree of each factors (Gao et al. 2013). The closer the shape of the curve is, the greater the correlation of the corresponding sequence is determined.

The calculation steps of grey correlation degree are as follows (Liang & Zhang 2009):

Step 1: $X_0 = \{a_0(k) \mid k = 1,2,\cdots n\}$ was determined as a reference sequence, and $X_i = \{a_i(k) \mid k = 1,2,\cdots n\}$ were the comparative sequences. Among them, $i = 1, 2,\ldots, m$, and there are m sequences and n attributes.

Step 2: Calculate the correlation coefficient $\gamma(a_0(k), a_i(k))$ of each attribute relative to the reference sequence.

$$\gamma(a_0(k), a_i(k)) = \frac{\min\limits_{i\in m}\min\limits_{k\in n}\left|a_0(k)-a_i(k)\right| + \rho\max\limits_{i\in m}\max\limits_{k\in n}\left|a_0(k)-a_i(k)\right|}{\left|a_0(k)-a_i(k)\right| + \rho\max\limits_{i\in m}\max\limits_{k\in n}\left|a_0(k)-a_i(k)\right|} \tag{1}$$

where, ρ means resolution coefficient, and the smaller the value is, the greater the differentiation is. Generally, $\rho \in (0,1)$, and when $\rho \le 0.5463$, the discrimination performance is the best. Here ρ is taken as 0.5.

Step 3: Calculating grey relational grade.

$$\gamma(X_0, X_i) = \frac{1}{n}\sum_{k=1}^{n}\gamma(a_0, a_i) \tag{2}$$

In a diesel engine wear fault decision table, if each row is considered as a factor leading to diesel engine fault, then the grey correlation grade of these factors can be sorted from large to small, eliminating some invalid, low correlation and redundant data.

2.2 *Attribute reduction based on information entropy*

2.2.1 *Rough set theory*

Rough set theory is based on an information system IS = (U, A, F), where U = (X_1, X_2,…,X_i,…,X_m) is called the universe and A = (a_1, a_2,…,a_k,…,a_n)

denotes attribute sets . $F = \{f_k : U \to V_k (k \le n)\}$ is the relation sets between U and A, and V_k is the range of a_k (Jia et al. 2016).

Definition 1 Let IS = (U, A, F) be the information system of diesel engine, and V_d is the range of fault state D. The mapping from universe U to fault state is denoted as d: $U \to V_d$, then DIS = (U, A, F, d) is called fault diagnosis information system.

$$R_A = \{(X_i, X_j) \big| f_k(X_i) = f_k(X_j)(a_k \in A)\} \tag{3}$$

$$R_d = \{(X_i, X_j) \big| d(X_i) = d(X_j)\} \tag{4}$$

If $R_A \subset R_d$, DIS is called coordinated diagnosis information system. On the contrary, it is called inconsistent diagnostic information system.

For inconsistent diagnostic information systems, the processing is no longer a simple inclusion relation, but the inclusion degree between sets (Zheng et al. 2014). The concept of inclusion degree is introduced as follows.

$$\begin{aligned} &B \subseteq A, [X_i]_B = \{X_j \big| (X_i, X_j) \in R_B\} \\ &R_B = \{(X_i, X_j) \big| f_k(X_i) = f_k(X_j)(a_k \in B)\} \end{aligned} \tag{5}$$

$$U/R_B = \{[X_i]_B \big| X_i \in U\} = \{X_1, X_1, \cdots, X_s\} \tag{6}$$

$$U/R_d = \{D_1, D_2, \cdots, D_r\} \tag{7}$$

For $X_i \in U(j = 1,2,\cdots,r)$, the inclusion degree is:

$$D(\mathrm{D}_j/[\mathrm{X}_i]_B) = \mathrm{D}_j \cap [\mathrm{X}_i]_B / \big|[\mathrm{X}_i]_B\big| \tag{8}$$

In the formula, $|X|$ denotes the cardinality of the set X.

In order to enhance the anti-interference ability of the rough set model, Ziarko proposed a variable precision rough set model, introducing the classification accuracy $\beta(0.5 < \beta \le 1)$.

Definition 2 Let DIS be an inconsistent diagnostic information system, $B \subseteq A$, precision threshold $\beta \in (0.5,1]$. For $X \subseteq U$,

$$\begin{aligned} \underline{R}_B^{\beta}(X) &= \{\mathrm{X}_i \big| \mathrm{D}(X/[\mathrm{X}_i]_B) \ge \beta\} \\ &= \cup\{[\mathrm{X}_i]_B \big| \mathrm{D}(X/[\mathrm{X}_i]_B) \ge \beta\} \end{aligned} \tag{9}$$

$\underline{R}_B^{\beta}$ is called β lower approximation of X.

Definition 3 Let DIS be an inconsistent diagnostic information system, $B \subseteq A$, precision threshold $\beta \in (0.5,1]$. The β approximate dependence of the fault state D on the parameter set B is defined as:

$$\eta(B, D, \beta) = \left| \bigcup_{j=1}^{r} \underline{R}_B^{\beta}(D_j) \right| \Big/ |U| \tag{10}$$

For inconsistent diagnostic information systems, the classification accuracy is first selected, and the corresponding approximate dependence is calculated. If the evaluation index meets the requirements, the system reduction should be continued.

2.2.2 *Information entropy and conditional entropy*

For diesel engine fault diagnosis, the purpose of attribute reduction is to use fewer parameters to obtain the same diagnosis effect as many parameters, and improve the diagnosis efficiency. Information entropy can measure the uncertainty of knowledge, and reveals that the roughness of knowledge is essentially the description of the information contained in it (Li et al. 2012).

Definition 4 For DIS, the information entropy of parameter set B is:

$$H(B) = -\sum_{i=1}^{s} \frac{|X_i|}{|U|} \log_2 \frac{|X_i|}{|U|} \tag{11}$$

Definition 5 the conditional entropy of the fault state D is relative to the parameter set B:

$$H(D|B) = -\sum_{i=1}^{s} \sum_{j=1}^{r} \frac{|X_i \cap D_j|}{|U|} \log_2 \frac{|X_i \cap D_j|}{|X_i|} \tag{12}$$

2.2.3 *Heuristic attribute reduction algorithm*

Attribute reduction is one of the key problems in rough set theory. Searching for all reductions or optimal reductions is proved to be a NP (nondeterministic polynomial) complete problem. Therefore, heuristic algorithms are usually used to search for optimal reductions (Zhang et al. 2009).

Definition 6 the mutual information of fault status D and parameter set B is defined as:

$$I(D;B) = H(D) - H(D|B) \tag{13}$$

Mutual information is used to measure the amount of information obtained from the parameter set B of the fault state D.

Definition 7 the importance of any parameter $a \in A - B$ relative to the fault status D is defined as:

$$SGF(a, B, D) = H(D|B) - H(D|B \cup \{a\}) \tag{14}$$

The attribute importance measures the amount of information about the fault state D from the parameters $\{a\}$ under the condition of the known parameter set B.

In order to reduce the parameter redundancy in the longitudinal dimension of the fault decision table, a forward heuristic search algorithm is proposed for attribute reduction. From the rough set

theory, the relative kernel of any decision information system is unique. Therefore, the relative core can be used as the starting point of searching the optimal reduction (Tian et al. 2014). The algorithm steps are as follows:

Step 1: Calculate mutual information $I(D;A)$ between attribute set A and fault state D in DIS.

Step 2: Calculate the core of the attribute set A relative to the fault state D. If relative core is $C = \phi$, then $I(D;C) = 0$.

Step 3: Let B = C and repeat 1) to 3) for the parameter subset A–B.

1. If $I(D;B) = I(D;A)$, then turn to step 4.
2. For each parameter $a \in A - B$, calculate the importance $SGF(a,B,D)$ of the attributes.
3. Select the attribute with the most important attribute value, which is denoted as p. Let B: = B $\cup$ {p}.

Step 4: Output reduction parameter set B.

3 FAULT DIAGNOSIS MODEL OF DIESEL ENGINE WEAR BASED ON SOM NETWORK

3.1 *Self-organizing map network*

SOM network is a self-organizing, unsupervised learning, self-learning neural network composed of fully connected neuron arrays. The typical SOM network structure is shown in Figure 1, which consists of an input layer and a competition layer (also known as an output layer). The number of neurons in the input layer is n, and the competition layer is a two-dimensional plane array composed of $a \times b$ neurons. Each input neuron is connected to all the neurons in the two-dimensional plane array (Xu et al. 2014). The training process of SOM network is to adjust the weights of network nodes continuously, so that different input types correspond to different neurons in two-dimensional plane array.

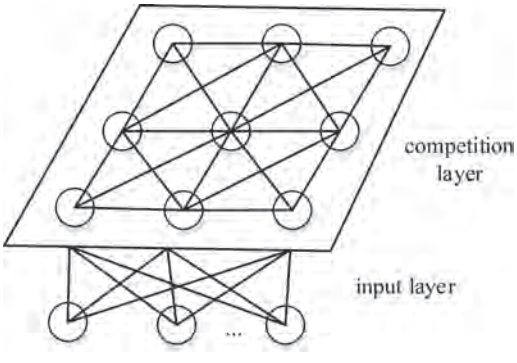

Figure 1. Network model of SOM.

The learning steps of the SOM network are as follows (Zhang et al. 2017):

Step 1: Network initialization. The random number is used as the initial value between the input neuron and the output neuron to connect weights.

Step 2: Accept input samples. The matrix $U = X1, X2, \cdots, Xm$ composed of the sample characteristic parameters is input to the SOM network.

Step 3: Calculate the Euclidean distance between the input vector and the connection weight vector. The neurons with the least Euclidean distance are determined, and they are denoted as the winning neuron O.

The Euclidean distance between the i-th input vector and the j-th neuron in the mapping layer is

$$d_j = \sqrt{\sum_{i=1}^{n} (X_i - \omega_{ij})^2} \tag{15}$$

where, ω_{ij} is the weight between the i-th neuron of the input layer and the j-th neuron of the mapping layer.

Step 4: Adjustment learning of the value. According to the formula (16), the weights between the winning neuron O and the neighboring neurons are corrected.

$$\Delta\omega_{ij} = \eta h(j, j^*)(X_i - \omega_{ij}) \tag{16}$$

where, η is the constant in the range of (0, 1).

$$h(j, j^*) = \exp\left(-\frac{|j - j^*|^2}{\sigma^2} \right) \tag{17}$$

In the formula, σ^2 decreases with learning and narrows the range of $h(j, j^*)$ from width to width. The weight adjustment is changed from coarse to fine. Ensure the accuracy of classification.

Step 5: stopping criterion. Determine whether the expected requirements, if achieved, then end. Otherwise, go back to step 2 and proceed to the next round of learning.

3.2 *The process of diesel engine wear fault diagnosis model*

By using grey relational analysis and rough set theory, the data of horizontal and vertical dimensions in a fault decision table are reduced. Therefore, the validity of the input data to SOM network is greatly improved, and the classification accuracy of the network is improved. The diesel engine wear fault diagnosis model based on Grey rough set and SOM network is shown in Figure 2.

The concrete steps are as follows:

Step 1: Initial fault decision table. The Ferrography and spectral analysis data of diesel engine oil monitoring information, as well as multi group sample data (Universe), form the initial fault decision table.

Step 2: The grey correlation grade of each row data is calculated and the data reduction of horizontal dimension is carried out.

Step 3: Discretization of continuous attributes and data reduction in longitudinal dimension.

Step 4: Before the analysis of the rough set method, the continuous attributes of the horizontal reduction are discretized by using the equal frequency binning. Then, attribute sets are reduced by using information entropy.

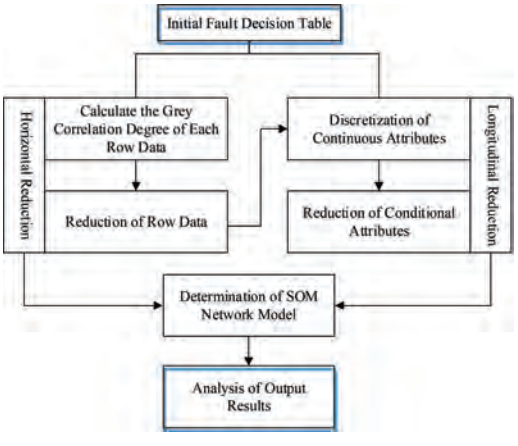

Figure 2. Diesel engine wear fault diagnosis model based on Grey rough set and SOM network.

Step 5: Determination of SOM network model. The number of neurons in the input layer is the number of attributes set B after reduction.

Step 6: Analysis of fault diagnosis results. The evaluation index of SOM network is defined as the classification accuracy, such as formula (18).

$$R(\%) = \frac{y_n}{y_m} \cdot \%$$ (18)

Where, y_n is the number of samples for correct classification and y_m is the total number of samples.

4 CASE EXPERIMENT

The oil spectrum and Ferrography data obtained in this paper are derived from a marine diesel engine. Rated power of marine diesel engine is 1760 KW and engine speed is 1800 r/min. There are 92 sets of oil monitoring data. Irregular sampling was carried out from 2013 to 2015, and the sampling position was the main oil duct of marine diesel engine. Oil is changed out regularly. There are 8 kinds of elements (Unit: ppm) in oil spectral analysis, including Cu, Fe, Cr, Ba, Zn, Si, Al and Pb. The oil Ferrography data is derived from Quantitative Ferrography Analysis, which contains the concentration value of large wear debris Dl (> 5 μm) and small wear debris Ds (1–2 μm) in the oil samples. In order to better characterize the wear conditions of diesel engines, we introduce the Total wear Dls = Dl + Ds; and Wear severity index IS = Dl^2-Ds^2. The data set (fault decision table) is shown in Table 2. Among them, the fault states include 3 types, namely, well condition (50 samples), degradation (21 samples),

Table 2. Oil monitoring data set.

U	Cu	Fe	Cr	Ba	Zn	Si	Al	Pb	Dl	Ds	Dls	IS	Wear-out status

X73	1.3	186.3	0	1.0	0.4	40.6	15.8	1.3	69.2	96.1	165.3	-4446.57	fault
…	…	…	…	…	…	…	…	…	…	…	…	…	…
X91	76.2	100.6	2.1	0.5	1.5	39.1	17.8	24.3	96.9	88.8	185.7	1504.17	fault
X92	100.6	78.6	1.6	0.4	3.0	30.3	29.6	36.4	96.9	62.3	159.2	5508.32	fault

and fault (21 samples). The judgment for the condition of diesel engine is given by experts.

4.1 *Grey relational analysis*

Sample ID represents the cycle of marine diesel engine oil monitoring. Therefore, the oil sample with the first fault is selected as the reference sequence. It is considered that the sequence of grey relation less than 0.85 cannot reflect the wear fault state of diesel engine effectively. Therefore, these invalid redundant data samples are deleted. In this study, samples of ID 2, 14, 17, 29, 43, 55, 63, 67, 71, 76, 80, 82, 85 and 90 were excluded from the fault decision table.

4.2 *Attribute reduction*

Firstly, the method of equal frequency binning is used to discretize the data after horizontal reduction. Due to $R_A \not\subset R_d$, the fault decision table shown in Table 2 is inconsistent diagnostic information system. At the same time, when the classification accuracy β is different, the classification performance of the system is not the same. We select different values of β, and their classification performance is shown in Table 3.

Therefore, this paper chooses the precision threshold $\beta = 0.8$, and uses the heuristic algorithm of 2.2.3 section to reduce the attributes. Finally, the attribute reduction result is B = {Fe, Al, Cu, Pb, Dl, IS}.

4.3 *Establishment of SOM network model*

The parameters of the attribute set B are normalized and then used as input to the SOM network. The competition layer of SOM network is set to $6 \times 6 = 36$ neurons, and the number of training iterations is defined as 200. There are 78 groups of samples after horizontal data reduction. 45 groups were selected as training sets (including 25 well condition, 10 degradation and 10 fault), and the remaining 33 (including 20 well condition, 7 degradation and 6 fault) were the test sets.

The Matlab toolbox was used to establish SOM network structure and the results as shown in Figure 3, Figure 4 and Table 4. Hexagons with numbers represent the winning neurons in Figure 3; the number of training samples represented by the neuron is described numerically. The hexagons with numbers in Figure 4 represent neurons, and the straight line in the middle represents the connection of neurons. The distance between neurons was calculated by Euclidean distance formula, and the distance between the neurons was reflected by the hexagon color background of the connected neurons. The darker the color is, the farther the distance between neurons is. That is, the greater the difference between the two neurons.

Table 4 illustrates the neurons excited by each wear state. The distribution of neurons in the whole competition layer can be explained by Table 4 and Figure 4.

Table 3. Comparison table of classification performance for the samples.

β	1.0	0.9	0.8	0.7
$\eta(A, D, \beta)$	0.1563	0.5721	1.000	0.8109

4.4 *Results analysis*

The diagnosis results of diesel engine wear fault based on SOM network are shown in Table 5. As

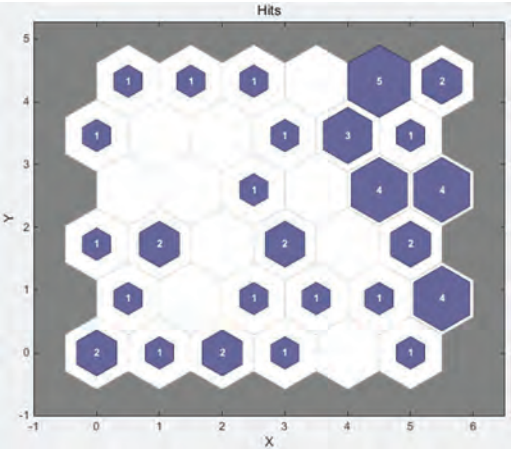

Figure 3. Winning neuron map.

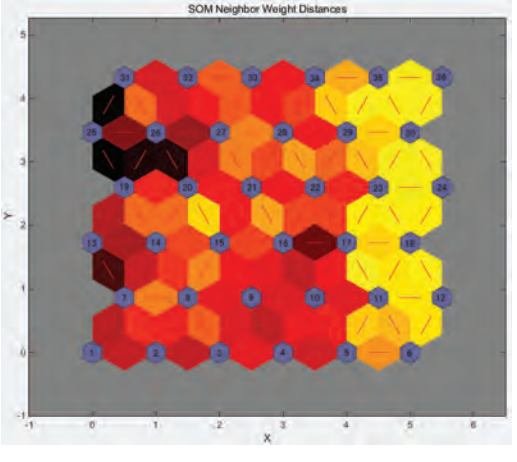

Figure 4. Distance between the neurons.

Table 4. Competitive layer neurons corresponding to wear states.

Wear-out status	Serial number	Index of excited neurons
Well condition	1	23, 30, 36, 24, 18, 12, 6, 11, 29, 35, 29
Degradation	2	3,13,2,1,14,7,31,25
Fault	3	4,9,10,32,33,28,21,3,16

Table 5. Diagnostic result statistics of SOM network model.

Sample type	Classification accuracy
Well condition	100%
Degradation	85.71%
Fault	100
Total	96.97%

Table 6. Classification accuracy of different models.

Model	Total classification accuracy
GRS-SOM	96.97%
RS-SOM	87.88%
PCA-SOM	75.76%
GRPCA-SOM	78.79%

shown in Table 5, the accuracy of the whole test set is 96.97%, and the diagnosis process is feasible and the results are satisfactory.

To illustrate the advantages of the model, we compare it with Rough set-SOM (RS-SOM) (without horizontal data reduction), Principal component analysis-SOM (PCA-SOM), and Grey relational principal component analysis-SOM (GRPCA-SOM) models. Using the same training set and test set, the results are shown in Table 6.

Compared with RS-SOM, PCA-SOM and GRPCA-SOM methods, GRS-SOM has higher classification accuracy. Therefore, it is feasible to use the SOM network model based on Grey rough set to diagnose the wear fault of diesel engine. In addition, it can solve the problem that the wear state of diesel engine is difficult to identify.

5 CONCLUSION

This paper presents a fault diagnosis method for marine diesel engine wear based on Grey rough set and SOM neural network. The horizontal and longitudinal dimensions of the two-dimensional fault decision table are reduced by using grey correlation analysis and rough set reduction theory respectively. The reduced data is used as the input of the SOM network, and the fault diagnosis model is established to identify the wear state of the marine diesel engine.

The grey relational analysis and rough set theory are used to reduce the input data, and the redundant data and attributes are completely removed. While simplifying the network mechanism, the accuracy of fault diagnosis is improved.

Compared with the traditional RS-SOM, PCA-SOM and GRPCA-SOM model, the fault diagnosis model based on Grey rough set and SOM neural network has smaller error and higher classification accuracy.

Anomaly indicators for Kaplan turbine components based on patterns of normal behavior

M.A. Sanz-Bobi

L. Eilertsen
GLITRE Energy, Norway

ABSTRACT: This paper describes and proposes some indicators for continuous monitoring of anomalous conditions in the hydraulic system of a Kaplan turbine using SCADA data. The indicators are based on significant deviations between the estimated values for key variables describing the current working conditions of the components at the plant, and those actually observed. This monitoring strategy requires models describing the expected values for variables through the whole range of possible working conditions of the monitored components. These models are normal behavior models able to characterize the typical relationships between a set of variables used as inputs to the models and the corresponding output of a target variable whose expected value has to be predicted. The criteria to select the variables to use in the models are based on the physical working principles of the component. The paper is focused on models of normal behavior applied to a real case of condition monitoring of a Kaplan turbine regulating mechanism.

1 INTRODUCTION

Hydropower is the leading renewable global source for electricity generation supplying 71% of all renewable electricity and reaching 1,064 GW of installed capacity in 2016 (WEC, 2017). It generated 16.4% of the electricity produced in the world from all sources. Hydropower is the most flexible and consistent of all the renewable energy resources, capable of meeting base load electricity requirements, as well as with pumped storage technology, meeting peak and unexpected demand due to shortages or the use of intermittent power sources. Also, hydroelectricity is a source of electrical energy coming from water that is clean and safe.

A large number of data is logged in the SCADA system (Supervisory Control And Data Acquisition) in hydropower plants, but the current status in Norway and Sweden is that SCADA data—apart for their use to control the plant—is not much used for other purposes, such as condition monitoring and maintenance planning. Thus, there is a large potential for using SCADA data for these new purposes. This may contribute to increased availability and energy production due to prevention of failures and shut downs.

The identification of possible failure modes in a hydropower plant (Topliceanu, 2016) is one of the key points in order to identify how failures could be detected in an early state. The analysis of the causes and effects of these failure modes can suggest the variables that can be useful for the detection of abnormal behaviors or anomalies (Chandola, 2009). Several references can be found in scientific literature proposing different methods for anomaly detection, and, in general, fault detection in industrial processes (Garcia Matyos, 2013) based on values of some variables measured in real time. One area in hydropower plants with an important research activity is related with the vibrational analysis focused on some key components (Mohanta, 2017), also the health condition of the components observed through several types of measurements is the goal of other studies such as those referred to in (Jamil, 2013) and (Selak, 2014).

In this paper, the hydraulic system of a Kaplan turbine was identified as a target of analysis and in particular the detection of a possible oil leakage in the system. This analysis is part of the results obtained in the research project MonitorX – "Optimal utilization of hydropower asset lifetime by monitoring of technical condition

and risk". MonitorX is a joint industry project initiated and led by Energi Norge (Energy Norway—the Norwegian electricity industry association) in cooperation with Energiforsk (the Swedish Energy Research Centre), more than 20 Norwegian and Swedish power companies, a number of equipment manufacturers and service providers, and the research institutions Comillas Pontifical University, SINTEF Energy Research and the Norwegian University of Science and Technology as R&D partners. The project is financially supported by the Research Council of Norway.

The aim of the MonitorX project is to develop models and algorithms for condition monitoring and the detection of faults in hydropower equipment. The main focus in the project is on models based on machine learning and artificial intelligence. The project is case-driven, and several relevant cases have been identified in the beginning of the project, whereof the case related to monitoring of the Kaplan turbine regulating mechanism and corresponding hydraulic system was considered as relevant for further work. Since several components and parts of the system are difficult to inspect, models that can be used to monitor the system condition and detect failures are valuable. Furthermore, oil leakage from the hydraulic system may cause environmental damage, especially when oil leaks into the river.

Usually, no separate condition monitoring systems are installed in power stations to surveil the condition of the regulating mechanism. The data that normally is available is from the SCADA system of the plant that usually presents one hour average values. Thus, one of the aims of the presented case is to study if such type of data is useful for modelling the normal behavior of hydropower components and detecting with these models anomalies that are related to faults.

The paper is organized in the following sections. Section 2 describes the method and objectives used for the creation of normal behavior models and detection of anomalies. Section 3 presents a description of the hydraulic system of the hydraulic power plant analyzed. Section 4 includes the description and development of normal behavior models used as references for detection of anomalies. Section 5 presents several cases about how the normal behavior models can be used as reference patterns for the detection of anomalies. Finally, section 6 summarizes some conclusions of the analysis developed throughout the paper.

2 METHOD AND OBJECTIVES

This section describes the main steps of the process to build anomaly indicators for detection of abnormal behavior in some functional characteristics of components in a hydropower plant. These indicators are based on patterns previously obtained from observing the typical normal behavior of the monitored components. The following sequential steps are required in order to detect anomalies based on an estimation for these indicators:

a. Selection of a data training set for learning the typical normal behavior of the component. This includes data selection and filtering, removing of outliers and treatment of missing measurements.
b. Identification of failure modes that could be detected with the variables available in the SCADA system, and selection of variables. Information available in a Failure Modes and Effects Analysis (FMEA) may help to select relevant failure modes and variables. The variables will be used for the characterization of normal behavior patterns developed in the next step.
c. Building of normal behavior patterns of a component described through variables collected in real-time from the hydropower plant. The cases studied in this paper are based on data samples collected every hour. The patterns were built using multi-layer perceptrons (Bishop, 1995), (Bishop, 2006). This technique is supervised requiring previous knowledge of behavior considered as normal and covering all the typical working conditions of the plant. A good selection of this behavior, considered as normal, is crucial in this method because the normal behavior will be learnt by the models as a reference to watch when new information is coming from the power plant.
d. Estimation of anomaly indicators. Once the previous steps are completed, the indicators of anomalies can be estimated. Its objective is to warn about data collected from the hydropower plant that do not correspond to the expected behavior by the reference patterns. The evolution of the values of the anomaly indicators over time will suggest whether or not it is necessary to pay attention to the components monitored from the point of view of scheduled maintenance and operation.

Sections 4 and 5 will describe details about each of the previous steps with examples demonstrating their use.

3 SYSTEM ANALYSED

The cases analyzed in the paper are from Embretsfoss 4, which is a hydropower plant using a Kaplan turbine for the production of electric energy. The Kaplan turbine is a propeller type turbine

controlled by the operation of the turbine runner blades (turbine blades) and the wicket gates (guide vanes). See illustration in Figure 1. A Kaplan turbine is a typical run-of-river turbine, which can be operated at different flows and at varying head. For each head and flow, there is a given ideal combination of the wicket gate and runner blade position to ensure the best efficiency of the turbine.

A turbine regulator controls and operates the turbine. Based on information about head and flow it uses predefined combination curves for the runner and wicket gate. The regulator controls the turbine by adjusting the blade and wicket gate positions with a correlated movement between the two. The acting mechanism for the wicket gates and runner blades are based on high-pressure hydraulics where an HPU (high-pressure unit) and an accumulator bank provide high-pressure oil for actuation of hydraulics servomotors.

3.1 *The high-pressure hydraulic system*

The turbine regulator controls the wicket gates and the runner blades by the use of a high-pressure hydraulic system which consist of the following main components:

- Turbine governor oil sump tank with oil pumps (HPU – High Pressure Unit)
- Pressure accumulator banks. One bank for runner blades and one bank for the wicket gates
- Hydraulic oil cooling/heating system
- Wicket gate control system
- Runner blade control system

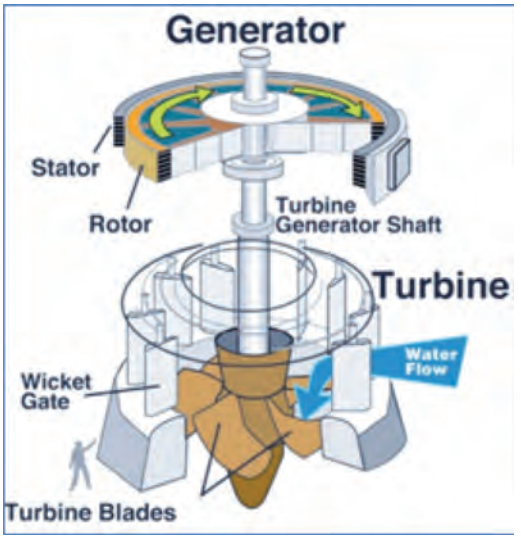

Figure 1. Illustration of the Kaplan turbine (Courtesy of Wikipedia).

- Quick stop/Emergency stop system
- Oil system for runner hub. The runner hub is the lowermost part of the runner. The cone part just below the runner blades. See Figure 1.

For a simplified view of the high-pressure hydraulics system, see Figure 2. The HPU is located at the turbine floor and it supplies the wicket gate and runner blade control system with high-pressure oil. The main components of the HPU are the oil reservoir, the oil pumps, valves, filters and coolers. In addition to supply oil to the control system, the HPU is "charging" in total five accumulator banks. The accumulator system is a safety system designed to handle a predefined number of safe shutdown cycles, in case of malfunction of the HPU system or a blackout of the station. The HPU have systems for monitoring the oil level, temperature and water-in-oil content. To prevent the pollution of the oil, each of the HPU pumps are equipped with a filter system.

For maintenance reasons, the oil reservoir is designed to be big enough for storage of all the oil in the system. However, during operation, the oil is in the different components of the hydraulic system hence only a limited amount of oil is contained in the reservoir. A minimum level is however required in the reservoir for avoiding dry running of the HPU pumps.

The hydraulics system has an oil cooling (and heating) system. The cooling system cools the oil during operation and the heating system heats the oil during standstill.

The wicket control system controls the wicket gates by the use of two hydraulic servos (cylinders). The servos actuate the control ring, which again provides the open/close movement on the wicket gates. When the control ring, seen from the top, turns clockwise, the wicket gates close.

The runner blade control system controls the position of the runner blades by the use of a servo actuator located in the runner hub. The actuator high-pressure oil supply/return is routed through the center of the turbine shaft via the oil supply head located at the top of the shaft.

The system is equipped with a system for safe emergency stopping of the turbine. This can be activated by a manual activation of the emergency stop or if the turbine is speeding and the overspeed trip valve is activated.

The turbine hub is filled with oil and has an oil pressure that is slightly higher than the surrounding water pressure. In the case of runner blade sealing degradation, this pressure prevents water from entering the hub. The oil pressure in the hub is a static pressure created by the elevated location of the hub oil tank (see Figure 2). The oil in the hub oil tank is pumped up from the HPU oil reservoir. The hub oil
