ABSTRACT: As of today, two of major topics in Reliability, Availability, Maintainability and Safety (RAMS) field are how to deal with the growing complexity of new systems and how to reduce the time required to perform RAMS analysis. Complexity is perceived as the most challenging factor when developing "safe proved" critical systems. During the last decade Model Based System Engineering has been broadly deployed in the industry in order to manage complexity. Complexity is also managed by adopting incremental and/or iterative development lifecycles. It is therefore imperative to integrate RAMS analyses with such means and processes. This implies dealing with a live, changing design baseline. To deal with the two major topics detailed above, a new practical RAMS modelling methodology is presented in this paper, based on a generic Model Based System Engineering (MBSE) tool with an Engineering Model (EM) shared between Design and RAMS teams. Requirements, Functional Trees, System Architecture and Detailed Design are included in this model. Furthermore the model includes Functional Failure Mode and Effect Analyses (FMEAs), Components FMEAs, Feared Events and related Fault Tree Analysis. In this way, safety and engineering models are intrinsically linked and RAMS teams can fully exploit traceability (established and maintained by the design team) between Functions and Components & Interfaces. An automated export of RAMS related data, (Reliability Data & Fault Tree topologies) allows numerical calculations in a reliability tool. This methodology can deal with both software and hardware technologies. It is valid for highly critical systems (safety related) but also for less critical systems with complex availability modelling (production means). A real use case for this methodology is presented; the Ariane 6 Control Bench Family (A6 CBF). A6-CBF is a family of 9 control benches, covering all the ground control needs of future Ariane 6 launcher in terms of production, validation, training and launch operations.

1 INTRODUCTION

Model Based Safety Analysis (MBSA) has become a trending topic in the dependability field since the mid-2000s (Lesage & Kruse, 2011; Joshi, Keimdahl, Miller, & Whalen, 2005). Formal methods will be the RAMS analyst's Swiss army tool to perform safety case of complex systems (Rauzy & Chaire, 2014). They already have been successfully used in highly regulated industries where safety certification is mandatory (e.g. certification of the flight control system of the aircraft Falcon 7X, Bieber et al., 2008). On the other hand, the use of formal methods or specific languages for dysfunctional modeling (AADL, Altarica, eventB, Safety Architect from ALL4TEC, Safety Designer from Dassault) requires a specific knowledge and a considerable amount of time which is usually only economically viable in systems to be produced in large series.

The proposed methodology in this paper is an intermediate strategy between traditional and innovative techniques. It allows the use of well-known methods (Fault Trees Analysis (FTA), Failure Mode Effects Criticality Analysis (FMECA), etc.) with very complex systems. Our approach ensures the completeness and consistency of the RAMS studies, the most challenging parts within "manual" safety analyses. It also allows to trace and link elements proper to RAMS analysis with any other element of an Engineering Model (EM). That may sound obvious but it adds a big value for design and exploitation teams. It results in something as simple but powerful as identifying which diagnostic cover a particular failure mode and in which test case the expected behavior has been validated with two mouse clicks.

2 PROPOSED METHODOLOGY

To integrate RAMS in MBSE lifecycle, system and dependability engineering should share a common EM. RAMS analysis shall be part of the whole system development cycle using information available on EM at every moment from Requirements Elicitation to Site Acceptance phases.

2.1 *Functional Analysis (FA)*

Functional Analysis (FA) is achieved by defining functions to be performed by the system. Main functions are decomposed into several subfunctions recursively until a sufficiently detailed functional tree is obtained. This decomposition allows functional specification of the system in a complete way. Every single functional requirement shall be linked to a function. Function performance requirements shall be identified usually as a non- functional requirement.

2.2 *Functional FMEA (F-FMEA)*

For each function established in the functional tree, five generic Functional Failure Modes (F-FM) based on (Betancourt, Birla, Gassino, & Regnier, 2011) are created. These 5 failure modes are defined as follows:

F-FM1: Fail to perform the function at the required time
F-FM2: Fail to perform the function with correct value
F-FM3: Performance of an unwanted action
F-FM4: Interference or unexpected coupling with another function
F-FM5: Unable to remove the function

Once these 5 F-FM are associated to each function, the effects of the failure modes of a function are studied in a systematic and recursive way and the relevant relationships are established with the failure modes of the higher functions following the functional arborescence defined. That builds up a Functional Failure modes Fault Tree. For that, OR and AND gates can be implemented defining an appropriate kind of aggregation/decomposition link between the functions. A crucial element is provided by F-FM4 which establishes relationships between F-FM whose functions are not directly related in the functional hierarchy tree but a possible failure in one of them could impact the correct performance of the other. This feature is very useful while analyzing transversal Uses Cases requiring a sequence of particular functions.

2.3 *Feared Event (FE) identification*

Feared Events (FE) are identified mainly by the requirements defined by the client based on previous Preliminary Risk Assessment (PRA). Each FE is assigned a certain severity level as defined in ECSS Q30 based on the impact that it may have on the system.

2.4 *Link between Functional Failure Modes (F-FM) and Feared Events (FE)*

Every FE shall be related to one or more F-FM, which become the cause for the occurrence of this FE. The "higher" the Functional Tree is related to a FE, the more F-FM and consequently the more C-FM are potentially involved. For each FE a Fault Tree Analysis (FTA) is generated whose result is the assignation of a criticality level to each function. This functional criticality level allows RAMS requirements allocation usually by using function performance requirements.

2.5 *Traceability between Functional Analysis (FA) and System Component Hierarchy (SCH)*

During the Preliminary Design Phase a system Architecture is defined and high level components in the Product Breakdown Structure (PBS) are identified. As the Detailed Design Phase progresses

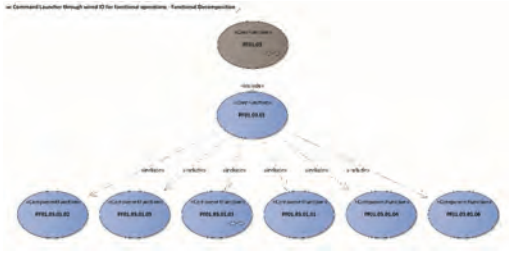

Figure 1. Functional analysis tree.

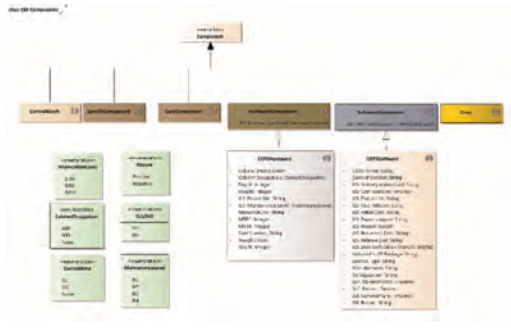

Figure 2. HW/SW component domain model.

Functional Analysis and component design is refined producing sub-functions implemented by subcomponents. In this way the function tree is related to a hierarchy of components in the PBS. The relationships between the components and the functions they implement must be established at the required level of detail. SCH decomposition should arrive until the Line-Replaceable Unit level the lowest system element to be exchangeable on the field. At the end, each LRU component shall implement one or various functions of the lowest level of the functional tree.

2.6 *Identification of Component Failure Modes (C-FM)*

For every component a set of C-FM is identified. For HW type components the use of a standard Failure Mode Distribution database (RMQSI Knowledge Center, 2016) is recommended. Similar HW_Components can be grouped in HW_Families sharing a list of common Failure Modes.

SW Failure modes are identified in relation to the functionalities of the SW component being analyzed. For SW components generics SW failure modes are available on the literature (Reifer, 1979). One of more general sets of SW failure modes is defined in. (ECSS, 2017) Three SW-FM are proposed:

SW-FM1: functionality not performed;
SW-FM2: functionality performed wrongly (e.g. wrong/null data provided, wrong effect);
SW-FM3: functionality performed with wrong timing (e.g. too late).

The persistence of the error causing the failure mode and the nature of the software application to be analyzed has to be taken into account carefully. In contrast to HW C-FM where the random nature of physical ageing plays a major role, most of the SW-FM can be covered/prevented by some level of testing (unit/integration/validation testing). EM allows traceability between these failure modes and the related diagnostic and tests to be implemented in further phases.

Figure 3. RAMS domain model.

2.7 *Link between Component Failure Modes (C-FM) and Functional Failure Modes (F-FM)*

Each Software/Hardware component (SW/HW) has its own C-FM which are identified following the procedure established in the previous sections. These C-FM can be linked to those F-FM that belong to the function or functions that the component implements. To achieve accurate results this analysis shall be performed by the RAMS team together with the team responsible for the component design.

2.8 *Results from RAMS studies implemented on the engineering model*

2.8.1 *Component criticality analysis*

Following the traces "Feared Event > Functional Failure Mode > Functional Failure Mode > … > Component Failure Mode > Component" it is possible to identify all components leading to a Feared Event. Components are then classified according to the criticality of the Feared Event. A set of Non-Functional requirements is imposed to each component depending of its criticality level.

2.8.2 *Quantitative and qualitative RAMS requirements verification*

Exportation from EM to BlockSim of related Fault Trees diagrams (via dedicated script generating an XML file per diagram) is possible. This exportation is limited to simple Fault Trees (managing OR & AND gates). However, the script manages "repeated" events and events present in different points of the same Fault Tree. Probabilities are then computed based on reliability parameters of component failure modes. This reliability data is available on the EM, and exported previously to BlockSim. For availability Fault Trees, a single fault mode per component is used, aggregating all failure mode distributions. Fault Trees in BlockSim can be used also to calculate Minimal Cut Sets allowing validation of qualitative requirements like the absence of Single Point of Failure, Fail Operational, Fail Safe or similar criteria.

3 USE CASE: ARIANE 6 CONTROL BENCH FAMILY

The Ariane 6 program, approved in 2014, aims to reduce the cost of space launch by half compared to Ariane 5. Europe will remain number one in the

commercial launch services market while responding to the needs of European institutional missions. In the particular case of Ariane 6, a MBSE approach is incorporated in the design of its control benches (Cherqui, Comery, & Lesens, 2016). Moreover, some MBSA efforts were taken within Ariane 5 environment (Ercilbengoa, Schoenig, & Hutinet, 2010). A6-Control Bench Family is the family of nine Control Benches (seven to be deployed in continental Europe, two in European Spaceport in Kourou), covering all Ground Control needs of Ariane 6 launcher in terms of production, validation, training and launch. A6-CBF will be developed by a consortium led by GTD, formed by GTD and CLEMESSY.

3.1 *A6-CBF: Core and instances*

A6-CBF its developed in an innovative iterative incremental life cycle. It is built around a "catalogue" of components with a reference architecture implementing a suite of main functions. This catalogue of components is called the Core. This Core has to be instantiated for a particular production site bench implementing components that perform the functions required in this site. Four versions of A6-CBF Core are planned, with the first bench (based on CORE 1) to be deployed operationally in the ArianeGroup Le Mureaux site in 2018.

3.2 *Selected MBSE tools*

3.2.1 *Enterprise Architect (EA)*

The A6-CBF engineering process is carried out with a commercial Model Based System Engineering tool, Enterprise Architect (EA). An Engineering Model is shared between Design and RAMS teams. This Engineering Model uses a SysML language subset to model system design and stores all data and elements needed to perform RAMS analyses.

3.2.2 *BlockSim/XFMEA by Reliasoft*

Two tools specialized in reliability engineering industry, BlockSim and Xfmea from Reliasoft, are selected to perform specific RAMS calculations. RAMS related data (FTA and reliability data) is exported from the EA model via XML format. BlockSim is used in the project to perform numerical and minimal cut sets computations. By using Fault Trees and Reliability Blocks Diagrams it is possible to validate the reliability of the system and the operational availability requirements.The size of the project implies a large amount of data that needs to be processed. Hence, Xfmea is used in the project as a tool to facilitate data management and reporting during the development of FMECAs.

3.2.3 *Enterprise architect scripting*

Since the design of the system is conceived in an iterative process, the design is expected to be changing continuously and information and elements needed for RAMS analysis will be updated continuously. Regarding the fact that RAMS analysis are performed outside the engineering model from EA and they are performed at same time the system is being developed, there is a need to constantly update the ReliaSoft database with the most recent information. In order to do so, scripts are developed to import information like reliability data, Fault Tree topologies or system architecture to ReliaSoft from EA and keep them up to date whenever it is needed.

3.3 *A6-CBF RAMS modelling objects*

An overview of RAMS modelling objects used is presented on Figure 4:

1. Client Requirement [YELLOW]: Requirement coming from any applicable documents.
2. CBF Requirements [GREEN]: Requirements declined by project team.
3. Feared Event [RED]: Technical Risk related to one CBF requirement that shall be analyzed by Fault Tree
4. Fatal Alarm [RED]: Alarm generated by Monitor Control that will put the bench in a predefined state. A FearedEvent Fatal_Alarm is used to show which conditions are required to activate this alarm.
5. Trigger [BLUE]: Condition that activates a StateMachine transition. (BENCH_Operational > BENCH_Failed trigger by Fatal Alarm)
6. Function (CORE or Component) [ROUND]: function defined in CBF Functional Analysis tree.
7. Functional Failure Mode [LIGHT ORANGE]: describing on the five generics failure mode of function
8. Component Level 1 [PINK]: CBF component to be developed & validated autonomously.
9. Component (HW or SW) [PINK]: decomposition of ComponentL1
10. COTS (HW or SW) [part of an ILS Family] [OLIVE]: Commercial off-the-shelf component
11. Component Failure Mode [DARK ORANGE: describing failure mode of component
12. MCS Diagnostic [LIGHT YELLOW]: permitting the diagnostic of a Component/Functional Failure Mode.
13. Open Issue [linked to IBTReq]: OpenPoint to discuss.
14. Assumption: [within OpenIssue] linked to open issues

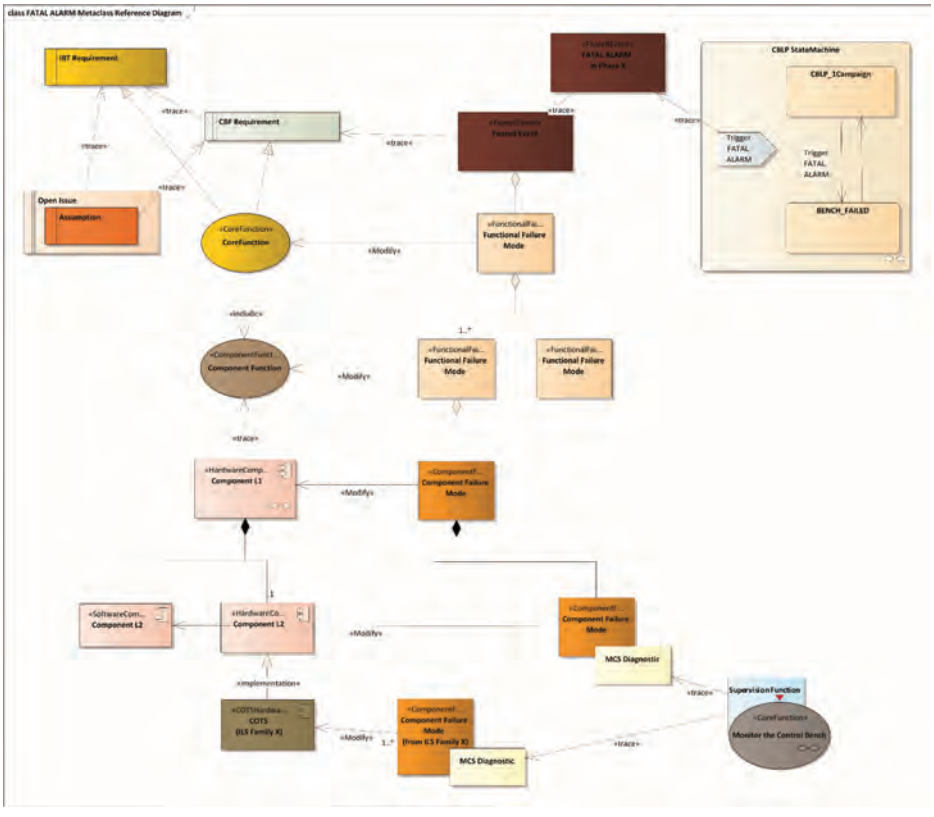

Figure 4. RAMS modelling objects in EA.

3.4 *A6-CBF functional analysis*

In the A6-CBF functional decomposition has been initially performed for Core Functions. Through the functional definition it is possible to distinguish two kind of functions: Core Functions (Core-F) and Component Functions (Comp-F). Additionally, some Instance Functions (Inst-F) may have been used to model specific functionalities not covered by the Core. The criteria for the use of Core-F or Comp-F Functions is based on the participation of one or more components in the function performance. In this way, for those functions where it is expected that only a single component will participate, Comp-F are used, whilst for the rest CORE-F are used. Comp-F will be located at the lowest levels of the functional tree and CORE-F, resulting from the integration of various Comp-F, at higher levels of the tree. A total of 21 main functions (PF) have been defined (eg: acquisition, commanding, data archiving, ...). They have been decomposed following the methodology exposed in section 2.1.

This results in more than 250 Core-F, more than 1200 Comp-F and about 10000 related requirements. Complementary, transversals Use Cases has been used to model system temporal behavior involving functions not directly linked on the functional tree.

3.5 *A6-CBF feared event identification*

Around 50 Feared Events have been identified. Feared Events are classified in five severity levels.

3.6 *A6-CBF Functional AMDEC*

Export of System hierarchy, FA, F-FM, C-FM, an diagnostics from EM model allows to interact with FMECA via a classical template, allowing a navigation around information in a practical way, easy to share with other non specialized stakeholders.

3.7 *Traceability between functional analysis and system components*

Around 70 different Components L1 (to be developed and validated unitary) are currently defined.

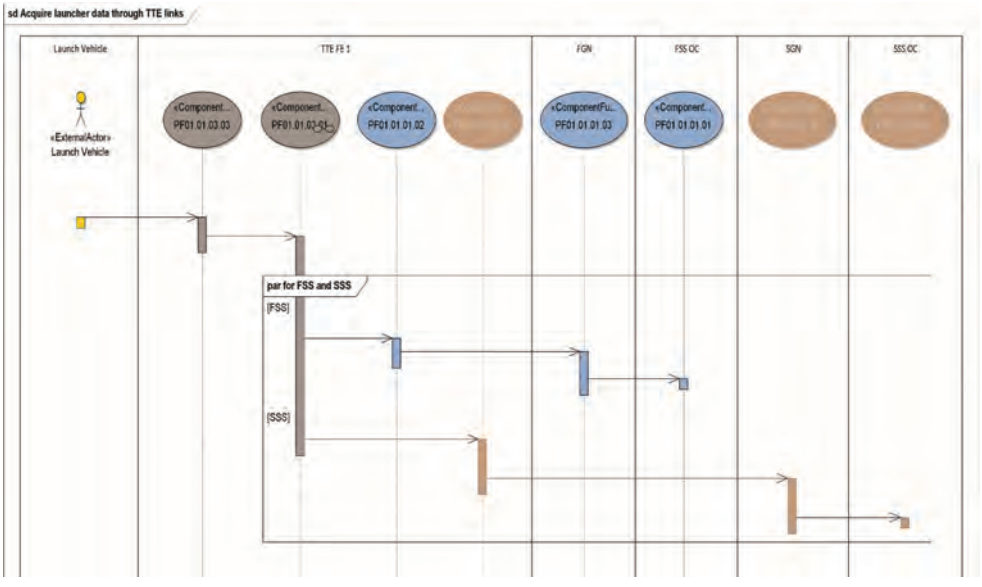

Figure 5. Example of CBF transversal function.

Recursive decomposition has been produced hundreds of component L2 (SW & HW). Each component implement a small subset of 1200 component functions, allowing Criticality Analysis.

3.8 *Identification of component failure modes*

As of today around 40 HW families have been identified. The Failure Mode/Mechanism Distributions database (FMD) by Quanterion is used to select appropriate failure modes for each HWFamily.

3.9 *Link between component failure modes and functional failure modes*

A stereotype object of type "Diagnostic" has been used to identify detection mechanisms associated to a C-FM or F-FM. In this way, it is easy to identify the Failure Modes that are not detectable. The diagnoses are identified with the nomenclature used by the supervision component (log code errors).

The general behavior of the A6 Control Bench defined by general state machine defined by Supervision component. States (the transitions of those states are Trigger type stereotypes, associated with feared Events. The dynamic effects of system behavior can also be modeled with activity diagrams or state machines, allowing triggers. In this way it is possible to know in what conditions a certain failure mode will produce the transition from the state bank Fail to the state (FatalAlarm).

Figure 6. A6-CBF feared events severity.

Figure 7. Components Vs Function traces.

These operating ways are used for Supervision components as well.

3.10 *A6-CBF RAMS results*

3.10.1 *Component criticality analysis*

A6-CBF Components L1 has been classified regarding criticality levels. Three components have been identified as the most critical regarding safety Feared Events. For each of this L1 components, a refinement work is perform in order to identify and isolate subcomponents with the high criticality.

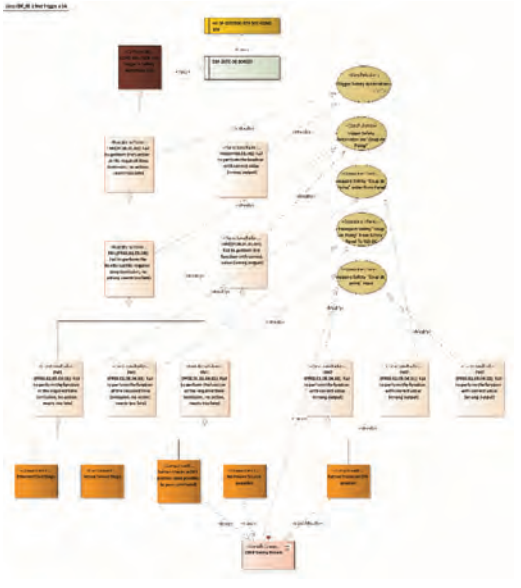

Figure 8. Feared event modelling diagram in EA.

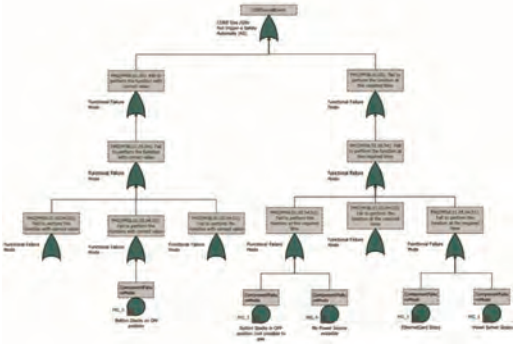

Figure 9. Feared event fault tree in BlockSim.

3.10.2 *Quantitative and qualitative RAMS requirements verification*

In this project phase, export and computation of FearedEvents Fault Tree from EA to BlockmSim allows to produce preliminary results, taking into account the current design definition. As design evolves, recursive iterations are performed to assure design complaint against RAMS requirements.

3.10.3 *Changes requested safety assessment*

A6-CBF shall operate for at least 30 years, so a specific Integrated Logistic Support program has been established to ensure operational capabilities during this period. Most of the components of the system have a useful life of less than 30 years which is why it is essential to manage the obsolescence of the material.

A component taxonomy has been created (HW Families) which allows to identify ILS Recommendations and defining RAMS requirements for each product. Each HWFamily can be implemented by different pre-qualified Part Numbers. The required reliability characteristics are defined at the HWFamiliy level (MTBFmin, MTTRmax, etc.). Failure mode distributions are also defined at this level based on the data available in the different reliability databases (NTNU, 2017). Even in this initial phase, during the three years between the first and the last Control Bench delivery, it is highly possible that some PartNumbers evolve due to obsolescence issues generating specific configurations for each bank.

Having defined the minimum RAMS requirements at the HWFamiliy level ensures that the system will continue to comply with requirements regardless of the PartNumber used.

4 OUTLOOK

This methodology can easily be extended to include cyber risk and human factors. It is possible to model realistic reliability and operational availability taking into account functions required for each of the operational phases of the bench (e.g. launch campaign, launch chronology, ignition sequence, post-launch revalidation phase).

4.1 *Cyber risk modelling*

In order to include cybersecurity analyses, functional analysis must be carried out until reaching a decomposition level with all required information transport functions (data flows). Data flows routing (components, ports and physical links involved) would have to be defined.

For each of these flows and any component where data is treated/storage following failure modes would have to be created:

– loss of data integrity,
– loss of data confidentiality,
– unavailability of data

Following the method presented in 2.4, these dataflow/component failure modes will induce functional failure modes which in turn could be part of an existing safety feared event Fault Tree (FE: To send an unexpected command). If specific feared events regarding cyber risks could be defined, (e.g. theft of information, deterioration of public image) every HW/SW component could be classified according to criticality of cyber risks induced. Cyber risk requirements could be allocated to each component according to this criticality.

4.2 *Human error factors modelling*

Following the same logic used previously for each interface between the system and a human-type actor Human Error Failure Modes (HE-FM) could be created. Different HE-FM taxonomies are used in the literature (e.g. THERP, SHERPA, HEART, see Pocock, S., Harrison, M. D., Wright, P. C., & Johnson, P. 2001). These HE-FM, can be linked to the F-FM of functions performed by components in interface with humans (usually IHMs). Components could be then classified according to criticality of human errors. Human reliability requirements could be allocated for each component according to this criticality.

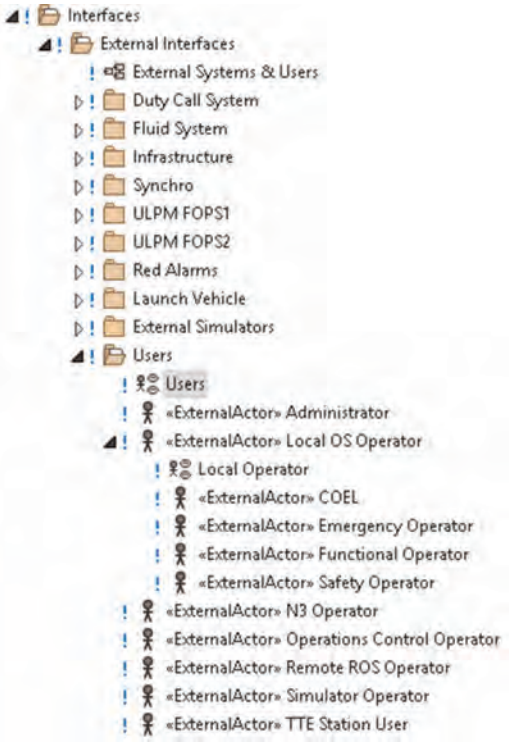

Figure 10. External actors, human type.

4.3 *Reliability and operational availability by operation phase*

The profile mission of each A6 Control Bench site is unique. In the case of Ariane 6 Control Bench Launch Pad (CBLP) it is used during 10 days and its exploitation is oriented to ensure safety during operations and availability at H0 (launch time). Production control benches are exploited to ensure continuous availability during the production checkout phase. The development of functional analysis by means of use cases enables the addition of "tag values" identifying which functions are required by phases.

5 CONCLUSIONS

A new methodology for direct integration of safety analysis in a MBSE process has been presented. System and safety engineering activities are carried out in a common Engineering Model. In this way functional FMECAs tasks can be started at a very early stage of the project identifying critical functions. Particularly for SW components, a detailed functional decomposition allows to identify and isolate high from low criticality components. Following design advancement (architecture & detailed design), FMECA's can be refined by performing criticality analysis of components/subcomponents. This kind of incremental approach reduces the required period for the RAMS analysis.

Coherence between RAMS and design configuration is always ensured since a single and centralized engineering model is the source of both types of information. Model scripting capabilities export the selected information to reliability tools generating according Fault Trees and FMECA in a more traditional format. This facilitates the exchange with other project actors. Likewise, quantitative and qualitative requirements can be computed numerically. The ability to manage permits, locks and warnings about design modifications on the model allows the RAMS engineers to have an accurate view of every design change. This guarantees a correct impact analysis.

Traditional system safety analysis is usually based on informal specifications and highly dependent on the skills of the RAMS analyst. Lastly, but not less important, another advantage provided by this methodology is the reduction of manual effort and related error-prone tasks. Again, this reduces cost and time and it increases the quality of the outcome.

ABSTRACT: Storage reliability is of importance for the products that largely stay in storage in their total life-cycle such as warning systems for harmful radiation detection, rescue systems, many kinds of defense systems, etc. The storage reliability of a product is commonly defined as the probability that the product can perform its specific function for a period of specific storage time under specific storage environment. Logically, the failures of the product in storage should be identified with the same criteria as in its operation process. However, the failure data in storage may be observed indirectly through the maintenance or inspection activities. Nevertheless, when the storage reliability is concerned in general, the reliability model should take into consideration the possibility that the operational reliability does not start at 100%, for example, the one-shot product may have only 96% operational reliability when they are newly produced. In this paper, the storage reliability model with possibly initial failures, which are usually neglected at the beginning of storage in most of storage models, is studied on the statistical analysis method when the masked data are observed. The parametric estimation procedure, based on the Least Squares method, is developed generally by applying an EM-like (Expectation and Maximization) algorithm for the storage data in which some information about which components have caused the system failures is not known, namely the failure data are masked. The estimates of the model parameters including the initial reliability are formalized. In the case of exponentially distributed storage lifetime and series system, a numerical example is provided to illustrate the method and procedure though the method is not limited to such case. The results should be useful for planning a storage environment, decision-making concerning the maximum length of storage, maintenance strategy optimization and identifying the production quality.

1 INTRODUCTION

Storage reliability is generally referred to the ability of a product that can still be able to perform its required functions after it has been in the storage state for a certain period of time. There are many examples of such products or systems whose life-cycle is mostly dominated by their storage time. The failure mechanisms of the product in storage and operation are completely different, and this implies that the storage reliability model should be considered by taking the operation reliability into account. There have been some storage models proposed under different assumptions [1–6].

In the literatures, the storage reliability models are commonly to assume that the products are perfect at the beginning of the storage, but as a result of the slow deterioration process, the operation reliability will degrade as the their storage time goes [5–6]. However, the operational reliability at the beginning of storage is not always 100% for many kinds of one-shot products [3]. Specifically, some one-shot products cannot be evaluated about if they are functioning or not, instead, they are only assessed to be good to fulfill the requirements on their performance measures under the periodical maintenance [7–14]. Note that a one-shot product is referred to those devices or equipment that can be used for only one time. After the use, they are destroyed or should be extensively rebuilt. Some examples are missiles, fire extinguishers, airbags in cars, etc.

To study the storage reliability with initial failures, a generalized storage reliability model was proposed by Zhao & Xie [15–16]. The model is expressed as

$$R(t) = R_0 R_s(t) \tag{1}$$

where R_0 can be interpreted as the initial reliability of the product and may not be completely known for the products in storage. $R_s(t)$ is called the inherent storage reliability [15] and entirely reflects the effect of the storage on the products. Note that the storage reliability can also be studied based on the knowledge of Physics of Failure (PoF), and various PoF based models can be found in [17–23].

Recently, the estimation methods for the model expressed by (1) have been considered by Zhang *et al.* [5–6]. In the study presented in [5], an integrated approach is proposed to estimate the storage reliability based on the combinational estimates of the failure numbers and current reliabilities at each testing times when groups of binomial-type failure data are available. The E-Bayesian estimation of the failure probabilities is further applied by Zhang *et al.* [6] into the integrated approach proposed in [5] for the same types of the testing data.

In general, the failure data in storage may be observed indirectly through the maintenance or inspection activities and can also be obtained through the measures of the product performance particularly based on their components. Furthermore, the field testing data can be available, but the failure causes cannot be always known due to various reasons such as high cost, difficulty to diagnosis, lack of enough information, etc. This is the case where the system lifetime data is masked for the causes of some failures are unknown or the components resulting in the system failures cannot be identified [24–26]. The masked data analysis has been considered by several authors. Miyakawa [24] proposed both parametric and nonparametric estimators in the case of a simple two-component series system by assuming that the lifetimes of components are exponentially distributed. For a general series system, the expression of the likelihood function was derived by Usher & Hodgson [25–26]. The Maximum Likelihood Estimation (MLE) was considered in the cases of two and three-component series systems and it was shown that the closed-form maximum likelihood estimators are algebraically intractable. The masked data analysis was also studied by Hansen & Thyregod [27] for a superimposed renewal process. The underlying lifetime distribution of the components are assumed to be identically mixed-exponential and each failure is masked with the same probability p for all components. The parameter p is unknown and has to be estimated from the field data. In software reliability, the MLE estimation of software reliability were also considered for superimposed nonhomogeneous Poisson processes in the case of the masked data [27–28]. To the author's knowledge, however, there has not been the study on the masked data analysis under the storage model with possible initial failures described in (1).

In this paper, the storage reliability model with the possible initial failures is studied for the masked failure data of systems. The masked data are the groups of binomial-type system failure data that may not be identified on which components caused the system failures. A general method of the parametric estimates is developed by applying a modified EM (Expectation and Maximization) algorithm for parametric ML estimation. In the case of exponentially distributed storage lifetime and series system, the method and procedure are formulized in detail. A numerical example is also provided to illustrate the method and procedure though the method is not limited to such case. The results should be useful for planning a storage environment, decision-making concerning the maximum length of storage, maintenance strategy optimization and identifying the production quality.

2 MODEL DESCRIPTION AND DATA STRUCTURE

2.1 *Model formulation*

Following the common definition, the storage reliability of products in this paper is defined as the probability that the product can perform its required function for a period of specific storage time under the defined storage environment [15]. Note that the definition given here implies that the product should be functioning in operation if it is said to be good. Consequently, it may not be possible for one-shot products to be identified as good or not by taking only the maintenance inspection.

Let T be the storage lifetime of a product, although its value can be hard to observe in reality for some types of products, it is a genuine random variable and often known to be greater, smaller or between some storage time points [5–6]. The storage reliability function given in (1) can be derived as

$$\begin{aligned} &R(t) = P(T > t) = \\ &P(T > t | \textit{product is good before storage}) * \\ &P(\textit{product is good before storage}) = R_0 R_s(t) \end{aligned} \tag{2}$$

Note that "*product is good before storage*" is referred to the random event that the product can be functioning when it is new without of storage.

The meaning of R_0 can simply be the successful probability for one-shot products to be applied. For electronic components, it will represent the proportion of non-defectives in the population, but mostly, it will be 100% for common products.

For the inherent storage reliability function $R_s(t)$, some common lifetime distributions, such as exponential, Weibull or lognormal distributions, can be applied to model the failure process of the products due to the material deterioration in storage. To simplify the method presented in this paper, the exponential distribution is applied for the inherent storage reliability although the method can be valid for a general lifetime distribution. The model expressed in (1) is therefore rewritten as

$$R(t) = R_0 e^{-\lambda t} \tag{3}$$

For a series system with k components, the storage reliability of the system, for the sake of simplicity, is given as

$$R(t) = R_1(t)\,R_2(t)\ldots R_k(t) = R_{01}R_{02}\ldots R_{0k}e^{-\lambda t} \tag{4}$$

where $\lambda = \lambda_1 + \lambda_2 + \cdots + \lambda_k, \lambda_i$ is the failure rate of ith component, $i = 1,2,\cdots,k$. Note that the system reliability given by (4) assumes that all components have the same type of lifetimes that are exponentially distributed with different failure rates.

2.2 *Masked failure data*

Suppose that the systems in storage have the binomial-type failure data at sequential observation times $t_1 < t_2 < \cdots < t_m$. The masked data can have the form as shown in the following table.

In Table 1, n_j and n_{ij} are the numbers of the system and ith component tested at observation time t_j, f_j and f_{ij} are the failure numbers of system and ith components, respectively, $i = 1,2,\ \ ,k;\ j = 1,2,\ \ ,m$.

Note that if there is not masked data, the storage reliability of each component at observation times can be simply estimated as

Table 1. Binominal-type masked failure data of a series system with k components.

Causes of failures	Observation times		⋮	
	t_1	t_2		t_m
*System	(n_1, f_1)	(n_2, f_2)		(n_m, f_m)
Component 1	(n_{11}, f_{11})	(n_{12}, f_{12})		(n_{1m}, f_{1m})
Component 2	(n_{21}, f_{21})	(n_{22}, f_{22})		(n_{2m}, f_{2m})
⋮				
Component k	(n_{k1}, f_{k1})	(n_{k2}, f_{k2})		(n_{km}, f_{km})

*The system failures are not identified on which component's failures caused its failures and then called to be masked.

$$\hat{R}_i(t_j) = \frac{n_{ij} - f_{ij}}{n_{ij}},\ i = 1,2,\ldots,k;\ j = 1,2,\ldots,m \tag{5}$$

It is also easy to write the likelihood function of the parameters of initial reliability and failure rate for each component, see e.g. [5–6] for detail. The parametric estimation of the component reliability can separately be made by ordinary methods. However, when the masked data are present, the likelihood function of all parameters of the components have to be considered and becomes a complex multivariable function with a very high dimension. It is therefore difficult to find out the MLE (Maximum Likelihood Estimate) of these parameters.

2.3 *Least squares estimation with non-masked data*

When the exponential distributions are applied for the inherent storage lifetimes of components, it is easier to obtain the initial reliability and failure rate of each component if the data are not masked. The MLE of these parameters can be obtained by solving the ML equations numerically, see [5–6] for detail. Nevertheless, the Least Squares (LS) estimates are more convenient in the case of exponential distributions since the analytic formulas can be written.

According to the reliability function of each component, the following linear equations hold:

$$Y_{ij} = a_i + b_i t_j, \tag{6}$$

where

$$ln\left(R_i(t_j)\right) = ln(R_{0i}) - \lambda_i t_j,$$
$$Y_{ij} = \ln\left(R_i(t_j)\right); a_i = \ln(R_{0i}); b_i = -\lambda_i;$$
$$i = 1,2,\ldots,k;\ j = 1,2,\ldots,m.$$

For a fix i, by using the estimates given in formula (5) to replace $R_i(t_j), j = 1,2,\ \ ,m$, it can easily be seen that the Least Squares estimates of a_i and b_i, therefore R_{0i} and λ_i, can be calculated as

$$\hat{R}_{0i} = \exp(\bar{R}_{iln} + \hat{\lambda}_i \bar{t}), \tag{7}$$

$$\hat{\lambda}_i = -\frac{\sum_{j=1}^{m}\left[\ln\left(\hat{R}_i(t_j)\right) - \bar{R}_{iln}\right]\left[t_j - \bar{t}\right]}{\sum_{j=1}^{m}\left(t_j - \bar{t}\right)^2}, \tag{8}$$

$$\bar{R}_{iln} = \frac{1}{m}\sum_{j=1}^{m} ln\left(\hat{R}_i(t_j)\right), \bar{t} = \sum_{j=1}^{m} t_j, \tag{9}$$

$i = 1, 2, \ldots, k$.

Note that the LS estimates of the initial reliability and failure rate for each component cannot be obtained from formulas (7), (8) and (9) if the masked data as displayed in Table 1 are applied. The ML estimates are also extremely difficult to obtain since the ML equations will contain too many parameters.

3 PARAMETRIC ESTIMATION USING MASKED DATA

3.1 *EM algorithm and its modification*

The EM (Expectation-Maximization) algorithm has recently been applied to solve the ML parametric estimation problem in software reliability when the masked data are presented, see e.g. [27–28]. The properties of this algorithm can also be seen in [30–33].

The general idea of the EM algorithm in the context of the masked data is to give the initial values of the parameters to be estimated, for example, θ^0, and calculate the expectations of the missing data. The ML estimates θ^1 can be obtained as if the complete data are available, and then repeat the procedure taking θ^1 as the new initial values until the stable values are obtained. The applicability of the EM algorithm should be that the ML estimates can easily be obtained. Unfortunately, the ML estimates of the component parameters in the storage reliability model considered here do not have analytic forms. This implies that the application of the EM algorithm is also complicated.

Note that the LS estimates of the component parameters have close analytic form as given in formulas (7), (8) and (9). A modified EM algorithm, called ELS algorithm, is therefore proposed and generally presented as follows:

E-step: Give the initial values of the parameters θ^0, find out the expectations of the missing data;

LS-step: Using the estimated missing data and unmasked data as if they are complete, find out the LS estimates of the parameters θ^1 that will be used as the new initial values of the E-step for the iterations until the convergence is reached.

To the author's knowledge, there is no similar study on the ELS algorithm found in the literature. In principle, the ELS algorithm can simply be applied for any model if the LS estimates can easily be obtained, for examples, in the case of Weibull, exponential or log-normal distributions of the storage lifetimes. In the following, the ELS algorithm is presented in detail in the case of exponential distributions of component storage lifetimes.

3.2 *ELS algorithm for binominal-type data*

For the masked data type shown in Table 1, the masked data are the numbers of system failures that are not identified as which components are the causes of these failures. To realize the ELS algorithm, one needs to find out what are the expected number of failures for each component at each observation time point when the system has f failures. For simplicity, the following discussion is given without considering the variable time.

Let n be the number of tested systems and f the failure number. The components have their storage reliability as $R_i, i = 1,2,\ \ ,k,$ then the system has the reliability $R = R_1 * R_2 * \cdots * R_k$. If it is assumed that these system failures are not identified due to which component, it can simply be proved that conditional on (n, f), the expected number of failures for ith component, f_i^E, is given by

$$f_i^E = \frac{1-R_i}{1-\mathrm{R}} f, i = 1,2,\ldots,k. \tag{10}$$

Note that the sum of all f_i^E is generally larger than the failure number f of the system since one system failure can be caused by more components. Concerning on the ELS algorithm, the formula (10) will be used to convert the system binomial data (n, f) into component binomial data $\left(n, f_i^E\right), i = 1,2,\ \ ,k.$

The ELS algorithm can now be specified for the masked data given in Table 1 on the storage reliability model (4):

E-step: Give the initial values of the component initial reliabilities $\left(R_{01}^0, R_{02}^0\ \ R_{0k}^0\right)$ and failure rates $\left(\lambda_1^0, \lambda_2^0\ \ \lambda_k^0\right)$, calculate the followings:

- Component and system reliabilities at observation times $t_1 < t_2 < \cdots < t_m$:

$$R_{ij} = R_{0\mathrm{i}}^0 e^{-\lambda_i^0 t_j},\ R_j = R_{1j} R_{2j} \cdots R_{kj};$$
$$i = 1,2,\ldots,k;\ j = 1,2,\ldots,m.$$

- For the masked system data (n_j, f_j), calculate the expected number of failures for each component using formula (10):

$$f_{ij}^E = \frac{1-R_{ij}}{1-R_j} f_j, i = 1,2,\ldots,k,\ j = 1,2,\ldots,m.$$

- Update the component binomial data in Table 1 as

$$n_{ij}^* = n_{ij}, +n_j, f_{ij}^* = f_{ij} + f_{ij}^E,$$
$$i = 1,2,\ \ ,k,\ j = 1,2,\ \ ,m. \tag{11}$$

LS-step: Use the estimated component binomial data calculated by formula (11), also apply formulas (5), (7), (8) and (9), the LS estimates of the initial reliabilities and failure rates of the components are obtained as

$$\hat{R}_i^*\left(t_j\right)=\frac{n_{ij}^*-f_{ij}^*}{n_{ij}^*},\ i=1,2,\ldots,k;\ j=1,2,\ldots,m \tag{12}$$

$$\hat{R}_{0i}^1=\exp(\bar{R}_{iln}^*+\hat{\lambda}_i\bar{t}), \tag{13}$$

$$\hat{\lambda}_i^1=-\frac{\sum_{j=1}^{m}\left[\ln\left(\hat{R}_i^*\left(t_j\right)\right)-\bar{R}_{iln}^*\right]\left[t_j-\bar{t}\right]}{\sum_{j=1}^{m}\left(t_j-\bar{t}\right)^2}, \tag{14}$$

$$\bar{R}_{iln}^*=\frac{1}{m}\sum_{j=1}^{m}\ln\left(\hat{R}_i^*\left(t_j\right)\right),\bar{t}=\sum_{j=1}^{m}t_j, \tag{15}$$

$i = 1, 2, \ldots, k$.

When the LS-step is finished, the E-step will be repeated, but the initial values $\left(R_{01}^0,R_{02}^0\quad R_{0k}^0\right)$ and $\left(\lambda_1^0,\lambda_2^0\quad\lambda_k^0\right)$ will be replaced by the LS estimates $\left(R_{01}^1,R_{02}^1\quad R_{0k}^1\right)$ and $\left(\lambda_1^1,\lambda_2^1\quad\lambda_k^1\right)$. The iteration of the E-step and LS-step can be terminated when the stable LS estimates are received.

4 NUMERICAL EXAMPLE

To illustrate the ELS algorithm to estimate the storage reliability, a series system of 2 components is considered. The binominal-type masked data created manually for the purpose of the illustration, is listed in Table 2:

Note that there are four parameters to be estimated in this example: two initial reliability R_{01}, R_{02}, and two failure rates λ_1, λ_2 of component 1 and component 2, respectively. By applying the ELS algorithm, the estimates of these parameters can be easily obtained numerically.

In Figure 1 and Figure 2, the original observations of reliability estimated by the successful ratio, the estimated reliability by the least squares method (without system data) and the ELS algorithm (with system data), respectively, are displayed for Component 1 and 2. The differences are obviously visible, but reasonable since the system failure data should be used when the component reliability is analyzed.

Table 2. Binominal-type masked failure data of a series system with 2 components.

Observation times 1000 h	Causes of failures		
	System	Component 1	Component 2
5	(40,3)	(55,3)	(45,2)
10	(40,4)	(50,4)	(45,3)
15	(20,2)	(60,5)	(55,6)
20	(20,3)	(70,7)	(65,5)
25	(20,3)	(60,7)	(55,10)
30	(15,2)	(55,9)	(50,11)
35	(12,2)	(55,12)	(50,10)
40	(15,3)	(60,14)	(60,12)
45	(20,4)	(58,15)	(53,14)
50	(15,3)	(50,13)	(45,13)

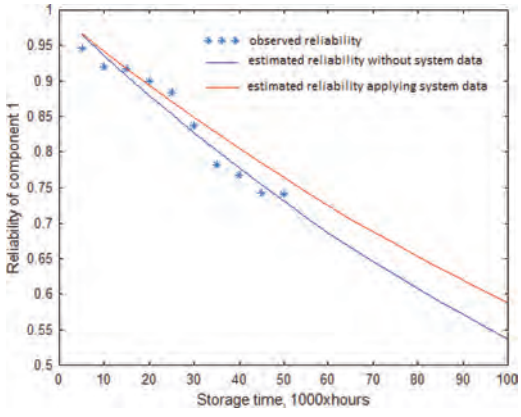

Figure 1. The observed and estimated reliability functions of Component 1.

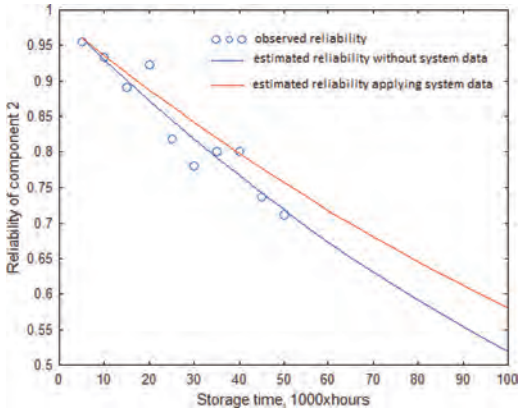

Figure 2. The observed and estimated reliability functions of Component 2.

The blue curves in Figures 1 and 2 represent the estimated storage reliability functions when the model parameters are estimated by the least squares method without applying the system data. The red curves represents the estimated storage reliability functions by the ELS method.

In Table 3, the compared results are also given to see the differences between the estimated parameters in the models. The estimates of the failure rates of the components with and without using the masked system data differ to each other. This indicates that it is important and necessary to apply the masked system data for component parameters.

Table 3. Comparison results of parametric estimates.

Methods	Component 1		Component 2	
	R_{01}	λ_1	R_{02}	λ_2
Estimates without system data	0.9949	0.0062	0.9927	0.0065
Estimates using system data	0.9920	0.0052	0.9861	0.0053

5 CONCLUSION

In this paper, the masked data analysis is considered for the storage reliability model with initial failures. To solve the problem that the estimation of the component reliability becomes difficult when the cause of system failures are hidden, an EM-like method (algorithm), the so-called ELS method is proposed for the series system with binomial-type failure data although the ELS algorithm can also be easily applied to other system configuration. A numerical example is provided to illustrate the method. By the illustrated example, it can be seen that the parameter estimations are quite different by the methods without and with the system failure data when the component reliability is estimated. The proposed ELS method has greatly simplified the parametric estimation in the case of the masked data.

Probability-based reliability and availability assessments for a lane at a signalised intersection

M. Maslak & K. Ostrowski
Cracow University of Technology, Cracow, Poland

ABSTRACT: An original computational approach allowing the reliability and the availability assessments of the lane located at an intersection with traffic signals is presented and discussed in detail. Operation of the lane of this type is described using a probabilistic model of an alternating renewal process. The occurrence of queues with vehicles waiting for the change of the lights, but only in the cases when the number of these vehicles is observed to be at least equal to the arbitrarily accepted number relating to the critical congestion level, is treated as the lane's failure. The proposed formal model is calibrated based on the empirical intensity function being a rate of occurrence of failures. The availability of the lane is interpreted as the probability that such lane will be serviceable at a predetermined time-point t, whereas its reliability—as the probability that it will be serviceable in the whole analysed time interval.

1 INTRODUCTION

A reliable assessment of lane's availability at a signalised intersection should be unambiguously linked to a detailed analysis of the queues which form randomly on the lane, whenever arriving vehicles do not encounter the green signal (Chodur, 2011; Tracz 2012). Of course, the formation of this type of queue is inevitable in a process of controlling the individual traffic flows, but the point is to ensure that the queue does not turn out to be unduly long (Ostrowski, 2014; Ostrowski, 2015). In the proposed calculation procedure, the authors determine a certain, arbitrarily set by the evaluator, number of queued vehicles on the analysed lane, subsequently designated as Q_{cr}, and treat it as a cut-off between a critical queue associated with a formal lack of the lane's availability for effective use, which the authors designate as a failure ("0" state), and a queue of an acceptable length, with a number of vehicles lower than Q_{cr}, which does not result in termination of the lane's serviceability (state "1"). In this way the lane performance is seen as a bi-polar relationship. In a given event, being equivalent to a single observation, it can be assigned to only one of two mutually exclusive assessments: serviceable ("0") or unserviceable ("1"). In such an approach, the process of use of the considered lane, viewed over a 24-hour cycle, can be modelled as a so-called alternative renewal process with alternating time-intervals of its serviceability and non-serviceability of random durations. In this model, each observation corresponds to a full cycle of signal changes of the lane's traffic signals. Usually, the cycle features a green-yellow-red sequence of a fixed length. Nevertheless, the constant length of the entire sequence does not mean the constant duration of each colour signal. In each sequence, these intervals can have random durations, which is typical of so-called accommodative signalling. Knowing the unified duration of the whole single sequence, it is easy to determine the number of observations, i.e. of complete sequences, specified per hour t. This number is referred to as n_t. Of course, in accordance with the above assumptions, it does not depend on the time at which the observations were carried out, thus $\forall_t n_t = n$. The authors subsequently relate with this value the numbers $n_t^{fail} = n_t^{(0)}$ and $n_t^{serviceable} = n_t^{(1)}$, where $n_t^{(0)} + n_t^{(1)} = n_t = n$, determined for each hour of the observations corresponding to the fixed number of signal change sequences. The first of these two values is the measure of the number of events when the lack of the lane's serviceability was noted in a given hour t while the second one—the measure of the number of observations evidencing the complete serviceability of such lane. Both values mentioned above are used here to create the empirical histograms—in the first case the one relating to a random number of the lane's failures and, in the second case, the other one associated with a random number of the lane's serviceability states. It can be noticed that the model proposed by us does not go into detail as for the structure of traffic on the lane, neither does it distinguish among types of vehicles nor their speed parameters. The authors are merely interested in the measured values of a random failure rate, specified in

each hour, and also in its empirical distribution, identified taking into account a whole 24-hour observation cycle.

2 EMPIRICAL FUNCTIONAL CHARACTERISTICS DETERMINING THE RELIABILITY OF THE LANE UNDER CONSIDERATION

2.1 *Histograms relating to the random numbers of the lane's failures and to the random number of the lane's serviceability states*

In order to enhance the clarity of the argument, the proposed procedure is presented here on a computational example containing an interpretation of the results of an experiment conducted by the authors over 100 observation days on a selected lane of one of Cracow's major signalised intersections. The signalling selected for the experiment had a sequence of exactly $n = 25$ full signal change cycles during each hour, which translates into $N = 24\,n$=600 such cycles observed each day. The results obtained by us on each observation day were used in histograms displaying a random number of $n_t^{(0)}$ the lane's failures and, separately, in histograms displaying a random number of the lane's serviceability states $n_t^{(1)}$, with a one-hour width of the class interval $(\Delta t = 1h)$ and with a half hour $t = 0$ *h* 30 *m*; 1 *h* 30 *m*; …; 23 *h* 30 *m* being a centre of each interval. The most probable daily histograms of a random number of the lane's failures are shown in detail in Figure. 1a while the most probable histograms of a random number of the lane's serviceability states in Figure. 1b. They were developed on the assuming that $Q_{cr} = 7$. It is easy to notice that at night, or specifically, between 20 *h* 30 *m* and 6 *h* 30 *m* of the next day, the traffic on the analysed lane was so small that in principle there were no failures. Such failures could happen sporadically, on separate days, but this was not reflected in the histogram averaging the results compiled throughout the duration of the experiment. On the other hand, in the morning hours, between 9 *h* 30 *m* and 10 *h* 30 *m*, the analysed lane was unavailable on each day of the study.

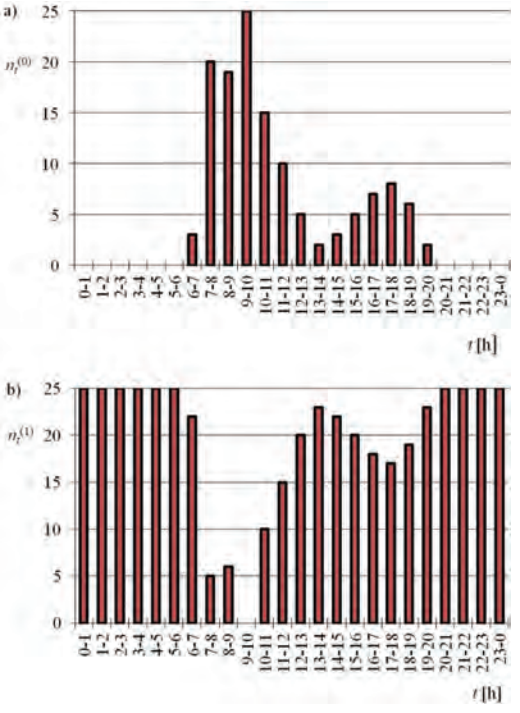

Figure 1. The most probable empirical histograms displaying on a day-by-day basis the random number of the lane's availability failures (Figure. 1a) and the random number of its serviceability states (Figure. 1b), obtained from the study of the analysed lane. The length of the critical queue was assumed at $Q_{cr} = 7$.

2.2 *Empirical functions of the lane's reliability and of the lane's unreliability*

The data in the histogram shown in detail in Figure. 1a allow assigning to the analysed lane the empirical function of its unreliability $\hat{S}(\tau)$ while the data given in Figure. 1b form the empirical function of the lane's reliability $\hat{R}(\tau)$. In this approach time τ means a selected value of variable *t*. The appropriate mathematical formulae look as follows (Migdalski, 1982):

$$\hat{S}(\tau) = \frac{\sum_{t=0h30m}^{\tau} n_t^{(0)}}{N} \tag{1}$$

$$\hat{R}(\tau) = 1 - \frac{\sum_{t=0h30m}^{\tau} n_t^{(0)}}{N} \tag{2}$$

The graphs of these functions, for the data considered in the example (and compiled in Tables 1 and 2), are presented in Figure. 2a and in Figure. 2b, respectively.

2.3 *Empirical probability density functions of the random occurrence of the lane's availability and failure states*

As the next step of our analysis the appropriate empirical probability density functions (*pdf*-s) are developed: first—for a random occurrence of the lane's availability states and then—for a random

occurrence of the lane's lack of availability. These functions are marked as $\hat{f}(\tau)$ and $\hat{g}(\tau)$, respectively. Based on (Migdalski, 1982) we have:

$$\hat{f}(\tau) = \frac{n - n_t^{(0)}(\tau)}{N \cdot \Delta t} \tag{3}$$

$$\hat{g}(\tau) = \frac{n_t^{(0)}(\tau)}{N \cdot \Delta t} \tag{4}$$

The graphs of these functions obtained for the data considered in the example and compiled in Table 2 are shown in Figure. 3a and in Figure. 3b, respectively.

2.4 *Empirical values relating to the lane's renewal intensity and other ones—determining its failure rate*

The next pair of the empirical dependencies determined by the authors for the lane considered in the example involves respectively the intensity of the lane's renewals $\hat{\upsilon}(\tau)$, when the lane returns to its availability state, and the lane's failure rate $\hat{\lambda}(\tau)$. In order to determine these values for the selected

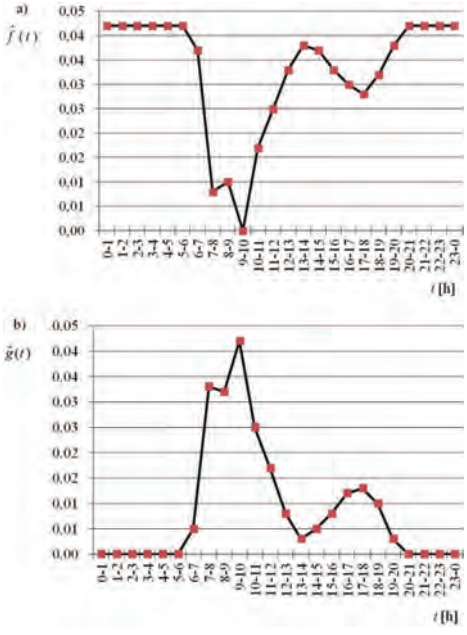

Figure 3. Empirical probability density functions of the occurrence of the state of the lane's availability (Figure. 3a) and of the state of the lane's unavailability (Figure. 3b).

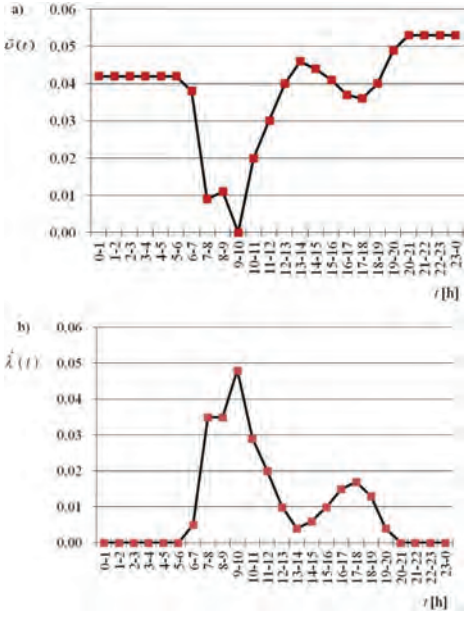

Figure 4. Empirical functions of the lane's renewal intensity (Figure. 4a) and of the lane's failure rate (Figure. 4b) relating to the analysed lane.

argument $t = \tau$, the authors first need to prepare the following auxiliary parameters:

$$N_{\tau}^{(1)} = N - \sum_{t=0h30m}^{\tau} n_t^{(0)} \tag{5}$$

$$N_{\tau+\Delta t}^{(1)} = N_{\tau}^{(1)} - n_t^{(0)}(\tau) \tag{6}$$

for which:

$$\overline{N_{\tau}} = 0.5\left(N_{\tau}^{(1)} + N_{\tau+\Delta t}^{(1)}\right) \tag{7}$$

Based on the above, the following is derived, respectively:

$$\hat{v}(\tau) = \frac{n - n_t^{(0)}(\tau)}{\overline{N_{\tau}}\Delta t} \tag{8}$$

and:

$$\hat{\lambda}(\tau) = \frac{n_t^{(0)}(\tau)}{\overline{N_{\tau}}\Delta t} \tag{9}$$

The detailed values of both these functions, calculated for subsequent values of argument $t = \tau$, are compiled in Tables 1 and 2. These functions are also shown in detail in Figure. 4a and in Figure. 4b, respectively.

3 RENEWAL FUNCTION AND RENEWAL DENSITY SPECIFIED FOR THE WEIBULL-TYPE RENEWAL PROCESS

3.1 *Idea of an alternative renewal process modelling the use of the lane*

As it was indicated in Chapter 1, the manner in which the lane is used during successive full cycles of signal change of a fixed duration of a single cycle can be formally described by a scheme of an alternative renewal process in which the time-intervals of lane's serviceability (availability) of random length T_i alternate with the time-intervals of lane's non-serviceability (failure) which are also of random length Θ_i. As a result of such assumption, we are dealing with a sequence $T_1, \Theta_1, T_2, \Theta_2, ..., T_i, \Theta_i, ...$ (Figure. 5).

3.2 *Modelled probability distributions for the random durations of the states with the lane's serviceability and of the states with the lane's non-serviceability.*

Careful analysis of the graph of the empirical probability density functions of respectively $\hat{f}(\tau)$

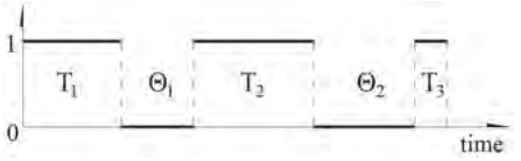

Figure 5. Scheme of an alternative renewal process considered in the example.

- related to a random occurrence in time τ of a state with the lane's availability, and of $\hat{g}(\tau)$ - related to a random occurrence of a state with the lane's failure, as shown in Figure. 3, indicates that it is difficult to assign the uniform probability distribution for the whole day to the random durations of these states. This conclusion is further corroborated by the non-monotonic graphs of functions $\hat{\upsilon}(\tau)$ and $\hat{\lambda}(\tau)$. Consequently, the full daily cycle is recommended to be broken down into shorter component time-intervals for which the fitted probability distribution modelling the use of the lane in such a short period becomes sufficiently reliable. Under this approach, in the night, when during the entire time of the lane use its availability seems to be fully ensured, the random duration of the state of the lane's serviceability should be undoubtedly modelled by a uniform probability distribution. Much more interesting, however, are the lane's states ("availability" or "unavailability"), with random durations, which alternate with each other during a day. Considering the fact that the values of a lane's failure rate did not turn out to be constant in any time-period being sufficiently long, the random durations of the lane's serviceability states T_i and also the random durations of the lane's non-serviceability states Θ_i are recommended by the authors to be assigned by the two-parameter Weibull probability distributions, for which the intensity of a failure occurrence is determined from the formula (Kaminskiy, 2013):

$$\lambda(\tau;\alpha_\lambda,\beta_\lambda)=\frac{\beta_\lambda}{\alpha_\lambda}\left(\frac{\tau}{\alpha_\lambda}\right)^{\beta_\lambda-1} \tag{10}$$

whereas the intensity of a successive renewal, leading to the lane's serviceability state, is derived from a similar formula:

$$\upsilon(\tau;\alpha_\upsilon,\beta_\upsilon)=\frac{\beta_\upsilon}{\alpha_\upsilon}\left(\frac{\tau}{\alpha_\upsilon}\right)^{\beta_\upsilon-1} \tag{11}$$

In this approach, parameters α_λ and α_υ are the scale parameters while the parameters β_λ and β_υ are interpreted as the shape coefficients. In time-intervals when function $\hat{\lambda}(\tau)$ rises non-linearly it is usually assumed that $\beta_\lambda \geq 3$. On the other hand, for time-intervals with a non-linearly decreasing function $\hat{\lambda}(\tau)$, a value $\beta_\lambda < 1$ should be assumed.

3.3 *Determining the renewal function relating to the considered process*

The choice of a renewal function that will fit well all the parameters of the considered formal model is difficult, especially in the case of a non-monotonic empirical failure intensity function $\hat{\lambda}(\tau)$ relating to this model. In our example this function during certain periods of a day turns out to be a growing function while during others, a decreasing function. It is recommended in the professional literature to use for such the complex design cases a mixture of the probability distributions (Kaminskiy, 2013). In the simplified model proposed by the authors in this paper the Weibull probability distribution is chosen in this field to describe both the random times of the lane's serviceability T_i and the random times of the lane's non-serviceability Θ_i. With such assumption, the conventional approach used to determine the appropriate renewal function, based on the use of the Laplace transform technique (Bobrowski, 1985), becomes rather ineffective. Some proposals of the way in which this function could be determined as accurately as possible in the case when the Weibull-type renewal process is considered were given for example in (Yannaros, 1994) and in (Lomnicki, 1966). In other papers, e.g. in (Smeitink & Dekker, 1990) and in (Jiang, 2008), it was recommended to use in this field some more or less simplified estimates. In our analysis we have chosen for practical use the approximate formula given in (Jiang, 2010). Such a formula is appropriate, however, only in time-intervals for which the failure rate can be estimated as growing. This formula is constructed as follows:

$$H(\tau)=\xi F(\tau)+(1-\xi)\Lambda(\tau) \tag{12}$$

As one can see, the renewal function $H(\tau)$ is calculated here by an appropriate combination of the cumulative distribution function (*cdf*) $F(\tau)$, being specific for the Weibull probability distribution, and of the other function being the measure of the cumulative frequency of the lane's failures $\Lambda(\tau)$. The combination coefficient ξ, estimated using the least-squares method, is derived in such an approach from the formula:

$$\xi=\xi(\beta)=1-\exp\left[-\left(\frac{\beta-1}{0.8731}\right)^{0.9269}\right] \tag{13}$$

Obviously, its value depends on the value of the shape coefficient, i.e. $\beta=\beta_\lambda$ or $\beta=\beta_\upsilon$, respectively.

It should be emphasised that the above mentioned formula was calibrated on the assumption that the scale coefficient was set at the level $\alpha = 1$. The cumulative distribution function for the Weibull probability distribution, described both according to (10) and according to (11), is expressed as:

$$F(\tau) = 1 - \exp\left[-\left(\frac{\tau}{\alpha}\right)^{\beta}\right] \tag{14}$$

The cumulative failure intensity function for the same distribution can be calculated directly based on the definition, which gives:

$$\Lambda(\tau) = -\ln\left[1 - F(\tau)\right] = \left(\frac{\tau}{\alpha}\right)^{\beta} \tag{15}$$

Detailed values of this function can also be derived directly from the empirical data, on the basis of the histograms presented in Chapter 2 of this paper. It is essential that the approach described above allows an efficient determination of the renewal function $H(\tau)$ only for those time-intervals of a day when the empirical function of failure intensity $\hat{\lambda}(\tau)$ is observed to be monotonically increasing. In future research the authors will try to determine a similar-type renewal function for time-intervals of decreasing failure intensity. In order to attain this objective, we want to apply a procedure proposed in (Smith & Leadbetter, 1963), according to which:

$$H(\tau) = \sum_{i=1}^{\infty} (-1)^{i-1} \eta_i \frac{z^i}{\gamma_i i!} \tag{16}$$

where:

$$z = \tau^{\beta} \tag{17}$$

$$\eta_1 = \gamma_1 \tag{18}$$

$$\eta_i = \gamma_i - \sum_{j=1}^{i-1} \gamma_i \eta_{i-j} \tag{19}$$

$$\gamma_i = \frac{\Gamma(i\beta + 1)}{i!} \tag{20}$$

$$\Gamma(k) = \int_0^{\infty} x^{k-1} e^{-x} dx \tag{21}$$

3.4 *Determining the renewal density*

Setting out from equation (12) defined for time-intervals with increasing values of functions $\hat{\lambda}(\tau)$, it is easy to determine the renewal density accompanying this phase of the lane's use. It can be expressed as:

$$h(\tau) = \frac{dH}{d\tau} = \xi f(\tau) + (1 - \xi)\frac{f(\tau)}{R(\tau)} \tag{22}$$

In this case, the lane's reliability function $R(\tau)$ approximates the empirical function described in formula (2), whereas the probability density function of the lane's failure $f(\tau)$ approximates the corresponding empirical function defined by equation (3). Application of formula (16) for time-intervals with decreasing values of function $\hat{\lambda}(\tau)$ leads to the dependence given in (Smith & Leadbetter, 1963):

$$h(\tau) = \frac{\beta}{\tau} \sum_{i=1}^{\infty} (-1)^{i-1} \eta_i \frac{i z^i}{\gamma_i i!} \tag{23}$$

4 AVAILABILITY AND RELIABILITY OF THE ANALYSED LANE

4.1 *Lane's availability in the model of the alternative renewal process*

So far, the random durations of the time of the lane's serviceability state T_i were described by a probability distribution characterised by the probability density function $f(\tau)$ (approximating the empirical function $\hat{f}(\tau)$) and by the cumulative distribution function $F(\tau)$. Similarly, the lane's random non-serviceability time-intervals Θ_i were described by a probability distribution with the probability density function $g(\tau)$ and with the cumulative distribution function $G(\tau)$. With such assumptions, according to the conventional renewal theory, the distribution of the probability of random time-intervals between consecutive renewals (interpreted as the restoration of the lane to the serviceability state), i.e. of the time-intervals arranged in sequence

$$T_1 + \Theta_1, T_2 + \Theta_2, ..., T_i + \Theta_i, ..., \tag{24}$$

can be described by the cumulative distribution function:

$$\Phi(\tau) = \int_0^{\tau} F(\tau - t) dG(t) \tag{25}$$

for which the Laplace transform is as follows:

$$\tilde{\Phi}(s) = s\tilde{F}(s)\tilde{G}(s) \tag{26}$$

A similar formula is true for the Laplace transform of the probability density functions, giving:

$$\tilde{\phi}(s) = \tilde{f}(s)\tilde{g}(s) \tag{27}$$

Based on the above, the authors compute the Laplace transform of the renewal function of an alternative renewal process analysed in the experiment described in the example, which produces:

$$\tilde{H}(s) = \frac{\tilde{f}(s)\tilde{g}(s)}{s\left[1-\tilde{f}(s)\tilde{g}(s)\right]} \tag{28}$$

Function $H(\tau)$ computed by the appropriate re-transform in this case is interpreted as the anticipated number of the lane's renewals within the (0, τ) time-interval. Likewise, for the same lane, the expected number of the lane's failures can be expressed as a renewal function $H_f(\tau)$, for which the Laplace transform is expressed by the formula:

$$\tilde{H}_f(s) = \frac{\tilde{f}(s)}{s\left[1-\tilde{f}(s)\tilde{g}(s)\right]} \tag{29}$$

The lane's availability $K(\tau)$ in this model expresses the probability that at a certain time τ such lane will be observed in a serviceability state. Therefore, this availability can be calculated as the sum of the probabilities of two fully separable random events formulated as follows:

- the first event—that the serviceability time-interval until the first lane's failure is longer than τ, which means that $T_1 > \tau$,
- the second event—that the n-th lane's renewal occurs within the $(t, t+\Delta t)$ time-interval, while within the (t, τ) time-interval the next lane's failure does not occur.

Hence:

$$K(\tau) = R(\tau) + \int_0^{\tau} R(\tau - t)\, dH(t) \tag{30}$$

The Laplace transform for such availability is expressed by the following formula:

$$\tilde{K}(s) = \left[1-\tilde{f}(s)\right]\left[\frac{1}{s} + \tilde{H}(s)\right] \tag{31}$$

which, after a substitution of (28), yields:

$$\tilde{K}(s) = \frac{1-\tilde{f}(s)}{s\left[1-\tilde{f}(s)\tilde{g}(s)\right]} \tag{32}$$

Ultimately:

$$\tilde{K}(s) = \tilde{H}(s) - \tilde{H}_f(s) + \frac{1}{s} \tag{33}$$

hence:

$$K(\tau) = H(\tau) - H_f(\tau) + 1 \tag{34}$$

This means that the probability that the analysed lane will be observed at time τ in a state of its non-serviceability, expressed as the difference 1 – $K(\tau)$, in the model of the alternative renewal process presented by the authors in this paper is equal to the difference between the expected number of the lane's failures and the number of the lane's renewals that have occurred until that time.

4.2 *Reliability of the analysed lane*

The basic difference between the availability $K(\tau)$ and the reliability $\Omega(\tau, \Xi)$ determined for the lane considered in the example is such that the first of these values is determined for a selected time-point $t = \tau$, while the second one—for the entire time of the observation, for example for $\Xi = 24$ h. In this approach, the reliability of the lane is interpreted as the probability that such lane will be observed in a serviceability state throughout the whole day. Therefore the following formula can be applied for practical use:

$$\Omega(\tau, \Xi) = R(\tau + \Xi) + \int_0^{\tau} R(\tau + \Xi - t)\, dH(t) \tag{35}$$

5 CONCLUDING REMARKS

The main aim of the research undertaken by the authors was to verify the possibility of describing the process of the use of the lane at a signalised intersection, having unambiguously random characteristics, using the classical formal model of an alternative renewal process. In this analysis, failures of such lane corresponded to the time-intervals when it was non-serviceable because the queue of vehicles awaiting before the red traffic signal turned out to be too long. However, in subsequent signal cycles with a fixed duration of a single cycle, the lane was renewed after each occurrence of a non-serviceability state, so that it became serviceable until the next failure. According to the authors, the choice of the formal model itself seems to be quite straightforward, although its authoritative and reliable mathematical description is difficult. The experiment considered in the example revealed that the use of the lane analysed in a 24-hour cycle is associated with complex, multimodal probabil-

ity distributions of subsequent failures and subsequent renewals of random duration. Therefore, a precise description of the process of this type seems to require an appropriate combination of the probability distributions, which significantly complicates both the mathematical formulae themselves and the resulting inferences. In the presented analysis the authors attempted to apply in practice certain, seemingly acceptable, simplifications. Due to the fact that the function defining the lane's failure intensity did not turn out to be a uniform with respect to the observation time at any stage of the cycle analysed daily the authors were unable to use in this field the simple formal model developed for the renewal processes of the exponential-type, well described theoretically. Therefore it has been proposed a different, more complex, calculation procedure, constituting a set of the analyses conducted separately at certain time-intervals, for which one could assume an unambiguously monotonically increasing or monotonically decreasing graph of the failure intensity function. This approach allowed us to describe the considered renewal process by using a two-parameter Weibull probability distribution, reduced further to the only one-parameter process due to the assumption that the scale parameter was set at a level $\alpha = 1$. The composition of the appropriate failure rate functions, where each of which will be specified in a given time-interval, should allow for the calculation of the reliability being accurate for the analysed lane. The basic problem involved in describing the actual process of the lane's use by means of a formal model of an alternative renewal process with random serviceability and non-serviceability time-intervals characterised by the Weibull probability distributions is that in this case it is impossible to effectively use the Laplace transform to specify the renewal function. In fact, the precise determination of this function in a strict manner becomes possible only on the basis of complex and time-consuming numerical calculations. For this reason, the authors recommend to use in this field a simplified estimate, presented in a mathematically-closed form, which seems to be acceptable, even if prone to quite a significant error of approximation for high values of the shape coefficient β. This estimation, however, can only be used during time-intervals with increased failure intensity function. Wherever the intensity of the failure occurrence is diminishing, the authors suggest using a more complex recursive procedure, which is well described in professional literature. The authors intend to verify the accuracy of this type of approach in the future. Undoubtedly, if the well-verified renewal function determining the proposed formal model will be unambiguously identified, for the available experimental data, it should enable to definitively calculate first the lane's availability, specified at a given time-point $t = \tau$, and subsequently its reliability, specified for the whole observation time-interval Ξ. As the functions of this type, proposed by the authors so far, do not seem to be determined accurately enough, in the final part of this study, the authors limit themselves to presenting subsequent steps of the planned future procedure, without providing numerical results of the applied formulae. Nevertheless, the authors hope that this description of the process of the lane's use at a signalised intersection will prove useful in the practical design of intersections of this type, even if the mathematical model itself seems to be relatively complex.

Application of failure classification schemes to technology qualification

T. Myhrvold, A. Hafver, S. Eldevik, F.B. Pedersen, O.I. Haugen,
K. Kvinnesland & D. McGeorge
DNV GL, Norway

ABSTRACT: Current methods for Technology Qualification (TQ) rely to a large degree on traditional reliability methods developed for hardware systems. However, as technology becomes more dependent upon software, leading to more complex systems, there is a need to better reflect the system perspective. One aspect of complexity is that the system constituents is heavily interconnected and dependent upon each other, i.e. the system shows emergent behavior. Systemic failures, not caused by component failures, but caused by how the constituents interact (i.e. emergence), need to be addressed differently than previous practices. This paper presents a consistent way of classifying failures to help discovering the critical failures and to guide how to handle the identified failures in a system TQ setting. To ensure that the identification process is consistent and as complete as possible, we advocate that failures should be classified according to different perspectives, where the classification within each perspective is Mutually Exclusive and Collectively Exhaustive (MECE). We show how this can be used to guide how evidence is collected in the technology qualification process.

1 INTRODUCTION

1.1 *Background*

Technology development can either enable a project to be realized or it can enhance the value of it. Either way the technology developer has to build the operator's confidence in the technology. The operator again needs to build the confidence of the other stakeholders in the project before a decision to implement the technology can be taken. To build this confidence, a systematic risk-based qualification process must be performed.

Technology qualification comprises activities to assess, improve and safeguard technology. It aims at providing evidence that the technology will function within specified limits with an acceptable level of confidence (DNVGL-RP-A203, 2017).

To qualify a system, different perspectives are needed to identify possible ways in which the system may fail, and to select appropriate ways of collecting evidence for the qualification process. There exist many different definitions of failure and failure types and many ways of classifying failures. This makes it challenging to get an overview of the completeness and consistency with respect to whether most failures have been identified and addressed or not. In this paper, we suggest a method that provides a structured and consistent way of classifying and handling failures, and relate it to the TQ process as described in DNVGL-RP-A203.

1.2 *Objective*

The purpose of this work is to develop a systematic method to identify an as-complete-as-possible set of relevant failures, that allows for an effective failure identification and that increase the confidence that most failures have been identified and addressed. The method is generic and can be used in combination with both new and conventional failure assessment methods in a system TQ setting.

2 DEFINITION OF FAILURE

The literature is abundant with definitions of failure. In this work we use a broad definition:

Failure is the loss of a function (fully, in part, or erroneous delivery).

We explicitly avoid to mention where or how the loss of the function materializes, to highlight that the failure is on the abstraction level of the *function*. This makes it easier to consider failures without limiting it to actual resources, or combinations thereof. The term resources is used here to refer to an individual part, component, device, functional unit, equipment, subsystem, software, people, environment, organizational structures, etc. or combinations of one or more of the above. This is closely related to how an item is defined in IEC 60050-192 (2015).

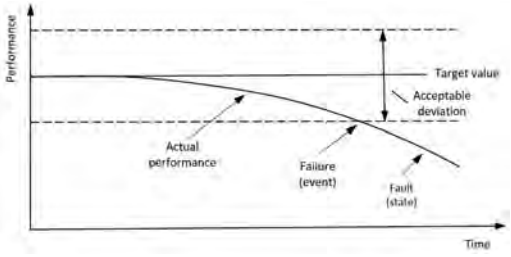

Figure 1. Illustration of the relationship between a failure event and a fault state (based on Rausand & Øien 1996).

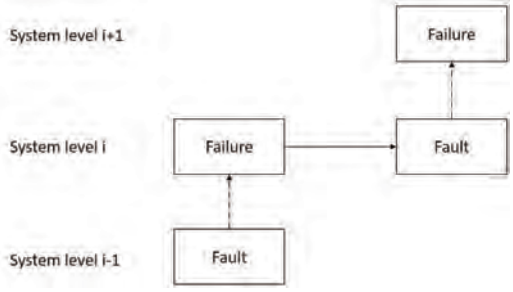

Figure 2. Failure model illustrating the relationship between failure at one level in a system hierarchy and fault at another level.

If failure is considered as the event when a function was lost, the failed state can then be related to the term *fault* state used by IEC 60050-192 (2015).

One illustration of the relationship between a failure event and a fault state is shown in Figure 1.

Figure 1 shows the relationship between a failure and a fault with respect to a specific function. Note that in Figure 1, a failure leads to a fault, and not the other way around. Figure 2 illustrates how a fault due to a failure at one level in a system hierarchy may lead to a failure at a higher level. Note, however, that a failed function on one level does not necessarily propagate to the next (e.g. if that level has redundancy or the failed function was non-critical for the next-level function), and that a failed function on one level does not necessarily imply a failure on a previous level (e.g. emergent failures).

3 EXISTING FAILURE CLASSIFICATION SCHEMES

As can be seen from the definition of failure given above, any method for failure identification and analysis strongly depends on the ability to identify all the required functions of the system subject to analysis. In this work it is assumed that these functions are known and will focus on ways that failures can be classified.

Various standards classify failures in different ways. IEC 61508-4 (2010) applies two main classification schemes, categorizing failures by its cause or by its mode. Failures categorized by its cause are either random (in hardware) or systematic (in hardware or software), where the definition of systematic failure are the same as given by IEC 60050-191 (1990).

IEC 61508-4 classify all (random hardware) failure by its mode as: dangerous undetected (DU), dangerous detected (DD), safe undetected (SU), and safe detected (SD).

ISO 14224 (2015) classifies failure after its failure mechanism, failure cause, and failure mode and provides a detailed list of failure modes down to component level.

ISO/TR 12489 (2013) provides three different classification schemes for use in reliability modelling and calculation of safety systems reliability: According to randomness, according to occurrence (state of the failing item: when running, on stand-by, due to demand), and by the way the failure is detected (revealed, hidden, or due to demand). Classification of failure according to randomness is divided into random and non-random (systematic) failure and are further broken down into hardware, software and human failure.

Blache and Shrivastava (1994) introduced a generic classification by using modified definitions from IEC-60050-191, which is shown in Figure 3.

Rausand and Øien (1996) stated that failure modes may be classified in three main groups related to the function of the item: total loss of function, partial loss of function, and erroneous function.

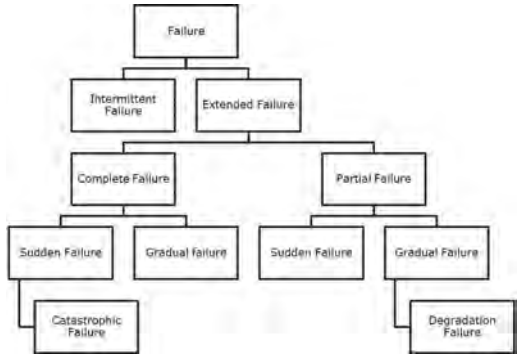

Figure 3. Failure classification scheme for failure modes by Blache and Shrivastava (1994).

Rausand and Øien (1996) also described an alternative classification scheme by failure cause as an option, where failure cause is "the circumstance during design, manufacture or use that have led to failure". The failure cause is a necessary information to avoid failures or re-occurrence of failures. Failure causes may be classified in relation to the life-cycle of an item or a functional block as illustrated in Figure 4. They also described classification of failure by its effect and severity (From MIL-STD 882): catastrophic, critical, marginal, negligible.

Håbrekke et al. (2013) classified failures into two main schemes based on the failure definitions given in IEC 61508-4 as mentioned above: either by its mode or by its cause. When classifying by its cause, Håbrekke et al. (2013) use the definitions given by the IEC 61508-4 standard (differentiate between random hardware failures and systematic failures), but give a more detailed breakdown of the systematic failures, as shown in Figure 5.

When classifying by its mode, they categorize failure (not limited to random hardware failures only) as (Håbrekke et al., 2013): DU, DD, SU, SD and non-critical (NC).

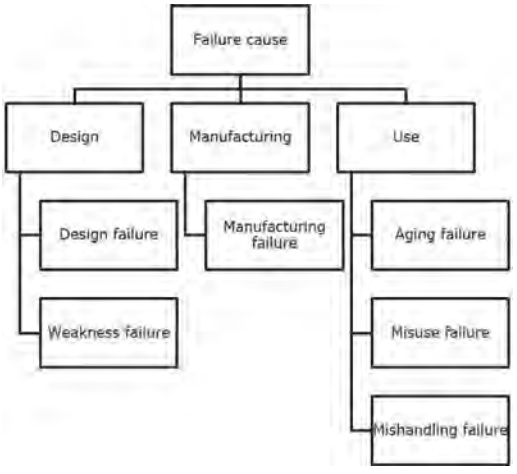

Figure 4. Failure classification after its cause (Rausand & Øien, 1996).

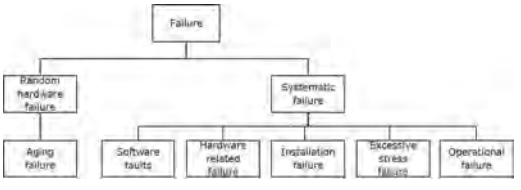

Figure 5. Failure classification after its cause by the PDS forum (Håbrekke et al., 2013).

The above show a wide variety of failure classification schemes, but no method to structure them or give guidance on use seems to exist.

In the current work we propose a simple and structured method for classification of failures and exemplify how it can be used for more consistent failure identification in a technology qualification context.

4 A STRUCTURED METHOD FOR IDENTIFYING FAILURES THROUGH PERSPECTIVES

A challenge with the classification structures described in the previous section is that it is difficult to know whether the schemes identify and address all possible and relevant failures and if some failures have been overlooked. Many of the classification schemes build elaborate hierarchies where failure classes are broken down into sub classes. A danger of following such a hierarchical approach is that the branches of the classification tree may differ with respect to how detailed they are and which criteria are used for the subdivision.

Rather than following a hierarchical approach, which may tend to narrow the perspective of the analyst, we propose a method where failures are identified by viewing the system from different perspectives, and alternating between these views, rather than creating one unified failure class hierarchy.

Within each perspective, a Mutually Exclusive and Collectively Exhaustive (MECE) set of categories are established. The MECE categories are intended to help the assessor structure the failure identification process by introducing complete sets of failure categories so that all aspects of a perspective is covered. This will increase the confidence that the failure identification method captures the relevant failures.

4.1 *Commingled structures*

Each of the perspectives and its MECE categories should trigger identification of different failures. That is, one should be able to identify and place failures in the MECE categories of each and every perspective.

This is fundamentally different than the hierarchical approaches described in Section 3. However, with the suggested approach, a variety of hierarchical classification schemes can be reproduced by combining the MECE categories of the different perspectives, and are thus fully compatible with previous methods.

This approach enables us to concentrate on N perspectives with M_N individually relevant MECE

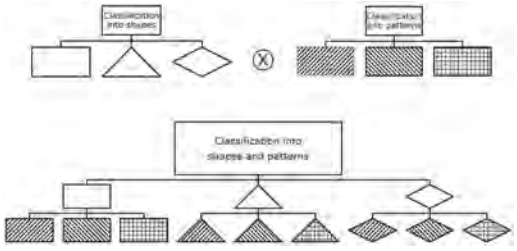

Figure 6. Independent classification schemes (upper panel) used to build a full classification structure (lower panel).

categories rather than complex structures of categories that may not be MECE. Figure 6 shows how two perspectives (here geometric form and pattern) can be assessed individually (upper panel), and if relevant can be combined to a commingled structure (lower panel).

The commingled classification structure will remain MECE, and thus complete. Note that all combinations may not be relevant, however this should not be regarded as a problem. Rather than assuming that some combination is impossible, the possibility of every combination is kept open. By considering the views independently, one avoids debates such as whether software failures can be random or not. This may help the analyst avoid limitations given by preconceived ideas.

5 FAILURE CLASSIFICATION IN ONE-DIMENSIONAL VIEWS

Technology qualification involves executing a work process comprising of a set of steps. In brief, the first four steps are:

- Establish a qualification basis identifying the technology, its functions, its intended use, as well as the expectations to the technology and the qualification targets.
- Assess the technology by categorizing the degree of novelty to focus the effort where the related uncertainty is most significant and identify the key challenges and uncertainties.
- Assess threats and identify failures and their risks.
- Develop a plan containing the qualification activities necessary to address the identified risks.

Part of the technology assessment is to break the top level system functions into sub-functions. The loss (partial or complete) of a function on any level in this functional hierarchy constitutes a failure of that function. Hence, what constitutes a failure, or which functions that fail is not the focus of this chapter. Rather, the focus here is to identify how functions may fail, by relating the functions to the resources and processes used to deliver the specific functions.

TQ is a process of assessing whether a particular solution, composed from a specific set of resources and involving a set of processes, is able to deliver the desired functions with sufficient confidence. This involves to identify how a function may fail and the associated risks. Based on this, the next step in the TQ process is to develop a plan of qualification activities necessary to address the identified risks. To accommodate this, we propose an approach where the system is analyzed from a set of different perspectives. Some relevant perspectives may be:

- Resource perspective
- Life-cycle perspective
- Randomness perspective
- System level perspective

In addition, two perspectives which may be used to guide the assessor on how to handle the identified failures may be:

- Controllability perspective
- Risk perspective

Each of these perspectives are described below, and we show how the individual perspectives may be used in TQ. For each perspective, we propose a list of MECE categories to ensure completeness and avoid confusion. Looping through a set of perspectives is intended to instruct the assessor to consecutively change her point-of-view, and thus help her identify a wider range of failures than if conventional methods were used. This is an alternative to using more elaborate hierarchical failure classification schemes that may be ambiguous or contain an unmanageable number of failure classes.

Note that other perspectives can also be relevant in TQ. This paper exemplify the use of relevant perspectives and categories, focusing on the principle of building unambiguous perspectives that can help the assessor in the failure identification process, and give guidance on how to handle the identified failures.

5.1 *Resource perspective*

The resource perspective provides a classification of failure based on its relation to the particular hardware, software or human components of a system (including their interactions), see Figure 7.

The core motivation of the resource view is to elicit which of the resources of the system are involved in the failure.

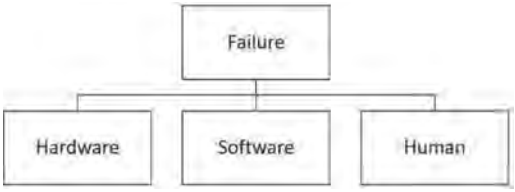

Figure 7. Classification of failure based on its origin.

Note that Figure 7 uses a coarse classification of resources into the groups hardware, software and human. This is only one possible set of MECE categories used for exemplification of the resource perspective. Other categories or granularity may be used as long as it is kept MECE.

Note that although the categories themselves are MECE (for consistency), a failure does not necessarily belong to only one category. The failure of a function may for example involve both hardware and software, or the interaction between them, even if neither of the individual resources have failed.

The resource perspective can help the assessor to identify the resources that need to be qualified to ensure that functions are adequately provided.

5.2 *Life-cycle perspective*

Classification of failure may be done in relation to time, i.e. when in the life cycle the failure is introduced s shown in Figure 8. We call this the life-cycle perspectives.

This is essentially similar to Rausand and Øien (1996) who described an alternative classification scheme by failure cause as an option, see Figure 4. In our case, we have also added failure occurring in concept, installation, and decommissioning of the system. The granularity of the categories is project dependent, depending on the nature of the system development and associated activities.

The importance of the life-cycle view in a TQ setting is that failures, or precursors to failures, may occur in any phase of the project. Some failures will materialize immediately while some may not materialize until later in the system's life-cycle. The TQ process is by nature iterative and flexible, and is used to reduce the possibility of unidentified failures that may propagate into later stages of the system life-cycle. Thus, taking a life-cycle perspective can help the assessor identify failures introduced at certain stages in the life-cycle, but that may not materialize until later stages. By identifying when a failure might be introduced and when it might materialize can help in finding ways of how it could be prevented or handled. For example, failures in specification, design, or manufacturing

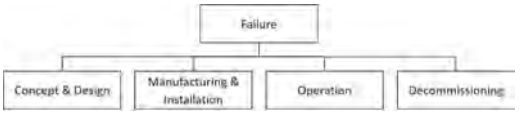

Figure 8. Classification of failure according to when in the life cycle the failure is introduced.

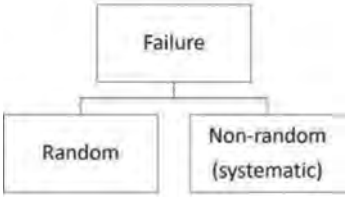

Figure 9. Classification of failure according to its randomness.

may be detected and handled through quality control, third party verification and testing. Other failures may develop and occur in operation and the assessor can then identify required contingency plans, monitoring, inspection, testing or maintenance plans, etc.

5.3 *Randomness perspective*

A commonly used failure classification scheme is to classify into random and systematic failure. Here we suggest to use random and non-random (see Figure 9) since this clearly states if a failure is random or not.

Note that we deliberately do not use the term random hardware failure, since random hardware failure is a subset of random failure. Both IEC 61508-4 (2010) and the PDS forum (Håbrekke et al., 2013) classify failures by its cause to be either random hardware failure or systematic. According to our understanding, none of these schemes are MECE.

In a TQ setting, whether a failure is considered a random (stochastic) process, or if it is systematic, will be very relevant with respect to how the failure is handled. If, for example, the assessed system function is to withstand a weather-related load, e.g. wave or wind loads, the maximum load the system will see throughout its lifetime, is stochastic. In this scenario, the usual approach is to estimate a maximum load distribution, and to require the structure to have the capacity to withstand some percentile of this maximum load distribution (e.g. a 100 yr load). On the other hand, if the assessed system is a small bridge designed for smaller cars, the bearing capacity (the system function) will always fail if a heavy-duty truck tries to cross. This

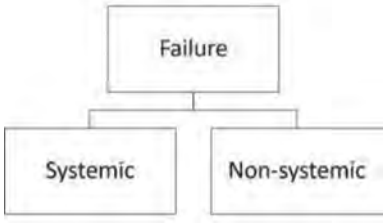

Figure 10. Classification of failure according to systemic behavior.

is a systematic, or non-random failure, and a TQ process would identify if the bridge may be subjected to such loads, and the bridge should either be re-designed, or limitations to vehicle weights could be imposed.

5.4 *System-level perspective*

Traditional reliability engineering methods derive failures on system level from failure on component level. However, a system function may fail even if none of its sub-functions or resources have failed. Such *systemic* failures are typically related to how different resources in a system interact. It may for instance occur based on interaction between the system and its environment, unintended or unfortunate interactions, or conflicting actions among the system resources. This perspective is shown in Figure 10.

Here we have used the ISO/TR 12489 (2013) definition of systemic failure:

"*Systemic failure* is failure at system level which cannot be simply described from the individual component failures of the system." Asking the question: Does the failure depend on failures on a lower system level, or is it a feature that only manifests itself on this level? A good example is the Mercedes A-class failure of the "Elk-test" (Teknikens Värld 2017). Here, the new Mercedes A-class was put through an evasive maneuver test, and above a certain speed, the car tipped over when performing the evasive maneuver. The steering performed within its intended range and the speed was within the car's limitations. Thus, no function was operated outside its intended range, however, the result was a total failure of the system's function, i.e. being able to drive and steer.

In a TQ setting, the distinction between systemic and non-systemic failures becomes important with respect to how they are identified and handled: A non-systemic failure can be addressed by ensuring that no subsystems or components fail. However, handling systemic failures requires that the entire system is considered as a whole (including architecture, life cycle, system control structures, etc.). Systemic failures cannot be identified by analyzing each of the system's resources separately. Some of the systemic failures may be identified through existing methods like system FMECA (Subburaman, 2010), STAMP/STPA (Leveson, 2011, 2013), FRAM (Hollnagel, 2004) or through system integration testing and system pilot testing. However, the assessor should, where relevant, also utilize virtual testing using e.g. simulations to discover systemic failures that cannot be anticipated based on the understanding of individual components, and which would be too expensive or dangerous to test in real-life. For the Mercedes A-class this would e.g. have been to explore the limits of the steering, the speed and the road friction.

5.5 *Controllability perspective*

According to control theory, the ability to control a process depends on the ability to observe the process, the ability to influence the process, having a defined objective, and sufficient understanding of how to influence the system, based on the above. In the controllability perspective we categorize failures as controllable or not. In reality, there might be degrees of controllability ranging from full control to no control at all. The granularity of the categorization can be modified according to project specific needs.

In a TQ setting, this perspective is important to identify which failures that can, or need to be, controlled, and which cannot. The latter must then either be accepted based on risk evaluations (see risk perspective below), or the system cannot be qualified.

For those failures that can be controlled, the control can be exercised at different stages in the life cycle of a system. Some can be controlled by design, e.g. according to standards, best practices, quality assurance, etc. Other failures may be controlled in fabrication through e.g. testing, quality assurance, procedural control, etc. Or similarly in other phases like installation, operation etc.

Sometimes it is possible to choose which phase control is implemented, e.g. through robust design, or alternatively operational monitoring and mitigation strategies.

5.6 *Risk perspective*

It is common to relate failures to risk. By risk we mean the consequences of the failure and its associated uncertainty (ISO 31000 2010, Society for Risk Analysis 2015). Different risk metrics may be used to measure the risk (either quantitatively or qualitatively). Here we only introduce the categories acceptable, and not acceptable. As with the other

perspectives, it is possible to use a more fine-grained set of categories if that is expedient for the project.

To define the border between acceptable and not acceptable risk, the ALARP principle (as low as reasonably practicable), is applied in many industries.

ALARP implies that risk should be reduced until the sacrifices necessary to reduce it further become disproportionate to the risk to be avoided (Health and Safety Executive UK 2017). Note that the risk perspective can be seen in conjunction with the controllability perspective as the ability to reduce risk is related to controllability. This is in essence the aim of the TQ process, i.e. to control, eliminate, or reduce the effect of, failures that are in the unacceptable risk category.

6 CONCLUDING REMARKS

This paper has presented a consistent way of classifying failures to help discovering the critical failures and to ensure that all types of failure are addressed, and to guide handling of identified failures in a system TQ setting. For failure identification, assessment and management, it is useful to explore the failures from different perspectives. To ensure that the identification process is consistent and as complete as possible, we suggest to use Mutually Exclusive and Collectively Exhaustive (MECE) failure classification schemes. These perspectives, or failure classes, can then be used to guide how evidence is collected in the qualification process.

The benefits of such an approach is that the failure identification process will become more practical and tractable by employing simple one-dimensional failure classification schemes and viewing them one at a time, rather than investigating hierarchical failure structures.

In addition, the method guides the assessor towards exploring the entire failure space, and do not exclude any possibilities from the start.

It should be noted that the method proposed in the current work is fully compatible with previous methods. For instance, by combining the one-dimensional MECE schemes, a more complicated structure is easily created, see Figure 6.

One of the perspectives suggested here explicitly focus on identifying and addressing system-level failures (also called systemic failures) that are not easily addressed by conventional methods.

In TQ this is useful since it gives guidance to identification of different types of failures and how to handle them, i.e. what the best method will be to collect the evidence that the critical failures will be managed in the best possible way.

ACKNOWLEDGEMENT

The work in this paper is partially based on work supported by ECSEL JU under the program HORIZON 2020 through SafeCOP (project number 270338).

ABSTRACT: The effect of natural and man made disasters on critical infrastructures are substantial, as evident from recent history. Break downs of critical systems such as electrical power grids, water supply networks, communication networks or transportation can have dire consequences on the availability of aid in such a crisis. That is why, reliability analyses of these networks are of paramount importance. Two important factors must taken into consideration during reliability analysis. First, the networks are subject to complex interdependencies and must not be treated as individual units. Second, the reliability analysis is typically based on some form of data and or expert knowledge. However, this information is rarely precise or even available. Therefore, it is important to account for different kinds of uncertainties, namely aleatory uncertainty and epistemic uncertainty. Aleatory uncertainty represents the natural randomness in a process, while epistemic uncertainty represents vaguness or lack of knowledge in the model. In this work we present an approach to the numerical reliability analysis of complex networks and systems extending a previously developed method based on Monte Carlo simulation and survival signature. The extended method treats both kinds of uncertainties, thus, yielding better results. We show how Monte Carlo simulation controls aleatory uncertainty and apply sets of distributions (probability boxes) to treat epistemic uncertainties in component failures. In this framework, dependencies are modelled using copulas. Copulas possess the unique property of decoupling the odelling of the univariate margins from the modelling of the dependence structure for continuous multivariate distributions. Analoguous to the p-boxes we use sets of copulas to include imprecision in the dependencies. Finally, the method is applied to an example system of coupled networks.

1 INTRODUCTION

Modern infrastructure systems are highly complex and subject to a multitude of different dependencies. Disasters in recent years have shown how critical the impact of these dependencies can be. Failures in one network such as a power outage will surely impact other dependent systems. In worst case scenarios these dependencies can lead to cascading effect ultimately breaking down entire networks (Buldyrev et al. 2010). This highlights the need for methods of reliability analysis that can deal with these complexities.

Recently, the survival signature (Coolen and Coolen-Maturi 2013) has gained in popularity as a tool to aid with this task. The survival signature allows to decouple the structural evaluation from the probabilistic analysis, allowing for highly efficient simulation. In Behrensdorf et al. 2017 we introduced a method for the reliability analysis of complex interdependent networks. Other efficient algorithms can be found for example in Patelli et al. 2017.

A secondary task during the reliability analysis is the accurate modelling of component failures and dependencies. Typically, this is done based on data or expert assessments. However, both are subject to two kinds of imprecisions, namely, aleatory and epistemic uncertainty (Beer et al. 2013). Aleatory uncertainty represents the randomness inherent in a process, such as component degradation and external forces affecting the system (natural hazards, earthquakes, etc.), while epistemic uncertainty describes the uncertainty in the model due to a lack of or vagueness of knowledge about the system. The latter is usually regarded as reducible through acquiring of additional data and information.

In this work we expand our previously developed technique by inclusion of imprecision. The method is based on Monte Carlo simulation and as such already deals with aleatory uncertainty. In this extension the modelling of component failures is refined by applying probability-boxes (p-boxes) to account for epistemic uncertainty. Feng et al. 2016 have shown the advantages of using p-boxes

in reliability analysis. Additionally, the rather simple dependency modelling of the initially developed method is replaced by imprecise copulas (Montes et al. 2015). Copulas split continuous multivariate distributions in a dependence structure and univariate marginals, which in turn allows for separate flexible modelling of the two (Joe 2014).

This paper is outlined as follows. First we introduce the previously developed method for the reliability analysis of networks. Then, after presenting basic theory and notation on copulas, we discuss how to model dependencies with copulas and how to translate these methodologies into an imprecise setting. Finally, we apply the developed techniques to a simple example. The paper closes with some concluding remarks and an insight into future work.

2 RELIABILITY ANALYSIS

This section presents the survival signature based method to calculate the reliability of a system, as first presented in Behrensdorf et al. 2017.

The survival signature was developed as an extension to the system signature (Samaniego 2007), overcoming the limitations that restrict the system signature to systems of one single component type (Coolen and Coolen-Maturi 2013). The main function of the survival signature is to separate the structural information of a network from its probabilistic characteristics.

2.1 *Survival signature*

Considering a system with m components, the survival signature for l out of m components working is defined as

$$\Phi(l) = \binom{m}{l}^{-1} \sum_{\underline{x} \in S_l} \varphi(\underline{x}), \tag{1}$$

where $\underline{x} = (x_1, \ldots, x_m)$ denotes the state vector of the system with $x_i = 1$ and $x_i = 0$ representing a working or failed component respectively and $\varphi(\underline{x})$ is the structure function returning the state of the full system with $\varphi(\underline{x}) = 1$ indicating a working system and $\varphi(\underline{x}) = 0$ indicating a failed system.

Extending the survival signature to systems with K component types and m_k components for each type $k (k = 1, \ldots, K)$ and l_k out of m_k components working results in

$$\Phi(l_1,\ldots,l_k) = \left[\prod_{k=1}^{K} \binom{m_k}{l_k}^{-1} \right] \times \sum_{\underline{x} \in S_{l_1,\ldots,l_k}} \varphi(\underline{x}). \tag{2}$$

An efficient algorithm to compute the survival signature can be found in Aslett 2012.

2.2 *Survival function*

The next step in calculating the reliability of a system is the definition of the survival function. This function uses the survival signature to calculate the probability that a system is working at time t and as such calculates the reliability. The survival function is defined as

$$P(T_s > t) = \sum_{l_1=0}^{m_1} \cdots \sum_{l_k=0}^{m_k} \Phi(l_1,\ldots,l_k) \cdot P\left(\bigcap_{k=1}^{K} \{ C_t^k = l_k \} \right). \tag{3}$$

Note especially the separation of structural information (left) and probabilistic information (right). This means, that the structural evaluation of the system must occur only once for the entire reliability analysis. In the last remaining step, the probabilistic part of the survival function is approximated using Monte Carlo Simulation in order to be able to include imprecisions and interdependencies in the analysis.

2.3 *Monte Carlo simulation*

The simulation starts by selecting a sufficient number of samples N_{MC} and small time step followed by the sampling of component failure times from the assumed copula (see section 3). Next, in two nested loops over all combinations $l_1, \ldots, l_k$ where $\Phi(l_1,\ldots,l_k) > 0$ and all time steps t the number of samples in the same configuration are counted as $N_{l_1,\ldots,l_k}(t)$. Then, the probabilistic part of the survival function is approximated by

$$P\left(\bigcap_{k=1}^{K} \{ C_t^k = l_k \} \right) \approx \frac{N_{l_1,\ldots,l_k}(t)}{N_{MC}} \tag{4}$$

Finally, the partial reliabilities obtained in the previous step are multiplied by their probability from the survival signature and summed up, yielding the full reliability of the network.

3 MODELLING DEPENDENCIES

This section introduces the necessary notation of copulas and how to apply them to model dependencies in and between networks. In more detail, section 3.4 presents how to use copulas to model common causes of failure while section 3.5 shows how to model interdependencies. This is a very basic introduction, for a thorough discussion of copulas see Nelsen 2006.

3.1 *Copulas*

The basis of copulas is built by what is today known as Sklar's theorem (Sklar 1959). The theorem states that any multivariate distribution H (in dimensions $d \geq 2$) can be separated into its univariate marginal distributions F_i and a copula function $C:[0,1]^d \rightarrow [0,1]$.

Theorem 1. Sklar's theorem *Let H be a d-dimensional distribution function with margins $F_1, \ldots, F_d$. There exists an n-dimensional copula C such that for all* $\mathbf{x}$ in $\mathbb{R}^d$

$$H(x) = C\left(F_1(x_1), \ldots, F_n(x_d)\right). \tag{5}$$

If the marginals $F_1, \ldots, F_d$ are continuous, then C is unique; otherwise, C is unique on Range$(F_1) \times \ldots \times$ Range(F_d).

Conversely, if C is a d-copula and $F_1, \ldots, F_d$ are distribution functions, then the function H defined by Eq. 5 is an d-dimensional distribution function with margins $F_1, \ldots, F_d$

This facilitates separate modelling of the marginal distributions from modelling of the dependence structure, in turn allowing for effective treatment of imprecisions in both parts (see section 4).

In this work we apply three distinct copula families, namely the Gaussian copula, the Independence copula, and the Clayton copula. For an encompassing discussion of copula families the reader is referred to Nelsen 2006 and Joe 2014.

The d-dimensional Gaussian copula is defined as

$$C_R(u_1, \ldots, u_d) = \Phi_d\left(\Phi^{-1}(u_1), \ldots, \Phi^{-1}(u_d)\right), \tag{6}$$

where $\mathbf{R} \in [-1,1]^{d \times d}$ is a positive definite correlation matrix and $\Phi_d(\cdot; \mathbf{R})$ is the d-variate cumulative distribution of a $\mathbb{N}_d(0, \mathbf{R})$ random vector. Φ^{-1} denotes the inverse of the univariate standard Gaussian cdf (Joe 2014).

The latter two copulas belong to the class of Archimedean copulas. This family is particularly popular due to their easy construction and wide range of applications (Nelsen 2006). The Archimedean copulas used in this work are one parameter families, which allow for easy treatment of imprecision as seen in the subsequent section. Any d-dimensional Archimedean copula is constructed using a so called *generator* function $\varphi:[0,\infty] \rightarrow [0,1]$ and its inverse φ^{-1} according to

$$C_\varphi(u_1, \ldots, u_d) := \varphi\left(\varphi^{-1}(u_1) + \ldots + \varphi^{-1}(u_d)\right), \tag{7}$$

where $u_1, \ldots u_d \in [0,1]$ (Mai and Scherer 2012). Table 7 shows the generators and parameter ranges for the Independence and Clayton copula families.

3.2 *Dependence measure*

Studies have shown, that correlation is not a suitable measurement of dependence for copulas (Schirma Schirmacher and Schirmacher 2008). Therefore, in this work, Kendall's tau is selected as the preferred dependence measure. Kendall's tau is based on *concordance*. A pair of random variables is said to be concordant if "large" values are associated with "large" values "small" values with "small". Formally, two observations (x_i, y_i) and (x_j, y_j) from a vector $(X,Y)(X,Y)$ are *concordant* if $(x_i - x_j)(y_i - y_j) > 0$ and discordant if $(x_i - x_j)(y_i - y_j) < 0$.

Then, Kendall's tau for a sample of n observations $\{(x_i, y_i), \ldots, (x_n, y_n)\}$ from a vector of continuous random variables (X,Y) can be defined as

$$t = \frac{c-d}{c+d} = (c-d) \Big/ \binom{n}{2}, \tag{8}$$

where c and d represent the number of concordant and discordant pairs among all possible pairs of observations. This value may also be interpreted as the probability of concordance minus the probability of discordance for a random pair of observations (x_i, y_i) and (x_j, y_j). Based on this fact, Kendall's tau for the random variables X and Y can be defined by

$$\begin{aligned} \tau(X,Y) = {} & P[(X - \tilde{X})(Y - \tilde{Y}) > 0] \\ & - P[(X - \tilde{X})(Y - \tilde{Y}) < 0], \end{aligned} \tag{9}$$

where $(\tilde{X}, \tilde{Y})$ is an independent copy of (X,Y) (Schirmacher and Schirmacher 2008).

Kendall's tau is not only used to measure dependence but also to find copula parameters representing a desired strength of dependence.

3.3 *Vine copulas*

In order to analyse the reliability of complex networks it one must build hight dimensional copulas. However, in comparison to bivariate copulas, the available literature on multivariate copulas is scarce (Mai and Scherer 2012). For this reason, we employ a technique called *pair copula construction* to break down multivariate copulas into combinations of bivariate copulas. More accurately, we use vine copulas as a graphical tool to model pair cop-

Table 1. Generators, generator inverses and parameter ranges for the Clayton and Independence copula.

Name	Generator $\varphi_\theta(\mathbf{t})$	Generator Inverse $\varphi_\theta^{-1}(\mathbf{t})$	Parameter θ
Clayton	$\frac{1}{\theta}(t^{-\theta} - 1)$	$(1+\theta t)^{-1/\theta}$	$\theta \in [-1,\infty) \setminus \{0\}$
Independence	$-\log(t)$	$\exp(-t)$	

ula constructions as sets of trees. An example of a five-dimensional vine copula is shown in Fig. 1.

A regular vine (R-Vine) $\mathcal{V}$ is defined as a set of trees $T_1,\ldots,T_{d-1}$, where T_1 consists of nodes $N_1 = \{1, \quad ,d\}$ and edges E_1. Every subsequent Tree T_j uses the edges E_{j-1} as nodes and connects them with the edges E_j. The last property needed to define a regular vine is the *proximity property*, stating that if a and b are connected by an edge in $T_j, j \geq 2$, then a and b must share a common node in T_{j-1}.

A plethora of different structures exist for a d-dimensional R-Vine based on the definition. Because of this and the fact, that a regular vine possesses 2^{n-1} sampling order we apply D-vines instead, which have a much more restrictive structure. As seen in Fig. 2, a D-Vine is characterized by each node $n \in N_i$ having a maximum degree of 2. Sampling from D-Vines is a lot simpler and in this work performed by using the MATLAB toolbox VineCopulaMatlab (Kurz 2016).

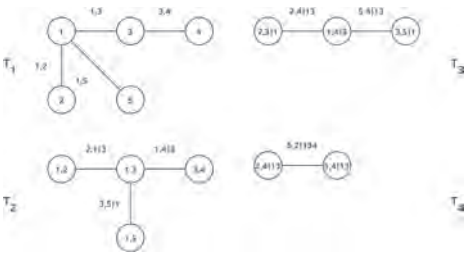

Figure 1. Five-dimensional copula represented as a regular vine.

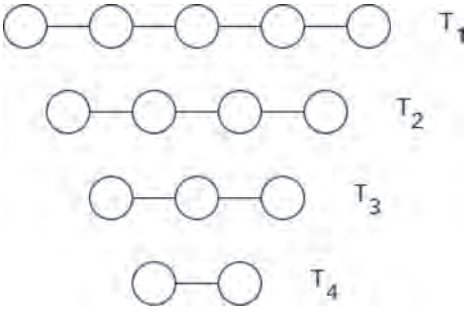

Figure 2. Structure of a five-dimensional D-Vine.

3.4 *Common cause of failure*

One type of dependent failure tackled in this work is common cause of failure. It is defined as two or more components failing at the same time due to common defects or weaknesses. Causes include but are not limited to: errors in manufacturing, errors during maintenance or operation, and environmental causes such as earthquakes or tsunamis (Hanks 1998). We model common cause of failure by application of Clayton copulas. This family possesses a property called lower-tail dependence, meaning that dependence is stronger in the lower-left quadrant of $[0,1]^2$. By modelling the failures this way, the dependence is much stronger in early component life and as such brings us closer to the traditional bathtub shape or component failure probabilities. Figure 3 shows samples drawn from a Clayton copula. Note, how the stronger dependence in the lower-tail is clearly visible in the scatter plot.

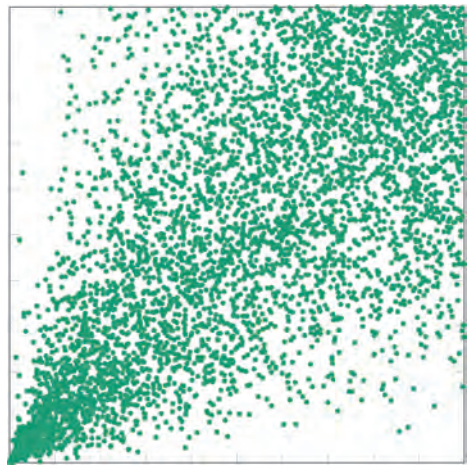

Figure 3. Samples drawn from a Clayton copula with the parameter chosen so $\tau = 0.5$.

3.5 *Interdependencies*

Interdependencies between nodes and networks are handled by application of Gaussian Copulas. Gaussian copulas possess no tail-dependence and show good results, although other families could be investigated for the same application in the future. In addition to the copula there is one more step required to accurately model the dependencies. We understand interdependencies as the phenomenon of one component failing due to the failure of another. As such, interdependencies imply causality. In order to represent this causality in the model, dependence is introduced in the marginals. During the transformation of the failure times sampled from the copula by the inverse transformation method, the marginal distributions are aggregated from the dependent marginals using Kendall's tau of the random variables u_1 and u_2 as

$$U_1 = (1-\tau)\cdot F_1^{-1}(u_1) + \tau \cdot F_2^{-1}(u_1), \tag{10}$$

where F_1 and F_2 are the marginals of a copula C.

4 HANDLING IMPRECISION

Two types of uncertainties must be taken care of during the reliability analysis, namely, aleatory and epistemic uncertainties. Aleatory uncertainty describes the natural randomness inherent in a process, while epistemic uncertainty represents the uncertainty due to vagueness in information or a lack thereof.

Aleatory uncertainty can automatically handled by our reliability analysis technique. Through assuming failure time distributions for the component failures and sampling these during Monte Carlo simulation, the randomness that our model is subject to is fully included. However, the selection appropriate failure time distributions is typically based on either data or expert knowledge, neither of which yield perfect results, in turn introducing epistemic uncertainty into the model. This uncertainty can be reduced by using *probability-boxes* (p-boxes) (Feng et al. 2016).

P-boxes are defined as bounds on the cumulative distribution function of a random variable. The left and right bounds can be found by for example selecting an appropriate distribution and giving the parameters as intervals. As such, a p-box comprises boththe aleatory and the epistemic uncertainty. An example of an exponential p-box with parameters $\lambda \in [1.2,2.2]$ is shown in Fig. 4.

By feeding the bounds of the p-box into the reliability analysis, the epistemic uncertainty propagates into the result. Thus, instead of one survival function, we obtain an upper and lower bound. Figure 5 shows an example of theupper and lower bounds obtained by performing a reliability analysis of a simple system of two parallel components of the same type, assuming the p-box of Fig. 4 for the failure time distributions.

Similarly to the application of p-boxes to handle epistemic uncertainty in the marginals, we can define the copula parameters as intervals and obtain *imprecise copulas* for the dependencies (Montes et al. 2015). This works especially well since all copula families, including the bivariate Gaussian copula, we apply in the vine copula are defined by a single parameter.

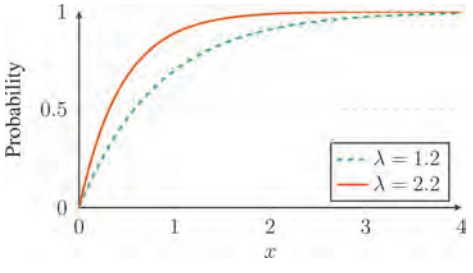

Figure 4. Example of an exponential p-box with $\lambda \in [1.2,2.2]$.

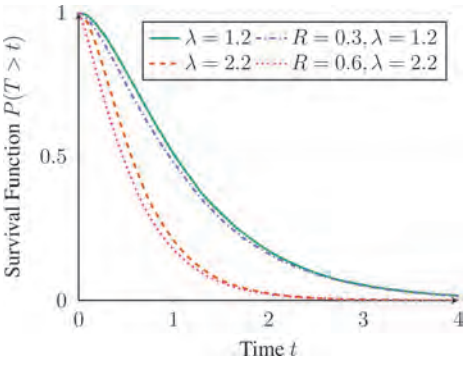

Figure 5. Upper and lower bounds of the reliability resulting from applying the p-box in Fig. 4 to a simple system of two parallel components.

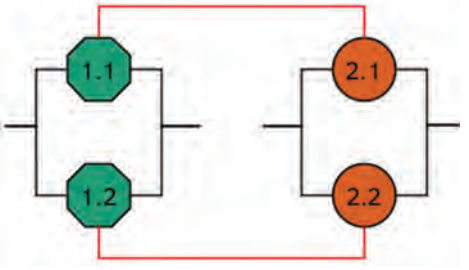

Figure 6. Structure of the example network. The red lines represent interdependencies between the two subsystems.

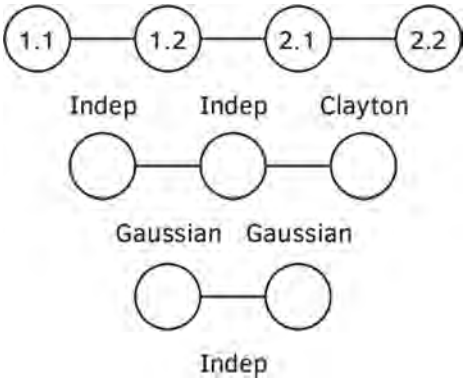

Figure 7. D-Vine used to model the common cause of failure in system 2 and the interdependencies between the two networks.

Finally, the bounds of the p-boxes as well as the bounds of the copula parameters are fed into the reliability analysis. Returning to the simple system of two parallel components and linking the components with an imprecise Gaussian copula $R \in [0.3, 0.6]$ results in the upper and lower bounds for the reliability as seen in Fig. 5.

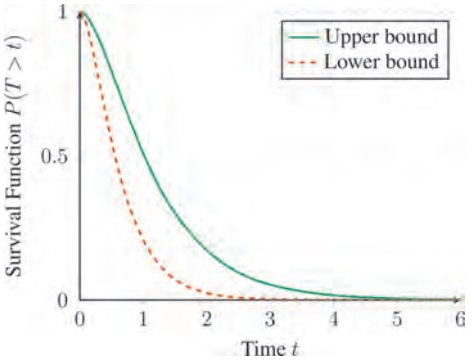

Figure 8. Bounds on the reliability of system 2 based on the assumed imprecisions.

5 NUMERICAL EXAMPLE

The methods that were introduced in the previous sections will now be applied to a simple toy example. All marginals and dependencies will be considered as imprecise in order to account for all aleatory and epistemic uncertainties. Figure 6 presents the example system build from two systems of two parallel components where the first and second components respectively are interconnected.

A four-dimension D-Vine copula, including the interdependencies and a common cause of failure shared among the components in system 2, is built in order to sample the component failure times. The structure of the vine is shown in Fig. 7.

The component failure times for systems 1 and 2 are assumed to be exponentially distributed with $\lambda_1 \in [1.5,1.7]$ and $\lambda_2 \in [0.7,1.1]$. The copula parameters are chosen such that $\tau \in [0.2,0.4]$ for the Clayton copula and $\tau \in [0.4,0.6]$ for the Gaussian copulas. The resulting bounds on the reliability of system 2 are plotted in Fig. 8.

6 CONCLUSION AND OUTLOOK

In this work we have presented how to perform reliability analyses of complex interdependent networks in a highly imprecise setting. The necessary theory on copulas and vine-copulas and applied to the modelling of dependencies in and between networks. Finally, the modelling of dependencies and a previously introduced method for the reliability analysis of networks were extended to account for both aleatory and epistemic uncertainties. As a result, we obtained bounds on the network reliability. The method was applied to a numerical toy example to prove the functionality.

It is obvious that this paper only serves as a short introduction into future work. The methods must be validated further and applied to complex real world networks in order to ensure usability. Especially the construction of the D-Vine copula for sampling of the component failure times must be further investigated. There exist a plethora of possible vine structures for a given problem and effective automatic construction techniques have to be created.

ABSTRACT: Several unmanned aerial vehicles (UAVs) flight in a formation fleet are used to improve the effectiveness of civilian missions such as firefighting, searching, rescuing, etc., as well as the success of military applications. The increase use of these cooperative systems in hazardous environments makes the reliability improvement essential in order to prevent any catastrophic event. In this article, we aim to ensure a successful communication between the drones from one side, and between the drones and the ground station from the other side. We propose to identify, the different fault states and their probabilities during a communication. An Absorbing Markov Analysis approach is developed for these states. This framework can be used to find the riskiest scenarios and elements that need to be addressed in order to improve the reliability.

1 INTRODUCTION

Nowadays, the interest of using the unmanned aerial vehicles (UAVs), recognized as drones, has increased due to their use in several civilian applications such as searching, border surveillance, natural disaster monitoring, and firefighting, etc (Rabbath & Léchevin, 2010). They are known for 3D missions that are 'dirty, dull or dangerous' (Hattenberger, 2008). Lately, the focus is shifted toward the cooperative UAV fleet formation due to their mission in a large hazardous environment, since a single UAV has a limited energy and payload. The multi UAV system needs to ensure several properties such as robustness, cooperativeness and scalability. These proprieties can be attained by assuring the navigation of each UAV, the control of the whole fleet as well as constant and reliable communication between the drones on one side and between the drones and the ground station control (GSC) on the other side. Their different size and payloads, their flight times, the distance between two UAVs and the communication ranges are the causes that affect the overall performance of the fleet formation flight. The essential role of these cooperative systems reflects the importance of enhancing the reliability in order to avoid the failure of the communication between the aerial vehicles. Coordination between them should always be guaranteed despite the uncertainties of the environment, the network and simple failure in the hardware of a vehicle. In hence, the detection of the anomalous aircraft prevents the collisions between the aerial vehicles and the degradation of the team performance. The information flow between UAVs can be collected by an entity on ground, Ground Station Control (GSC), that controls the mission and makes decisions for the aircrafts; or alternatively, they share the information between them and make collective decisions.

Considering the importance of the reliability of the communication system, this paper presents, based on Markov model, a novel approach to evaluate it. The proposed framework takes in consideration the internal elements, both hardware and software, of the system as well as the surrounding environment.

The paper is organized as follows. Section 2 presents the related work on the reliability of the aerial vehicles focusing on the Markov chain. Section 3 provides a description of the proposed model of state diagram for the communication failure between UAVs. Section 4 gives a brief description of the proposed framework. The conclusion is attributed in Section 5.

2 RELATED WORK

Since the UAV's accidents and failure rates are higher than the manned aircraft, the reliability analysis of these systems presents an important focus for the researchers. The fault-tolerant system and the redundancy hardware do not always represent the efficient solution for this formation fleet flight due to incurred costs and weight. Different methods like the Fault Tree Analysis (FTA) (Abdallah, Kouta, Sarraf, Gaber, & Wack, December 2017), Failure Modes and Effects Analysis (FMEA) has been used to improve the reliability of the helicopters. In some cases, various FTA are needed to represent the different failure conditions of a complex system.

The evaluation of reliability of a system considers the state-space models, such as Markov Chain (Frattini, Bovenzi, Alonso, & Trivedi, 2010), that handle the failure/repair of its components and surrounding elements that might impact the reliability model. The Markov chain defines the derogation states of operation, where the functions are not all performed or where the state functions are absolutely stopped. In (Kitchin, 1988), distinct techniques used for establishing Markov models for the reliability of systems are provided emphasizing on the exponential model. It is devised to detect the failure and the method to recover it.

The reliability of the flight computer system (FCS) components including the flight computer and the navigation system is discussed in (Pashchuk, Salnyk, & Volochiy). It enquires a fault tolerant model considering two cases: the case where no additional standby microprocessors are implemented and the case of inherent standby microprocessor. A mathematical model based on Markov chain is applied to improve the reliability for the FCS components. An explanation of the Markov chain and Markov process is given in (Fuqua, 2003). It clarifies the powerful relation between the Markov chain and the reliability, maintainability and safety engineering (RMS) insisting of the International Standards that deal with this approach such as IEC 61165 and IEC 61508 that estimate the probability of failure of a critical system.

The issue of packet dropout for the drones' communications via wireless is investigated in (Zhou, Li, Lamont, & Rabbath, 2012). The authors proposed a two state Markov model in order to model the wireless channels taking into consideration the impacts of the Ricean fading. Their computer simulations are better than those of the most known models for wireless channels, the Gilbert-Elliott model (Gilbert, 1960), (Elliott, 1963), since their approach simulate the non-stationary errors.

A distributed computing system (DCS) is multiple processors that are interconnected via a network. In DCSs, the information is spread out among the nodes that consist of the data files, the processing elements, the shared resources and programs. In order to ensure the exchange of the information and the control of the data, the reliability of this system is important to be studied. It focuses on the analysis of the distributed program reliability (DPR) and the distributed system reliability (DSR). (Wang, 2004) suggested two reliability stochastic measures for these distributed systems: Markov-chain distributed program reliability (MDPR) and Markov-chain distributed system reliability (MDSR). The article describes the employment of one absorbing state for this problem and the probability of transition between the states. An Adaptive Markov Model Analysis (AMMA) is proposed in order to isolate the faults in the critical components. This proposed approach serves to make better the robustness and the availability of the UAV autopilot by incorporating the Fault Detection Isolation (FDI) approach (Krishnaprasad, Nanda, & Jayanthi, 2016). In (Kumar & Jackson, 2009), the paper discusses the reliability models based on the stochastic approach of Markov analysis, merged with the probabilistic approach of Weibull distribution in order to approximate the failure attributes of wear out components. This method is used since the components with wear out failure are characterized with variable failure rates depending on the operation time of the components. For this issue, a state transition diagram for six components optical telescope calibration system (OTCS) is shown. The partially observable Markov decision processes (POMDPs) is used in (Ragi & Chong, 2013) in order to determine a path planning for the UAVs to track different targets. The failure analysis of the flight control system of Air Force Institute of Technology (AFIT) UAV based on Markov analysis is elaborated in (Okafor & Eze, 2016). It shows the failure states and the probability of being in these states.

3 PROPOSED APPROACH

An Absorbing Markov Chain (AMC), where there is at least one absorbing state, is considered. An

absorbing state is characterized by the fact of once it is entered, it cannot be left. Each state in the transition diagram can be taken as an absorbing state. The transition between states can have multiple steps in order to attain the absorbing state. Two important variables should be calculated: the mean time t_{mean} in addition to the length of the path until the state is absorbed. We aim to evaluate the probability of being in each transient state leading to the absorbing state. Transitions between states are based on the probabilities that are function of the failure rates, of internal components as well as the occurrences of related events within the surrounding environments.

The main focus is to maintain a communication between the drones although all the uncertainties that can occur. We propose an Absorbing Markov Chain to model the problem and show the transition between the events that affect the communication.

First, the exchange of information and the communication is considered in a normal state. However, several causes can affect this state. The causes can be divided in internal causes at the level of the software and hardware failures and the external causes that are related to the human and the environment.

3.1 *Hardware failure*

The hardware failure can attack the engine, the power, the propellers and the antenna of transmission and reception. The issue is that during a flight, a hardware failure cannot be repairable and lead to an absorbing state of communication failure (Figure 1).

Figure 1 shows the causes of the hardware failure of a drone in addition to the transition between the transient states. The antenna failure can directly lead to a communication failure. The drones cannot send and receive anymore the information between them or to/from their ground station control. Moving to the power failure, it can be caused from the ventilation default and the disruption of the cables that induce an overheating of the drone and consequently a power failure. It is also attributed to an overcurrent/undercurrent, physical damage, overheating or exhaustion of the battery. The loss of the UAV transceiver affects the servomotor which its failure involves the actuator default and in hence the engine failure. So on, the

Table 1. Failure rates of the hardware events.

Events	Minimum Failure Rate (λ_{min}) ($\times 10^{-6}$)	Maximum Failure rate (λ_{max}) ($\times 10^{-6}$)	Mean Failure Rate (λ_{mean}) ($\times 10^{-6}$)
Loss of UAV transceiver ($\lambda_{ns\text{-}lt}$)	7,285E-01	3,740E+00	9,635E-01
Servomotor default ($\lambda_{ns\text{-}sd}$)	3,575E-01	3,952E+00	2,961E+00
Actuator default ($\lambda_{ns\text{-}ad}$)	1,218E-01	8,569E-01	3,444E-01
Disruption of cables ($\lambda_{ns\text{-}dc}$)	4,000E-05	4.087E+00	4.800E-05
Ventilation Default ($\lambda_{ns\text{-}vd}$)	3,483E-01	4.087E+00	2,891E+00
Overheating ($\lambda_{ns\text{-}oh}$)	12,617E+00	778,2E+00	44,421E+00
Power Failure ($\lambda_{ns\text{-}pf}$)	2,352E+00	9,104E+00	4,813E+00
Default assembly of propellers ($\lambda_{ns\text{-}da}$)	8,992E+01	6,296E+02	2,07E+02
Antenna failure ($\lambda_{ns\text{-}af}$)	3.662E+00	11.886E+00	20.467E+00

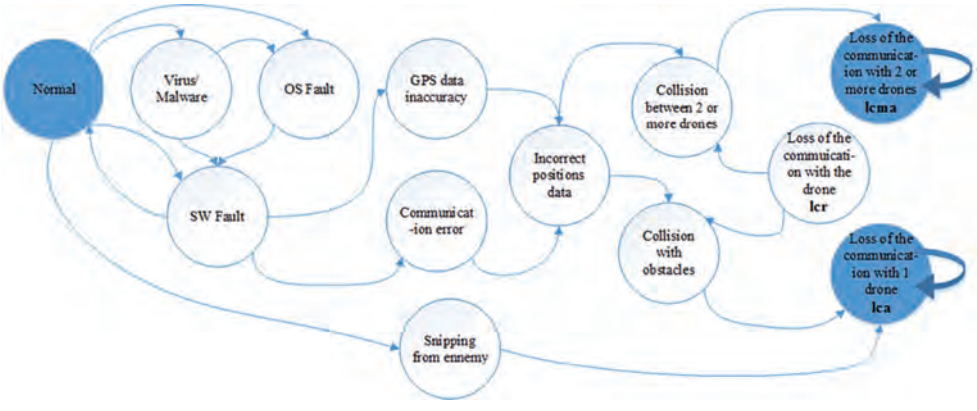

Figure 1. Hardware failure.

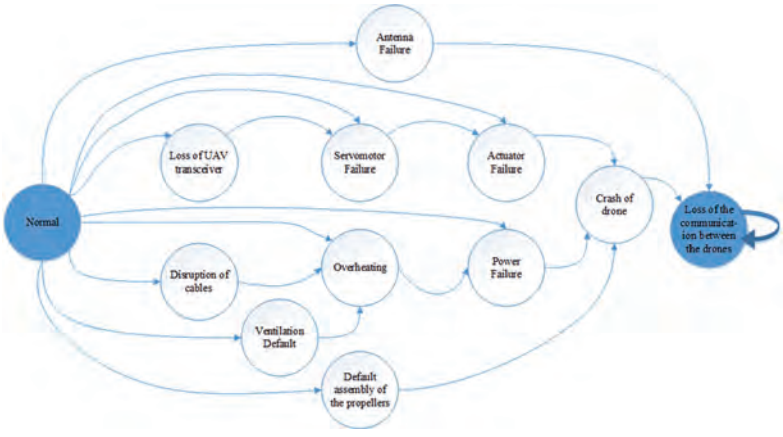

Figure 2. Software failure and collision events.

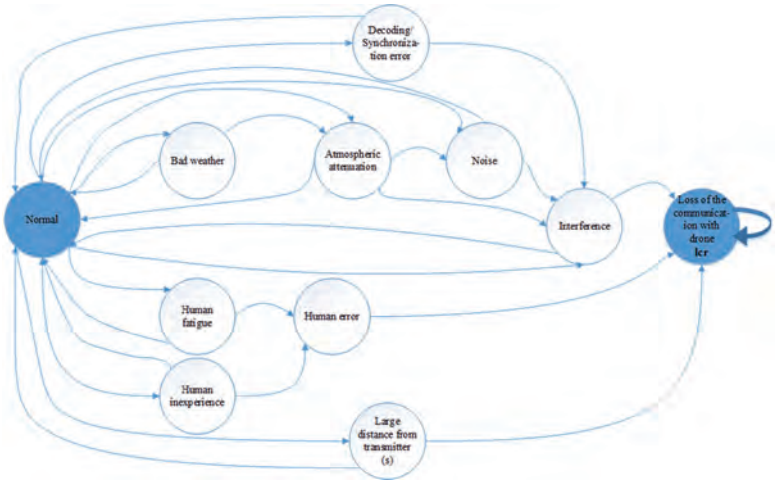

Figure 3. Exterior factors events.

engine failure, the power failure and the default assembly of the propellers can lead to the damage of a drone. The crash of the leader of the fleet formation flight is the most risky case since the leader controls the exchange of information between the fleet. Since the crash of a drone cannot be repairable, it leads to an absorbing communication failure between the drones. The failure rates of these events are known from the Nonelectronic Parts Reliability Data Publication (NPRD-2016) database.

Table 1 exhibits the failure rates of these hardware events considering the previous state as normal state ns. The annotation of the failure rates is λ from the previous status of transition to the next status of transition. The database gives only the failure rates from the normal states. The other transition failure rates are not known.

3.2 *Software failure and collision events*

The normal situation can be affected by a software failure bringing a disruption to the communication between the drones (Figure 2). An infected virus or malware represents an important reason for a mal-functioning of the UAV. It disturbs the

operating system OS of the drone in a manner that the two causes engender a software fault. The virus/malware and the OS fault can also attack the ground station control (GSC). The reliability of the software is ensured by regular updates of the operating system in addition to a good antivirus. The software faults affect the GPS data leading to a communication error between the drones or between one drone and the base station in a manner that the communication is not lost but there is an error in exchanging the information. The GPS data inaccuracy permits a confusion of the position of other's drones that influences the coordination of the fleet formation flight.

The wrong positions' data received from other drone might lead to collision between two or more UAVs or even to collision of the drones with an obstacle such as a building, trees, birds, etc. From the one hand, the collision between two drones leads to an absorbing state that cannot be avoided and repairable, the loss of communication between two or more drones *lcma.* On the other hand, the collision with obstacles in addition to the snipping of a drone from an enemy cause the loss of communication with only one drone *lca*, since it will not be presented in the fleet. This event is also an absorbing state.

3.3 *Exterior factors*

Different exterior factors influence the communication of the fleet formation flight. It englobes the animals, the weather, the obstacles and the human. The bad weather is an important state to prevent it. It includes temperature, wind, clouds, rain, ice, thunderstorms and fog. The transmitted signals might be subjected to an atmospheric attenuation due to a bad weather or other environmental conditions. An attenuation involves an interference and a noise that contributes to a bad signal transmitted between the aerial vehicles. If the medium of communication is exposed to jamming, echoes and noise, then that might interfere with what is transmitted, affecting the overall communication. Synchronization and the decoding of the message is an essential mechanism in the transmission of the message that can be affected by the interference phenomenon.

The human plays an important role in the communication especially with the GSC. The exhaustion of the GSC operator and his lack of experience and qualification in flying a certain type of drones contribute to the human error. The distance between the source and the destination can influence the quality of the received information as when the distance increases, the transmitted signal can be exposed the attenuation and atmospheric noises.

In order to avoid these events, the operator should chose the typical environment for the fleet. He might take in consideration the weather, the season and the time of flight. However, although all these events lead to the loss of communication with the drone, but this state is not absorbing. It is repairable since we can change the environment, chose the right persons to flight the fleet, the interference could affect the signal for a certain time then the fleet continues its mission. Figure 3 resumes the external factors.

On the contrary of hardware failure, the loss of communication with the drone lcr is a repairable state. It could be caused by software faults or environmental effects. A software fault in the communication could be repaired through alternative channels or by the ground station. The environment effects can be controlled by making the drones flying in close distances or alternatively planning the mission in some other time with better weather conditions. Once the lcr occurs, it might attribute to the collisions between the drones or with an obstacle.

4 BRIEF DESCRIPTION OF THE STATES

Table 2. Brief description of the states.

ns	Normal State	This is the normal situation where the communication system, between drones and with GSC, is functioning normally.
vm	Virus or malware	The system has been infected by a virus or malware leading to mal-functioning and abnormal behavior
OSf	Operating System fault	The operating system of a drone or GSC is not properly functioning due to being infected by virus or malware or due to some internal fault or error
swf	Software fault	A fault in the software that handles GPS data or the communication system within the drone or the communication system within the GSC
gpsf	GPS data inaccuracy	GPS data of one or more drones are inaccurate
wpd	Incorrect positioning data	Wrong positions of one or more drones have been communicated to other drones and/or GSC

(*Continued*)

Table 2. (*Continued*).

cf	Communication error	No communication between 2 or more drones and/or between 1 or more drones and GSC
cd	Collision between drones	Collision between 2 or more drones have occurred
co	Collision with obstacle(s)	A drone has collided with obstacle(s)
se	Snipping from enemy	A drone or more have been shut down by enemies or third parties
bw	Bad weather	A bad weather that might have impacts on the communications between drones and/or between the drones and GSC
aa	Atmospheric attenuation	Transmitted signals might be subjected to attenuation due to bad weather or other environmental conditions
no	Noise	Transmitted signals might be subjected to noise
in	Interference	Transmitted signals might be subjected to interference
de	Decoding/synchronization errors	Transmitted data might be subjected to decoding and/or synchronization errors
ld	Large distance	One or more drones have flown away from transmitters of other drones and GSC
hf	Human fatigue	GSC operator is experiencing exhausted and tired
he	Human error	GSC operator(s) committed error(s), due to fatigue or lack of experience and qualification, that might affect the communication system
af	Antenna failure	Hardware fault affecting the transmitter and/or receiver antennas of one or more drones of GSC
lt	Loss of UAV transceiver	Loss of an electronic device that transmits and receives the signal
sd	Servomotor default	Hardware default of the motor that permits the control of the position, the acceleration and velocity.
ad	Actuator default	Hardware default of an electronic speed controllers that is linked to the engine, servomotors and propellers UAV actuators
dc	Disruption of cables	Internal incident that cut the cables
vd	Ventilation default	The cooling system is in failure
oh	Overheating	The temperature of the drone is high due to a disruption of cables or due to a default in the cooling system
pf	Power failure	Due to short-circuit, overcurrent/undercurrent, battery damage, overheating
da	Default assembly of propellers	Loss of more than two propellers
l1d	Loss of one drone	Loss of one drone due to collision with obstacles, snipped by enemies, and/or due to internal operation failure
lmd	Loss of 2 or more drones	Loss of 2 or more drones due to collision between them
lcr	Loss of communication with a drone	Loss of communication with a drone due to environmental conditions or software faults. This state is repairable and the system could go back to its normal state (*ns*)
lca	Loss of communication with a drone due to the loss of the drone	Loss of communication with a drone due to the loss of the drone itself caused by collision, snipping with enemies, environmental conditions and/or some internal faults. This state is not repairable and therefore it is an absorbing state.
lcma	Loss of communication with multiple drones	Loss of communication with multiple drones due to collision between them. This state is not repairable and therefore it is an absorbing state.

5 CONCLUSION

Different state diagram are presented in this paper showing the causes of loss of communication between the drones or between the drones and the ground station control. It includes the hardware failure, the software failure in addition to the external factors that affect transmitted signals. The software failure is a repairable state in addition to the external factors that we can prevent them by choosing the suitable environment, season and time. On the contrary, as they are not recoverable, hardware failures will lead to an absorbing state for the loss of communication. We aim to consider in our future works the failure rates of the external and software events, the failure rates of transitions in addition to the repairable rates taking in consideration the different strategies of fleet formation flight.

ABSTRACT: Connected vehicles such as Vehicular Ad hoc Networks (VANET), a subset of Mobile Ad hoc Networks (MANETs), is a wireless communication technology applied to transportation, referring to a set of smart vehicles used on the road. These vehicles provide communication services among one another (V2V) or with Road Side Infrastructure (V2I). The main benefits of VANET are enhancing road safety, reducing energy use and emissions, and giving information services. Reliability is one of the most critical issues related to VANET since the information transmitted is distributed in an open access environment. We focused in this paper, on the reliability of VANET as a function of reliable hardware and their functionality taking into consideration the needed security equipment. Reliability Block Diagrams (RBD) and Fault Tree (FT) were used to analyze the reliability of the vehicles and the Road Side equipment (RSU). In order to prove our result, a simulation was occurred using the RBD and FT probability and it has been conducted to validate the proposed approach. The data (Failure ratio) used were from professional database concerning the type of components presented in the system. Our scientific approach was structured with methods that combine qualitative approaches (such as functional analysis, Failure Modes and Effects Analysis (FMEA),...) and quantitative methods (Fault tree, probabilistic models of degradation, etc.) for the VANET. From this data an exponential model of reliability was proposed. The probability calculation was performed in relation to a reference time of use. Thereafter a sensitivity analysis was suggested concerning the reliability parameters and redesign proposals are developed for the components.

1 INTRODUCTION

Each year 1.25 million people die worldwide as a result of road traffic accidents according to the WHO's Global status report on road safety 2015 [1]. Connected Vehicles such as vehicular ad hoc networks (VANET) and the autonomous vehicles are proposed as solutions to improve road safety [2].

On-Board Unit (OBU) computers give a smart vehicle the ability to communicate with other vehicles (V2V) and with intelligent Road Side Unit (RSU) infrastructure (V2I). In this context, wireless vehicular network technologies will allow significant reduction of vehicular accidents [2]. Since 90% of accidents are caused by humans, connected vehicle systems will help the driver to avoid these accidents and to divide the percentage accident ratio by ten [3].

These smart vehicles must comply with the safety integrity obligations. Indeed, safety is a major concern for the user of automotive vehicles. Reliability is one of the most critical issues related to the connected vehicle since the information transmitted is distributed in an open access environment and also due to the high mobility, dynamic topology, delay constraints, varying environments and different traffic patterns in VANET [4].

With the evolving of the Internet of Things, ensuring the dependability and the reliability of vehicular networks is becoming critical, and any lack of this requirement can lead to accidents and catastrophic results [5].

This paper presents a design of reliability block diagrams for: (1) the OBU based on Dedicated Short Range Communication (DSRC) Standard,

(2) the RSU and (3) the devices that are especially interesting for security purposes such as Trusted Platform Module (TPM). TPM is often mounted on vehicles to offer reliable storage (e.g. user credentials and keys) and to compute cryptography. TPM hardware is assumed to be tamper resistant so that hackers can't gain access, even with physical presence [6].

In VANET, the reliability of networks must be given special attention since the system aims at safeguarding road safety and accomplishing secured communication. Currently, in VANET, most of the work carried out relates to the evaluation of the communication performance and for routing protocols, without taking into consideration the dependability and the operational safety of the system. Network reliability is greatly reliant on the availability of hardware components and their life time cycle. Given that this problem is relatively new for applications in the mobile environment using ad-hoc networks, hence the development of methods and models to assess the reliability of smart vehicles by the approaches of reliability analysis that combine qualitative approaches (such as functional analysis) and quantitative methods such as reliability block diagrams (RBD), and fault trees (FT) for the VANET, has become indispensable. Evaluating these problems leads to a sensitivity analysis concerning reliability parameters in order to propose a redesign for the components that aims to increase the reliability and the availability for the whole system.

The paper is organized as follows: Section 2 presents the related work, section 3 describes the analytical approach and the hardware architecture of VANET: OBU, RSU, TPM. Using the reliability block diagrams and the fault tree we calculate the reliability of the system in section 4. Section 5 describes the simulation performed and the results. Finally, Section 6 concludes the paper with lessons learned from this work, and points out future research directions on VANET.

2 RELATED WORK

Generally, reliability is defined as the ability of a functional unit to perform a required function under given conditions for a given time interval [7].

Technically speaking, reliability is the probability that the VANET systems will work without failure during its running time under wireless environment operating conditions.

It is important to differentiate between availability and reliability concepts; reliability refers to failure-free operation during an interval, while availability refers to an operation free of failure at a given instant of time [8].

Many research works have been proposed in literature to define the reliability for VANET and focus on protocols such as the DSRC and Wireless Access in Vehicular Environments (WAVE) protocols [9,10]. Moreover, most of the proposed approaches emphasize on reliability in terms of successful delivery and the optimization of the number of packet drops. For example, in [9] communication reliability metrics are defined such as packet delivery ratio, and distribution of consecutive packet drops are reduced. DSRC based scenarios are proposed. In [10], the authors investigate additional metrics, such as reliability, packet reception ratio, and effective range of coverage.

Le Lann in [11] presents the safety and reliability for Intelligent Vehicular Networks (IVN) for platoons and cohorts. To avoid failure, he introduces diversified functional redundancy, giving a replacement in case of telemetry failures as an example.

A lot of researches focus on finding a reliable routing in connected vehicles, and on classifying routing protocols [12,13,14].

In [12], the authors present a new algorithm with 2 notations: virtual equivalent node (VEN) and differentiated reliable path (DRP) to solve problem of link failures, RSU will play the role of VEN if the route failed. In [13], authors introduce a routing protocol ROVER (Robust Vehicular Routing) based on positions of local-aware vehicles to define the zones. The protocol broadcasts control packets and works as Ad hoc On-Demand Distance Vector (AODV) protocol to discover the best routing path. A classification is described in [14] to classify the existing VANET routing protocols into five categories according to their used routing metrics.

In [15], the authors calculate the reliability of OBU in function of hardware reliability and channel availability without taking hardware security into consideration and by using simulations instead of real data.

Waqar *et al*, lists all the papers working on the reliability of communication networks and classify them according the modeling and analysis techniques. For each paper listed in their work, Waqar *et al*, provides a survey of each application in communication networks mentioning the strong and weak points of different approaches [16]. Concerning VANET applications, only Ref. [15] mentioned above is listed.

Further, the authors in [17] proposed an evaluation method of the performance reliability of the Mobile Ad hoc Networks (MANET) and studied the effect of interference. However, reliable communication in VANET is more complex compared to MANET, due to its characteristics, such as the high mobility and the dynamic topology.

In all mentioned articles earlier, we notice that the reliability of hardware and the quantitative and qualitative reliability analysis for the connected vehicle system are ignored in realizing their performance. Hence, we propose to analyze the

reliability of VANET, in terms of network reliability, as function of hardware reliability and functionality while taking into consideration the needed security equipment. Several approaches are applied to evaluate the reliability and the availability for communication systems. In this paper, the investigation is directed using RBDs, for both V2V and V2R communications. RBD analysis is used to conduct both qualitative and quantitative analysis of the systems. RBD deals with the identification of critical or weak components of the VANET system. The reliability of the overall system is calculated on the basis of reliability of the individual components in the OBU. The exponential distributions are used to model the failure characteristics of the OBU equipment nodes.

The California Department of Motor Vehicles (CA DMV) is the state agency that registers motor vehicles and issues driver's licenses in the U.S. state of California, and is responsible for permitting and monitoring the testing of autonomous vehicles. DMV published reports concerning AV failures or disengagement. Disengagement is the failure event where the autonomous of the car (OBU algorithms) fail to take the right decision. In these situation the control should reverts to the human driver.

Studying this report for 2616 disengagements events from September 2014 to December 2016, show that 52% of this disengagement were due to system failure, which refers to a hardware, and/or software failure of the vehicle technology that causes the impossibility for the vehicle to continue the autonomous operations. System failure is a broad category that includes issues such as a discrepancy between onboard GPS systems, incorrect perception of external objects, incorrect prediction of other traffic behavior, and so forth.

The valuation of these problems is the object of quantitative and qualitative reliability analysis for the connected cars. As shown later, the reliability prediction helps us to precise the redundant component in the OBU and in the RSU in order to get a higher acceptable reliability level.

3 THE PROPOSED APPROACH

3.1 *The analysis approach*

In this paper, we focus on reliability and availability related to hardware failure issues because of their importance and wide utilization in the area of communication networks.

Using the Reliability analysis methods, we can identify the problems in VANET that lead to the improvement of the system design and avoid future problems. Reliability analysis plays an important role in the prediction of the behavior of wireless networks versus time, and gives us a clear view to take the right decision concerning the redesigning of the system in order to have an efficient communication network [18].

Fig. 1 shows the reliability procedure analyses approach; this approach begins with the functional analysis and the development for conceptual behavioral model of the system.

In the first step, we describe our mode of communication (wireless in our case) and the desired network behaviors, such as network protocols (e.g. DSRC, WAVE), network topologies (adhoc, broadcast) and fault tolerance of the connected vehicular network.

For this purpose, we tackled the preliminary risk analysis of the smart vehicles. The functional analysis studies how each of the parameters identified above are ensured by the components of the system. Based on this analysis of the functioning of the VANET, dysfunctions and failures could be identified.

The failure analysis of VANET research sources (causes) of system and their consequences

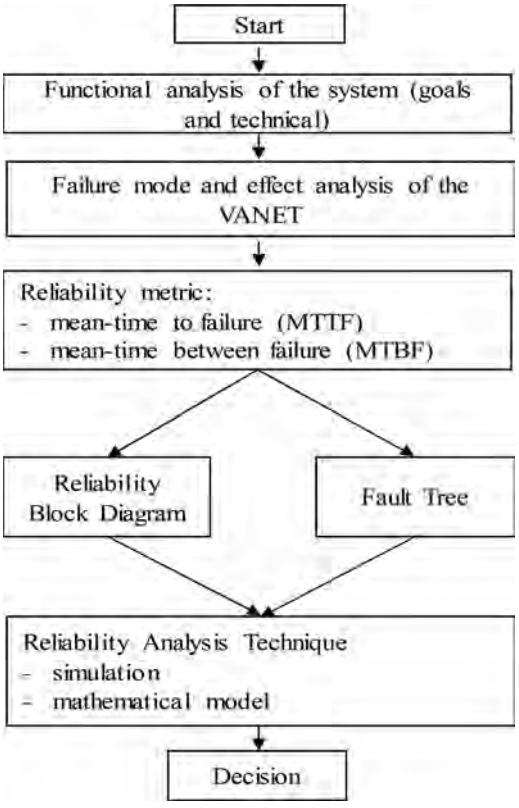

Figure 1. Reliability analyses procedure.

(effects). Two large families of analyses are commonly used. Some inductive, such as hazard and operability study (HAZOP) or analysis of failure modes (FMEA) used in our study, and others are deductive (such as fault tree analysis). The inductive analysis distinguishes systematically the causes and effects of failures. Deductive analysis, meanwhile, are top-down approaches. (step 2).

The third step is the calculation of basic metrics of reliability and availability, such as Mean-Time to Failure (MTTF), Mean-Time Between Failures (MTBF) [19], for each equipment used in VANET. In our case, we obtain these metrics from a professional data base called Quanterion Automated Databook (QAD) that uses Electronic Parts Reliability Data (EPRD). The MTTF and MTBF are measured in hours. These metrics can be obtained by statistically calculating the failure rates of the GPS that are embedded in OBU. The failure rate of components is calculated below:

$$\lambda_{failure/hour} = f / (n.t)$$

where f represents the number of failures occurred during the observations; n: represents the number of components observed and t: represents the total time of observation.

This data is used in order to calculate the reliability of OBU and RSU and then for the system as a whole.

RBD and FT are the most usually used formalisms in system reliability modeling. They are used through two different approaches: in a reliability block diagram, the OBU and the RSU are represented by components connected according to their function or reliability relationships, while fault trees show which combinations of the components failures will result in a system failure. (step 4).

In step 5 the reliability analysis technique and the simulation were carried out, since the understanding and choosing the right probability distributions is very important at this stage. The exponential distribution is widely used to describe events recurring at random points in time, such as the time between failures of electronic equipment of the OBU and the RSU or the time between arrivals at a service booth. It is related to the Poisson distribution, which describes the number of occurrences of an event in a given interval of time.

3.2 *Connected vehicles: Vanet*

The VANET system is composed of several sub-systems.

3.2.1 *On Board Unit (OBU)*

An OBU is a mobile or portable wireless device that is located inside intelligent vehicles [20]. It works as a communication device and allows DSRC communications with other OBUs or RSUs. OBU includes other communication systems (e.g. GPS.), and other subcomponents like: application unit hardware, Human Machine Interface (HMI) and power supply. Each vehicle equipped with an OBU collects data and information, (such as vehicle's speed, position, brake status, signal status, etc…) analyzes, processes and encrypts the data in order to send it as a safety message to other vehicles (V2V) or RSUs (V2R) through the wireless medium;

An automated vehicle is equipped with an OBU system designed to ensure a number of functions. In addition to processing, inputs/outputs, and storage functions, an OBU system provides other major functions such space-time localization and scene recognition, longitudinal telemetry and short-range omnidirectional communications.

The set of system components required for OBU are:

- Resource Command Processor (RCP): It directs the operation of the other units by providing timing and control signals. All other resources are managed by the RCP which is the processing unit of the system. It must permit a local elaboration of the data gathered from the infrastructure and from the smart vehicle.
- GPS system: 360° positioning and global time keeping in order to allow the vehicle to communicate its own position to perform geo-location.
- Wireless communication: VANET uses DSRC to provide an omnidirectional 360° radio wireless communication between moving vehicles. DSRC refers to 802.11p which is an improvement of IEEE 802.11a.
- Antenna: used with a transmitter or a receiver in order to achieve the dedicated range of wireless networks.
- HMI: an electronic display screen that is used for driver assistance in collision avoidance applications. HMI shows awareness messages such as: indications, warnings, and advices using different ways of interaction like visual (flashing light, image) and auditory (sound, alarm).
- Vehicle services: interacts directly with the body chassis systems of the car doing a tactile and kinesthetic functions such as the vibrations of the driver's chair or the steering wheel.

3.2.2 *Trusted Platform Module (TPM)*

In VANET, data is broadcasted over shared communication media: a malicious node may easily intercept, modify or inject data [21, 22]. Data injection can provoke collisions in a vehicular system.

Weak security leads to many traffic problems putting human lives at risk. In Vehicle-Based Security System (VBSS), the OBU generates the

Basic Safety Messages (BSM) that collect vehicle and road conditions data. These BSM should be certificated and signed in order to preserve privacy and enhance essential security services, such as authentication, integrity, confidentiality and nonrepudiation.

A secured vehicle needs some hardware requirements, such as TPM which can be integrated into the OBU; TPM is the hardware module that forms the security issues such as encryption/decryption, hashing and digital signature. It is able to protect and store data and keys in shielded locations.

From hardware point of view, a TPM contains the below components:

- Assembled controller: A TPM contains a controller bus, for the connection and coordination among its memory and peripherals.
- NVRAM: Non-volatile random-access memory is used for permanent storage of the startup configuration that is writeable. It is also used for permanent storage of hardware revision, identification information and the cryptographic keys.
- Crypto unit: as its name indicates, it is responsible for random number generation, public-key cryptographic algorithm, cryptographic hash functions, symmetric-key algorithms, digital signature generation and verification, and Elliptic Curve Cryptography (ECC).

3.2.3 *Road Side Unit (RSU)*

RSU is installed at the road side [23]. It includes communication hardware (e.g. Wi-Fi, UMTS, ITS G5, etc.), and serves as a gateway between OBUs and the communications infrastructure. It could provide location based services and Internet access for mobile devices to improve the communication connectivity. The main functions of RSUs are as follows:

– Network coverage extension of the Ad Hoc network and communication medium between OBUs and RSUs.
– Source of safety and awareness information like weather status.
– Prioritize management messages to and from the OBU.
– Gateways that allow vehicles to establish connection with the internet.

The RSU is connected to the V2I communications network. Prioritization of messages, is also managed by the RSU to and from the vehicle.

Similar to OBU, an RSU is composed of a communication transceiver (802.11 & 1609), GPS and a processor. RSU contains a router that acts as an interface to the V2I cloud network. RSU is also connected to a local safety processor which is related to traffic light signal controller.

4 THE RELIABILITY

In this section we used RBD and FT, the 2 most effective techniques for modeling reliability and availability of communication networks [16].

4.1 *RBD*

RBD for the OBU (Fig. 2) are graphical structures consisting of blocks representing the system components and the connection to these components. The system is functional, if at least one path of properly functional components from input to output exists, otherwise it fails [24].

Thus, the reliability of an OBU, represented by R_{OBU}, is given below:

$$R_{OBU} = R_{Anl} R_{DSRC} R_{GPS} R_{PS} R_{RCP} \left[\left(R_{HMI} + R_{VC} \right) - R_{HMI} R_{VC} \right] R_{TPM} \quad (1)$$

where the reliability of the TPM is set below:

$$R_{TPM} = R_{Cryp} R_{Mem} R_{Cont} \quad (2)$$

In this section we used Reliability Block Diagram (RBD) and the Fault tree (FT), the 2 most effective techniques for modeling reliability and availability of communication networks [16]

The RBD of RSU will be as show in Figure 3.

Consequently, the reliability of an RSU, represented by R_{RSU}, is given by:

$$R_{RSU} = R_{Anl} R_{DSRC} R_{GPS} R_{PS} R_{Process} R_{STL} \quad (3)$$

4.2 *Fault tree of OBU failure*

Fault Tree analysis is a graphical technique performed to know the probability of occurrence of the top event; i.e., a DSRC fail event can cause the whole system to fail. These causes of system failure are represented in the form of a tree rooted by the top event as depicted in Figure 4. Logic

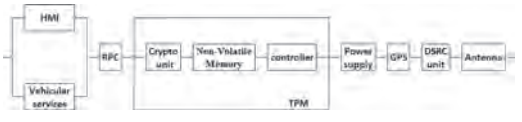

Figure 2. Reliability block diagram for OBU including the TPM.

Figure 3. Reliability block diagram for RSU.

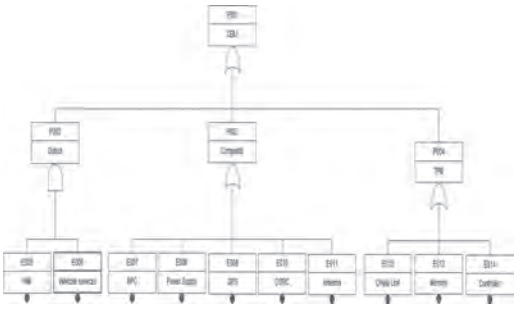

Figure 4. Fault tree event of OBU.

Boolean gates are used to link two or more cause events provoking one fault. The OR gate is presented when one fault from any node is enough to cause a fault. While the AND gate is used when the fault (output) occurs when all inputs fail (inputs are independent).

Many quantitative data are needed in order to achieve this analysis; hence the necessity that the data should be accurately targeted. QAD contains field failure rate data on a variety of electrical, mechanical, electromechanical, and microwave parts and assemblies. It is used as a source of reliability failure rate data. Data contained in EPRD reflects industry average failure rates, especially the summary failure rates which were derived by combining several failure rates on similar parts/assemblies from various sources. At t = 0, the population of parts has not experienced operation. As operating time increases, parts in the original population are replaced and the failure rate increases.

Probability of events is modelled from component failure rates. These are defined by the average of failure rate (Failure rate Mean (λ_{Mean})), (Failure rate Lower (λ_{Min} Failure Rate Upper (λ_{Max})), and by standard deviation of failure rate (Failure rate SD (λ_{SD})).

T The component failures of the system follow an exponential distribution on a total duration of 1year (8760 hours) to take into account the history of degradation in the estimation of the fault. During this time, we consider that the OBU system and the RSU system are operating in real conditions (Figure 4)

5 PROBABILISTIC MODELLING OF THE FAULT TREE EVENTS

The objective of this section is to present the probabilistic approach applied on data from the event tree. The top event is the OBU Failure. Reliability data expressed in failure rate are random.

The reliability information of these events are: λ_{Min} = minimum degradation rate, and λ_{Max} = maximum degradation rate, and λ_{Mean} = mean degradation rate, and λ_{SD} = standard deviation of degradation rate.

The exponential distributions, with failure rate $\boldsymbol{\lambda}$ and time-to-failure random variable, are used in order to express the reliability or availability of these individual components of the OBU. The dependability of each component is then used in order to determine the reliability of the overall VANET system by utilizing the mathematical expressions that are presented in eq. 1. The exponential model is the wieldiest used for electronics components such in the OBU and the RSU, even for a pessimistic scenario. The failure λ rate is considered as a random variable which is defined between two limits. Its mean and standard deviation are known.

Table 1 depicts the failure events data for all the components of the OBU; the power supply (E008) has the greater failure rate, and has a significant influence on the reliability of the OBU, since the power supply is implemented in series in the RBD, that means definitely when the power supply of OBU fails the whole system will fail. As an improvement we suggest to use a dual power supplies in the OBU.

The redundant power supply, shown in Figure 5, might be connected in parallel. After the redesigned RBD for the OBU, we noticed an improvement in reliability between the OBU having a single power supply and the redesigned OBU having dual power supplies.

Thus, the reliability of an OBU, after adding a redundant power supply R_{PS2}, represented by R_{OBU2}, is given below:

$$R_{OBU2} = R_{Ant} R_{DSRC} R_{GPS} \left[\left(R_{PS1} + R_{PS2} \right) - R_{PS1} R_{PS2} \right] R_{RCP} \left[\left(R_{HMI} + R_{VC} \right) - R_{HMI} R_{VC} \right] R_{TPM} \quad (4)$$

As shown in Figure 6, After 8760 hours (1 year) of running, the OBU1 powered by a single

Table 1. Failure events data.

Basic event	Label	λ_{Min}	λ_{Max}	λ_{Mean}	λ_{SD}

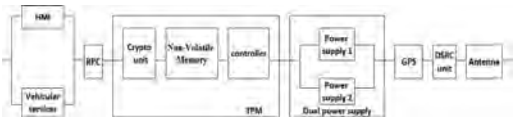

Figure 5. RBD for OBU2 using dual power supply.

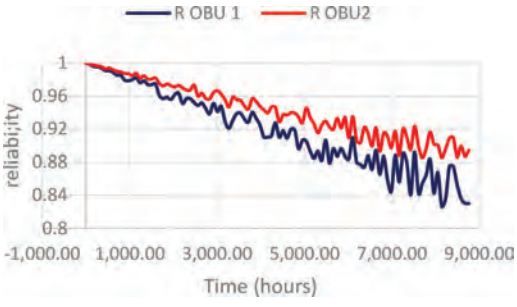

Figure 6. Reliability comparison between OBU1 and OBU2.

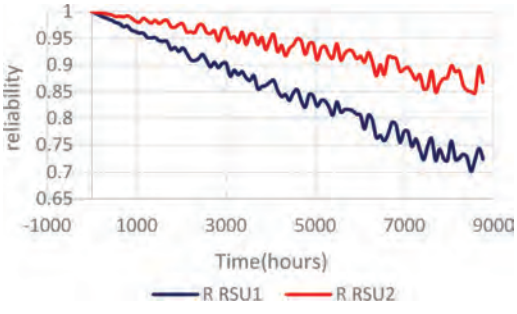

Figure 7. Reliability comparison between RSU1 and RSU2.

power supply reaches a reliability value equal to 82%, however the OBU2 powered by a dual power supply reaches 88% of reliability, that means an increase of at least 6%. This improvement becomes more evident and visible as time passes.

Concerning the RSU, and since all the components are implemented in serial, the remodeling proposed to implement the RSU with dual power supplies increases the reliability for more than 17%. In (Figure 7) it is clear that the degradation in reliability in RSU2 powered by dual power supplies is less severe than RSU1 that powered by a single power supply.

6 CONCLUSION AND FUTURE WORK

Connected vehicles are classified as "safety critical" because they are directly related to human safety. For this reason, in this paper we used the exponential model which is very conservative and pessimistic. A failure occurs whenever some function is lost, and no other function can supersede the lost function in due time.

Any OBU failure can lead to crashes. In similar domains (e.g. in aircraft), the control system and communication parts may be triplicated or quadrupled [25]. The model used in the aviation system, where the system reliability is very high and failure ratio should be in range of 10^{-9} per hour, can be used as a reference. The solution used in aircraft could be cloned into vehicle context in order to provide distinct redundancy of hardware. However, a trade off between the disadvantages of redundancy (cost, weight, power saving and design complexity...) and the reliability should always be considered.

In this article we demonstrated the importance of reliability analysis using mixed approach between qualitative and quantitative methods. As a result, we detected that the reliability of a system with a single point of failure such as the OBU system with serial subcomponents—will immensely degrade with time. Using a very pessimistic exponential model as showed in Figure 6, resulted in the degradation of the OBU 's reliability by 16% over a short period of one year—the failure rates of the OBU electronic components were in the range of E-07 to E-06. Moreover, one of the most important advantages of vehicular networks is that there are no energy constraints, unlike wireless sensor networks and other types of mobile devices used in MANETs where limited battery life is a major concern. Taking into consideration this feature we can implement the redundancy components for the VANET without worrying about energy consumption.

Autonomous Vehicles could also operate in isolation from other vehicles using internal sensors. A combination between the autonomous vehicle and the connected vehicle is called Automated Vehicle (CAV), which leverages autonomous and connected vehicle capabilities thus making the system more complex. For this reason, it is very important to analyze each component functionality to identify its failure rate ratio in order to redesign for redundancy.

The paper mainly emphasized on the reliability of the connected vehicle networks primarily with respect to hardware components and the needed security equipment involved in communications. However, a future study might tackle the reliability degradation using other models such as Weibull model which is classified as realistic model. Another future study will also tackle the reliability of the whole system in the operation mode and evaluate the reliability of communication from sender to receiver to include the reliability of data transmission while using real network and traffic conditions on the proposed modeling technique.

Daniel D. Raj
Department of Ocean Engineering, Indian Institute of Technology Madras, Chennai, India

ABSTRACT: The Bayesian Network approach is a probabilistic method with an increasing use in the risk assessment of complex systems. It has proven to be a reliable and powerful tool with the flexibility to include different types of data (from experimental data to expert judgement). The incorporation of system reliability methods allows traditional Bayesian networks to work with random variables with discrete and continuous distributions. On the other hand, probabilistic uncertainty comes from the complexity of reality that scientists try to reproduce by setting a controlled experiment, while imprecision is related to the quality of the specific instrument making the measurements. This imprecision or lack of data can be taken into account by the use of intervals and probability boxes as random variables in the network. The resolution of the system reliability problems to deal with these kinds of uncertainties has been carried out adopting Monte Carlo simulations. However, the latter method is computationally expensive preventing from producing a real-time analysis of the system represented by the network. In this work, the line sampling algorithm is used as an effective method to improve the efficiency of the reduction process from enhanced to traditional Bayesian networks. This allows to preserve all the advantages without increasing excessively the computational cost of the analysis. As an application example, a risk assessment of an oscillating water column is carried out using data obtained in the laboratory. The proposed method is run using the multipurpose software OpenCossan.

1 INTRODUCTION

Nowadays, experimental research in engineering deals with systems with high complexity due to the number of components used in the procedures. Occasionally, the limited capacity of the experimental arrangements to test different configurations and obtain a number of relevant measurements, hinders the impact of the study. In addition, the effects of epistemic uncertainty derived from the procedure and, the uncontrollable conditions under which the study is carried out can provide results with limited applicability or lack of meaning. There are different methods developed for modeling the dependability and evaluation of large engineering systems allowing to take into consideration both qualitative and quantitative information. Among the most used methods, the reliability block diagrams, fault trees and, event trees, can be identified as the techniques with reliable results providing a robust mathematical background (Hamada et al. 2008). However, several assumptions are made with these techniques.

The Bayesian Network (BN), is a probabilistic method to study and analyze the genuine dependencies or independences of variables that make up a system. This concept was proposed by Judea Pearl in 1988, originally for the artificial intelligence area (Pearl 1991). Currently, the BNs have many more applications ranging from system dependability (Castillo et al. 1997) and risk analysis (Hudson et al. 2002), to system maintenance (Kang and Golay 1999). It is worth noticing that this method has attracted an increasing interest, reaching 800% according to (Weber et al. 2012), during the last 20 years. The success of Bayesian networks rests on the graphical representation of the system, which renders them intuitive and easy to understand even by for non-experts. In addition, this method can be used to provide a diagnostic or predictive reasoning, a combination of both (Korb and Nicholson 2004) and also they accept new evidence that can be used to update the network and to adapt the model to the new parameters. Moreover, information of different types (e.g. expert judgment, experimental data, historical records, feedback experience, theoretical models, etc.) can be merged in the same network, inside structures called probability tables (or conditional probability tables in the case of children nodes). These tables are filled with crisp probability values, providing a global dependability estimation (Jensen and Nielsen 2007).

On the other hand, the high acceptance of the traditional Bayesian networks for uncertainty

reasoning is limited to the use of only crisp probabilities (Spiegelhalter 1987). This type of probabilities leads to discretization methods or hard assumptions, impoverishing the quality of the analysis (Tolo et al. 2016a). In order to work with continuous probabilities that can take into account the uncertainty of the variables in the network and avoid discretization of the input information, Daniel Straub and Armen Der Kiureghian (Straub and Der Kiureghian 2010) proposed to enhance BNs with structural reliability methods since these techniques support the use of continuous random variables. This approach embraces all the advantages of BNs and furthermore allows working with discrete, continuous, as well as small probability variables (ideal for low-probability high-impact events). Some applications have been done with this method, focusing on the risk assessment of technological facilities considering climate change (Tolo et al. 2016a).

Although the enhanced Bayesian networks consider a broader spectrum of variables, usually the information available rarely meets the requirements of the method. For example, often expert beliefs do not agree in an exact same probability value or the information is scarce, in which cases data have to be averaged or the analyst makes assumptions to perform the study. In engineering, it is common to perform measurements during an experiment, the results obtained will have attached an epistemic uncertainty that cannot be eliminated and underestimated. Consequently, the incorporation of imprecise probabilities becomes an imperative need that can improve the employability of BNs.

The proposed method attempts a naive implementation of Credal sets and p-boxes as a way to characterize imprecise probabilities in discrete and continuous variables, respectively. This approach is expected to overcome two main problems when dealing with uncertainty in Bayesian networks. The method is implemented on the multipurpose software OpenCossan, (Patelli et al. 2018). On one hand, the use of all the advantages of parametric and non-parametric p-boxes to work with continuous imprecise random variables and obtain the quantile bounds of the final distribution representing the system under analysis so they can be used after with the structural reliability methods. The network reduction process can be done with the *advanced line sampling* method, since it is capable of approximating the upper and lower bounds of the failure probability under the assumption of a monotone system. Once the network is reduced and the uncertainty of continuous variables propagated to the reduced network through the bounded probability of failure, the result will be a Credal network with only discrete but bounded variables. The method used, allows to compute the exact bounds of the query probability in the absence of evidence. In the case of evidence introduced in the network the method will provide the intervals, such that the true bounds of the query probability are located.

2 THEORETICAL BACKGROUND

2.1 *Bayesian network*

A Bayesian network, as established before, is presented in the form of a directed acyclic graph (DAG) made of *nodes* and arrows (called *links*) connecting those nodes. Each node represents a random variable with information about observable quantities or hypothesis of the system, whilst the links show the dependency among the nodes. Nodes can be differentiated as *parent* and *child*. A child node depends directly on another node, called the parent node and graphically they are connected by a link starting in the parent and ending in the child. Nodes with no parents are called *roots*. The dependence of nodes is ruled the d-separation concept. Two variables, namely, A and B, are d-separated if there is an intermediate variable, C, different from A and B, such that in a serial or diverging connection C is instantiated (with a specific probability value, i.e. evidence). In the case of a converging connection, if neither C nor any of its descendants are instantiated they are d-separated (Jensen and Nielsen 2007).

The arrangement of parents and children nodes connected by links allows performing diagnostic and predictive reasoning. The first approach can be done to know the causes of an event by querying a parent node given the information in children nodes. The predictive reasoning follows the direction of the links and uses the causes (information in the parents) to predict the effects (children). The probability values denoting the dependency between a child node with its parents is stored in a conditional probability table. In this arrangement, the probability of each state of the child is provided given each of the states of the parents. The total dependability of the network is quantified by the *joint probability distribution* which is defined as the product of all the conditional and unconditional probabilities specified in the network. This is governed by the chain rule for Bayesian networks (Jensen and Nielsen 2007) and, it is given as follows,

$$P\left(X_i\right)=\prod_{i=1}^{n}P[X_i \mid pa\left(X_i\right)] \tag{1}$$

where X_i represents each of the random variables of the network and, pa(X_i) is the probability of the parents of X_i. As an example, the joint probability of the Bayesian network presented in Figure 1 is given by the expression,

$$\begin{aligned} P\left(X_1X_2,X_3,X_4\right) &= P\left(X_1\right)P\left(X_2\right) \\ &\cdot\ P(X_3 \mid X_1,X_2)P(X_4 \mid X_1) \end{aligned} \tag{2}$$

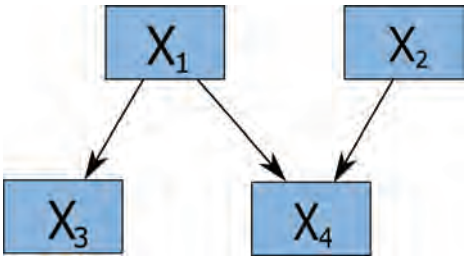

Figure 1. Example of a traditional Bayesian network.

The joint probability distribution function can be used to calculate the probability of any individual variable (Hosseini and Barker 2016). For instance, to calculate the probability only of the node X_3, the rest of the nodes are marginalized out from Eq.(2). So, $P(X_3)$ will be given as follows,

$$P(X_3) = \sum_{X_1,X_2,X_4} P(X_1)P(X_2) \times P(X_3 \mid X_1, X_2)P(X_4 \mid X_1) \quad (3)$$

Marginalization is a distributive process to calculate the total probability of a variable of interest by the summation of the products of all the possible combinations of local joint probabilities. This process allows to isolate the probability of the parameter of interest and to remove the rest of the variables from the joint probability distribution (Jensen and Nielsen 2007).

It is possible to remove variables that are not relevant to know the probability of the variable of interest, namely A. This process is called *variable elimination*. It consists of simply removing from the joint probability, variables that are outside the Markov blanket of A (i.e. variables that are parents or children of A, or sharing a children with A). The eliminated variables (those out of the Markov blanket), do not influence the probability measures of the variable of interest.

The type of information that can be adopted in this method involves real probability values (discrete nodes) or Gaussian distribution functions. The latter works with crisp value probabilities (Tolo et al. 2016b). However, this characteristic turns into the main drawback of this technique when the data comes in the way of continuous distributions. Nevertheless, this disadvantage is overcome with the use of structural reliability methods.

2.2 *Enhanced Bayesian networks*

Structural Reliability methods (SRMs) are used to work out the conditional probability tables of a BN containing both discrete and continuous random variables (enhanced Bayesian network) resulting in the reduction of the network to a traditional BN. Suppose the nodes in the network on Figure 2

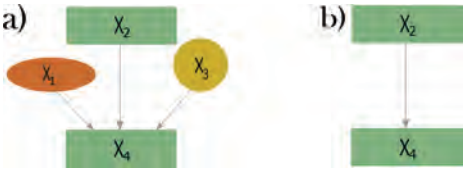

Figure 2. a) Simple enhanced Bayesian network with discrete nodes (rectangular shaped), probability function nodes (circle shaped) and, interval discrete nodes (elliptical shaped). b) Reduced Bayesian network with crisp probabilities.

a) correspond to independent random variables. Here X_1 is an interval node (with $f(X_1)$ its cumulative distribution function, CDF), X_2 and X_1, are discrete nodes (representing probability mass functions, $P(X_2)$, $P(X_4)$, respectively) and X_3 a continuous node (representing a CDF $f(X_3)$). According to (Straub and Der Kiureghian 2010) the enhance Bayesian network joint probability can be computed by approximating the equation below,

$$P(X_i) = \int_{X_1,X_3} f(X_1)f(X_3)P(X_2) \times P(X_4 \mid X_1, X_2, X_3)dX_1dX_3 \quad (4)$$

if the Markov properties are considered, node X_3 and X_1 are d-separated from X_2 since X_4 has not received any evidence yet. So, the joint probability of X_4 given X_2, from the equation above, can be written as,

$$P(X_4 \mid X_2) = \int_{X_1,X_3} f(X_1)f(X_3) \times P(X_4 \mid X_1, X_2, X_3)dX_1dX_3 \quad (5)$$

It has to be noticed that each entry in the conditional probability table of X_4 is defined by the domain $\Omega^{X_4}_{X_4,x_2}$ in the continuous space of X_1 and X_3 for a given value x_2 of the variable X_2. So the Eq. 5 can be further reduced as,

$$P(X_4 \mid X_2) = \int_{\Omega^{X_4}_{X_4,x_2}} f(X_1)f(X_3)dX_1dX_3 \quad (6)$$

The integral shown in Eq. 6 is equivalent to that of a reliability problem (Tolo et al. 2016b). Solving a structural reliability problem, i.e. approximating the system failure probability, a reduction of a network with continuous nodes to one with only discrete probability values is obtained.

There are certainly several approaches for the solution of problems like that shown in Eq. 6. These methods range from numerical approximations like Monte Carlo simulations, to the well-known and widely used *first-order* and *second-order reliability methods* (Hasofer and Lind 1974). Moreover, some advanced sampling techniques like Importance Sampling, Stratified Sampling or Advanced Line

Sampling (Hasofer and Lind 1974), among others, have been used as an alternative to the computationally expensive numerical approximations.

2.3 *Credal networks*

Credal networks can be referred as an extension of Bayesian networks to manage intervals of discrete probability values representing the lack of information and uncertainty about the variables involved. A Bayesian network constructed exclusively with discrete nodes such that, only one probability value is associated with the state of the variable. Such a state can belong to the variable itself, in the case of roots, or can be conditioned on the parents of that node, in the case of children. However, in a Credal network, probabilities are presented in the form of intervals that are associated with probabilistic inequalities. In this manner, a Credal network will represent the different variable states, each of them associated with one specific probability value inside the interval, of the same Bayesian network (Tolo et al. 2018). The graphical structure of such a network is the same as the Bayesian case, as well as the Markov blanket concept and d-separation of nodes. Nevertheless, the probability of a variable x is indicated in the form of the so-called credal set $K(X)$, whilst the set of joint probability measurements $P(X_i \mid pa(X_i))$ is named a joint credal set, given by $K(X_i \mid pa(X_i))$ (Cozman 2000). So, two different interval probabilities of variables X and Y (where Y is the complement of X) can be characterized by their upper and lower bounds, $[\overline{p}(X), \underline{p}(X)]$ and $[\underline{Y} = 1 - \overline{p}(X), \overline{Y} = 1 - \underline{p}(X)] \epsilon [0\ 1]$, respectively.

2.4 *Probability boxes*

Probability boxes (or p-boxes) allow making fewer assumptions about the values used in the study when correlations of the variables employed in the study are ignored due to the effect of aleatory and epistemic uncertainties. A p-box is specified for a random variable X by the interval bounds $\left[\underline{F}, \overline{F}\right]$ on a cumulative distribution function F with values between 0 and 1, such that $\underline{F}(X) \le F(X) \le \overline{F}(X)$ (Ferson et al. 2003). If a probability measure $\underline{p}$ (since it is the lower bound of that measure) for the random variable X_1 is given, the lower, $\underline{F}(X_1)$, and upper $\overline{F}(X_1)$, bounds of the p-box can be computed as follows (Walley 1991),

$$\underline{F}(X_1) = \underline{p}(X_i \le X_1), \overline{F}(X_1) = 1 - \underline{p}(X_i > X_1) \quad (7)$$

The p-box has a dual interpretation, i.e. $\overline{F}$, represents the probability (CDF axis) upper bound and quantile (x-values axis) lower bound. The opposite happens with $\underline{F}$. Therefore, this concept is applicable in cases of imprecise continuous probabilistic distributions and two types can be differentiated, parametric non-parametric p-boxes. A parametric p-box is defined when the shape of the probability distribution is known, but there is no precise information about the parameters of that distribution. The non-parametric case is rarer but can exist especially when an experiment has been performed and a set of measurements was obtained. It occurs when parameters regarding the probabilistic distribution, e.g. mean and variance, of a variable, are known but no information about the type of distribution is available (Ferson et al. 2003).

2.5 *Computational tool*

The open source software OpenCossan exploits the Object-Oriented programming paradigm that Matlab offers with the use of *classes* (entities containing the data and the functions or methods that the members of the same class have in common) and *objects* (instances of a class). This basis is employed in order to efficiently provide solutions to problems regarding uncertainty quantification, sensitivity and reliability analysis, robust design, among others (Patelli 2015). The object-oriented methodology allows reutilizing parts of code to create more complex objects in a systematic and condensed way. OpenCossan offers a wide flexibility to integrate new methods that enhance, improve or complement the current tools available in this software. This opens the gate for new developments that enrich the software robustness to provide solutions.

Within the framework of OpenCossan, three main toolboxes can be used for Bayesian networks. These are, *BayesianNetwork*, *EnhancedBayesianNetwork* and, *CredalNetwork*. The first one can be used in cases were variables only correspond to crisp probability values whilst the second one, also considers continuous probability distributions and bounded variables. The third toolbox is the one chosen for this study, since it allows working with continuous probabilities and interval variables representing imprecise probabilities. However, the graphical display process is done with the same method, *makeGraph* which is a class of *EnhancedBayesianNetwork*.

3 CASE STUDY: OSCILLATING WATER COLUMN

An Oscillating Water Column (OWC) is a type of the so-called wave energy converters that capture the energy that sea waves deposit once reaching the named structure. The popularity of this type of energy converters has increased over the last few decades, since it is an alternative for the clean energy production (Falcão 2010). The structure of an OWC consists of a chamber, partially

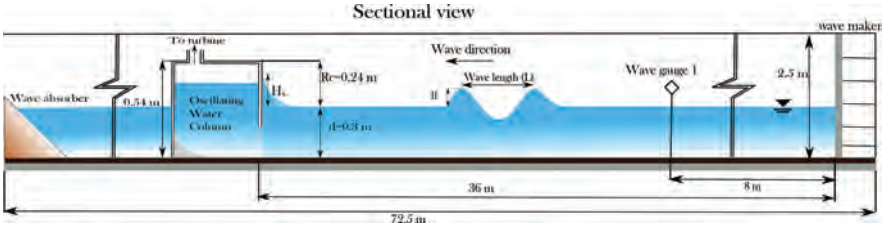

Figure 3. Sectional view wave flume with OWC on the left-hand side.

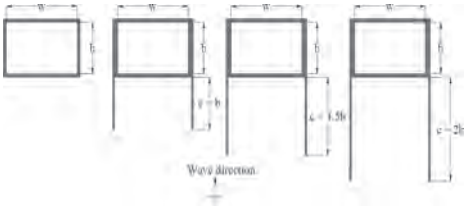

Figure 4. Schematic layout from a top view of harbour walls with different lengths (Daniel Raj et al. 2016a).

submerged in the sea, generally with two orifices. One is typically at the top of the chamber inside which turbine is placed, and the other one is below the water line facing the coming sea waves, see Figure 3. An entombed mass of water column formed inside the chamber oscillates as a result of the wave inside in the structure. This, in turn, drives an air flow through the orifice coupled to a turbine, thus generating electricity (Cruz 2008).

Since the system is always surrounded by sea waves (especially when it is built away from the shoreline), it is susceptible to overtopping events that can cause serious damages to the structure, particularly in the operational mode. Horizontal sliding, overturning, scouring and collapsing of the structure may be possible during extreme sea conditions (Cruz 2008). It is preferred to study such overtopping possibilities to be more on the conservative side. Generally, a conventional-OWC device is constructed with adequate height such that the overtopping event is quite not possible. As the addition of harbor walls increases the wave amplification, the possibility of an overtopping event should be carefully addressed.

A very simple Bayesian network was built to test the inclusion of imprecise probability nodes in the computational toolbox based on the OpenCossan software. The network represents the components involved in an experimental work carried out by Daniel Raj and his team (Daniel Raj, D. et al, 2016) at the Indian Institute of Technology Madras in India, to study the influence of harbour walls of an OWC on its energy efficiency characteristics. The present network is used to provide an assessment of the risk of structure overtopping triggered by the waves generated in the laboratory.

3.1 *Description of the experiment*

The experimental arrangement was 72.5 m long, 2 m wide, and with a deep wave flume of 2.5 m, please refer to Figure 3. The scaled OWC model was 0.540 *m* height, in a 1:20 ratio from a real prototype. To generate random water waves (it is able to reproduce either shallow or deep water waves) the flume is equipped with a wave maker system to generate waves with steepness characteristics within the limits of the operational range of the system. The generated waves for this experiment covered a range of relative water depths, d/L, from 0.074 to 0.23 and a wave steepness, H/L, from 0.0074 to 0.065. Here, d denotes water depth, H corresponds to the wave height (in metres) registered from the first wave gauge 1 (situated at 8 *m* from the water generator), and L denotes wavelength (in metres). The crest periods, T_p, adopted were from 1 to 2.5 *s* in 0.25 *s* intervals. For more information about this experiment please refer to (Daniel Raj et al. 2016a), (Daniel Raj et al. 2016b).

The experiment was carried out in two stages; the first stage involved the identification of efficient resonating length of harbour wall, as seen in Figure 4, which enhances the energy conversion capacity of the system. Four testing criteria have been chosen in the first stage, so as to investigate the effect of projecting sidewalls length on the efficiency of the OWC. Among them, one is without the sidewalls (conventional) and rest with the projecting sidewalls in three criteria such as c/b of 1, 1.5 and 2. In the second stage, the effect of the harbour walls on each side of the OWC was studied by varying the angle of the harbour walls within the range of $[4\pi/8, 7\pi/8]$ at intervals of $\pi/8$ with respect to the front lip wall of OWC, as seen in Figure 5. This angle variation is called *wall inclination* from now on. The wall length, c, was maintained constant in this stage at its optimal configuration identified from the first stage of experiment.

3.2 *The Bayesian network*

The goal of the experiment was to analyse the influence of different configurations of harbour walls in order to modify the resonance frequency of the water wave coming towards the structure so

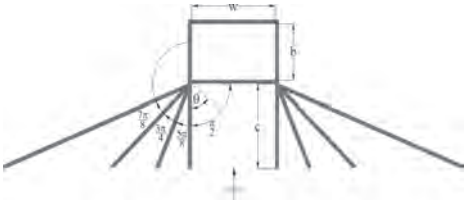

Figure 5. Schematic layout different harbour wall inclinations (top view) (Daniel Raj et al. 2016b).

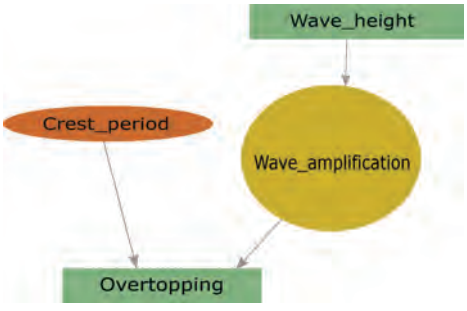

Figure 6. Enhanced Bayesian network for OWC experiment.

that the wave amplification was maximized. The maximization of wave amplification poses a potential risk of structure overtopping that can damage the rearward face of the experiment equipment or to bring unexpected consequences. The probability of having this event is quantified through the network presented in Figure 6 that takes into account the epistemic uncertainty characterizing the measurements of the amplified waves running up the structure. In addition to that, the wave properties, as well as the OWC configurations studied in the experiment, were considered as influencing factors for the occurrence of structure overtopping.

Since imprecise variables are employed in this simple study, the network for this problem is defined in the toolbox for Credal networks node by node, in the form of computational objects. Once all the variables are defined, an object of the class *CredalNetwork* is created to store the information regarding the nodes on the network, so further calculations can be performed. Then, the method *makeGraph* is invoked to display the network shown in Figure 6. The nodes are defined as follows.

Different harbour wall inclinations and lengths were tested to study their effects on wave amplification. In order to select the case to be studied with the BN, the *Experiment_case* node was defined as an interval node containing the maximum and minimum length ratio, for the variation of harbour wall lengths experiment, or the maximum and minimum angle for the remaining case. The values in the intervals are defined in such way that they can cover all the possible values used in the experiment.

Wave properties were used in the Bayesian network as follows, the *Crest_period* interval node contains the information of the mean level-up-to-down-crossing time of the incident waves. The crest periods were changed from 1 to 2.5 *s* intervals of 0.25 *s*. Meanwhile, the *Wave_height* node has the information of the wave height used in the experiments. The waves studied were 0.03, 0.06 and 0.09 *m* high for each of the harbour wall configurations. It has to be noted that the *Wave_height* will influence directly how high the amplified wave is.

According to some authors, as shown by Allsop review (Allsop et al. 1985), wave amplification phenomenon (or wave run-up) in steep structures slopes follows approximately Rayleigh distribution. For this reason, the *Wave_amplification* is assumed to follow this probability distribution with a scale parameter based on the experimental results obtained from the wave amplification measurements. However, the parameters to define this variable in the experiment are uncertain due to the lack of probabilistic data (i.e. only one measurement was taken for a given value of wave crest period, wall inclination or length). So, the use of p-boxes becomes handy. The *Wave_amplification* p-boxes were defined in such manner that all the possible values tested experimentally were enclosed in the p-box of each case. These values are presented in the Table 1, for the given harbour wall length and inclination configurations as well as each of the different wave heights, respectively.

In this work, the Owen equation proposed, by Mase (Mase et al. 2013), for overtopping discharge ratio Q is used to describe the *Overtopping* node and the probability of exceedance, $P(Z)$, of the maximum admissible wave overtopping is given as:

$$Z = Q_{max} - \left(A T_p g \, H_s \right) e^{-B \frac{R_c}{T_p \sqrt{g \, H_s}}} \tag{8}$$

where A and B are dimensionless empirical coefficients depending on the slope ratio of the structure. In this case, A and B are given as 0.0079 and 20.12 (Owen 1980), respectively. H_s is considered as the significant wave height of the amplified waves in meters, g the gravitational acceleration and, R_c the structure freeboard. If the condition

2.5	[0, 0.009]	[0.2, 0.263]	[0.164, 0.557]

$P(Z \leq 0)$ is exceeded the event is considered a failure of the system meaning a wave overtopping of the OWC for a given maximum overtopping rate Q_{max}. Once all the nodes are defined in the toolbox, the network is reduced using the Adaptive Line Sampling method. In the Figure 7 can be observed the reduced network used for this study. The overtopping events are given in the continuous space of the *Wave_amplification* node for each given state of *Experiment_case*.

In this simple network there is only one p-box employed per simulation (regarding the *Wave_amplification* node), so the lower bound would correspond to the minimum amplification that a wave under those conditions can have. Thus, overtopping probability resulting from this calculation will be the minimum probability that this variable can have, assuming monotonicity in the system. In order words, given the lower bound of *Wave_amplification* the lower bound of *Overtopping* will be found. The same reasoning is used for the case of the upper bounds.

The lower and upper bounds of the overtopping probability are displayed in the Table 2, for the case of harbour wall length experiment, and in Table 3, for the case of harbour wall inclination experiment. In each *Wave Height* column in the tables are stored the overtopping probability bounds computed for each height, i.e., 0.03, 0.06 and 0.09 m for each of the different crest periods (T_p). This was done in order to provide a combinatorial study of the overtopping probability change for all the experimental set ups.

It can be observed that T_p does not influence significantly the structure overtopping occurrence. In fact, changes in overtopping results obtained from the different crest periods may be due to the randomness of the simulation functions used. A major influence comes mainly from the *Wave_height* and *Experiment_case*. It is logical that higher waves will increase the height of the amplified wave, in consequence, the probability of an overtopping event will increase as well. Comparing the results from both experiment arrangements, it can be resolved that the wall inclination factor increases the most the probability of overtopping occurrence. The wave amplification factor of 0.237 corresponding to a wall inclination of $3\pi/4$ with 0.09 *m* wave height can be referred as the worse case scenario. This can be useful when the values are only scaled up to prototype dimensions. For instance, a structure overtopping assessment can be provided without performing any experimental work, as long as the physical behavior of the variables preserves the same probabilistic distribution.

Table 3. Occurrence of structure overtopping for wall inclination case. The bounded values in $Overtopping_{a,b,c}$, correspond to the *Wave_amplification* p-boxes in each of the *Wave_height* cases, i.e. 0.03, 0.06 and 0.09 *m*, respectively.

4 CONCLUSIONS

From the case study presented here, an approximation to the worst case scenario was found with the use of a very simple Bayesian network with the implementation of p-boxes and interval variables (credal sets). The original network containing continuous, interval and discrete variables was reduced using structural reliability methods (adaptive line sampling) to a simpler network containing only crisp probabilities. Since the values used as input in the p-boxes and in the interval variables contain all the possible cases in the experiment, none of the those should overcome the maximum probability given. So, epistemic uncertainty affecting this experiment can be quantified with this method. If specific data (different from that considered here) regarding any of the variables in the experiment, inside the bounds, are given, the overtopping probability results can be provided for that specific case and they will remain below or be equivalent than the maximum value achieved.

The implementation of imprecise data in Bayesian networks is a very necessary tool in engineer-

ing. However, the methods currently available are computationally expensive. Most importantly, when systems with a large number of variables are studied, the algorithms may suffer combinatorial explosion. Adaptive line sampling will be further studied to deal with bounded failure probabilities. In addition to that, random set theory (combined with Subset Simulation to improve calculation speed) appears as a good option to the limitations of the current tool, since the latter method is specially useful for small probability cases and good performance in both low- and high-dimensional spaces as well as in nonlinear limit functions.

Interval-based parameters for stress diffusion in granular medium

D. Boumezerane
Middle East Technical University, Northern Cyprus, METU
Formerly Norwegian University of Science and Technology, NTNU, Norway

ABSTRACT: According to Bourdeau (1986), diffusion of stresses in a granular medium can be described using a probabilistic approach. A point load applied on the surface of a granular media will follow an erratic path, depending on the probability of transition between the grains. The diffusion of the expected vertical stress in the granular medium can be described by a Fokker-Planck type equation. In terms of expected vertical stresses, an equation of diffusion is obtained and the parameter of diffusion is shown to approximate the coefficient of lateral pressure of the material at a given depth z. The coefficient of lateral pressure of the material can be expressed in terms of intervals with upper and lower values to account for uncertainty.

In the present approach, we propose to solve the diffusion equation using interval-based parameters to account for uncertainty. Uncertain parameters are considered as discretized fuzzy numbers; they are combined with finite difference method to solve the diffusion equation. Comparisons are made with experimental and available data.

1 INTRODUCTION

Diffusion of stresses in granular media is a phenomenon that provokes rearrangement in grains and thus settlements. Soils as granular media are constituted of an assembly of particles of different sizes, mineralogy and morphologies. The particle sizes vary from less than 0.002 mm in clays to some tens of millimeters in gravel materials. Despite their granular aspect, they are considered, from the soil mechanics viewpoint, as a continuum. Theories of continuous media are often applied to model the behavior of cohesive materials such as clays. Cohesionless soils behavior on the other hand is difficult to capture using continuum approaches. Their granular aspect, especially when they are in loose states, makes their behavior complex to predict using conventional theories of continuum media.

Harr (1977) proposed an approach to estimate the expected vertical stress in a granular medium subjected to surficial loading. A concentrated load applied on the surface of a semi-infinite ground will follow an uncertain path between the grains. The resulting stress in one point is a random variable. Its distribution will reflect the composition of the media. Following a binomial law of diffusion on one side or the other given a reference mark, the transmission of the load in the granular medium will be expressed as an equation of diffusion of stresses. The main parameter characterizing the equation is the coefficient of lateral pressure in soils. Bourdeau (1986) extended this approach and proposed a formulation in terms of displacements diffusion in loose cohensionless granular medium.

We revisited the formulation in terms of stress diffusion to account for parameter uncertainty using intervals which can be combined and expressed also as fuzzy discretized numbers. A numerical approach based on finite difference method is combined with interval-based parameters to simulate diffusion of stresses in granular media. Interval-based parameters are used to account for uncertainty and comparisons are made with experimental data. The aim of this research is to study parameter uncertainty and its quantification in the context of stress diffusion in a granular medium.

2 DIFFUSION OF STRESSES IN A GRANULAR MEDIUM

Diffusion of stresses in soils is a fundamental aspect of soil mechanics. It is observed in all soil-structure interaction problems as a consequence of applied loads. Harr (1977) build a model for stress diffusion in a granular medium based on the idea of expected stress distribution at a point. A unit force applied on the surface will follow a random path between the grains. The vertical normal stress acting at a point within a medium is the total accumulated effect of many random variables; shape and distribution of particles, the spatial distribution of voids as well as their local configurations.

The central limit theorem assures that the distribution of stress will converge to the normal distribution as the number of particles becomes large (Harr, 1977).

In Figure 1 is shown, schematically, the transmission of vertical forces between particles. The effect of the boundary force will spread laterally in the positive and negative directions. At a representative particle, the input stress can be taken to divide in the left and right directions consistent with a Bernoulli trial. The division of stresses is expected to be equal. For a random distribution the frequency of moving to the left is the same as moving to the right. Figure 2 shows the distribution of stresses within a homogeneous random medium. If Δx is the average spacing of the stresses at row, with the rows taken to be Δz apart, the expected stress will follow a binomial distribution with the recurrence equations (Harr, 1977):

$$\bar{S}_z[x, z+\Delta z] = \frac{1}{2}\left\{\bar{S}_z[x-\Delta x, z] + \bar{S}_z[x+\Delta x, z]\right\} \tag{1}$$

Subtracting the expected vertical stress $\bar{S}_z[x, z]$ from each side of the expression and dividing by Δz, we get:

$$\frac{\bar{S}_z[x, z+\Delta z] - \bar{S}_z[x, z]}{\Delta z} = \frac{(\Delta x)^2}{2\Delta z} \left\{\frac{\bar{S}_z[x+\Delta x, z] - 2\bar{S}_z[x, z] + \bar{S}_z[x-\Delta x, z]}{(\Delta x)^2}\right\} \tag{2}$$

In the limit as Δx and Δz become very small, the equation can be expressed as a differential one:

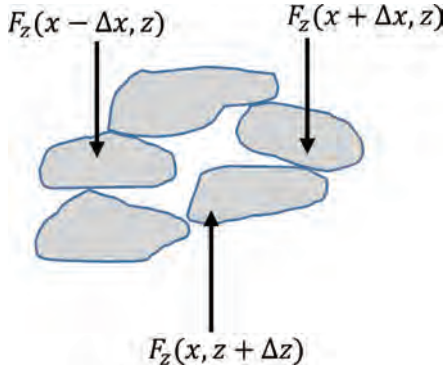

Figure 1. Transmission of vertical forces.

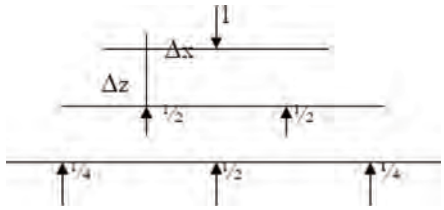

Figure 2. Unit stress distribution in terms of probabilities.

$$\frac{\partial \bar{S}_z}{\partial z} = D\frac{\partial^2 \bar{S}_z}{\partial x^2} \tag{3}$$

where $D = \lim_{\Delta x, \Delta z \to 0}\left\{\frac{1}{2}\frac{\Delta x^2}{\Delta z}\right\}$

The ratio $\frac{\Delta x^2}{\Delta z}$ is seen to reflect a characteristic of the particulate medium. Harr (1977) has shown that ($D = v.z$) is dependent on the depth z and the coefficient of lateral stress v. The author also showed that v can be approximated by the coefficient of earth pressure at rest K (using Jaky's formula for example).

Equation (3) is an equation of diffusion of expected vertical stresses in a granular media, with D the parameter of characterization.

The main objective of our research is to study the variability of the coefficient D and its influence on the diffusion of stresses in a granular medium. Uncertainty analysis will be carried out based on interval analysis and fuzzy representations of D. Different sources of information are used to consider the coefficient of diffusion.

2.1 *Uncertainty in the diffusion coefficient*

Uncertainties in geotechnics are generally classified into two categories, "epistemic" related to lack of data or knowledge and "aleatory" related to natural randomness (Baecher & Christian, 2003). The diffusion parameter D is subjected to epistemic uncertainties which have influence on the diffusion process in the granular medium. The main sources of uncertainty of D come from evaluation of lateral pressure coefficient K as $= K.z$. In situ and laboratory measures are used to evaluate lateral pressure coefficient in soils via empirical relations (Jaky's formula for example). Empirical correlations combining Jaky's formula $(1-\sin\varphi')$ with OCR from laboratory are also used to determine the lateral pressure coefficient at rest K_0 (Cai et al. 2011). When experimental results are given in terms of intervals the average values are generally used.

Figure 3 shows variation of lateral earth pressure based on different tests (Chen & Fang, 2008).

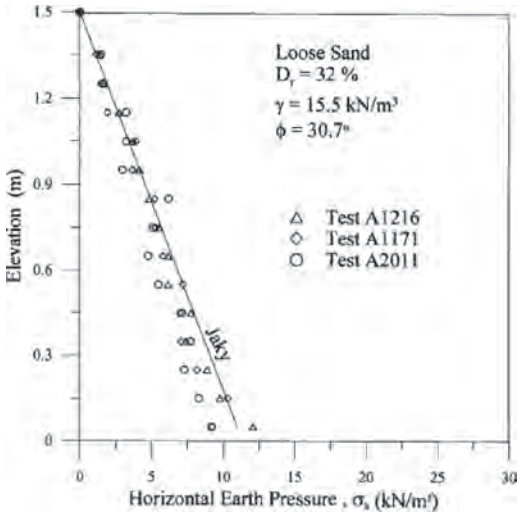

Figure 3. Distribution of horizontal earth pressure against model wall (Cheng & Fang, 2008).

Chen & Fang (2008) studied variation of lateral earth pressure in a block of sand. They presented experimental data on the variation of lateral earth pressure against a non-yielding retaining wall due to soil filling and vibratory compaction.

Schmertmann et al. (2005) used a K-Box device to describe stress diffusion in sand under a surface circular plate loading. The experiment intended to improve understanding of stress distribution in a particulate medium. Comparisons were made with obtained stresses from the probabilistic approach (Harr 1977). According to the authors the particulate-probabilistic theory seems approximately correct when $K = K_a$.

As we can observe, uncertainties are inherent to the testing method, in other terms using interval values can be suitable to handle the perturbations. Intervals are often used as a tool to handle uncertainties which arise during experiments. In different types of tests uncertainties propagate during measuring procedures and from the use of different devices. Using Jaky's Formula for example uncertainty lies essentially in measuring the material angle of friction φ′. Whatever the techniques used for measuring such a parameter, there are uncertainties to consider.

3 FORMULATION OF INTERVAL-BASED PARAMETERS FOR DIFFUSION

Interval analysis was introduced by Moore (1966) and is considered as a mathematical discipline that deals with quantities expressed as intervals which are common in engineering problems. Intervals are a convenient tool to deal with uncertainty when there is lack of data. As probabilistic approaches require important amounts of data, when in geotechnics information is scarce and small data available in general, the use of interval analysis could be of interest. In practice, it may be difficult sometime to get a large number of experimental data so we need an alternative method in which we may handle the uncertainty with few experimental data. In our problem, the diffusion parameter D will be considered as interval-based. Applied pressure on the ground can also be considered as an uncertain parameter expressed in terms of interval.

Finite difference schemes are usually applied to solve the type of diffusion equation we have in our case. We can either use a forward or backward scheme to solve it when dealing with deterministic values of the parameter D.

$$\frac{\partial \bar{S}_z}{\partial z} = D\frac{\partial^2 \bar{S}_z}{\partial x^2}$$

where

$$D = K.z$$

(For simplicity we use S instead of $\bar{S}_z$)

In finite difference method, the forward scheme can be expressed by:

$$S_j^{i+1} = S_j^i + Kz^i \frac{\Delta z}{(\Delta x)^2}\left(S_{j+1}^i - 2S_j^i + S_{j-1}^i \right) \qquad (4)$$

Index i is used in z direction and j in x direction.

The formulation of the problem to deal with interval valued parameters is conducted following interval arithmetic and rules. In Moore et al. (2009), Hanss (2005) we can find more details on derivation and application of interval arithmetic.

3.1 *Reminder on intervals*

Interval valued approach gained significant use in engineering especially when information is uncer-

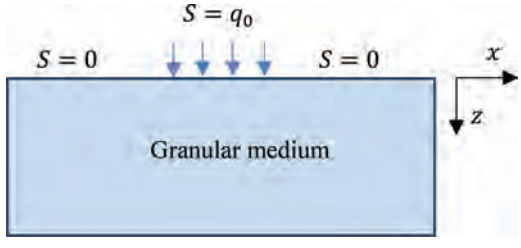

Figure 4. Scheme and Boundary Conditions.

tain. Studies were conducted in different fields, such as thermal conductivity to account for uncertainty using interval approaches and fuzzy sets (Wang 2014). Wang (2014) proposed a new numerical technique named as fuzzy finite difference method to solve the heat conduction problems with fuzzy uncertainties in both the physical parameters and initial/boundary conditions. The α level-cut method is used to study the problem in terms of interval equations. Kermani & Saburi (2007) presented a numerical method for solving "Fuzzy Partial Differential Equation" (FPDE) with some examples.

In soil mechanics the solutions for stress diffusion are based on continuum mechanics which considers the media as a continuum. Even constituted of particles, the granular aspect of the soil is not considered. The probabilistic approach from Harr (1977) considers the soil as a particulate media. The diffusion equation (1) is used with a parameter of diffusion D as a deterministic value. Deterministic values of D are not common, but we tend to use approximations. In the following the equation of diffusion of stresses in a granular medium will be considered in terms of intervals. The parameter of diffusion D and initial/boundary conditions are taken as intervals to account for uncertainty.

Using $\tilde{S}$, equation (3) can be written in terms of intervals as follows;

$$\frac{\partial \tilde{S}}{\partial z} = \tilde{D}\frac{\partial^2 \tilde{S}}{\partial x^2} \tag{5}$$

$\tilde{S}$ is replaced by S_α^I. We notice S_α^I for a given interval I of α level. $\underline{S}(\alpha), \overline{S}(\alpha)$ are the lower and upper values of the interval at α level

$$\frac{\partial \tilde{S}}{\partial z} = \frac{\partial \left[\underline{S}(\alpha), \overline{S}(\alpha) \right]}{\partial z}$$
$$\frac{\partial S_\alpha^I}{\partial z} = \frac{S_\alpha^{I.i+1} - S_\alpha^{I.i}}{\Delta z} \tag{6}$$

$$\frac{\partial^2 \tilde{S}}{\partial x^2} = \frac{\partial^2 S_\alpha^I}{\partial x^2} = \frac{S_{\alpha,j+1}^I - 2S_{\alpha,j}^I + S_{\alpha,j-1}^I}{(\Delta x)^2} \tag{7}$$

Then the forward scheme of finite difference approach using interval-based parameters can be written;

$$S_{\alpha,j}^{I,i+1} = S_{\alpha,j}^{I,i} + D_{\alpha,j}^{I,i}\frac{\Delta z}{(\Delta x)^2}\left[S_{\alpha,j+1}^{I,i} - 2S_{\alpha,j}^{I,i} + S_{\alpha,j-1}^{I,i} \right] \tag{8}$$

where

$$D_{\alpha,j}^{I,i} = K_{\alpha,j}^{I,i} z_j^i \tag{9}$$

α level cuts are used to characterize a fuzzy number.

A triangular fuzzy number, denoted by $u = \langle a, b, c \rangle$ where $a \le b \le c$ has α-cuts

$$[u]_\alpha = [a + \alpha(b-a), c - \alpha(c-b)], \alpha \in [0,1]$$

And membership function

$$\mu_{Tri}(x) = \begin{cases} \dfrac{x-a}{b-a} & if\ a \le x \le b \\ \dfrac{c-x}{c-b} & if\ b \le x \le c \\ 0 & otherwise \end{cases}$$

Elementary operations of interval arithmetic are used (Hanss, 2005).

$$[a_1, b_1] + [a_2, b_2] = [a_1 + a_2, b_1 + b_2]$$
$$[a_1, b_1] - [a_2, b_2] = [a_1 - b_2, b_1 - a_2]$$

$$[a_1, b_1] \times [a_2, b_2] = [\min(M), \max(M)]$$
$$M = \{a_1 a_2, a_1 b_2, b_1 a_2, b_1 b_2\}$$

4 CASE STUDY

Turedi and Ornek (2017) performed laboratory experiment on sand to investigate the stress and bearing capacity. The vertical stresses resulting from strip and rectangular footings are measured at different depths of the tank model of dimensions 1.25m length, 1.0 m width and 1.0 m depth. The loading is considered under a model footing of B = 0.1 m breadth and L = 5B length. The measured average peak friction angles ϕ were 36° and 42° for loose and dense sands, respectively. The results of measured vertical stress (kPa) are given in Figure 5.

The model was calibrated using the results from Turedi and Ornek (2017). Figure 6 shows the vertical stress distribution using the probabilistic approach when we consider a deterministic diffusion parameter $D = K.z$. Jaky's formula is used, $K = 1 - \sin\phi'$. As the experiment was performed in loose sand we used for our simulation $\phi' = 36°$ as given by the authors.

The purpose of our study is to take into account uncertainties using interval-valued parameters. The proposed model permits to consider the parameter of diffusion D in terms of intervals, or as triangular fuzzy number. The loading on the surface can be taken into account as interval also.

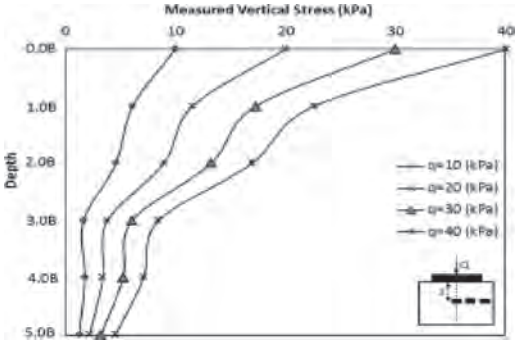

Figure 5. Vertical stress distribution along the depth at different loading levels (Experiment Turedi & Ornek, 2017).

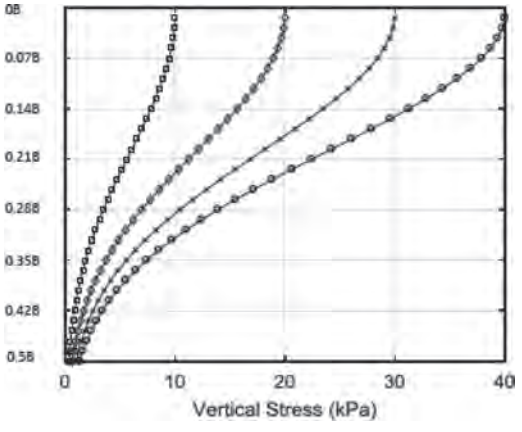

Figure 6. Vertical stress distribution along the depth at different loading levels (Probabilistic approach, $K = 1 - \sin\varphi'$).

Considering ranges of values for the coefficient of lateral pressure K around the friction angle of sand φ', the used interval values of K are given at different α level cuts. The applied load is taken as point valued q = 40 kPa. The triangular fuzzy number for K can be written in terms of intervals at level α, $[K]_\alpha = [0.35 + 0.03\alpha, 0.41 - 0.03\alpha]$.

And the membership function is given as

$$\mu_K(x) = \begin{cases} \dfrac{x - 0.35}{0.03} & \text{if } 0.35 \le x \le 0.38 \\ \dfrac{0.41 - x}{0.03} & \text{if } 0.38 \le x \le 0.41 \\ 0 & \text{otherwise} \end{cases}$$

Figure 7 shows distribution of vertical stress at α cut levels; $\alpha 0 = 0, \alpha 1 = 1/3, \alpha 2 = 2/3$ and $\alpha 3 = 1$.

Parameter D being dependent on depth, it is noticed that uncertainty is more pronounced with z increasing. Uncertain parameter of diffusion has important impact on stress distribution, especially at deeper levels. The observed dispersion suggests that using deterministic values for D gives only an approximation of the stress. It can underestimate or overestimate the real level of stress in the medium. Using interval values for the diffusion parameter helps estimating the evolution of stress spreading with depth.

One can also consider uncertainty in the loading using intervals for the surficial charge q. Influence of interval values of q is shown in Figure 8 for $q = [\underline{q}, \overline{q}] = [38\text{ kPa}, 40\text{ kPa}]$. The parameter of diffusion is kept point valued in this case with $K = 0.38$.

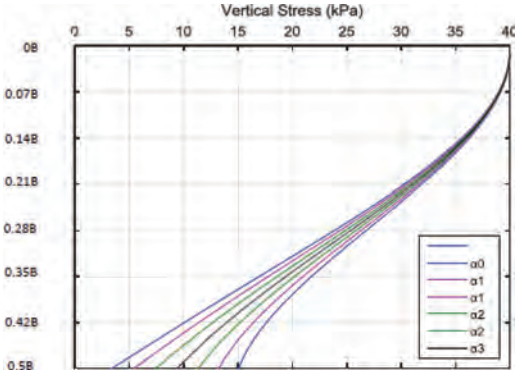

Figure 7. Vertical stress distribution under axis for different level cuts of K.

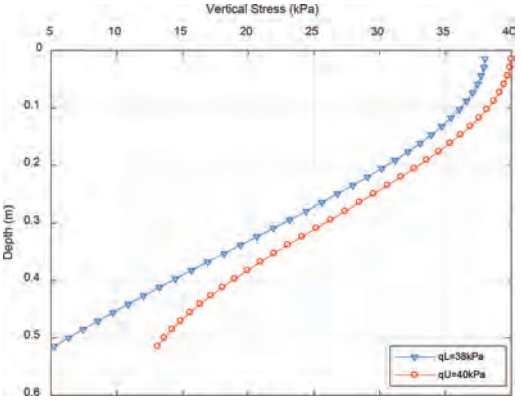

Figure 8. Vertical stress distribution under axis for inter-val surficial pressure $[q, \overline{q}]$.

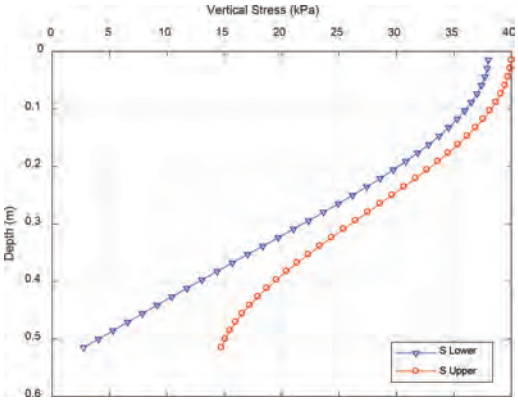

Figure 9. Vertical stress distribution for inter-val surficial pressure $\left[\, q, \overline{q} \,\right]$ and interval coefficient $\left[\, \underline{K}, \overline{K} \,\right]$.

The uncertainty on the load has effect on the distribution as the diffusion shows the vertical stress evolving as an interval from the surface, and it continues with the depth. It is slightly augmented for z deeper than half of the domain.

Combination of uncertainty due to K and q has higher effect on the evolution of uncertainty in vertical stress as it is illustrated in Figure 9. The surficial pressure is kept as $\mathrm{q} = \left[\, 38\ \mathrm{kPa}, 40\ \mathrm{kPa} \,\right]$ and the lateral pressure coefficient $K = \left[0.35, 0.41\right]$.

As uncertainty is combined between the surficial pressure q and the coefficient K we notice fast dispersion in the vertical stress S with depth as it was illustrated in Figure 7 already, but the effect is more pronounced because uncertainty originates from both the load and the soil parameter.

5 CONCLUSION

The probabilistic approach from Harr (1977) needed only one parameter for characterizing the particulate medium. It was shown in (Bourdeau, 1986) that lateral pressure coefficient can be a good estimate of the parameter for vertical stress diffusion in a granular soil. We revisited the theory from Harr to account for uncertainty in the diffusion parameter D and in the surficial loading. The purpose was to show the ability of interval valued method to handle uncertainty due to lack of knowledge and data. The finite difference scheme is practical for this type of equations. The construction of such a scheme for interval analysis is not straight forward as it obeys number of specific conditions. It was shown that uncertainty in the diffusion parameter affects significantly the distribution of vertical stress in the granular medium. And, when combined with the uncertainty from surficial pressure the stress distribution shows more dispersion with depth. Interval valued parameters are suitable when dealing with lack of data and uncertainty.

ABSTRACT: For the optimization of renewable energy systems, uncertainties associated to technical and economic parameters are scarcely taken into account, which may lead to a weak confidence in results. In this paper, we propose and investigate a 4-steps methodology for uncertainty sensitivity assessment, with the objective to improve confidence in the assessment results and to support decision-making process following techno-economic optimization of the design and the operation of an autonomous power system. The methodology is applied to off-grid system including photovoltaic production, battery and hydrogen components (electrolyser, pressure storage and fuel cell). This energy system is modelled and optimized with Odyssey—a simulation software developed by CEA-LITEN since 2010. We focus on static parametrical uncertainties, linked to the energy system parameters.

1 INTRODUCTION

1.1 *Optimization of complex energy systems*

Energy systems are getting more and more complex, and difficult to assess because of (i) the variability of the renewable power sources and of the demand, (ii) the resultant necessity of storage and (iii) the presence of different and new energy vectors. The modelling and simulation software Odyssey (Guinot 2013) enables the realization of techno-economic optimizations of such energy systems design and operation. However, many parameters used to simulate the systems are uncertain (e.g. static component performances or economic properties, but also time series of production or load profiles) and it is necessary to evaluate the impact of these uncertainties on the design and operation arising from the optimization process to help decision-making about these systems.

1.2 *Problem statement*

Up to now techno economic studies carried out with Odyssey, as with most other similar simulation tools, have not taken into account uncertainties, but only have provided sensitivity analysis on uncertain key input parameters. Thus, the objective of our work is to develop a comprehensive approach to enhance the platform with capacities of uncertainty management, from the identification of the main sources of uncertainty to results analysis and support to decision making.

We identified two main ways to account for the uncertainty influence on the results of a techno-economic optimization. The first one consists in optimizing the system taking into account the uncertain parameters so as to get results robust to the considered uncertainties. The second way consists in optimizing the system and then apply the uncertainties to evaluate the sensitivity of this optimized design to uncertainties; this paper presents an application of this second one. In the first part, we will present a 4-step methodology for uncertainty assessment. In the second part, we will present a representative example of energy system optimization, which allows dealing with problematic of competition between technologies, the problematic of energy storage in off-grid power-system and the optimization of this system design and operation without uncertainty. In the third part, we will apply our methodology on the described study case, showing how we modelled uncertainties on selected parameters and how to assess the sensitivity of results to these uncertainties. Finally, the fourth part will expose our conclusions and give directions for our future research work.

2 PROPOSED METHODOLOGY

The methodology of uncertainty treatment proposed and implemented in this work is based on the four-steps approach described by de Rocquigny (de Rocquigny 2006a, b), schematized in Figure 1. This methodology is summarized below.

2.1 *Model of the system*

For step A, we assume that the considered energy system model is available and implemented in the software Odyssey, used as a black box.

The entries of this black box are technical and economic parameters divided in two types: design variables and uncertain parameters. The uncertain parameters are arbitrarily decided by the decision-maker or by the software user. On the contrary, the design variables can be set, and even optimized, like the optimization variables in Table 1. The next part will describe with precision the model of our case study.

The outputs of the black box are technical and economic indicators, which assess the performances of the design of the system. These indicators will be described later.

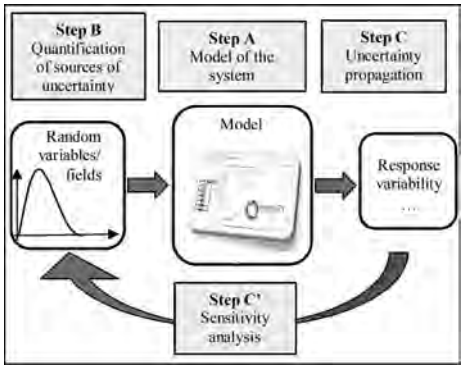

Figure 1. Uncertainty analysis common framework.

Table 1. Optimization variables.

Variable	Units	Optimization borders Minimum	Maximum
Number of Modules PV*	–	1	no
Number of Battery Units**	–	1	150
Number of electrolyze cells	–	5	no
Fuel Cell Stack Max Power	W	1	no
Volume of pressure tank	m^3	1	no

*Each module has a peak power of 1 kWp.
**Each unit has a rated capacity of 10 kWh.

2.2 *Uncertainty modelling*

Regarding the quantification of sources of uncertainty, at step B, we model the sources of uncertainty in a probabilistic framework, with probabilistic density laws. In this study, we assume that all the considered uncertainties are independent.

The three classical probabilistic laws are consid-ered: uniform, beta and Weibull, detailed in Table 3, in paragraph 4.1 where the whole uncertainty modelling is applied to our study case.

2.3 *Uncertainty propagation*

At step C, the propagation of uncertainties allows us to see how the outputs of the model respond to the uncertainties: we achieved this by coupling a Monte Carlo launcher provided by the Uranie software (Bouloré 2012) and the executable Odyssey, as schematized in Figure 2.

2.4 *Sensitivity analysis*

Finally, at 'step C', the sensitivity analysis permits to identify the uncertainties that have the strongest influence on the outputs of the model. This identification gives us the possibility to try to reduce the uncertainty of the most influent sources, in order to reduce the uncertainty of the outputs and facilitate decision making (Borgonovo 2016). Among the different methods of sensitivity analysis, we chose the Morris method and the Sobol indexes computation, which are closely complementary.

The Morris method (Morris 1991) allows first to classify the uncertain parameters in three categories:

- the parameters with negligible effects,
- the parameters with linear effect and without interaction,
- the parameters with nonlinear effects and/or interactions (without distinction of these two effect types).

Table 2. Optimized study cases design and indicators.

Case	0	01	05	1
Number of Modules PV (–)	735	735	660	600
Number of Battery Units (–)	146	145	135	138
Number of electrolysis cells (–)	8	5	5	5

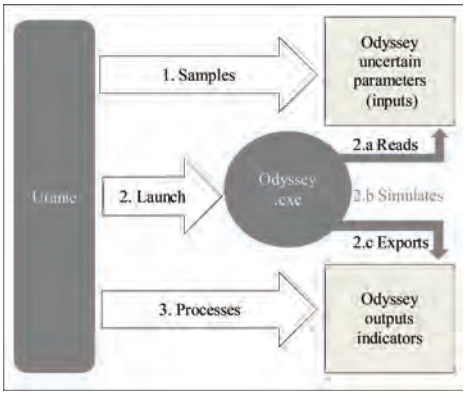

Figure 2. Odyssey/Uranie coupling.

This screening method presents the advantage to sort the uncertain parameters with a limited calculation cost. In fact, the Morris method requires N code computations, with:

$$N = r*(d+1) \quad (1)$$

with:

– r∈ $[\![4;10]\!]$,
– d: number of uncertain parameters.

We used the Morris method to eliminate the uncertain parameters with negligible effects on the output indicators, in order to calculate the Sobol indexes (Sobol 1993). This second part of the sensitivity analysis requires many more code computations, which explains why the Morris method is relevant to use before. Indeed, the calculation on the Sobol indexes required N code computations, with:

$$N = n*(d+2) \quad (2)$$

with:

– n: size of the sample,
– d: number of uncertain parameters.

The Morris method and the Sobol indexes computation combination compose the sensitivity analysis step.

3 MODELLING AND OPTIMIZATION OF THE SYSTEM WITHOUT UNCERTAINTY

3.1 *Case study description*

The case study investigated in this paper is a standalone power system located in Nigeria and is shown on Figure 3. It includes:

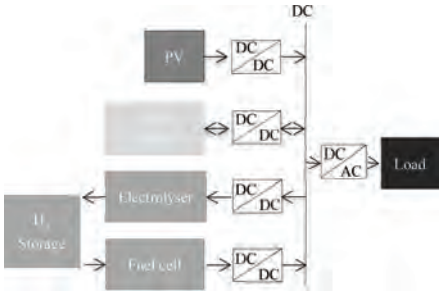

Figure 3. Architecture of the case study.

– an electrical load (Load),
– a photovoltaic (PV) plant,
– a bank of Lead-acid batteries,
– a complete hydrogen chain made of: a PEM electrolyser, a pressurized tank to store the hydrogen and a PEM fuel cell.

This example is representative of (i) the operating competition occurring between batteries and a hydrogen chain, (ii) the problematic of energy storage in off-grid power-system, and (iii) the PV over-sizing linked to the load satisfaction research.

The implemented power management strategy is based on the on/off switches of the electrolyser (ELY) and the fuel cell (FC), as was originally developed by Ulleberg (Ulleberg 2004), and exploited on a similar case by Guinot et al. (Guinot et al. 2015). The operation depends on the state of charge (SOC) of the battery and on levels fixing switching operations the fuel cell and the electrolyser (FC+, FC-, ELY- and ELY-, i.e. the operation parameters) given in Figure 3.

In this case study, the replacement of the components is not considered.

3.2 *Optimization criteria and variables*

The operation parameters are considered constant during the whole exploitation simulation. The optimization of the system operation consists in finding the best suited operation parameters to minimize both electrical cost and unsatisfied load, as for any other design parameters. No distinction is made between plant and controller optimization problems, as it would have been necessary if the operation parameters had been evolving according to the dynamic of the system (Fathy et al. 2001). However, in this study the operation are not optimized.

We selected as optimization variables the five dimensioning variables shown in Table 1.

Odyssey multicriteria optimization process uses a genetic algorithm in order to minimize the standard Levelized Electricity Cost (LEC) in €/MWh on the one hand and to minimize the unsatisfied load (UL) in %, i.e. the energy based percentage of unmet electrical load, on the other hand. Therefore, two objective functions are in competition. It is often observed that lowering the load satisfaction, by reducing the storage system size for example, leads to a lower cost of the system and thus the cost of the produced electricity. While on the contrary, improving the satisfaction of the load by oversizing the system tends to increase the cost of the produced electricity.

The simultaneous optimization of design and operation parameters allows to take maximum benefit from each optimized design.

The multicriteria algorithm used in this work is the Strength Pareto Evolutionary Algorithm 2 (Zitzler et al. 2001).

3.3 *Optimization results*

Due to the competition between both optimization criteria LEC and UL, the optimization results take the shape of a Pareto front as on Figure 5. On this Pareto front, four different design points were selected corresponding to different indicators values (LEC and UL). We selected the point according to the UL and we defined four different cases named from their UL value and with the designs given in Table 2.

The resulting cost distribution for the four selected cases given in Figure 6 illustrate the relative importance of the component costs within the overall system cost. We noticed that the component influencing the most the price was the PV array, which contributes for more than the half of it, in every case, followed by the battery bank (electrical storage). The fuel cell has a significant part in the price only in the case 0, which is intuitive regarding to the maximal power of the fuel cell stack (Table 2).

This part describes the way we identified and selected the optimal system designs without uncertainty consideration. In the following, we will

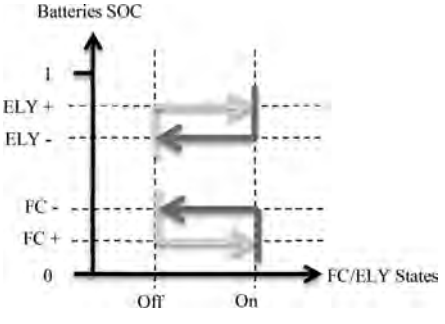

Figure 4. Power management strategy of hydrogen chain.

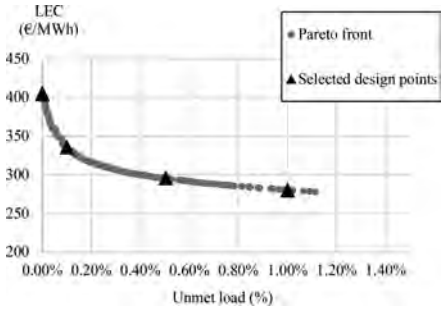

Figure 5. Pareto front resulting from the optimization of the system.

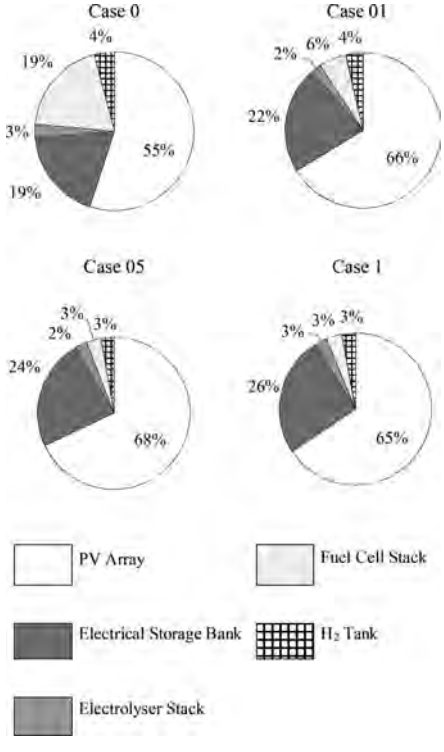

Figure 6. Cost distributions for the 4 different cases.

investigate the influence of uncertainties on the selected cases (optimized without uncertainties) and through them on the Pareto front. In fact, these four cases show similar cost distributions and thereby, it is interesting to observe if applying uncertainties may modify the comparison between them. As we optimized operating parameters, it will however not be possible to check whether operating parameters may counter-balance the effect of uncertainties on the design or not.

4 APPLICATION OF THE PROPOSED METHODOLOGY TO THE CASE STUDY

4.1 *Uncertainty modelling*

In this paper, we decide to focus on static parametrical uncertainties, linked to the energy system parameters. We have identified 25 parameters sources of uncertainty, all with an epistemic nature. In fact, the parameters of components that are not completely mature (such as the electrolyser and the fuel cell) are not well known. Moreover, even the mature components do not have parameters with perfectly known values.

An extensive literature research has been carried out to identify existing, validated or accepted uncertainty probabilistic models for components of energy systems. Table 3 summarizes the different uncertain characteristics of the system components considered in the study, with their associated probability distribution, and with the reference for the chosen uncertainty model. Uniform probability distributions have been associated to the uncertain characteristics of the innovative components (in order to report the equiprobability between the possible values) and to the uncertain parameters of mature components when no other "better" (e.g. from expert judgements) distribution is available.

There are too many uncertain parameters to be de-scribed exhaustively, but the following subsections will focus on three particularity types.

4.1.1 *Uncertain parameters modelled by polynomial models*

Three uncertain parameters, i.e. the cell voltage of the electrolyser, the efficiency of the fuel cell and the CAPEX of the hydrogen pressure tank are modelled by polynomials, respectively functions of the current density in the electrolyser, the pressure (P/Pnominal) of the fuel cell and the volume of the hydrogen pressure tank. We assumed that only the constant coefficient was uncertain, thus generating an area of possible values instead of a curve.

4.1.2 *Uncertain parameters of the photovoltaic panels*

No technical parameter of the photovoltaic panels was considered as uncertain in this paper. This is due to the fact that the solar production is defined directly by a time series data representing the electrical production, not considered as uncertain in this paper.

4.2 *Uncertainty propagation through Odyssey*

The immediate effect of the uncertainties are observed thanks to the Monte Carlo approach using the Odyssey model. Then the dispersions of the indicators (LEC and unmet load) are analyzed. They are not the same for these two indicators and

they depend on the case, i.e. on the design of the system. A realization of all the uncertain parameters is sampled, and based on this realization the system is simulated using its Odyssey model to propagate the uncertainty on the model output performance indicators (UL and LEC). This simulation is iterated for 300 Monte Carlo history. The results are given in Figure 7.

We observe the relative dispersion of the LEC and the unmet load, calculated by the ratio of the standard deviation and the average (Fig. 8). The relative dispersion of the unmet load decreases significantly from case 0 to case 1, i.e. inversely to the nominal unmet load characteristic of the design. While the relative dispersion of the LEC increases slowly from case 0 to case 1, i.e. also inversely to the nominal LEC characteristic of the design.

4.3 *Sensitivity assessment*

After propagating uncertainties, the sensitivity analysis described below aims to identify the most influent uncertain parameters on the output variance.

4.3.1 *Application of Morris method*

The Morris method permits us to select those uncertain parameters that have a non negligible influence on the output indicator (marked with + in the Table 4). Both for the LEC and the UL, whatever the design configuration, the method eliminates the same parameters.

However, the eliminated parameters are not the same for LEC and the UL. Indeed, the UL is decorrelated from the economic parameters, so we do not keep them for the Sobol indexes calculation. On the contrary, the LEC is not influenced only by economic parameters, since it depends also on the electricity production. For the Sobol indexes calculation related to the LEC, we also keep the more influent technical parameters based on the Morris method.

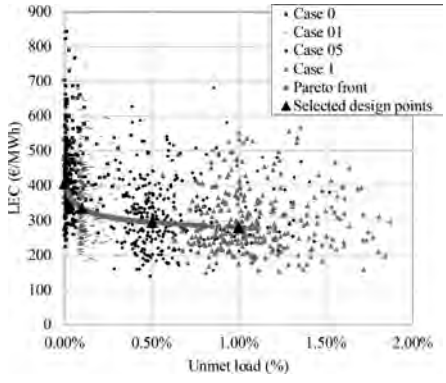

Figure 7. LEC and UL indicators for the four selected design configurations with uncertainties.

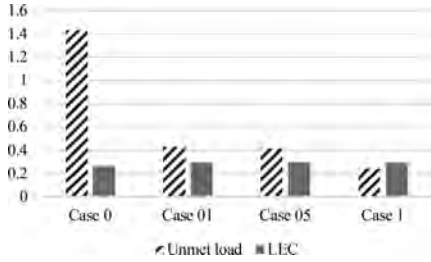

Figure 8. Relative dispersion of LEC and UL for the four study cases.

4.3.2 *Analysis with Sobol indexes*

The Sobol indexes give with precision the contributions of the variance of one output indicator due to the considered parameters.

4.3.2.1 Unmet load

Considering the unmet load variance, the Sobol indexes represented in the Figure 9 indicate that the most influencing uncertain parameter, whatever the case, is the capacity loss of the battery, followed by the discharge efficiency of the battery. The importance of these two parameters, linked to the battery bank shows the major role played by this component in the load satisfaction. The discharge efficiency is much more influent than the charge efficiency, because the PV panel installation is oversized and therefore the solar production is in excess, limiting the role of the charge efficiency. The charge efficiency takes a bigger importance only in case 05 and case 1 (responsible of respectively 3 and 5% of the unmet load variance) where the PV panel installation size is smaller (Table 2).

The ascendancy of the battery on the hydrogen chain is due to the design and the control of those. The powers delivered by the battery on one side and by the hydrogen chain (i.e. by the fuel cell) on the other side illustrate that the hydrogen chain supplies a negligible electric power, even in the case 0, in which the fuel cell has the biggest design, i.e. in which the hydrogen chain production is the most favorable (Fig. 10).

4.3.2.2 Levelized electricity cost

The Sobol indexes indicate that whatever the case, the most influent uncertain parameter on the LEC variance is the PV CAPEX, far before the PV OPEX and to a lower degree the battery bank CAPEX.

We notice that the hydrogen chain plays a significant role in the unmet load variance only in the case 0, i.e. with its largest design: 26% of the total cost in its integrality and 19% for the fuel cell (Fig. 6).

We can observe that if the Sobol index of a given parameter is linked to the cost weight of the corresponding component (studied in Sec-

Table 4. Morris method results.

tion 2), there is however no direct proportional relation, because of the influence of the probability distribution of the input parameters values. For instance, the battery bank that plays an important role in the system cost (between 19% and 26%) has a relatively small impact (inferior than 8%) on the LEC variance. While the PV panel installation, which is the main contributor to the system cost, but no more than 68%, represents (CAPEX and OPEX unified) the overwhelmingly part (between 88% and 94%) of the LEC variance cause.

5 CONCLUSIONS AND FUTURE RESEARCH WORK

In this paper, we investigated a comprehensive 4-steps methodology to evaluate the impact of uncertainties, in order to improve the confidence in the assessment results of a complex autonomous power system modelled and optimized with Odyssey. We first chose to optimize the system before considering the uncertainties that were considered uncertainties as independent.

The results of the uncertainty propagation and of the sensitivity analysis teach us that the most influencing uncertain parameters are linked to the design of the system and in our case study are:

– the capacity loss followed by the discharge efficiency of the battery for the unmet load,
– the PV CAPEX followed by the PV OPEX and the battery CAPEX for the LEC.

There are several interesting points that still have to be thoroughly investigated. We want to investigate now (i) the incidence of the choice of the

probabilistic distributions associated to the uncertain parameters, (ii) the inclusion of the uncertainty relative to time series, (iii) the optimization of operation parameters as a way to counter-balance uncertainties on the design of the system, and mainly (iv) the optimization taking directly into consideration the uncertainties.

Modular global uncertainty analysis of event-driven indicators of system's availability

Pawel M. Stano & Michal Spirzewski
National Centre for Nuclear Research, Swierk, Poland

ABSTRACT: The purpose of this manuscript is to propose a novel methodology for conducting uncertainty analysis for event-driven indicators of system's availability. In this approach the system's availability depends on the frequency of components' failures and their duration. For all the components the parameters that determine their behavior are obtained from statistical analysis, which means they are given with certain uncertainty, hence the system's availability is also uncertain. In this paper we present a numerically effective algorithm that assesses uncertainty about system's availability. A modular approach has been adopted, in which the uncertainty about the complete system's availability is estimated by combining the information obtained for separate subsystems using the knowledge about the functional relationships between them. Furthermore, to assure numerical efficiency, a novel approach has been adopted, which combines screening approach with quasi-random Sobol sampling approach. The functionality of the proposed method is visualized on an illustrative example.

1 INTRODUCTION

In this paper we develop a methodology to investigate complex input-output stochastic system used in reliability studies. We consider systems with the inputs defined as stochastic renewal processes that model occurrences of the so-called basic events, i.e., the events that cause the system's failure and the outputs of the systems defined as RAMI metrics.

There are two types of failures that might occur to the system: direct, or indirect, e.g., by igniting a sequence of chain events that leads to system failure. The events and their corresponding parameters are usually identified during a standard Failure Mode and Effects Analysis (FMEA) (Stamatis, 2003), which combines a detailed analysis of technical specifications of plant components, in order to identify their failure modes, with a detail analysis of operational interactions within the plant subsystems to discover the effects of previously identified failure modes. Thus, performing FMEA allows for efficient description of systemic structural dependencies (in a form of logic trees or functional block diagrams). Properly performed FMEA is considered as a prerequisite of the analysis described in this paper. In other words, we assume that the complete collection of basic events together with the paths of failure propagation are already identified. With such assumptions in place, it is possible to analyze operational metrics of the system. This is normally done by performing full Reliability, Availability, Maintainability and Inspectability (RAMI) analysis (Stapelberg, 2009). The full RAMI analysis is out of scope of this paper. Instead, the focus is put on investigating what impact the uncertainty in input parameters has on selected availability metrics of the system, which, in general, measure the proportion of time the system in operational with respect to the total system's life time. We adopt block-wise approach, similar to Dynamic Reliability Block Diagrams (DRBDs) (Distefano & Xing, 2006), in which a complex system is broken down into several layers of smaller subsystems. The operational conditions of components are modelled as stochastic processes whose evolution is determined by occurrences of failure events. Each component is associated with an effect function, which determines whether the failure of the component leads to system's deterioration (non-critical failure) or complete shutdown to conduct necessary repairs (critical failure).

The paper is organized in the following manner: Section 2 briefly covers preliminaries necessary to understand the content of the paper, Section 3 describes the general procedure to conduct modular global uncertainty analysis for event-driven indicators. In Section 4 the algorithm described in Section 3 is applied to an illustrative case study coming from the examination of an injector designed for International Fusion Materials Irradiation Facility (IFMIF) (Bargallo Font, 2014). Section 5 concludes the paper with a discussion about the advantages of the proposed method but also about its limitation in the current state of development.

2 PRELIMINARIES

The analysis presented in this paper is a two-level probabilistic approach. In this approach the prior knowledge Priors(θ) about uncertainty associated to basic events e_i identified in FMEA is fed to the quasi-random uncertainty sampler. This higher level algorithm generates a representative sample of the uncertain parameters $\theta_i,\ldots,\theta_j$ of the stochastic input variables, which are sent in parallel to the lower level algorithm. In these blocks probabilistic Monte Carlo simulations of the system are performed to compute the RAMI metrics for a given set of the uncertain parameters $\theta_i,\ldots,\theta_j$ of the stochastic input variables. These metrics are combined in a non-parametric filter for post-processing that leads to final global RAMI analysis. The structure of such a two-level algorithm is presented in Figure 1.

The structure of the higher level algorithm (Uncertainty Sampler) is presented in detail in Section 3. In this section we shall briefly describe how the lower level algorithm works.

2.1 *Probabilistic Monte Carlo RAMI simulations*

The lower level algorithm is designed to study the effects of the basic events mentioned in the previous section on the functionality of the system. In this work this was done by running a probabilistic Monte Carlo simulations of the DRBD model of the system using the Availsim 2.0 program (Bargallo Font, 2014). With this engine it was possible to repeatedly simulate the operation of a system over long periods of time with fixed parameters but random initial conditions, which in our case were times of failure associated with identified basic events. Thus, each simulation run was associated with different failure sequences. When a failure occurs, the performance of the system is affected by a certain factor. As failures accumulate, the performance decreases until it drops below a critical threshold when it is necessary to shut the system down for time necessary to perform corrective repairs that raise the system's performance above its minimal threshold. Note that in case of critical components a single failure leads to immediate shut down of the system. After the system is restarted, a new operational cycle begins until new failures, possibly of the same components, cause the system to shut down again. After the simulation is over, the total down time due to failures is calculated by adding all the down times caused by individual events. Then, the expected down time to the system is computed by averaging the total down times obtained in individual Monte Carlo runs of the simulation. Due to the high complexity of the considered systems, the time to complete a single run of the simulation can be significant. Therefore, it is advisable to stop the further Monte Carlo runs as soon as the expected down time to the system (computed over all the Monte Carlo runs) stabilizes.

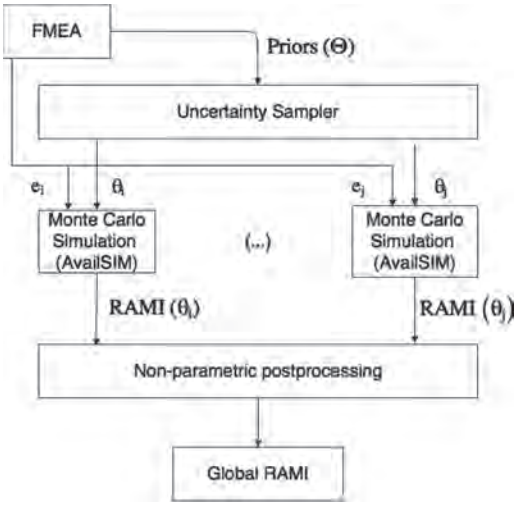

Figure 1. The schematic depiction of the complete two-level Global Uncertainty Analysis (GUA) algorithm.

2.2 *Output indicators of availability*

With every single run of the simulation a realization of a collection of independent stochastic renewal processes E_i is obtained. Each E_i models the occurrence of failure basic events e_i, where the failure rate follows exponential distribution with expectation defined by the Mean Time Between Failure (MTBF) parameter. The time required for the process to renew, the down time T_{down}, is stochastic itself, as it is determined by the sum of independent random variables:

$$T_{down} = T_{access} + T_{repair} + T_{recovery}. \quad (1)$$

where the variables are defined as follows:

a. T_{access} - time required to access the component to be repaired. The variable follows exponential distribution with the Mean Access Time (MAT);
b. T_{repair} - time required to perform repairs of the broken components. The variable follows exponential distribution with the Mean Time To Repair (MTTR);
c. $T_{recovery}$ - time required for the system to recover to the nominal operating conditions. The variable follows exponential distribution with the Mean Recovery Time (MRT).

An important distinction between the variables listed above is that the parameters of the variable T_{repair} usually depend only on the characteristics of the components the basic events are associated with, thus, normally, they vary from event to event. On the other hand, the parameters of the variables T_{access} and $T_{recovery}$ usually depend directly on the system and are often the same for multiple components (e.g., those that share the same location within a subsystem).

The stochastic realizations of variables T_{down}, T_{access}, T_{repair}, $T_{recovery}$ are used to define the output indicators of availability, which are functions of the basic events that cause system failure (inputs). We consider standard system's availability indicators (Stapelberg 2009, Lie & Hwang & Tillman, 1977) such as:

1. Inherent Availability (IA), which is defined as:

$$IA = \frac{\mathrm{T}\sum_{up}}{\mathrm{T}\sum_{up} + \mathrm{T}\sum_{down}}. \tag{2}$$

2. Achieved Availability (AA), defined as:

$$AA = \frac{\mathrm{T}\sum_{up}}{\mathrm{T}\sum_{up} + \mathrm{T}\sum_{down} + \mathrm{T}\sum_{maintenance}}. \tag{3}$$

3. Operational Availability (OA), defined as:

$$OA = \frac{\mathrm{T}\sum_{up}}{\mathrm{T}\sum_{total}}. \tag{4}$$

where:

- $\mathrm{T}\Sigma_{up}$ counts the total time the system is operational;
- $\mathrm{T}\Sigma_{down}$ counts the total time the system is shut down due to failures;
- $\mathrm{T}\Sigma_{maintenance}$ counts the total time the system is shut down due to routine maintenance;
- $\mathrm{T}\Sigma_{total}$ counts the total life time of the system, which includes $\mathrm{T}\Sigma_{up}$, $\mathrm{T}\Sigma_{down}$, $\mathrm{T}\Sigma_{maintenance}$, but also potential logistic delays typically associated with the operating cycle (insufficient service personnel, lack of spare parts, etc.).

Depending on a particular application, the uncertainty of any of the three indicators of the system availability can be investigated.

2.3 *Uncertainty problem formulation*

With the probabilistic simulations described in previous subsections it was possible to determine the average availability of the system for a given set of input parameters. Unfortunately, this information is often not sufficient because for reliable assessment of system's functionality the impact of the uncertainty of parameters such as MTBF, MTTR, MAT, MRT, on the system availability must be analyzed as well. To determine the exact nature of this impact, a thorough uncertainty and sensitivity analysis should be performed. The latter type of analysis, which aims to identify the basic events that introduce the highest sensitivity to the system's availability (Saltelli et al., 2008) is beyond the scope of this paper but is discussed in detail in (Stano, 2018). Instead, the goal of this paper is to describe a method to conduct the uncertainty analysis that aims to describe how the uncertainty in inputs propagate to the outputs of the system. Note that although the uncertainty about inputs is parametrized (the priors about MTBF, MTTR, etc., are given in parametric form, usually lognormal distributions), the uncertainty about outputs is usually nonparametric.

3 GLOBAL UNCERTAINTY ANALYSIS FOR EVENT-DRIVEN INDICATORS OF RAMI

This section presents the higher level algorithm mentioned in Section 2 that aims to generate the representative distribution of prior parameters.

The structure of the algorithm is schematically depicted in Figure 2. The algorithm is composed of three sequential steps, where the first one is of qualitative nature and the following two are of quantitative nature. Firstly, in Section 3.1 the sources of uncertainty associated with basic events are identified; secondly, in Section 3.2 the

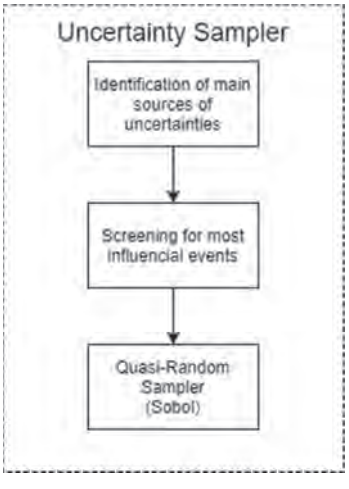

Figure 2. The schematic depiction of the uncertainty sampler.

most influential events are selected; and thirdly, in Section 3.3 the prior distribution of the input parameters is generated via quasi-random Sobol sampler. Finally, the description of modular GUA approach is presented.

3.1 *Identification of main sources of uncertainty*

Each basic event corresponds to a failure of a component or a group of components that cause system's performance deterioration (and eventual shut down) or immediate shut down to perform corrective maintenance. In this paper we assume the components to be within their Normal Life cycle, which means that they fail with a constant rate over time. With some extra effort, it is possible to adopt our methodology to events with time-varying failure rates but this is out of the scope of this paper.

In Section 2.2, we have described four main sources of uncertainty: MTBF, MTTR, MAT, MRT. Out of these two, the MTBF and MTTR are directly associated with the inputs to the system and are aleatory uncertainties with known parametric distributions. On the other hand, the MAT and MRT are structural uncertainties associated only with the system construction. Thus, because the stated purpose of GUA is to study the impacts the inputs have on the outputs, only the uncertainty about MTBF and MTTR parameters shall be investigated. The uncertainty in parameters MAT and MRT should be studied in the context of structural uncertainty analysis, which is devoted to studies of intrinsic system uncertainties (Schueller, 2009).

The prior uncertainties in MTBF and MTTR are modelled by the lifetime distributions derived from reliability tables of appropriate components. Sometimes it is enough to analyze impact of one parameter only (e.g., when the MTTR is very short compared to MAT and MRT, the only important uncertainty about inputs lies in MTBF).

The general model for the uncertainty analysis for the event-driven indicators is given by the following equation:

$$Y = F\left(X_1, \quad , X_d\right), \tag{5}$$

where:

- output Y is a system availability defined by (2–4);
- inputs X_s are random variables with lifetime distributions reflecting uncertainty in failure parameters of basic events (MTBF, MTTR).

It is important to distinguish the uncertainty in failure rates, which is modeled by variables X_s, from the uncertainty of failure occurrences, which are modelled by the renewal processes E_i i = 1,…,d. Thus, the model (5) should be understood as an expectation of a function of d stochastic processes E_i, conditional on realizations of d independent random variables X_s.

3.2 *Screening for most influential events*

The first quantitative part of the analysis is to identify failures that are most detrimental to system's availability. This is done by computing for all events the Fraction Contribution (FC), which is a ratio of unavailability due to an event divided by total unavailability due to all events:

$$FC_i = \frac{unavailability\ due\ to\ event\ e_i}{total\ unavailability}. \tag{6}$$

To compute such defined screening factor, the plant is simulated with nominal parameter settings for all events, i.e., failure and repair rates are fixed at the mean values derived from the reliability tables. Then, the n_0 events with cumulative FCs above a predefined threshold 1-ε are labeled as the most significant and selected for further analysis, i.e., we select those events for which the following holds:

$$\sum_{i=1}^{n_0} FC_i > 1 - \varepsilon. \tag{7}$$

With such restriction introduced, the numerical complexity of the problem is reduced significantly by not taking into consideration events with very low expected contributions to facility's unavailability due to failures. On a downside, by excluding the least influential events from the further analysis a certain amount of information about the system is lost. Thus, the cut-off threshold 1-ε should be selected very carefully so that the price of computational efficiency is not too high. On the top of that, the quantitative screening should be accompanied with the qualitative analysis in which one should investigate whether any events with critical importance to the functionality of the analyzed system are among the discarded events with low FCs. If that is the case it might be advisable to re-incorporated these critical events into GUA despite them having low values of quantitative indicator FCs.

3.3 *Sobol sampling sequences*

Although the dimensionality of the problem was greatly reduced by the screening procedure described in Section 3.2, for complex systems the dimensionality of RAMI simulations remains a numerical challenge. Therefore, we apply Sobol

approach in which the uncertain parameters are generated using quasi-random low-discrepancy Sobol sequences. Thanks to this approach it is possible to obtain a sample that densely covers the sampled space with smaller number of sampling points than those required by the orthogonal grid or the Monte Carlo method. This is because the Sobol sequences satisfy the so-called uniformity properties A and A' (Kucherenko et al., 2015) and at the same time avoid clustering of the samples, which commonly occurs with Monte Carlo samplers. The samples generated for n-dimensional unit cube $[0,1]^n$ are transformed, via inverse cumulative distribution function to get an accurate approximation of system's priors. This approach is visualized on an example of 512 Sobol 75-dimensional points projected on a two-dimensional plane defined by uncertain MTBFs of Acquisition modules and PLC (see Figure 3). Note that the Sobol points cover densely not only the full space (75 dimensions) but also all the lower-dimensional hyper spaces.

3.4 *Modular global uncertainty analysis*

Despite all the steps undertaken above to reduce the numerical load of the GUA algorithm, if it is executed on the complete system it might still be very expensive numerically. Therefore, to conduct numerically effective GUA we propose the following approach: firstly, we divide the system into modules that correspond to the most important parts of the system; secondly, we conduct the GUA described in Sections 3.1–3.3 independently for each module assuming that all the components of the remaining modules are 100% operational; thirdly, we combine the information obtained from separate modules using the knowledge about the functional relationships between events from different modules. This procedure allows for parallelization of the computations which significantly reduces the computational load of the algorithm that uses sequential architecture.

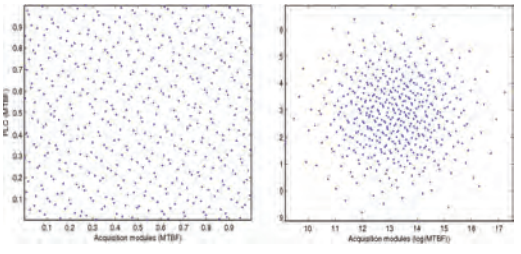

Figure 3. Sample of 512 Sobol sequences projected on two-dimensional plane approximating: uniform distribution (left) and lognormal distribution (right).

It is useful to introduce the following algebraic notation. Let us define System Unavailability (SU) by:

$$SA = 1 - SU \tag{8}$$

where SA denotes random variable defined by (2–4). Then let us introduce the following algebraic operation:

$$SA_1 \oplus SA_2 \underline{\underline{\text{def}}} 1 - SU_1 - SU_2, \tag{9}$$

where SA_1 and SA_2 follow the general form described in (9). The next step necessary to complete the uncertainty analysis for the whole system is to observe that:

$$SA_{SYS} = SA_1 \oplus \cdots \oplus SA_N + Residual, \tag{10}$$

where:

- $SA_{i=1\ldots N}$ are indicators of availability for N individual modules;
- $Residual$ is the term that accounts for interactions between the modules.

Note that with availability of the system assessed by (8–10), the *Residual* is always a nonnegative term. Indeed, in the modular approach we double count all the down times of modules that happen while some other module is already down. Thus, the *Residual* term measures the influence of all these almost-simultaneous occurrences of failure events from distinctive modules with the formula:

$$Residual = \sum_{j=1}^{N} \sum_{1 \le i_1 < \ldots < i_j \le N} \sum_{\substack{1 \le k^{i_1} \le N_{i_1} \\ \vdots \\ 1 \le k^{i_j} \le N_{i_j}}} SA\left(e_{k^{i_1}}^{i_1} \wedge \ldots \wedge e_{k^{i_j}}^{i_j}\right), \tag{11}$$

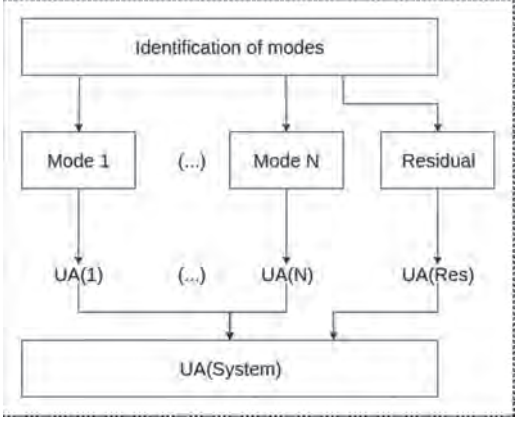

Figure 4. Schematic depiction of the modular GUA approach of a typical figure.

This means that even without analyzing the Residual, with (10) we obtain a conservative estimate of the availability of a system.

$$SA_{SYS} \geq SA_1 \oplus \cdots \oplus SA_N. \tag{12}$$

The schematic depiction of the modular approach described above is shown in Figure 4.

4 CASE STUDY

The practical implementation of the proposed GUA procedure is illustrated on an example, which involves the analysis of the model of the Injector System within the International Fusion Materials Irradiation Facility (IFMIF). The IFMIF is an accelerator-based neutron source, developed jointly by Europe and Japan, which is conceived for fusion materials testing. The main purpose of the Injector System of the linear accelerator under study is to deliver sufficient beam current to the first accelerating cavity (RFQ—Radio Frequency Quadrupole) (Bargallo Font, 2014), and thus to achieve a 125 mA RFQ output current. The Injector is composed of four subsystems: Source and Extraction System (SES); Low Energy Beam Transport (LEBT); Local Control System (LCS); and Auxiliaries System (AUX), which are connected sequentially reliability-wise. Thus, in case of the analyzed Injector, the GUA decomposition into modes naturally overlaps with the decomposition into subsystems.

In case of the Injector, all the identified basic events ignite failure sequences that cause immediate shutdown of the system so that the accelerator vault can be accessed by the repair crews to conduct corrective maintenance operations. Out of considered availability indicators (2–4), we have selected the IA because it measures the direct impact of system failures on accelerator's availability whereas the remaining two accounts also for other events (scheduled maintenance time, logistics delay, etc.).

4.1 *Identification of main sources of uncertainty in the Injector system*

The analysis of the Injector system within the IFMIF accelerator revealed that the main sources of uncertainty in the system lay in failure rates (MTBF parameters). Indeed, the MTTR associated with the basic events are relatively low and dominated by constant access time (MAT) and recovery time (MRT), which are determined by the accelerator technical specification. Consequently, the variations in MTTR do not influence the IA output indicator significantly. The uncertainties in MTBF are parametrized by lognormal distributions with parameters defined in the reliability tables of events detected for the IFMIF accelerator (for details see Bargallo Font (2014)).

4.2 *Screening for the most influential events in the Injector system*

In the analyzed system, according to (Bargallo Font, 2014), there are overall 508 basic events identified for the Injector, each characterized by the uncertainty about the MTBF. It has been established experimentally that for the nominal setting of uncertain parameters, the mean downtime of the Injector system stabilizes after 200 Monte Carlo runs of AvailSIM, which is depicted in Figure 5.

Thus, for a grid of n samples from a prior associated with each event and 200 Monte Carlo runs, the computational load of the rough GUA algorithm is:

$$n^{508} \cdot \ 200 \cdot \ \textit{single run}, \tag{13}$$

which is unfeasible even for a small n. Therefore, following the modular approach of Section 3.4, the space of basic events have been screened independently to identify these events that are the most detrimental to the functionality of each module. The events that contribute cumulatively to more than 90% to the inherent unavailability of each mode are selected for further analysis. These, ordered by the strength of their contribution are presented in Figure 6.

4.3 *Sobol sampling sequences in the Injector system*

For the events detected in the previous section, the uncertainties in MTBF need to be sampled from their lognormal priors. This is done with high-dimensional low-discrepancy Sobol sequences.

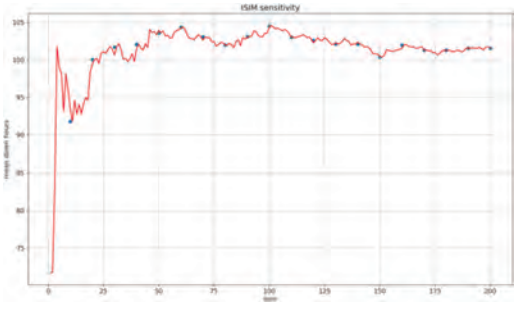

Figure 5. Mean downtime versus number of Monte Carlo runs (nominal parameters).

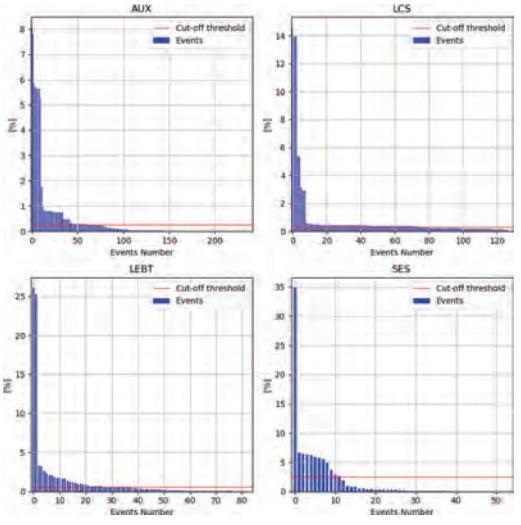

Figure 6. Fractional contributions of the most influential events for each mode considered (SES, LEBT, LCS, AUX).

Following the suggestions of (Kucherenko et al., 2015), the number of Sobol points is set to 512, which, as they argue, give lower discrepancy coverage than both pseudo-random Monte Carlo and Latin Hyper-cube methods. Thus, the computational load of the algorithm is reduced from (13) to:

$$512 \cdot \quad 200 \cdot \quad \textit{single run}, \tag{14}$$

which is manageable even for standard machines.

4.4 *Results of GUA for individual modules*

Four subsystems have been simulated with corresponding number of variables, identified in the screening process, on AvailSIM code. The computational load defined in eq. (14) was evenly distributed on two Xeon E5-2680 v3 processors with total number of 96 cores. There was no significant difference in computation time between subsystems, it took 15 minutes to finish on average, apart from AUX subsystem which required almost 12 hours of calculations to finish.

Since lognormal distribution was applied in the Sobol sequence generation, a non-parametric distribution of the Inherent Unavailability will be fitted to a lognormal distribution. The IU estimators of mean and standard deviation of the log(IU), denoted by μ and σ, respectively, are calculated in twofold.

First method is based on direct calculation of estimators of the μ and σ from standard equations:

$$\hat{\mu} = \frac{1}{N}\sum_{i=1}^{N} x_i \tag{15a}$$

$$\hat{\sigma} = \left(\frac{1}{N}\sum_{i=1}^{N} \left(x_i - \mu \right)^2 \right)^{1/2} \tag{15b}$$

Second method is based on application of the python module *scipy.stats*, specifically *lognorm.fit* function. This function returns, apart from μ and σ estimators, the "loc" parameter, which add an extra degree of freedom in the estimator by allowing for shifts in the data. For each scenario simulated, the Kolmogorov-Smirnov test was performed on both estimators in order to check the goodness of each fit. Based on obtained p-values the better fit was selected to represent the empirical data. All estimators are summarized in Table 1.

For the estimators that give the closest fits, the probability density functions (PDF) and the cumulative distribution functions (CDF) were plotted to see how they compare to the data. The PDFs are compared with histograms of IU data for each considered scenario (see Figure 7) while the CDFs

Table 1. Lognormal estimators of IU.

Mode	$\hat{\mu}$	$\hat{\sigma}$	'loc'
AUX	–5.8	0.44	0.001
LCS	–8.12	0.46	5e-5
LEBT	–7.24	0.28	–
SES	–6.53	0.50	–

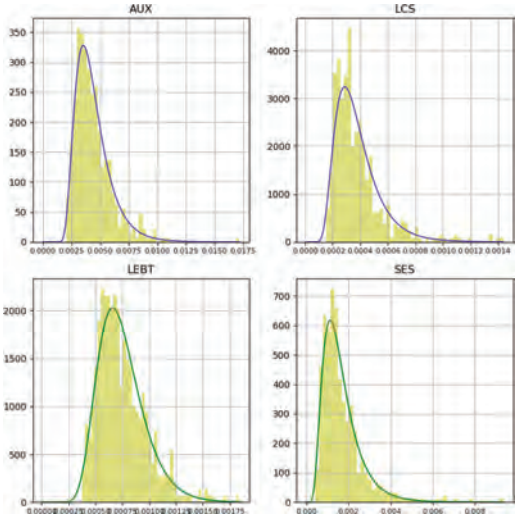

Figure 7. The PDFs fitted to simulated IU (histogram) obtained with lognormal.fit (blue) or classic estimators (green) for each mode considered (SES, LEBT, LCS, AUX).

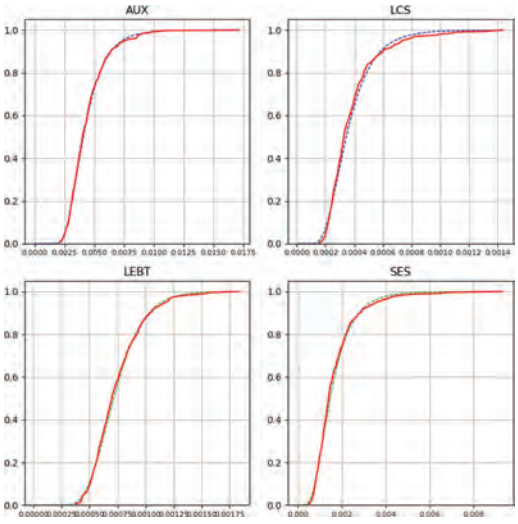

Figure 8. The CDFs fitted to simulated IU (histogram) obtained with lognormal.fit (blue) or classic estimators (green) for each mode considered (SES, LEBT, LCS, AUX).

are compared with empirical CDF of the dataset for each simulated scenario (see Figure 8).

4.5 *Complete GUA for the overall Injector system*

After the procedure was performed on all the four modes, the subsystem data were then combined in order to describe the complete Injector system of the IFMIF in the modular fashion described in Section 3.4.

To complete the analysis it is first necessary to estimate the impact of the Residual term on the uncertainty of the Injector system. To do that it is required to estimate the probability of the coincidental occurrences of the events from distinctive four subsystems. With some simple but tedious combinatorial calculations it can be shown that the probability of the coincidence of the multiple failure events (i.e., of the components coming from distinctive subsystems of the Injector) is bounded by 5e-5, where the boundary is very conservative by taking maximum failure probabilities across all the considered events. This means that the impact of *Residual* is similar to the impact of a single failure event. Thus, given that there are more than 500 events considered in the complete Injector system, the impact of *Residual* on the uncertainty of the IA can be assessed as negligible.

Consequently we estimate the IA of the complete Injector with the lower bound given in (12). Note that for each module considered the lognormal uncertainties in the input propagate into

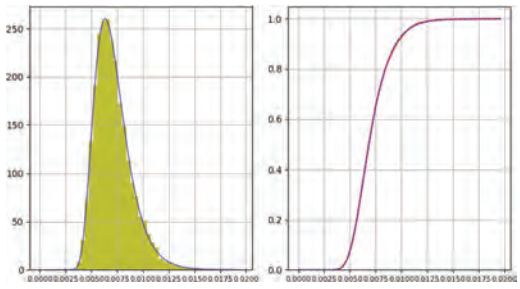

Figure 9. The PDF and CDF fitted to simulated IU (histogram, red) obtained with parametric estimators for the complete Injector.

Table 2. Summary statistics for the IA.

Mode	Mean [%]	Std [%]	1st percentage [%]	Error factor [%]
AUX	99.56	0.17	99.03	1.0057
LCS	99.96	0.019	99.89	1.0008
LEBT	99.93	0.023	99.85	1.0008
SES	99.83	0.104	99.39	1.0047
INJ	99.29	0.177	98.75	1.0057

quasi-lognormals in the outputs. Thanks to this property we were able to approximate the posterior IU distribution of the complete Injector in a parametric way, i.e., the sample distribution of IU for the complete Injector system is obtained by summing samples generated independently from lognormals obtained in previous section. The empirical distribution of 10,000 such generated system data is presented in Figure 9, which shows that the posterior uncertainty distribution of the complete Injector system can also be well approximated with lognormals.

To complete the analysis Table 2 presents summary statistics for individual modes and for the complete Injector system.

5 CONCLUSIONS & DISCUSSION

In this paper a general framework to conduct Modular Global Uncertainty Analysis (GUA) for event-driven RAMI indicators has been introduced. The method proposed is based on a two-level probabilistic simulations conducted in a modular manner, which makes it applicable to a broad range of RAMI problems. The main advantages of the proposed method lie in:

a. numerical efficiency: when compared with standard simulation technics based on Monte

Carlo methods, the proposed algorithm significantly reduces the computational complexity of the problem;

b. completeness: performing GUA makes it possible to estimate the posterior uncertainty distribution of systems' outputs from marginal distributions of systems' inputs;
c. modularity: with the proposed method it is possible to estimate the posterior distributions of systems' modules independently and combine them to produce the complete posterior distribution of the systems' outputs.

We have demonstrated that these three properties are satisfied by applying the proposed Modular GUA method to study the Injector system within the International Fusion Materials Irradiation Facility (IFMIF). For this system, the indicator of inherent availability (IA) can be well approximated with IA indicators obtained independently for four modules: SES, LEBT, LCS, AUX. This is possible due to a weak influence of the Residual that characterizes the impact of the coincidental failures of at least two events from different modules.

We finish the paper with the discussion on limitations of the proposed Modular GUA procedure. Firstly, the presented approach is focused on the analysis of the impacts of the uncertainty in the inputs to the system and does not deal with the impacts of structural uncertainties present in the system (e.g., uncertainties about MAT, MRT, logistic processes). Secondly, within the proposed GUA algorithm it is assumed that the uncertain failure rates of the components are within a Normal Life Cycle, which means that the failure rates are fixed for the whole duration of the simulated system life cycle. Consequently, further research is required to make the method applicable to problems with time-varying failure rates that are associated with infant or wear out exploitation stages of system's components. Thirdly, in general, the impact of Residual might not be negligible as was the case for the Injector system and without analyzing it in detail the right-hand side of (12) will underestimate the true uncertainty in system output. There are several possible ways to analyze the uncertainty associated with non-negligible residual, e.g., if the residual had an impact of another module, it could be handled by incorporating a virtual module of equivalent characteristics into online simulations to update global uncertainty profile. Another possible approach would be to perform (offline) screening on interactions to identify these that matter the most and incorporate them as an interaction module into the simulations—this could be useful in the analysis of sensitivity of the system. Finally, the events rejected during the screening phase due to their marginal contribution on system's availability, might have influential impact taken cumulatively. Therefore, it is desirable to incorporate into the existing procedure a routine that would quantify the uncertainty impact of the least influential events taken collectively. With such procedure we could validate the correctness of cut-off threshold setting.

All the three aforementioned concerns regarding the proposed Modular GUA procedure are a subject of ongoing research.

A performance-margin-based belief reliability model considering parameter uncertainty

Qingyuan Zhang, Meilin Wen, Rui Kang & Tianpei Zu
School of Reliability Engineering and Systems Engineering, Beijing, China

ABSTRACT: Belief reliability is a newly developed reliability metric considering aleatory and epistemic uncertainty. Since Performance Margin (PM) is an important concept in belief reliability, there is a great need to develop PM-based belief reliability models. In this paper, we consider the parameter uncertainty of PM and propose a new belief reliability model. In this model, the performance parameter and its threshold, which determines the PM of a system, can be modeled as an uncertain variable or a random variable, and three belief reliability formulas are put forward based on different cases. To illustrate the model, a case study about belief reliability estimation of a contact recording head is performed.

1 INTRODUCTION

Nowadays, there is a growing interest in physical model-based reliability metric (cf. Physics-of-Failure (PoF) model based metric (Zeng et al. 2016), structural reliability metric (Choi et al. 2007), etc.), where reliability is predicted using deterministic physical models. The only uncertainty comes from the parameter variations, which are modeled as probability distributions. However, in real cases, besides the random variations (referred to as aleatory uncertainty (Kiureghian & Ditlevsen 2009)) affecting parameters, the physical model is also influenced by epistemic uncertainty caused by our lack of knowledge (Kiureghian & Ditlevsen 2009). For example, the model parameters may not be estimated accurately due to our limited knowledge about the system operation environment (Aven et al. 2014).

Considering the effect of epistemic uncertainty, many reliability metrics are proposed, such as evidence theory-based reliability metric (Bae et al. 2004), interval analysis-based reliability metric (Zhang et al. 2017), fuzzy interval analysis-based reliability metric (Flage et al. 2013) and posbist reliability metric (Cai 1996). The first three metrics are essentially reliability intervals which may cause interval extension problems, while the last one is a possibility measure which does not satisfy duality property (Kang et al. 2016). Recently, a new reliability metric called belief reliability is developed considering both aleatory and epistemic uncertainty Zeng et al. 2017b). To model uncertainty, belief reliability introduces uncertainty theory and chance theory to measure system reliability. Uncertainty theory is proposed by Liu (2007) as a new branch of axiomatic mathematic, founded on normality, duality, subadditivity and product axioms, and chance theory can be regarded as a mixture of uncertainty theory and probability theory. According to Kang et al. (2016), since belief reliability overcomes the shortcomings of other reliability metrics, it is regarded as a more appropriate metric in reliability engineering.

The concept of performance margin plays an important role in belief reliability (Zeng et al. 2017a). Performance Margin (PM), denoted as m, describes the distance between a critical performance parameter p to its associated threshold p_{th}. By analyzing the physical model of a system, we can obtain the PM model. In this process, there may be two types of uncertainties affecting the physical model: parameter uncertainty caused by indeterministic model parameters and model uncertainty due to the inaccuracy of the physical model. Till now, several research have considered the model uncertainty and applied the belief reliability model to real industrial systems (see Zeng et al. (2017a) and Yu et al. (2017)). However, there are still strong needs to develop PM-based belief reliability models considering parameter uncertainty. Therefore, in this paper, we managed to propose a simple model accounting for parameter uncertainty for future application. To represent aleatory and epistemic uncertainty, the PM of a system is modeled as an uncertain random variable. If the system is mainly influenced by aleatory uncertainty, PM will degenerate to a random variable; if the system is mainly affected by epistemic uncertainty, PM will degenerate to an uncertain variable. Since the parameter uncertainty will essentially affect the p and p_{th}, we discuss the model from three aspects, i.e., p and p_{th} are all modeled as uncertain variables, p is a random variable while p_{th} is an uncertain variable, and p is an uncertain variable while p_{th}

is a random variable. Some basic belief reliability formulas based on uncertainty theory and chance theory are then proposed based on the three cases.

The remainder of this paper are organized as follows. In section 2, we will introduce some basic concepts and results of the theory basis, i.e., uncertainty theory and chance theory. The developed PM-based belief reliability model will be introduced in section 3. We will first give the definition of belief reliability in the sense of PM, and then put forward three formulas. Finally, a real case study is performed in section 4 to illustrate the model.

2 PRELIMINARY

In this section, some basic concepts and results of uncertainty theory and chance theory are introduced.

2.1 *Uncertainty theory*

Uncertainty theory is a new branch of axiomatic mathematics built on four axioms, i.e., Normality, Duality, Subadditivity and Product Axioms. Founded by Liu (2007) in 2007 and refined by Liu (2010) in 2010, uncertainty theory has been widely applied as a new tool for modeling subjective (especially human) uncertainties. In uncertainty theory, belief degrees of events are quantified by defining uncertain measures:

Definition 2.1. Uncertain measure, Liu (2007)). Let Γ be a nonempty set, and $\mathcal{L}$ be a σ-algebra over Γ. A set function $\mathcal{M}$ is called an uncertain measure if it satisfies the following axioms,

Axiom 1. Normality Axiom $\mathcal{M}\{\Gamma\}=1$ *for the universal set* Γ.

Axiom 2. *Duality Axiom* $\mathcal{M}\{\Lambda\}+\mathcal{M}\{\Lambda^c\}=1$ *for any event* $\Lambda\in\mathcal{L}$.

Axiom 3. Subadditivity Axiom *For every countable sequence of events* $\Lambda_1,\Lambda_{2,\cdots}$, we have

$$\mathcal{M}\left\{\bigcup_{i=1}^{\infty}\Lambda_i\right\}\le\sum_{i=1}^{\infty}\mathcal{M}\{\Lambda_i\}.$$

Uncertain measures of product events are calculated following the product axiom (Liu 2009):

Axiom 4. Product Axiom. *Let* $(\Gamma_k,\mathcal{L}_k,\mathcal{M}_k)$ *be uncertainty spaces for* $k=1,2,\cdots$. *The product uncertain measure* $\mathcal{M}$ *is an uncertain measure satisfying*

$$\mathcal{M}\left\{\prod_{k=1}^{\infty}\Lambda_k\right\}=\bigwedge_{\infty}^{k=1}\mathcal{M}_k\{\Lambda_k\},$$

where $\mathcal{L}_k$ *are* σ*-algebras over* Γ_k, *and* Λ_k *are arbitrarily chosen events from* $\mathcal{L}_k$ *for* $k=1,2,\cdots$, *respectively.*

Definition 2.2. Uncertain variable, Liu (2007)). An uncertain variable is a function ξ from an uncertainty space $(\Lambda,\mathcal{L},\mathcal{M})$ to the set of real numbers such that $\{\xi\in\mathcal{B}\}$ is an event for any Borel set $\mathcal{B}$ of real numbers.

Definition 2.3. Uncertainty distribution, Liu (2007)). The uncertainty distribution Φ of an uncertain variable ξ is defined by $\Phi(x)=\mathcal{M}\{\xi\le x\}$ for any real number x.

For example, a linear uncertain variable $\xi\sim\mathcal{L}(a,b)$ has an uncertainty distribution

$$\Phi_1(x)=\begin{cases}0, & \text{if } x<a\\ \dfrac{x-a}{b-a}, & \text{if } a\le x\le b\\ 1, & \text{if } x>b\end{cases}\tag{2.1}$$

and a normal uncertain variable $\xi\sim\mathcal{N}(e,\sigma)$ has an uncertainty distribution

$$\Phi_2(x)=\left(1+\exp\left(\frac{\pi(e-x)}{\sqrt{3}\sigma}\right)\right)^{-1},\ x\in\Re\tag{2.2}$$

An uncertainty distribution Φ is said to be regular if it is a continuous and strictly increasing with respect to x, with $0<\Phi(x)<1$, and $\lim_{x\to-\infty}\Phi(x)=0,\lim_{x\to+\infty}\Phi(x)=1$. A regular uncertainty distribution has an inverse function, which is defined as the inverse uncertainty distribution, denoted by $\Phi^{-1}(\alpha),\alpha\in(0,1)$. Inverse uncertainty distributions play a central role in uncertainty theory, since the uncertainty distribution of a function of uncertain variables is calculated using the inverse uncertainty distributions:

Theorem 2.1. (Operational law 1, Liu (2010)). *Let* $\xi_1,\xi_2,\cdots,\xi_n$ *be independent uncertain variables with regular uncertainty distributions* $\Phi_1,\Phi_2,\cdots,\Phi_n$, *respectively. If* $f(\xi_1,\xi_2,\cdots,\xi_n)$ *is strictly increasing with respect to* $\xi_1,\xi_2,\cdots,\xi_m$ *and strictly decreasing with respect to* $\xi_{m+1},\xi_{m+2},\cdots,\xi_n$ *then* $\xi=f(\xi_1,\xi_2,\cdots,\xi_n)$ *has an inverse uncertainty distribution*

$$\psi^{-1}(\alpha)=f\left(\Phi_1^{-1}(\alpha),\cdots,\Phi_m^{-1}(\alpha),\Phi_{m+1}^{-1}(1-\alpha),\Phi_n^{-1}(1-\alpha)\right).$$

Theorem 2.2 (Operational law 2, Liu (2010)). *Let* $\xi_1,\xi_2,\cdots,\xi_n$ *be independent uncertain variables with continuous uncertainty distributions* $\Phi_1,\Phi_2,\cdots,\Phi_n$, *respectively. If* $f(\xi_1,\xi_2,\cdots,\xi_n)$ *is strictly increasing with respect to* $\xi_1,\xi_2,\cdots,\xi_m$ *and strictly decreasing with respect to* $\xi_{m+1},\xi_{m+2},\cdots,\xi_n$, *then* $\xi=f(\xi_1,\xi_2,\cdots,\xi_n)$ *has an uncertainty distribution*

$$\psi(x)=\sup_{f(x_1,x_2,\cdots,x_n)=x}\left(\min_{1\le i\le m}\Phi_i(x_i)\wedge\min_{m+1\le i\le n}\left(1-\Phi_i(x_i)\right)\right).$$

2.2 *Chance theory*

Chance theory is founded by Liu (2013b) as a mixture of uncertainty theory and probability theory, to deal with problems affected by both aleatory uncertainty (randomness) and epistemic uncertainty. The basic concept in chance theory is the chance measure of an event in a chance space.

Let $(\Gamma,\mathcal{L},\mathcal{M})$ be an uncertainty space, and $(\Omega,\mathcal{A},\Pr)$ be a probability space. Then $(\Gamma,\mathcal{L},\mathcal{M})\times(\Omega,\mathcal{A},\Pr)$ is called a chance space.

Definition 2.4. (chance measure, Liu (2013b)). Let $(\Gamma,\mathcal{L},\mathcal{M})\times(\Omega,\mathcal{A},\Pr)$ be a chance space, and let $\Theta\in\mathcal{L}\times\mathcal{A}$ be an event. Then the chance measure of Θ is defined as

$$\mathrm{Ch}\{\Theta\}=\int_0^1\Pr\{\omega\in\Omega\mid\mathcal{M}\{\gamma\in\Gamma\mid(\gamma,\omega)\in\Theta\}\ge x\}\,dx.$$

Definition 2.5 (Uncertain random variable, Liu (2013b)). An uncertain random variable is a function ξ from a chance space $(\Gamma,\mathcal{L},\mathcal{M})\times(\Omega,\mathcal{A},\Pr)$ to the set of real numbers such that $\{\xi\in B\}$ is an event in $\mathcal{L}\cdot\mathcal{A}$ for any Borel set B of real numbers.

Random variables and uncertain variables are two special cases of uncertain random variables. If an uncertain random variable $\xi(\gamma,\omega)$ does not vary with γ, it degenerates to a random variable. If an uncertain random variable $\xi(\gamma,\omega)$ does not vary with ω, it degenerates to an uncertain variable.

Definition 2.6. Let ξ be an uncertain random variable. Then its chance distribution is defined by $\Phi(x)=\mathrm{Ch}\{\xi\le x\}$ for any $x\in\Re$.

Theorem 2.3. (Liu 2013a) *Let $\eta_1,\eta_2,\cdots,\eta_m$ be independent random variables with probability distributions $\Psi_1,\Psi_2,\cdots,\Psi_m$, respectively, and let $\tau_1,\tau_2,\cdots,\tau_n$ be uncertain variables. Assume f is a measurable function. Then the uncertain random variable $\xi=f(\eta_1,\eta_2,\cdots,\eta_m,\tau_1,\tau_2,\cdots,\tau_n)$ has a chance distribution*

$$\Phi(x)=\int_{\Re^m}F(x;y_1,y_2,\cdots,y_m)\,d\Psi_1(y_1)\,d\Psi_2(y_2)\cdots d\Psi_m(y_m),$$

where $F(x;y_1,y_2,\cdots,y_m)$ is the uncertainty distribution of the uncertain variable $f(y_1,y_2,\cdots,y_m,\tau_1,\tau_2,\cdots,\tau_n)$.

3 THE BELIEF RELIABILITY MODEL

This section will develop the belief reliability model based on performance margin (PM). In subsection 3.1, we first give some basic definitions about PM and belief reliability, and discuss the source of uncertainty in PM. Then, three theorems are developed as reliability formulas in subsection 3.2 to calculate belief reliability indexes based on PM.

3.1 *Performance-margin-based belief reliability*

In an industrial system, there is usually a critical performance parameter with a failure threshold, describing the functional behavior and requirement of the system. In most cases, two categories of performance parameters exist:

1. Smaller-the-better (STB) parameters: Failure occurs when $p\ge p_{th}$.
2. Greater-the-better (GTB) parameters: Failure occurs when $p\le p_{th}$.

Definition 3.1. (Performance margin Let p be the critical performance parameter of a system, and p_{th} be its associated failure threshold. Then the performance margin m related to p is defined as:

$$m=\begin{cases}p_{th}-p, & \text{if } p \text{ is } STB,\\ p-p_{th}, & \text{if } p \text{ is GTB.}\end{cases}\tag{3.1}$$

It is easy to find that PM describe the distance between the performance parameter and its threshold, and failure occurs whenever $m\le 0$. In real cases, the PM is usually affected by both aleatory and epistemic uncertainties. Therefore, in this paper, we model the PM as an uncertain random variable and we have the following definition of belief reliability in the sense of PM.

Definition 3.2. (Belief reliability.) Let the system performance margin m be an uncertain random variable, then the system belief reliability is defined as the chance that m is greater than 0, i.e.,

$$R_B=\mathrm{Ch}\{m>0\}.\tag{3.2}$$

Remark 3.1. If the PM is mainly affected by aleatory uncertainty, m will degenerate to a random variable, and the belief reliability becomes $R_B=\Pr\{m>0\}$.

Remark 3.2. If the PM is mainly affected by epistemic uncertainty, m will degenerate to an uncertain variable, and the belief reliability becomes $R_B=\mathcal{M}\{m>0\}$.

The uncertainty of m comes from p and p_{th}. For the performance parameter, in practice, it is usually described by a physical model:

$$p = g(x_1, x_2, \cdots, x_n), \tag{3.3}$$

where $g(\cdot)$ denotes the deterministic model predicting p and $x_i, i = 1,2,\cdots,n$ denote input parameters. Due to the effect of aleatory and epistemic uncertainty, the input parameters are not crisp values anymore. To deal with the parameter uncertainty, the input parameters are usually modelled as random variables or uncertain variables. Therefore, p can be a random variable, an uncertain variable, or an uncertain random variable. For the failure threshold associated with p, it is usually regarded to be constant in traditional analysis. However, in some cases, p_{th} is also affected by uncertainty. For example, if p_{th} is estimated by experts, we model it as an uncertain variable; if p_{th} is estimated by experimental data, we tend to regard it as a random variable.

According to the above discussions, there may be four common conditions about p and p_{th}: (1) p and p_{th} are all random variables; (2) p and p_{th} are all uncertain variables; (3) p is random while p_{th} is uncertain; (4) p is uncertain while p_{th} is random. Since the first condition is similar to the traditional stress-strength interference reliability model, we only discuss the latter three conditions and develop some reliability formulas in next subsection.

3.2 *Reliability formula*

3.2.1 *Case I: p and p_{th} are all uncertain*

Theorem 3.1. *Suppose the system performance parameter p* and its associated threshold p_{th} are uncertain variables with uncertainty distributions $\Phi(x)$ *and* $\Psi(x)$, *respectively. Then the PM-based belief reliability of the system can be calculated by:*

$$R_B = \begin{cases} \sup\limits_{y \in \Re} \left(\Phi(y) \wedge \left(1 - \Psi(y)\right)\right), & \text{if } p \text{ is STB}, \\ \sup\limits_{y \in \Re} \left(\left(1 - \Psi(y)\right) \wedge \Psi(y)\right), & \text{if } p \text{ is GTB}. \end{cases}$$

Specially, if p_{th} is constant, the belief reliability will be

$$R_B = \begin{cases} \Phi(p_{th}), & \text{if } p \text{ is STB}, \\ 1 - \Phi(p_{th}), & \text{if } p \text{ is GTB}. \end{cases}$$

Proof Let $\xi = p - p_{th}$. Since p and p_{th} are all uncertain variables, ξ is also an uncertain variable. Here we assume the uncertainty distribution of ξ is $\Upsilon(x)$. According to Theorem 2.2, we have

$$\Upsilon(x) = \sup_{x_1 - x_2 = x} \left(\Phi(x_1) \wedge \left(1 - \Psi(x_2)\right)\right).$$

If p is a STB parameter, the belief reliability can be calculated as

$$\begin{aligned} R_B &= \mathcal{M}\{m > 0\} = \mathcal{M}\{p - p_{th} < 0\} = \Upsilon(0) \\ &= \sup_{y \in \Re} \left(\Phi(y) \wedge \left(1 - \Psi(y)\right)\right). \end{aligned}$$

When p_{th} is constant, it is easy to find

$$R_B = \mathcal{M}\{p < p_{th}\} = \Psi(p_{th}).$$

If p is a GTB parameter, the belief reliability can be calculated as

$$\begin{aligned} R_B &= \mathcal{M}\{m > 0\} = \mathcal{M}\{p - p_{th} > 0\} = 1 - \Upsilon(0) \\ &= 1 - \sup_{y \in \Re} \left(\Phi(y) \wedge \left(1 - \Psi(y)\right)\right) \\ &= \sup_{y \in \Re} \left(\left(1 - \Phi(y)\right) \wedge \Psi(y)\right). \end{aligned}$$

When p_{th} is constant, we have

$$R_B = \mathcal{M}\{p > p_{th}\} = 1 - \Phi(p_{th}).$$

3.2.2 *Case II: p is random while p_{th} is uncertain*

Theorem 3.2. *Suppose the system performance parameter p is a random variable with a probability distribution* $\Phi(x)$ *and the associated threshold p_{th} is an uncertain variables with an uncertainty distribution* $\Psi(x)$. *Then the PM-based belief reliability of the system can be calculated by:*

$$R_B = \begin{cases} \int_{-\infty}^{+\infty} 1 - \Psi(y) d\Phi(y), & \text{if } p \text{ is STB}, \\ \int_{-\infty}^{+\infty} \Psi(y) d\Phi(y), & \text{if } p \text{ is GTB}. \end{cases}$$

Proof The proof will be given from two aspects:

1. p is a STB parameter

Let $\xi = p - p_{th}$. Since p is a random variable while p_{th} is an uncertain variable, ξ is an uncertain random variable. Here we assume the chance distribution of ξ is $\Upsilon_1(x)$. According to Theorem 2.3, we have

$$\Upsilon_1(x) = \int_{-\infty}^{+\infty} F_1(x; y) d\Phi(y), \tag{3.4}$$

where $F_1(x;y)$ is the uncertainty distribution of an uncertain variable $q = y - p_{th}$. Based on Theorem 2.1, we have $F_1^{-1}(\alpha) = y - \Psi^{-1}(1 - \alpha)$, so $F_1(x;y)$ is $F_1(x; y) = 1 - \Psi(y - x)$. Then, (3.4) will be

$$\Upsilon_1(x) = \int_{-\infty}^{+\infty} 1 - \Psi(y - x) d\Phi(y).$$

Therefore, the belief reliability can be calculated by

$$\begin{aligned} &R_B = Ch\{p - p_{th} < 0\} = \Upsilon(0) \\ &= \int_{-\infty}^{+\infty} 1 - \Psi(y) d\Phi(y) \end{aligned}$$

2. p is a GTB parameter

Let $\eta = p_{th} - p$. It is easy to find η is an uncertain random variable. Assume its chance distribution if $\Upsilon_2(x)$, then we have

$$\Upsilon_2(x) = \int_{-\infty}^{+\infty} F_2(x;y)\, d\Phi(y), \tag{3.5}$$

where $F_2(x;y)$ is the uncertainty distribution of an uncertain variable $s = p_{th} - y$. Similarly, we have $F_2(x;y) = \Psi(x+y)$. Then, (3.5) will be

$$\Upsilon_2(x) = \int_{-\infty}^{+\infty} \Psi(x+y)\, d\Phi(y)$$

Therefore, the belief reliability can be calculated by

$$\begin{aligned} R_B &= Ch\{p_{th} - p < 0\} = \Upsilon(0) \\ &= \int_{-\infty}^{+\infty} \Psi(y)\, d\Phi(y) \end{aligned}$$

3.2.3 *Case III: p is uncertain while p_{th} is random*

Theorem 3.3. *Suppose the system performance parameter p is an uncertain variable with an uncertainty distribution $\Phi(x)$ and the associated threshold p_{th} is a random variables with a probability distribution $\psi(x)$. Then the PM-based belief reliability of the system can be calculated by:*

$$R_B = \begin{cases} \int_{-\infty}^{+\infty} \Phi(y)\, d\Psi(y), & \text{if } p \text{ is STB,} \\ \int_{-\infty}^{+\infty} 1-\Phi(y)\, d\Psi(y), & \text{if } p \text{ is GTB.} \end{cases}$$

Proof Since the proof of this theorem is similar to the previous one, it will not be repeated here.

4 CASE STUDY

In this section, we try to use the proposed model to analyze the static belief reliability of a contact recording head (Kawakubo, Miyazawa, Nagata, & Kobatake 2003). The contact recording head is a vital component of a contact recording system, which is used to achieve a recording density over 100 Gbits/in^2. Wear is the main failure mechanism of the recording head. To satisfy the recording density, the wear depth of the head cannot exceed 2 nm (determined by the overcoat thickness of the head) after 100h of using. Since a track seek also reciprocates during the disk rotation, the worn area is a donut.

Because the wear rate of the recording head decreases with increasing sliding distance in wear tests, to quantify the wear volume, an extended Archard's wear equation developed by Kawakubo, Miyazawa, Nagata, & Kobatake (2003) is utilized:

$$V = k_s \cdot L_s \cdot W \cdot \left(\frac{L}{L_s}\right)^{1-a} \left(\frac{B}{b}\right)^{a}, \tag{4.1}$$

where V denotes the wear volume, k_s denotes specific wear amount (SWA) at a standard sliding distance L_s, W denotes the sliding load, L denotes the total sliding distance, a denotes running-in coefficient ranging from 0 to 1, B denotes the sliding width, and b denotes the head contact width.

The uncertainty of this physical model may come from the input parameters. Among them, the coefficient a is relatively precise obtained by real experiment, k_s is calculated based on a and the material properties, L_s is determined by k_s, L is easily controlled to be a crisp value (total function time is 100h and the sliding speed is controlled to be 10m/s), and B and b are controlled during design and manufacturing phase. The only uncertain parameter is the W, which may be affected by many factors in real cases and we don't have enough data to estimate an accurate value. Therefore, in this paper, we model W as an uncertain variable following normal distribution (the form is shown in 2.2). Through uncertainty propagation, the uncertainty distribution of V can be easily calculated. In addition, since the threshold of V is given by experts according to the overcoat thickness of the head, it may be affected by epistemic uncertainty. To be more precise, we describe V_{th} as an uncertain variable as well. The values or the distributions of critical parameters are summarized in Table 1.

Table 1. Values or distributions of parameters.

Parameter	Value or distribution
SWA	$k_s = 2.55 \times 10^{-20}\,(m^2/N)$
Standard sliding distance	$L_s = 1000(m)$
Running-in coefficient	$a = 0.39$
Total sliding distance	$L = 3.6 \times 10^6\,(m)$
Sliding width	$B = 0.015(m)$
Head width	$b = 10^{-4}\,(m)$
Head contact area	$10^{-8}\,(m^2)$
Contact load	$W \sim \mathcal{N}(\mu = 0.7, \sigma = 0.03)\,(mN)$
Wear volume threshold	$V_{th} \sim \mathrm{L}(a = 2, b = 2.5)\,(10^{-17} m^3)$

1. $\mathcal{N}(\mu,\sigma)$ and $\mathcal{L}(a,b)$ are normal and linear uncertainty distributions in the form of (2.2) and (2.1), respectively.

Based on the operational laws of uncertainty theory, the wear volume of the head after 100h of using also follows a normal uncertainty distribution, i.e.,

$$V \sim \mathcal{N}\left(\mu_V = 1.8606, \sigma_V = 0.07974\right)\left(10^{-17} m^3\right),$$

Assume the distribution function of V and V_{th} are $\Phi_V(x)$ and $\Phi_{V_{th}}$, respectively. Since the wear volume V is a STB parameter, by using Theorem 3.1, the static belief reliability can be calculated to be

$$R_B = \sup_{x \in \Re}\left(\Phi_V(x) \wedge \left(1 - \Phi_{V_{th}}(x)\right)\right) = 0.97078.$$

5 CONCLUSIONS

In this paper, we develop some performance-margin-based belief reliability models using uncertainty theory and chance theory. Considering the uncertainty of performance parameter and its threshold, we discuss the model from three aspects: p and p_{th} are all uncertain variables, p is a random variable while p_{th} is an uncertain variable, and p is an uncertain variable while p_{th} is a random variable. Three theorems as belief reliability formulas are given. Finally, a case study about the static belief reliability evaluation of a contact recording head is performed to illustrate the reliability formulas.

Bayesian updating with time dependent models

P. Beaurepaire
CNRS, SIGMA Clermont, Institut Pascal, Université Clermont Auvergne, ClermontFerrand, France

ABSTRACT: Bayesian updating is increasingly used in structural engineering; it is applicable as an inverse method to identify the model of uncertainty which best matches some available experimental data. This paper introduces a novel method for the definition of the likelihood function in case the numerical model is a time dependent function. The set of time instants which best describes the experimental data is identified using the maximum entropy principle. The marginal distributions of the model response are identified as well using the maximum of entropy. The dependence between the responses of the model for the different time instants is implemented using the linear coefficients of correlation obtained after a mapping into standard normal distributions. The joint probability density function is subsequently used in the formulation of the likelihood function. The relevance of the method is demonstrated through an application example.

1 INTRODUCTION

Inverse methods are widely used in science and engineering; they consist of identifying the input parameter of a numerical model leading to an adequate match with available experimental data. Model updating techniques provide an appropriate framework and received considerable attention from structural engineers during the past decades (Friswell & Mottershead 1995, Imregun & Visser 1991, Arora 2011). They are applied in case a forward numerical model is available but it is not possible or numerically too demanding to evaluate the inverse model. Such methods are used for instance in case sensors collect the vibration data, which are subsequently used to identify modal information (amplitudes, modes, damping, etc). A finite element model is then implemented and model updating is used to identify the input parameters leading to the best fit with the experimental data.

Bayesian updating methods allow to identify the optimal parameter values and as well the probability density function associated with them (Beck & Katafygiotis 1998, Katafygiotis & Beck 1998). Considering a model $\mathcal{M}$, $\boldsymbol{\theta}$ the set of parameters to be updated from the experimental data $\mathcal{D}$ using Bayes' theorem, which expresses as:

$$p(\boldsymbol{\theta}|\mathcal{D},\mathcal{M}) = \frac{p(\mathcal{D}|\boldsymbol{\theta},\mathcal{M})\,p(\boldsymbol{\theta}|\mathcal{M})}{p(\mathcal{D}|\mathcal{M})} \tag{1}$$

where $p(\boldsymbol{\theta}|\mathcal{M})$ is the *prior distribution*, which gathers the initial knowledge on the parameters; $p(\mathcal{D}|\boldsymbol{\theta},\mathcal{M})$ is the *likelihood function*, which quantifies the match between the experimental data and the outcome of the numerical model; $p(\boldsymbol{\theta}|\mathcal{D},\mathcal{M})$ is the *posterior distribution*, a probability density function associated with the model parameters which considersthe information provided by the experimental data $\mathcal{D}$ and $p(\mathcal{D}|\mathcal{M})$ is the *evidence*, a constant guaranteeing that Equation (1) integrates to one.

Much research efforts on Bayesian updating are geared towards the implementation of computationally efficient numerical methods. The most frequently used approach consists of generating realizations of the posterior distribution and subsequently assuming that this set of realizations fully describes the posterior distribution. Markov chain Monte Carlo is frequently used in this context, as it can be applied to any arbitrarily given distribution. For instance, Ching and Chen (2007) proposed an efficient algorithm based on a sequence of intermediate distributions with a gradual convergence from the prior distribution to the posterior distribution, combined with an appropriate selection of the first state of the Markov chains; Beck and Zuev (2013) implemented a method based on importance sampling, Markov chain Monte Carlo and simulated annealing; Straub and Papaioannou (2015) introduced Bayesian Updating with Structural reliability methods (BUS), a procedure used to transform the updating problem into a reliability problem, which is subsequently solved with reduced efforts as multiple efficient algorithms are available for reliability analysis.

The focus of this paper is on the formulation of the likelihood involved in Equation (1). The formulation of this function is not difficult in case the

numerical model is a scalar function, it is possible to use for instance kernel density estimation (Goller 2011, Nagel & Sudret 2016). Specific formulations are available in case the problem involves modal data (Vanik, Beck, & Au 2000, Ching, Muto, & Beck 2006). In this paper, a novel implementation of the likelihood function is proposed in case the response of the numerical model is a time dependent function of the form:

$$y = f(t, \boldsymbol{\theta}) \tag{2}$$

where $\boldsymbol{\theta}$ denotes the uncertain parameters and t denotes time.

This manuscript is organized as follows: the methods of analysis are described in Section 2; Section 3 presents application examples and the paper closes with conclusions and perspectives in Section 4.

2 METHODS OF ANALYSIS

2.1 *Distribution at a given time instant*

In case Bayesian updating is applied, a set of experimental realizations of the numerical model is available and used to define the likelihood function. It is assumed here that it consists of a set of curves of the response of the model expressed in termsof time of the form $\left(y^{(1)}(t), y^{(2)}(t), ..., y^{(N_R)}(t)\right)$. The method developed here is applicable only in case the response of the model greater than zero for all the time instants.

The first step of the procedure is the discretization of the time dependent response of the model (as shown in Figure 1). A finite set of time instants $\boldsymbol{t} = \left[t_1, t_2, ..., t_{N_d}\right]$ is defined and the same discretization points are applied to all the experimental responses.

The response of the numerical model at the time t_i is a function involving uncertain parameters, it can therefore by modeled as a random variable Y. The probability density function associated with the model response needs to be identified for any predefined time instant. It is not possible to assign *a priori* a probability distribution (e.g. Gaussian, lognormal, uniform) with Y, as the most suitable distribution is problem dependent. Novi Inverardi and Tagliani (2003) proposed a flexible strategy to model the probability density function of an arbitrarily given distribution from a set of experimental data, it is expressed as:

$$p_Y(x \mid t_i) = \exp\left(-\sum_{j=0}^{M_i} \lambda_{ij} x^{\alpha_{ij}} \right) \tag{3}$$

where $p_Y(\cdot \mid t_i)$ denotes the probability density associated with the model response at the time t_i, $\lambda_i = \left(\lambda_{i1}, ..., \lambda_{iM_i}\right)$ and $\alpha_i = \left(\alpha_{i1}, ..., \alpha_{iM_i}\right)$ denote a set of parameters identified using the maximum entropy principle.

The distribution described in Equation (3) may be characterized by its fractional moments at the time instant t_i; which are expressed as:

$$\mu_{ij} = \mathrm{E}\left[y(t_i)^{\alpha_{ij}} \right] = \int_0^{\infty} x^{\alpha_{ij}} p_Y(x \mid t_i) \mathrm{d}x \tag{4}$$

These fractional moments can be estimated from the experimental data:

$$\mu_{ij} \approx \hat{\mu}_{ij} = \frac{1}{N_R} \sum_{j=1}^{N_R} \left(y^{(j)}(t_i) \right)^{\alpha_{ij}} \tag{5}$$

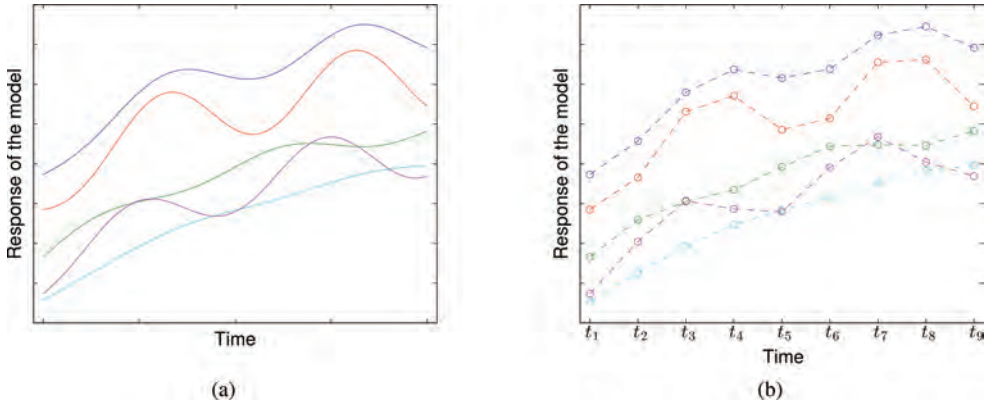

Figure 1. Schematic aspect of a time dependent response. Each curve can be associated with a realizations of the available data. (a) Original functions. (b) Discretization of the functions.

The identification of the maximum entropy distribution may be simplified using equispaced moments (see e.g. (Taufer, Bose, & Tagliani 2009)), i.e. $\alpha_{i0} = 0$ and $\alpha_{ij} = j\alpha_{i1}$ for $j > 1$. The coefficient λ_{i0} is used to guarantee that Equation (3) integrates to one; it is expressed as:

$$\lambda_{i0} = \ln\left[\int_0^{\infty} \exp\left(-\sum_{j=1}^{M_i} \lambda_{ij} x^{\alpha_{ij}} \right) \mathrm{d}x \right] \tag{6}$$

The integral involved in Equation (6) is estimated using Gauss-Laguerre quadrature.

The entropy associated with the distribution is expressed as:

$$\Gamma_i\left(\boldsymbol{\alpha}_{i1}, \ddot{\boldsymbol{e}}_i \right) = \lambda_{i0} + \sum_{j=1}^{M_i} \lambda_{ij} \hat{\mu}_{ij} \tag{7}$$

The maximum entropy distribution is subsequently identified using an optimization procedure to maximize Equation (7). The design variables of the optimization (i.e. the adjustable parameters) are α_{i1} and λ_i. The values of these coefficients obtained through the optimization procedure define a probability density function in good agreement with the experimental data.

The probability density function $p_Y(x \mid t_i)$ and its coefficients $\boldsymbol{\alpha}_i$ and $\boldsymbol{\lambda}_i$ should be expressed in terms of $\mathscr{D}$, as the experimental data is used to identify the coefficient value. However, this dependence is omitted in the notation to simplify the formulas.

It is referred to (Novi Inverardi & Tagliani 2003) for a detailed derivation of the equations described above, an in-depth discussion of the method and a procedure applicable to set the total number of fractional moments M_i to be used.

2.2 *Distribution associated with a set of time instants*

The experimental values of the numerical model for a set of time instants $\boldsymbol{t}$ are characterized by the marginal distributions and by the linear correlation coefficient. The procedure described in Section 2.1 is applied independently for all the time instants to identify the marginal distributions. The joint probability density function is subsequently defined using the Nataf' model (Nataf 1962, Liu & Der Kiureghian 1986), which is equivalent to using a Gaussian copula (see e.g. (Mai & Scherer 2012, Schölzel & Friederichs 2008)). Theiso-probabilistic transformation is used and auxiliary random variables with a standard normal distributions are introduced, they are defined as:

$$Z_i = \Phi^{-1}\left(P_{Y|_{t_i}}\left(Y\left(t_i \right) \right) \right) \tag{8}$$

where $P_{Y|_{t_i}}$ denotes the cumulative distribution function associated with the response of numerical model at the time instance t_i and Φ^{-1} denotes the inverse of the cumulative distribution function of the standard normal distribution. In the general case, the responses of the numerical model at the time instants t_i and t_j are correlated. Therefore, the random variables Z_i and Z_j are correlated as well. Their correlation coefficient is determined by applying the iso-probabilistic transformation to the experimental data:

$$\begin{aligned} z_i^{(k)} &= \Phi^{-1}\left(P_{Y|_{t_i}}\left(y^{(k)}\left(t_i \right) \right) \right) \\ &= \Phi^{-1}\left(1 - \int_{y^{(k)}(t_i)}^{\infty} p_Y(x \mid t_i) \mathrm{d}x \right) \end{aligned} \tag{9}$$

Gauss-Laguerre quadrature is used for the integral involved in Equation (9).

The coefficients of correlation are directly determined once all the experimental data are mapped into standard normal distributions. The joint probability density function of the numerical model's response is:

$$\begin{aligned} p_Y(\boldsymbol{x} \mid \boldsymbol{t}) = {} & p_Y(x_1 \mid t_1) p_Y(x_2 \mid t_2) \ldots p_Y(x_{N_d} \mid t_{N_d}) \\ & \cdot \frac{\varphi_{N_d}\left(\boldsymbol{z}, \boldsymbol{R} \right)}{\varphi\left(z_1 \right) \varphi\left(z_2 \right) \ldots \varphi\left(z_{N_d} \right)} \end{aligned} \tag{10}$$

where φ denotes the probability density function of a standard normal distribution, φ_{N_d} denotes the joint probability density function associated with a multivariate standard normal distribution, $\boldsymbol{R}$ being the matrix containing thecoefficients of correlation.

Alternative strategies may be considered to account for the correlation between the responses of the numerical model at different time instants. For instance, copulas offer a rational framework to considered alternative dependence structures. However, thejoint probability density function described in Equation (10) is involved in the definition of the objective function of an optimization problem (as discussed in the next subsection). Therefore, a large number of density functions need to be defined in an iterative way, which may become challenging in case multiple structures of dependence need to be considered. Only the Nataf model is implemented in this work for the sake of simplicity.

2.3 *Identification of a representative set of time instants*

A reduced set of time instants $\boldsymbol{t}$ needs to be identified to define the likelihood function and the maximum entropy principle is used as the quantity of information extracted from the experimental data can

be maximized using this technique (Jaynes 1957a, Jaynes 1957b). The entropy associated with $\boldsymbol{t}$ is:

$$\Gamma(\boldsymbol{t}) = \int_0^\infty \ldots \int_0^\infty p_Y(\boldsymbol{x}\,|\,\boldsymbol{t}) \ln\left(p_Y(\boldsymbol{x}\,|\,\boldsymbol{t})\right) \mathrm{d}\boldsymbol{x} \tag{11}$$

The expression of the joint probability density function expressed in Equation (10) can be injected in Equation (11); this formula can be expanded and simplified. This procedure is not derived in details herein and the simplified formulaof the entropy is:

$$\Gamma(\boldsymbol{t}) = \sum_{j=0}^{M} \Gamma_i + \frac{1}{2} \ln \det\left(2\pi e \boldsymbol{R}\right) \tag{12}$$

where Γ_i is the entropy defined in Equation (7). The term on the left-hand side of Equation (12) is the contribution of the marginal distributions to the total entropy and the term on the right-hand side is the contribution of the correlation. The set of time instants which best represents the experimental data is obtained by maximizing Equation (12):

$$\hat{\boldsymbol{t}} = \boldsymbol{t} \arg\max \Gamma(\boldsymbol{t}) \tag{13}$$

$\hat{\boldsymbol{t}}$ may be interpreted as the set of N_d instants which contains the maximum of information from the experimental data. It is therefore subsequently used in the definition of the likelihood function.

2.4 *Bayesian updating*

The likelihood function involves the numerical model y, which needs to be evaluated for the time instants maximizing Equation (12). It involves as an input the values of the uncertain parameters $\boldsymbol{\theta}$. The formulation of thelikelihood function is well known and widely applied in statistics in case realizations of a random variable and its probability density function are available. In the present problem, the joint probability density function described in the previous subsequently is used and only one realization is considered; it is the response of the numerical model associated with $\boldsymbol{\theta}$. The likelihood function is:

$$p(\mathscr{D}\,|\,\hat{\boldsymbol{e}}, \mathscr{M}) = p_Y(\boldsymbol{y}(\hat{\boldsymbol{t}}, \hat{\boldsymbol{e}})\,|\,\hat{\boldsymbol{t}}) \tag{14}$$

with $\boldsymbol{y}(\hat{\boldsymbol{t}}, \boldsymbol{\theta}) = \left[y(\hat{t}_1, \boldsymbol{\theta}), y(\hat{t}_2, \boldsymbol{\theta}), \ldots, y(\hat{t}_{N_d}, \boldsymbol{\theta}) \right]$. The dependence with respect to the experimental data $\mathscr{D}$ is not explicitly stated in the right hand side of refeqeq:likelihood. Nevertheless, this dependence is carried by the correlation matrix and by the coefficient α_{i1} and ν_i involved in the definition of the marginal distributions. Therefore, the value of the likelihood functions associated with $\boldsymbol{\theta}$ is changed in case the experimental data is modified or expanded. Samples of the posterior distribution expressed in Equation (1) are generated using crude Monte Carlo simulation as the application examples are numerically inexpensive. Advanced methods may be applied as well as the choice of the updating algorithm does not affect the relevance of the proposed formulation of the likelihood function.

3 APPLICATION EXAMPLES

3.1 *Damped oscillator*

The methods described in the previous section are applied to an example involving a mass spring damper system as shown in Figure 2. A force F is applied at the time $t = 0$ and the quantity of interest is the displacement of the mass during 25 seconds. This problem has an analytical solutions which is used as the numerical model. The applied force and the mass are deterministic and arbitrarily set to 1 N and 1 kg, respectively, and the same parameter value is used during the updating.12 samples of the damping and of the stiffness are selected arbitrarily and the corresponding displacement of the mass is determined. These trajectories of the displacement of the mass are used as the experimental data and Bayesian updating is subsequently used to identify the posterior distribution of the uncertain parameters. Therefore, this example does not consider model uncertainty, as the same model is used to generate the experimental data and during the updating procedure.

The prior distributions are uniform between 0.5 and 2 for both the stiffness of the spring and the damping coefficient, which corresponds to a *non-informative* prior distribution between the predefined ranges. It is initially assumed that all the regions of the domain are equally likely to contain samples of the uncertain parameters. Two fractional moments are used to define the marginal probability density functions associated with the experimental data expressed in Equation (3), i.e. $M_i = 2$ for all the time instants.

The procedure described in Section 2 does not provide any strategy to set N_d, the total number

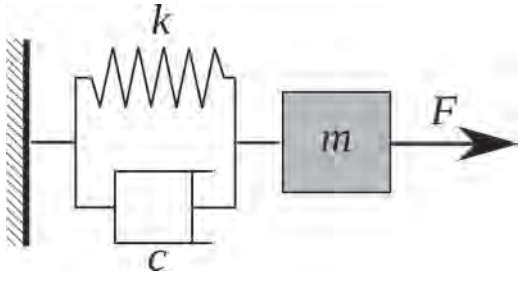

Figure 2. Mass spring damper system.

of representative time instants to be used for the updating. It is arbitrarily set to 1, 2, 3 and 5 and the results are shown in Figure 3.

3.2 *Over-constrained beam model*

The second example considered here is an over-constrained beam model as shown in Figure 4. The left hand side of the beam is clamped, the right hand side is simply supported and two forces are applied. All the units are expressed using the metricsystem (and the forces are therefore defined in Newtons). The Young's modulus of the material is equal to 200GPa, the total length of the beam is L = 1m and the moment of inertia is equal to 10^{-4}m^4. The random variables involved in the model are the forces f_1 and f_2. 20 samples are arbitrarily generated, the corresponding deflection of the beam is computed for all the coordinates of the beam and subsequently used during the Bayesian updating procedure. Therefore, the quantity of interest (i.e. the beam deflection) is expressed with respect to a space parameter. Even though a time parameter is considered in the description of the methods in Section 2; these procedures remain applicable without loss of generality to any parameterdependent problem and can therefore be applied to this example.

For both forces, the prior distribution is uniform between 4 and 16kN. Three fractional moments are used in the definition of the marginal distributions which define the likelihood function. As in the previous example, the parameter N_d (i.e. the dimensionality of the set of random variables used in the definition of the likelihood function) is arbitrarily set to 1, 2, 3 and 5. Figure 5 shows the results obtained from the Bayesian updating procedure.

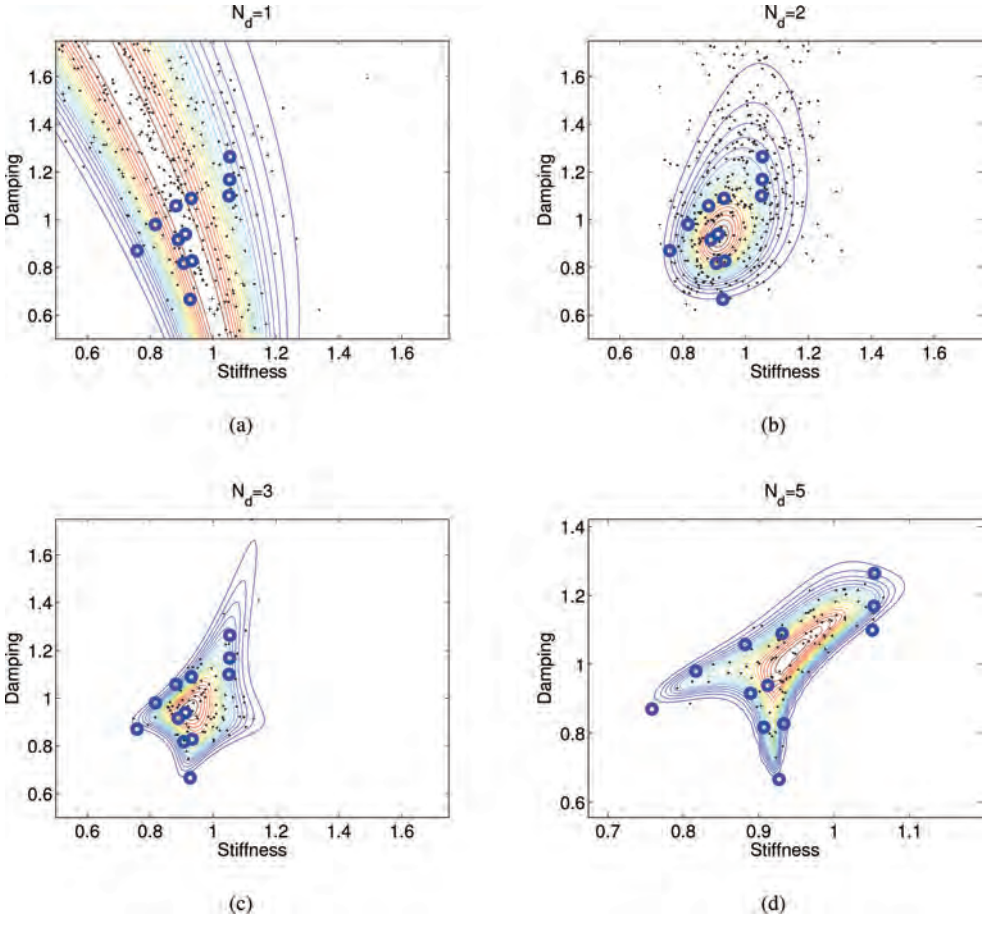

Figure 3. Results of the Bayesian updating procedure for the damped oscillator. The contour lines represent the iso-values of the posterior distribution, the dots represent realizations of this distribution and the circles are the samples used to generate the experimental data. (a) $N_d = 1$. (b) $N_d = 2$. (c) $N_d = 3$. (d) $N_d = 5$.

3.3 *Discussion*

For the two considered examples, the results are strongly influenced by N_d, the dimensionality of the set defining the likelihood function.

In case $N_d = 1$, a poor match between the posterior distributions and the samples used to generate the experimental data is observed. It is indeed not possible to identify the bivariate distribution function associated with the input parameters using a single response of the model, as an infinite number of values of the input parameters can be associated with the response.

The posterior distribution is smooth and regular for $N_d = 2$. In this case, the results are also in good agreement with the dependence in the experimental data. Moreover, it is graphically observed in the first example that the experimental input values are slightly positively correlated and negatively correlated in the second example. The same trend can be seen in the posterior distribution for both examples.

In case $N_d = 3$ and $N_d = 5$, the posterior distribution becomes irregular; it seems that the experimental data are over-fitted. The surface included in a contour line of the posterior distribution is non-convex and the regions of the parameter domain inthe vicinity of the samples used to generate the experimental data are favored (i.e. the posterior distribution has higher values in these regions).

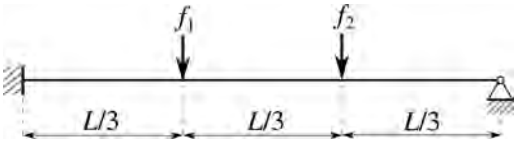

Figure 4. Over-constrained beam model.

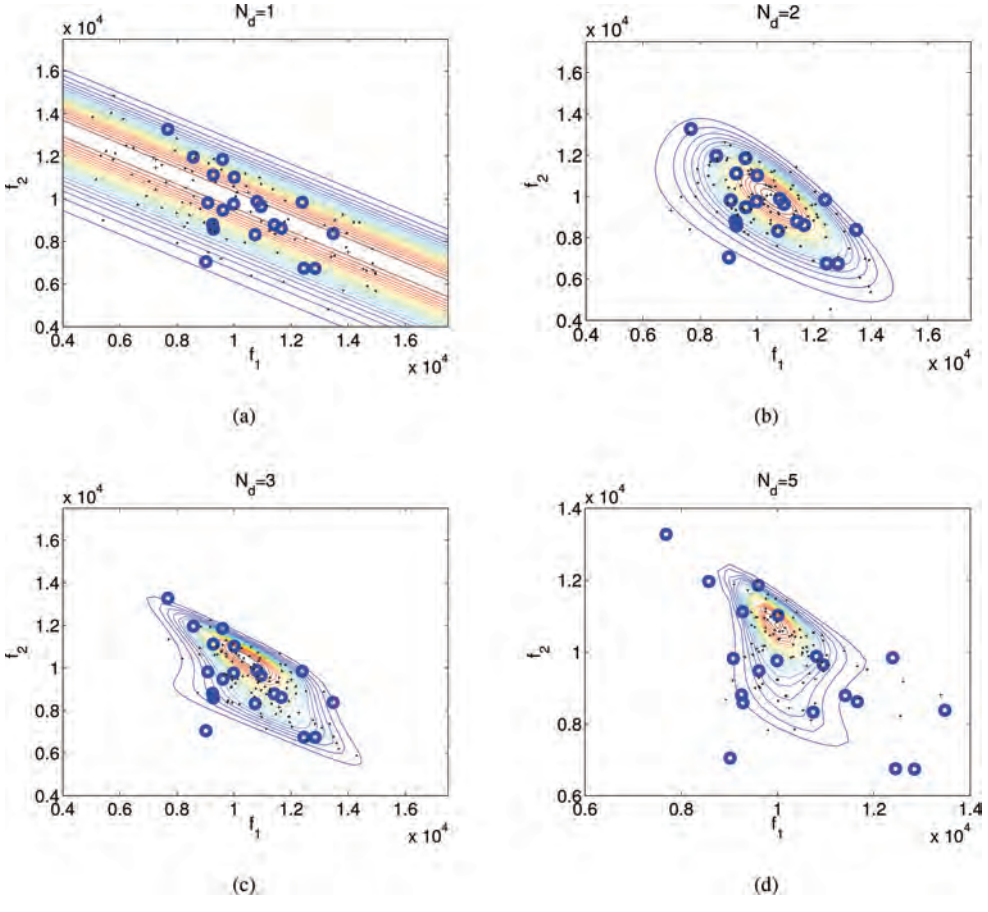

Figure 5. Results of the Bayesian updating procedure for the beam model. The contour lines represent the iso-values of the posterior distribution, the dots represent realizations of this distribution and the circles are the samples used to generate the experimental data. (a) $N_d = 1$. (b) $N_d = 2$. (c) $N_d = 3$. (d) $N_d = 5$.

In case the Bayesian updating problem does not include model uncertainties, N_d should not be greater than the dimensionality of the problem. For both examples, all the samples of the models' response used to define the likelihood function lay on a bidimensional manifold (included in a space of dimension three or five). The strategy used to define the joint probability density function associated with the response of the model becomes inappropriate, leading to the poor fit between the posterior distribution and the samples used to define the experimental data. example. As the the linear correlation coefficients are used to model the dependence between the model's response for the various time instants, the first two eigenvalues of the correlation matrix are non-negligible and all the other eigenvalues are verysmall

It seems to be empirically observed from these examples that the N_d should be equal to the total number of parameters involved in the model of uncertainty in case the problem does not involve model uncertainties.

4 CONCLUSIONS

This paper describes a method for the formulation of the likelihood function used for Bayesian updating of time dependent models. The maximum entropy principle is used to (I) define the marginal distributions for all the time instants; (II) identify the set of time instants which best represent the response of the model. The joint probability density function is defined by its marginals and by the matrix of the linear coefficients of correlation obtained after the Nataf transformation. This probability density function is subsequently used in the formulation of the likelihood, the definition of this function generally used in statistics is applied here.

The method is applied with success to a problem involving the response in the time domain of a spring damper system with two uncertain parameters: the stiffness of the spring and the damping coefficient.

The example heuristically suggests to use a parameter N_d equal to the total number of uncertain parameters involved in the numerical model (at least in case there are no model uncertainties).

Future work is geared towards the application of this method to examples involving model uncertainties and a larger number of random variables.

Advanced methodology for uncertainty propagation in computer experiments with large number of inputs: Application to accidental scenario in a pressurized water reactor

ABSTRACT: Complex computer codes are often too time expensive to be directly used to perform uncertainty propagation or sensitivity analysis. A solution to cope with this problem consists in replacing the cpu-time expensive computer model by a cpu inexpensive mathematical function, called metamodel. Among the metamodels classically used in computer experiments, the Gaussian process (Gp) model has shown strong capabilities to solve practical problems. However, in case of high dimensional experiments (with typically several tens of inputs), the Gp metamodel building process remains difficult. To face this limitation, we propose a general methodology which combines several advanced statistical tools. First, an initial space-filling design is performed providing a full coverage of the high-dimensional input space (Latin hypercube sampling with optimal discrepancy property). From this, a screening based on dependence measures is performed. More specifically, the Hilbert-Schmidt independence criterion which builds upon kernel-based approaches for detecting dependence is used. It allows ordering the inputs by decreasing primary influence, for the purpose of the metamodeling. Furthermore, significance tests based either on asymptotic theory or permutation technique are performed to identify a group of potentially non-influential inputs. Then, a joint Gp metamodel is sequentially built with the group of influential inputs as explanatory variables. The residual effect of the group of non-influential inputs is captured by the dispersion part of the joint metamodel. Then, a sensitivity analysis based on variance decomposition can be performed through the joint Gp metamodel. The efficiency of the methodology is illustrated on a thermal-hydraulic calculation case simulating accidental scenario in a Pressurized Water Reactor.

1 INTRODUCTION

Quantitative assessment of the uncertainties tainting the results of computer simulations is nowadays a major topic of interest in both industrial and scientific communities. One of the key issues in such studies is to get information about the output when the numerical simulations are expensive to run. For example, in nuclear engineering problems, one often faces up with cpu time consuming numerical models and, in such cases, uncertainty propagation, sensitivity analysis, optimization processing and system robustness analysis become difficult tasks using such models. In order to circumvent this problem, a widely accepted method consists in replacing cpu-time expensive computer models by cpu inexpensive mathematical functions, called metamodels (Fang et al. 2006). This solution has been applied extensively and has shown its relevance especially when simulated phenomena are related to a small number of random input variables (see Forrester et al. (2008) for example).

However, in case of high dimensional numerical experiments (with typically several tens of inputs), depending on the complexity of the underlying numerical model, the metamodel building process remains difficult, even unfeasible. For example, the Gaussian process (Gp) model (Santner et al. 2003) which has shown strong capabilities to solve practical problems, has some caveats when dealing with high dimensional problems. The main difficulty relies on the estimation of Gp hyperparameters. Manipulating pre-defined or well-adapted Gp kernels (as in Muehlenstaedt et al. (2012), Durrande et al. (2013)) is a current research way, while coupling the estimation procedure with variable selection techniques has been proposed by several authors (Welch et al. 1992, Marrel et al. 2008, Woods and Lewis 2017).

In this paper, following the latter technique, we propose a rigorous and robust method for building a Gp metamodel with a high-dimensional vector

of inputs before using it to perform variance-based sensitivity analysis.

To build this metamodel, we use a sequential methodology where the technical core are updated with more relevant statistical techniques. For example, the screening step is raised by the use of recent and powerful techniques in terms of variable selection using a small number of model runs. Second, contrary to the previous works, we do not remove the non-selected inputs from the Gp model, keeping the uncertainty caused by the dimension reduction by using the joint metamodel technique (Marrel et al. 2012). The integration of this residual uncertainty is important in terms of robustness of subsequent safety studies and sensitivity analysis. Finally, a sensitivity analysis based on variance decomposition is performed through the joint Gp metamodel, yielding both the estimation of the influence of each selected inputs and the total effect of the group of non-selected inputs.

Each step of our methodology is detailed in a dedicated section and illustrated on a guideline application, namely a thermal-hydraulic calculation case simulating accidental scenario in a nuclear reactor. This use-case is first described in the following section.

2 THERMAL-HYDRAULIC TEST-CASE

Our use-case consists in thermal-hydraulic computer experiments, typically used in support of regulatory work and nuclear power plant design and operation. Indeed, some safety analysis considers the so-called "Loss Of Coolant Accident" (LOCA), which takes into account a double-ended guillotine break with a specific size piping rupture. It is modeled with code CATHARE 2.V2.5 which simulated the thermalhydraulic responses during a LOCA in a Pressurized Water Reactor (Mazgaj et al. 2016).

In this use-case, $d = 27$ scalar input variables of CATHARE are uncertain. They correspond to various system parameters as initial conditions, boundary conditions, some critical flowrates, interfacial friction coefficients, condensation coefficients, … The output variable of interest is a single scalar which is the maximal peak cladding temperature during the accident transient.

In our problem, minimal and maximal values are defined for each uncertain input and, in the framework of probabilistic approach, their uncertainties are modeled by probability laws defined on the domain of variation (uniform, log-uniform, truncated normal and truncated log-normal laws). Moreover, the d inputs are supposed independent. Our first objective with this use-case is to provide a good metamodel for sensitivity analysis, uncertainty propagation and, more generally, safety studies. Indeed, the cpu-time cost of this computer code is too important to develop all the statistical analysis required in a safety study only using direct calculations of the computer code. A metamodel would allow to develop more complete and robust demonstration.

In what follows, the system under study is generically denoted

$$Y = g\left(X_1, \quad , X_d\right) \tag{1}$$

where $g(\cdot)$ is the numerical model (also called the computer code), whose output Y and input parameters $X_1, \ , X_d$ belong to some measurable spaces $\mathcal{Y}$ and $\mathcal{X}_1, \ , \mathcal{X}_d$ respectively. $\mathbf{X} = \left(X_1, \quad , X_d\right)$ is the input vector and we suppose that $\mathcal{X} = \prod_{k=1}^{d} \mathcal{X}_k \subset \mathbb{R}^d$ and $\mathcal{Y} \subset \mathbb{R}$. For a given value of the vector of inputs $\mathbf{x} = \left(x_1, \ldots, x_d\right) \in \mathbb{R}^d$, a simulation run of the code yields an observed value $y = g(\mathbf{x})$.

3 STEP 1: INITIAL DESIGN OF EXPERIMENTS

The objective of the initial sampling step is to investigate the whole variation domain of the uncertain parameters in order to fit a predictive metamodel which approximates as accurately as possible the code in the whole domain of variation of the uncertain parameter. For this, we use a space-filling design (SFD) of a certain number n of experiments, providing a full coverage of the high-dimensional input space (Fang et al. 2006). This design enables to investigate the domain of variation of the uncertain parameters and provides a learning sample.

For the SFD type, a Latin Hypercube Sample (LHS) with optimal space-filling and good projection properties (Woods and Lewis 2017) would be well adapted. In particular, Fang et al. (2006) and then Damblin et al. (2013) have shown the importance of ensuring good low-order sub-projection properties. Maximum projection designs (Joseph et al. 2015) or low-centered L^2 discrepancy LHS (Jin et al. 2005) are then particularly well-suited.

Mathematically, this corresponds to the sample $\left\{\mathbf{x}^{(1)}, \ , \mathbf{x}^{(n)}\right\}$ which is performed on the model g. This yields n model output values denoted $\left\{y^{(1)}, \ , y^{(n)}\right\}$ with $y^{(i)} = g\left(\mathbf{x}^{(i)}\right)$. The obtained learning sample is denoted $\left(X_s, Y_s\right)$ with $X_s = \left[\mathbf{x}^{(1)T}, \ldots, \mathbf{x}^{(n)T}\right]^T$ and $Y_s = \left[y^{(1)}, \ldots, y^{(n)}\right]^T$. The goal is to build an approximating model of g using the n-sample $\left(X_s, Y_s\right)$.

The number n of simulations is a compromise between the CPU time required for each simula-

tion and the number of input parameters. Some thumb rules propose to choose n at least as large as 10 times the dimension d of the input vector (Loeppky et al. 2009, Marrel et al. 2008).

To build the metamodel for the LOCA test case, $N = 500$ CATHARE simulations of this test case are performed following a space-filling LHS with good projection properties as the design of experiments. The obtained inputs-output sample constitutes the learning sample.

Remark 3.1 Note that the input values are sampled following their prior distributions defined on their variation ranges. Indeed, as we are not ensured to be able to build a sufficiently accurate metamodel, we prefer sample the inputs following the probabilistic distributions in order to have at least a probabilized sample of the uncertain output, on which statistical characteristics could be estimated. Moreover, as explained in the next section, dependence measures can be directly estimated on this sample, providing first usable results of sensitivity analysis.

4 STEP 2: INITIAL SCREENING BASED ON DEPENDENCE MEASURE

From the learning sample, a screening technique is performed in order to identify the primary influential inputs (PII) on the model output variability. It has been recently shown that screening based on dependence measures (Da Veiga 2015, De Lozzo and Marrel 2016, Raguet and Marrel 2018) or on derivative-based global sensitivity measures (Kucherenko and Iooss 2017, Roustant et al. 2017) are very efficient methods which can be directly applied on a SFD. One of their great interest is that, additionally to their screening job, the sensitivity indices that they provide can be quantitatively interpreted and used to order the PII by decreasing influence, paving the way for a sequential building of metamodel. Note that Mara et al. (2017) recently compared the efficiency of several sensitivity measures to address the issue of factors fixing setting: Sobol'indices estimated with sparse polynomial chaos expansion method, density-based dependence measure and derivative-based global sensitivity measures.

In the considered LOCA test case, the adjoint model is not available and the derivatives of the model output are therefore not computed because of their costs. This considerably limits the interest of using derivative-based sensitivity measures. Moreover, as the number of uncertain inputs is large and HSIC dependence measures has showed good convergence properties (De Lozzo and Marrel 2016), we choose to use the latter for the screening step, directly estimated from the inputs-output sample (metamodel-free estimation).

4.1 *Screening based on HSIC dependence measure*

Da Veiga (2015) and more recently De Lozzo and Marrel (2016) have proposed to use dependence measures for screening purpose, by applying them directly on a SFD. These sensitivity indices are not the classical ones variance-based measures (see Iooss and Lemaître 2015 or Borgonovo and Plischke 2016, for a review on global sensitivity analysis methods). They consider higher order information about the output behavior in order to provide more detailed information. Among them, the Hilbert-Schmidt independence criterion (HSIC) introduced by Gretton et al. (2005) builds upon kernel-based approaches for detecting dependence, and more particularly on cross-covariance operators in reproducing kernel Hilbert spaces (RKHS).

If we consider two RKHS $\mathcal{F}_k$ and $\mathcal{G}$ of functions $\mathcal{X}_k \to \mathbb{R}$ and $\mathcal{Y} \to \mathbb{R}$ respectively, the crossed-covariance $C_{X_k,Y}$ operator associated to the joint distribution of $t(X_k, Y$ is the linear operator defined for every $f_{X_k} \in \mathcal{F}_k$ and $g_Y \in \mathcal{G}$ by:

$$< f_{X_k}, C_{X_k,Y} g_Y >_{\mathcal{F}_k} = \mathrm{Cov}\left(f_{X_k}, g_Y\right). \tag{2}$$

$C_{X_k,Y}$ generalizes the covariance matrix by representing higher order correlations between X_k and Y through nonlinear kernels. The HSIC criterion is then defined by the Hilbert-Schmidt norm of the cross-covariance operator:

$$\mathrm{HSIC}(X_k, Y)_{\mathcal{F}_k,\mathcal{G}} = \| C_k \|^2_{HS} . \tag{3}$$

From this, Da Veiga (2015) introduces a normalized version of the HSIC which provides a sensitivity index of X_k:

$$R^2_{\mathrm{HSIC},k} = \frac{HSIC\left(X_k, Y\right)}{\sqrt{HSIC\left(X_k, X_k\right) HSIC\left(Y, Y\right)}}. \tag{4}$$

Gretton et al. (2005) also propose a Monte Carlo estimator of $\mathrm{HSIC}\left(X_k, Y\right)$ and a plug-in estimator can be deduced for $R^2_{\mathrm{HSIC},k}$. Note that Gaussian kernel functions with empirical estimations of the variance parameter are used in our application (see Gretton et al. 2005 for details).

Then, from the estimated R^2_{HSIC}, independence tests can be performed for a screening purpose. The objective is to separate the inputs into two sub-groups, the significant ones and the non-significant ones. For a given input X_k, it aims at testing the null hypothesis "$\mathcal{H}_0^{(k)}$: X_k and Y are

independent", against its alternative "$\mathcal{H}_1^{(k)}$: X_k and Y are dependent". The significance level[1] of these tests is hereinafter noted α. Several statistical hypothesis tests are available: asymptotic versions, spectral extensions and bootstrap versions for non-asymptotic case. All these tests are described and compared in De Lozzo and Marrel (2016); a guidance to use them for a screening purpose is also proposed. At the end of the screening step, the inputs selected as significant are also ordered by decreasing R^2_{HSIC}. This order will be used for the sequential metamodel building in step 3.

4.2 *Application on LOCA test case*

From the learning sample of $N = 500$ simulations, R^2_{HSIC} dependence measures are estimated and bootstrap tests with $\alpha = 0.1$ are performed. Eleven inputs are selected as significantly influential. Ordering them by decreasing R^2_{HSIC} reveals the predominance influence of X_{10} ($R^2_{\text{HSIC}} \approx 0.39$), followed by X_2, X_{12} and X_{22}, ($R^2_{\text{HSIC}} \approx 0.04$, 0.02 and 0.02 respectively). X_{15}, X_{13}, X_9, X_5, X_{14}, X_{26} and X_{27} have a lower influence (R^2_{HSIC} around 0.01)) and the others variables are considered as negligible by statistical tests.

Note that the estimated HSIC and the results of significant tests are relatively stable when the learning sample size varies from $N = 300$ to $N = 500$. Only two or three selected variables with a very low HSIC (R^2_{HSIC} around 0.01) can differ. This confirms the robustness of the HSIC indices and the associated significance tests for qualitative sorting and screening purpose.

In the next steps, the eleven significant inputs are considered as the explanatory variables, denoted PII, in the joint metamodel and will be successively included in the building process. The other sixteen variables will be joined in a so-called *uncontrollable* parameter.

5 STEP 3: JOINT GP METAMODEL WITH SEQUENTIAL BUILDING PROCESS

Among all the metamodel-based solutions (polynomials, splines, neural networks, etc.), we focus our attention on the Gaussian process (Gp) regression, which extends the kriging principles of geostatistics to computer experiments by considering the correlation between two responses of a computer code depending on the distance between input variables. The Gp-based metamodel presents some real advantages compared to other metamodels: exact interpolation property, simple analytical formulations of the predictor, availability of the mean squared error of the predictions and the proved efficiency of the model (Santner et al. 2003).

However, for its application to complex industrial problems, developing a robust implementation methodology is required. Indeed, fitting a Gp model implies the estimation of several hyperparameters involved in the covariance function. In complex situations (e.g. large number of inputs), some difficulties can arise from the parameter estimation procedure (instability, high number of hyperparameters, see Marrel et al. 2008 for example). To tackle this issue, we propose a progressive estimation procedure which combines the result of the previous screening step and a joint Gp approach (Marrel et al. 2012).

5.1 *Sequential building process based on successive inclusion of explanatory variables*

At the end of the screening step, the inputs selected as significant (group of PII) are ordered by decreasing influence. The sorted PII are successively included in the metamodel explanatory inputs while the other inputs (remaining PII and the sixteen non-selected inputs) are joined in a single macro-parameter which is considered as an uncontrollable parameter (i.e. a stochastic parameter, notion detailed in section 5.2). Thus, at the j^{th} iteration, a joint Gp metamodel is built with, as explanatory inputs, the j sorted PII. The definition and building procedure of a joint Gp is fully described in Marrel et al. (2012) and summarized in the section 5.2.

However, building a Gp or a joint Gp involves to perform a numerical optimization in order to estimate all the parameters of the metamodel (covariance hyperparameters and variance parameter). As we usually consider in computer experiments anisotropic (stationary) covariance, the number of hyperparameters linearly increases with the number of inputs. In order to improve the robustness of the optimization process and deal with a large number of inputs, the estimated hyperparameters obtained at the $(j-1)^{th}$ iteration are used, as starting points for the optimization algorithm. This procedure is repeated until the inclusion of all the PII. Note that this sequential estimation process is directly adapted from the one proposed by Marrel et al. (2008).

5.2 *Joint Gp metamodel*

In the framework of stochastic computer codes, Zabalza et al. (1998) proposed to model the mean and dispersion of the code output by two interlinked Generalized Linear Models (GLM), called "joint GLM". Marrel et al. (2012) extends this approach to several nonparametric models and

[1]The significance level of a statistical hypothesis test is the rate of the type I error which corresponds to the rejection of the null hypothesis $\mathcal{H}_0$ when it is true.

obtains the best results with two interlinked Gp models, called "joint Gp". In this case, the stochastic input is considered as an uncontrollable parameter denoted $\mathbf{X}_\varepsilon$ (i.e. governed by a seed variable).

We extend this approach to a group of non-explanatory variables. More precisely, the input variables $\mathbf{X} = (X_1, \quad , X_d)$ are divided in two subgroups: the explanatory ones denoted $\mathbf{X}_{\mathbf{exp}}$ and the others denoted $\mathbf{X}_\varepsilon$. The output is thus defined by $y = g(\mathbf{X}_{\mathbf{exp}}, \mathbf{X}_\varepsilon)$. Under this hypothesis, the joint metamodeling approach yields building two metamodels, one for the mean Y_m and another for the dispersion component Y_d:

$$Y_m(\mathbf{X}_{\mathbf{exp}}) = \mathbb{E}(Y \mid \mathbf{X}_{\mathbf{exp}}) \tag{5}$$

$$Y_d(\mathbf{X}_{\mathbf{exp}}) = \mathrm{Var}(Y \mid \mathbf{X}_{\mathbf{exp}}) = \mathbb{E}\left[\left(Y - Y_m(\mathbf{X}_{\mathbf{exp}}) \right)^2 \mid \mathbf{X}_{\mathbf{exp}} \right]. \tag{6}$$

To fit these mean and dispersion components, we propose to use the methodology proposed by Marrel et al. (2012). First, an initial Gp denoted $Gp_{m,1}$ is estimated for the mean component with homoscedastic nugget effect. A nugget effect is required to relax the interpolation property of the Gp metamodel, which would yield zero residuals for the whole learning sample. Then, a second Gp, denoted $Gp_{v,1}$, is built for the dispersion component with, here also, an homoscedastic nugget effect. $Gp_{v,1}$ is fitted on the squared residuals from the predictor of $Gp_{m,1}$. Its predictor is considered as an estimator of the dispersion component. The predictor of $Gp_{v,1}$ provides an estimation of the dispersion at each point, which is considered as the value of the heteroscedastic nugget effect. The homoscedastic hypothesis is so removed and a new Gp, denoted $Gp_{m,2}$, is fitted on data, with the estimated heteroscedastic nugget. Finally, the Gp on the dispersion component is updated from $Gp_{m,2}$ following the same methodology as for $Gp_{v,1}$.

Remark 5.1 Note that some parametric choices are made for all the Gp metamodels: a constant trend and a Matérn stationary anisotropic covariance are chosen. All the hyperparameters (covariance parameters) and the nugget effect (when homoscedastic hypothesis is done) are estimated by maximum likelihood optimization process.

5.3 *Assessment of metamodel accuracy*

To evaluate the accuracy of the metamodel, we use the predictivity coefficient Q^2:

$$Q^2 = 1 - \frac{\sum_{i=1}^{n_{test}} \left(y^{(i)} - \hat{y}^{(i)} \right)^2}{\sum_{i=1}^{n_{test}} \left(y^{(i)} - \frac{1}{n_{test}} \sum_{i=1}^{n_{test}} y^{(i)} \right.} \tag{7}$$

Table 1. Evolution of Gp_m metamodel predictivity during the sequential process building, for each new additional PII.

Additional PII	X_{10}	X_2	X_{12}	X_{22}	X_{15}	X_{13}
Q^2	0.60	0.64	0.70	0.79	0.81	0.83
Additional PII	X_9	X_5	X_{14}	X_{26}	X_{27}	
Q^2	0.85	0.85	0.87	0.87	0.87	

where $(x^{(i)})_{1 \le i \le n_{\text{test}}}$ is a test sample, $(y^{(i)})_{1 \le i \le n_{\text{test}}}$ are the corresponding observed outputs and $(\hat{y}^{(i)})_{1 \le i \le n_{\text{test}}}$ are the metamodel predictions. Q^2 corresponds to the coefficient of determination in prediction and can be computed on a test sample independent from the learning sample or by cross-validation on the learning sample. The closer to one the Q^2, the better the accuracy of the metamodel.

5.4 *Application on LOCA test case*

The joint Gp metamodel is built from the learning sample of $N = 500$: the eleven PII identified at the end of the the screening step are considered as the explanatory variables while the sixteen others are considered as the uncontrollable parameter. Gps on mean and dispersion components are built using the sequential building process described in section 5.1 where PII ordered by decreasing R^2_{HSIC} are successively included in Gp. Q^2 coefficient of mean component Gp_m is computed by cross validation at each iteration of the sequential building process. The results which are given by Table 1 show an increasing predictivity until its stabilization around 0.87, which illustrates the robustness of building process. The first four PII make the major contribution yielding a Q^2 around 0.8, the four following ones yield minor improvements (increase of 0.02 on average for each input) while the three last PII does not improve the Gp predictivity.

Thus, only 13% of the output variability remains not explained by Gp_m, this includes both the inaccuracy of the Gp_m (part of Y_m not fitted by Gp) and the total effect of the uncontrollable parameter, i.e. the group of non-selected inputs.

6 STEP 4: VARIANCE-BASED SENSITIVITY ANALYSIS

Sensitivity Analysis (SA) methods allow to answer the question "How do the input parameters variations contribute, qualitatively or quantitatively, to the variation of the output?" (Saltelli et al. 2008). These tools can detect non-significant input parameters in a screening context, determinate the most significant ones, measure their respective contributions to the output or identify an interaction between several inputs which impacts strongly

the model output. From this, engineers can guide the characterization of the model by reducing the output uncertainty: for instance, they can calibrate the most influential inputs and fix the non-influential ones to nominal values. Many surveys on SA exist in the literature, such as Kleijnen (1997), Frey and Patil (2002) or Helton et al. (2006). SA can be divided into two sub-domains: the Local SA (LSA) and the Global SA (GSA). The first one studies the effects of small input perturbations around nominal values on the model output (Cacuci 1981) while the second one considers the impact of the input uncertainty on the output over the whole variation domain of uncertain inputs (Saltelli et al. 2008). We focus here on one of the most widely used GSA indices, namely Sobol' indices which are based on output variance decomposition.

6.1 *Sobol' indices*

A classical approach in GSA consists of computing the first-order and total Sobol' indices which are based on the output variance decomposition (Sobol 1993, Homma and Saltelli 1996). If the variables $X_1, \ldots, X_d$ are independent and if $\mathbb{E}\left[g^2(X)\right] < +\infty$, we can apply the Hoeffding decomposition to the random variable $g(X)$ (Hoeffding 1948):

$$g(X) = \sum_{u \subset \{1,\ldots,d\}} g_u(X_u) \tag{8}$$

where $g_\phi = \mathbb{E}\left[g(X) \right]$, $g_i(X_i) = \mathbb{E}[g(X) \mid X_i] - g_\phi$ and $g_u(X_u) = \mathbb{E}[g(X) \mid X_u] - \sum_{v \subset u} g_v(X_v)$, with $X_u = (X_i)_{i \in u}$, for all $u \subset \{1,\ldots,d\}$. All the 2^d terms in (8) have zero mean and are mutually uncorrelated with each other. This decomposition is unique and leads to the Sobol' indices. These are the elements of the $g(X)$ variance decomposition according to the different groups of input parameter interactions in (8). More precisely, for each $u \subset \{1,\ldots,d\}$, the first-order and total Sobol' sensitivity indices of X_u are defined by:

$$S_u = \frac{Var\left[g_u(X_u)\right]}{Var\left[g(X)\right]} \text{ and } S_u^T = \sum_{v \supset u} S_v.$$

S_u represents the part of the output variance explained by X_u, independently from the other inputs, and S_u^T is the part of the output variance explained by X_u considered separately and in interaction with the other input parameters.

In practice, we are usually interested in the first-order sensitivity indices $S_1, \ldots, S_d$, the total ones $S_1^T, \ldots, S_d^T$ and sometimes in the second-order ones S_{ij}, $1 \le i < j \le d$. The model g is devoid of interactions if $\sum_{i=1}^{d} S_i \approx 1$.

Sobol' indices are widely used in GSA because they are easy to interpret and directly usable in a dimension reduction approach. However, their estimation (based on Monte-Carlo methods for example) requires a large number of model evaluations, which is intractable for time expensive computer codes. An common solution consists in using a metamodel to compute these indices. Note that, when the Q^2 of the metamodel is estimated on a probabilized sample of the inputs, it provides an estimation of the part of variance unexplained by the metamodel. This can be kept in mind when interpreting the Sobol' indices estimated with the metamodel.

6.2 *Sobol' indices with a joint Gp metamodel*

In the case where a joint Gp metamodel is used to take into account an uncontrollable input X_ε, we have shown in Marrel et al. (2012) how to deduce Sobol' sensitivity indices from this joint metamodel. Indeed, the variance of the output variable $Y\left(\mathbf{X_{exp}}, X_\varepsilon\right)$ can be rewritten and deduced from the two metamodels:

$$\mathrm{Var}\, Y\left(\mathbf{X_{exp}}, X_\varepsilon\right) \mathrm{Var}_{\mathbf{X_{exp}}}\left[Y_m\left(\mathbf{X_{exp}}\right)\right] + \mathbb{E}_{\mathbf{X_{exp}}}\left[Y_d\left(\mathbf{X_{exp}}\right)\right] \tag{9}$$

where $\mathbb{E}_X$ (resp. Var_X) denotes the mean (resp. variance) operator with respect to the pdf of X. Furthermore, the variance of Y is the sum of the contributions of all the d controllable inputs $\mathbf{X_{exp}} = (X_1, \ldots, X_d)$ and the uncontrollable one X_ε:

$$\mathrm{Var}(Y) = V_\varepsilon(Y) + \sum_{i=1}^{d} \sum_{|J|=i} [V_J(Y) + V_{J\varepsilon}(Y)] \tag{10}$$

where $V_\varepsilon(Y) = \mathrm{Var}_{X_\varepsilon}[\mathbb{E}_{\mathbf{X_{exp}}}(Y \mid X_\varepsilon)]$, $V_i(Y) = \mathrm{Var}_{\mathbf{X_i}}[\mathbb{E}_{\mathbf{X_{-i}}}(Y \mid X_i)]$, $V_{i\varepsilon}(Y) = \mathrm{Var}_{X_i X_\varepsilon}[\mathbb{E}_{\mathbf{X_{exp,-i}}}(Y \mid X_i X_\varepsilon)] - V_i(Y) - V_\varepsilon(Y)$, $V_{ij}(Y) = \mathrm{Var}_{X_i X_j}[\mathbb{E}_{\mathbf{X_{-i,-j}}}(Y \mid X_i X_j)] - V_i(Y) - V_j(Y)$...

Variance of the mean component $Y_m(\mathbf{X})$ denoted hereafter Y_m can be also decomposed:

$$\mathrm{Var}(Y_m) = \sum_{i=1}^{d} \sum_{|J|=i} V_J(Y_m). \tag{11}$$

As $V_i(Y_m) = \mathrm{Var}_{X_i}\mathbb{E}_{\mathbf{X_{exp,-i}}}[\mathbb{E}_{X_\varepsilon}(Y \mid \mathbf{X_{exp}}) \mid X_i] = V_i(Y)$, Sobol' indices according to input variables $\mathbf{X}_{exp} = (X_i)_{i=1\ldots d}$ can be derived and estimated from Y_m:

$$S_J = \frac{V_J(Y_m)}{Var(Y)} \text{ for any } J \subset \mathbf{X}_{exp}. \tag{12}$$

Similarly, the total sensitivity index of X_ε is given by:

$$S_{\varepsilon}^{tot} = \frac{V_{\varepsilon}(Y) + \sum_{i=1}^{d}\sum_{|J|=i} V_{J\varepsilon}(Y)}{Var(Y)} = \frac{\mathbb{E}_{\mathbf{X}_{exp}}\left[Y_d\left(\mathbf{X}_{exp}\right)\right]}{Var(Y)}. \quad (13)$$

Note that, as $Y_d\left(\mathbf{X_{exp}}\right)$ is a positive random variable, positivity of S_{ε}^{tot} is guaranteed. In practice, Var(Y) can be estimated from the data or from simulations of the fitted joint model, using equation (9).

S_{ε}^{tot} is interpreted as the total sensitivity index of the uncontrollable process. The limitation of this approach is that only the total part of uncertainty related to X_{ε} is estimated; its individual effect is not distinguished from its interaction with the other parameters. However, these potential interactions could be pointed out, considering all the primary and total effects of all the other parameters. The SA of Y_d can also be a relevant indicator: if an input variable X_i is not influential on Y_d, we can deduce that $S_{i\varepsilon}$ is equal to zero.

6.3 *Results on LOCA test case*

From the joint Gp built in section 5.4, Sobol' indices of PII are estimated from Gp_m metamodel using equation (12), Var(Y) being estimated with Gp_m and Gp_d using equation (9). For this, intensive Monte Carlo methods are used (see e.g. pick-and-freeze estimator of Gamboa et al. 2016). The first Sobol' indices of PII are given by Table 2 and represent 85% of the total variance of the output. X_{10} remains the major influential input with 59% of explained variance, followed to a lesser extend by X_{12} and X_{22} with for each of them 8% of variance. The *partial* total Sobol' indices involving only PII and derived from Gp_m show that additional 4% of variance is due to interaction between X_{10}, X_{12} and X_{22}. The other PII have negligible influence. Lastly, all PII explain around 89% of the output variance, of which 79% is only due to X_{10}, X_{12} and X_{22}. From Gp_d metamodel and using equation (13),the total effect of the uncontrollable parameter, i.e. the group of the sixteen not-explanatory inputs, is estimated to 9.7%. This includes the effect of the uncontrollable parameter alone and in interaction with the PII. To further investigate these interactions, Sobol'-based SA and HSIC-based statistical dependence tests are applied on Y_d and reveal that only X_{10}, X_{14}, X_2, X_{22} and X_4 potentially interact with the uncontrollable parameter.

Table 2. First Sobol' indices of PII (in %), estimated with Gp_m metamodel.

Input	X_{10}	X_2	X_{12}	X_{22}	X_{15}	X_{13}
1st Sobol' index	59	3	8	8	2	1
Input	X_9	X_5	X_{14}	X_{26}	X_{27}	
1st Sobol' index	2	0	2	0	0	

7 CONCLUSION AND PROSPECTS

Using an efficient sequential building process, we fitted a predictive joint Gp metamodel on a high dimensional thermal-hydraulic test case simulating accidental scenario in a Pressurized Water Reactor (LOCA test case). An initial screening step based on advanced dependence measures and associated statistical tests enabled to identify a group of significant inputs, allowing dimension reduction. The efforts of optimization when fitting the metamodel fitting can be concentrated on the main influential inputs and the robustness of metamodeling is thus increased. Moreover, thanks to the joint metamodel approach, the non-selected inputs are not completely removed: the residual uncertainty due to dimension reduction is integrated in the metamodel and the global influence of non-selected inputs is so controlled.

From this joint Gp metamodel, several statistical analyses, not feasible with the numerical model due to its computational cost, become accessible. Thus, on LOCA application, a sensitivity analysis based on variance decomposition is performed using the joint Gp: Sobol' indices are computed and reveal that the output is mainly explained by four uncertain inputs: one input is strongly influential with around 60% of output variance explained, the three others being of minor influence. The quite less influence of all the other inputs is also confirmed.

The next step is to use the joint Gp metamodel to perform uncertainty propagation for the estimation of failure probabilities and quantiles. In the LOCA test case, we are particularly interested by the estimation of high quantile (at the order of 95% to 99%) of the model output temperature. In nuclear safety, methods of conservative computation of quantiles (Nutt and Wallis 2004) have been largely studied. However, several complementary information are often useful and are not accessible in a high-dimensional context. Then, we expect that the joint Gp metamodel could help to access this information: the uncertainty of the influential inputs will be directly and accurately propagated through the mean component of the joint metamodel while a confidence bound could be derived from the dispersion component in order to take into account the residual uncertainty of the other inputs. On this last point, the interest of heteroscedastic approach in joint Gp could also be illustrated and compared with its homoscedastic version.

Accelerated degradation model based on geometric Liu process

Ji-Peng Wu, Xiao-Yang Li & Rui Kang
School of Reliability and Systems Engineering, Beihang University, Beijing, China
Science and Technology on Reliability and Environmental Engineering Laboratory, Beijing, China

ABSTRACT: Through evaluating stress levels, Accelerated Degradation Testing (ADT) can obtain degradation data in a limited period of time and then use these data for reliability evaluations. However, because of the high price of the test items or the test equipment, the sample size used in ADT is usually small, which causes a lack of knowledge on recognizing the population and then lead to the epistemic uncertainty. The small sample problem makes the probability theory based models, which need large samples, not appropriate any more. To address this problem, based on the uncertain theory, this paper uses the general geometric Liu process to construct an uncertain acceleration degradation model, and gives the corresponding statistical analysis method with objective measures. A carbon-film resistors case is used to illustrate the proposed methodology, and discussions are conducted on the sensitivity analysis of the proposed methodology to the sample sizes. Results show that the proposed methodology is a suitable choice for the reliability evaluations of ADT data under small sample situations.

1 INTRODUCTION

Products' reliability and lifetime are usually assessed by the life testing that uses time-to-failure data. But for highly reliable products, there are usually few or even no failure during the life testing, which makes it unappropriated to use life testing to assess these products' reliability and lifetime. Therefore, the accelerated reliability testing (ADT) has attracted much attention and been widely applied. ADT can obtain degradation data in a limited period of time by evaluating stress levels, and then uses these data for the reliability and lifetime assessments.

In a standard ADT analysis, there is a degradation model and an acceleration model. The degradation model describes the degradation paths under each stress level. Some of the parameters are assumed to be functions of stress levels, i.e., the acceleration model. In general, there are two broad categories of degradation models based on the probability theory, which are the degradation path models (Meeker et al., 1998) and the stochastic process models (Ye and Xie, 2015). These models are suitable for the situation where there are large samples. But in practical applications, the sample size in ADT is usually small due to the high price of the test items or the test equipment, which will cause a lack of knowledge on recognizing the population, and then lead to the epistemic uncertainty. Therefore, the probability theory based models are not appropriate for the small sample situation.

To quantify the epistemic uncertainty, various methods have been applied by utilizing subjective information such as belief degrees, including the Bayesian method (Li and Meeker, 2014), the interval analysis (Moore et al., 2009), and the fuzzy probability theory (Beer et al., 2013). The prior distributions, the intervals or the fuzzy variables are used respectively in these methods to utilize subjective information to quantify the epistemic uncertainty (Kang et al., 2016).

However, there still exit some problems. On the one hand, these methods quantify the epistemic uncertainty by subjective measures, which could result in different results from different researchers. On the other hand, these methods origin from the probability theory, which makes them unsuitable for the ADT data with small sample size.

Motivated by these problems, the uncertainty theory proposed by Liu (Liu, 2015) is introduced to the field of ADT modeling. The uncertainty theory is a branch of mathematics for modeling belief degrees and is used for the small sample (or even no sample) situations (Liu, 2012). It has been widely used in many fields such as risk assessment (Liu, 2010), reliability analysis (Zeng et al., 2013), supply chain (Huang et al., 2016), and so on.

In this paper, based on the uncertainty theory, a positive uncertain process named the general geometric Liu process is proposed to construct an uncertain accelerated degradation model, and the statistical analysis method for parameter estimations is proposed correspondingly. The proposed methodology quantifies the epistemic uncertainty by objective measures. The rest of the paper is organized as follows. Section 2 introduces preliminaries about the

uncertainty theory. Section 3 presents the uncertain accelerated degradation model, derives the reliability and lifetime distributions and gives the corresponding statistical analysis method. Section 4 conducts the case study and the sensitivity analysis. Section 5 concludes the paper.

2 PRELIMINARIES

In this section, we introduce some preliminaries about uncertain measure, uncertain variable, and uncertain process that will be used in the subsequent sections.

Definition 1 (Liu, 2015): Let Γ be a nonempty set, and $\mathcal{L}$ be a σ-algebra over Γ. Each element Λ in $\mathcal{L}$ is called a measurable set. A set function M from $\mathcal{L}$ to [0, 1] is called an uncertain measure if it satisfies the following axioms:

1. **Normality axiom:** $\mathrm{M}\{\Gamma\}=1$ for the universal set Γ.
2. **Duality axiom:** $\mathrm{M}\{\Lambda\}+\mathrm{M}\{\Lambda^c\}=1$ for any event Λ.
3. **Subadditivity axiom:** For every countable sequence of events $\Lambda_1,\Lambda_2,\ldots$, we have

$$\mathrm{M}\left\{\bigcup_{i=1}^{\infty}\Lambda_i\right\}\le\sum_{i=1}^{\infty}\mathrm{M}\{\Lambda_i\}. \tag{1}$$

4. **Product axiom** (Liu, 2009): Let $(\Gamma_k, \Gamma_k, \mathrm{M}_k)$ be uncertainty spaces for $k = 1, 2, \ldots$, then the product uncertain measure M is an uncertain measure satisfying

$$\mathrm{M}\left\{\prod_{k=1}^{\infty}\Lambda_k\right\}=\bigwedge_{k=1}^{\infty}\mathrm{M}_k\{\Lambda_k\}, \tag{2}$$

where Λ_k are arbitrarily chosen events from $\mathcal{L}_k$ for $k = 1,2,\ldots$, respectively.

Definition 2 (Liu, 2015): Liu introduced the concept of uncertainty distribution to describe uncertain variables. The uncertainty distribution Φ of an uncertain variable ξ is defined by

$$\Phi(x)=\mathcal{M}\{\xi\le x\},\quad\forall x\in\mathcal{R}. \tag{3}$$

Let be ξ an uncertain variable with regular uncertainty distribution $\Phi(x)$. Then the inverse function $\Phi^{-1}(\alpha)$ is called the inverse uncertainty distribution of ξ.

Definition 3 (Liu, 2008): Let T be a totally ordered set (that is usually "time"), and let $(\Gamma,\mathcal{L},\mathrm{M})$ be an uncertainty space. An uncertain process is defined as a measurable function from $T\times(\Gamma,\mathcal{L},\mathrm{M})$ to the set of real numbers, i.e., for each $t\in T$ and any Borel set B of real numbers, the set

$$\{X_t\in B\}=\{\gamma\in\Gamma\mid X_t(\gamma)\in\mathrm{B}\}\} \tag{4}$$

is an event. In other words, an uncertain process is a sequence of uncertain variables indexed by time.

Definition 4 (Liu, 2014): An uncertain process X_t is said to have an uncertainty distribution $\Phi_t(x)$ if at each time t, the uncertain variable X_t has the uncertainty distribution $\Phi_t(x)$.

Theorem 1 (Liu, 2014): (Sufficient and Necessary Condition) A function $\Phi_t^{-1}(\alpha):T\times(0,1)\to\Re$ is an inverse uncertainty distribution of independent uncertain process if and only if 1) at each time t, $\Phi_t^{-1}(\alpha)$ is a continuous and strictly increasing function; and 2) for any times $t_2<t_1$, $\Phi_{t_1}^{-1}(\alpha)-\Phi_{t_2}^{-1}(\alpha)$ is a monotone increasing function with respect to α.

3 METHODOLOGY

In this section, we use an uncertain process called the general geometric Liu process (Liu, 2015) to for ADT modeling, derive the reliability and lifetime distributions, and gives the corresponding statistical analysis method.

3.1 *Accelerated degradation modeling*

In practical applications, the degradation process is usually positive. To describe the positive degradation process under the small sample situation, we consider the following uncertain process

$$X(t)=\exp(e\cdot t+\sigma/\sqrt{t}\,C(t)), \tag{5}$$

where e is the log-drift parameter, also known as the degradation rate. $\sigma/\sqrt{t}$ is the log-diffusion parameter. $C(t)$ is the Liu process that follows a normal uncertainty distribution (N_u) with mean 0 and variance t^2, i.e. $C(t)\sim N_u(0,t)$. Eq.(5) is called the general geometric Liu process. Note that $X(t)$ in Eq.(5) follows a lognormal uncertainty distribution (Log_u), i.e., $X(t)\sim Log_u(et,\sigma\sqrt{t})$. Its uncertainty distribution can be expressed as

$$\Phi_t(x)=\left(1+\exp\left(\frac{\pi(e\cdot t-\ln x)}{\sqrt{3}\sigma\sqrt{t}}\right)\right)^{-1}. \tag{6}$$

In ADT modeling, acceleration models are usually utilized to describe the relationship between the degradation rate and the accelerated stress level, which can be expressed as

$$\ln e(s_i)=a+b\cdot s_i, \tag{7}$$

where a and b are unknown parameters. s_i is the normalized stress level that can be expressed as

$$s_i = \begin{cases} \dfrac{1/S_0 - 1/S_i}{1/S_0 - 1/S_H} & \text{Arrhenius model,} \\ \dfrac{\ln S_i - \ln S_0}{\ln S_H - \ln S_0} & \text{Power law model,} \\ \dfrac{S_i - S_0}{S_H - S_0} & \text{Exponential model.} \end{cases} \quad (8)$$

where S_0 is the normal stress level, S_i is the i^{th} accelerated stress level, and S_H is the highest accelerated stress level. From Eq.(8), it is easy to know that $s_0 = 0$, and $s_H = 1$.

For simplicity, our proposed uncertain accelerated degradation model in Eq.(5) and Eq.(7) is denoted by M_1. The unknown parameters in model M_1 are summarized as $\Omega = (a, b, \sigma)$, in which a and b are shown in Eq.(7), σ is shown in Eq.(5).

3.2 *First hitting time and reliability distributions of the proposed model*

After getting the proposed model M_1, we need to derive the reliability and lifetime distributions correspondingly.

Define ω as the failure threshold of the degradation process, then the lifetime T can be defined as the first hitting time (FHT) when the degradation process $X(t)$ reaches ω. Liu (2013) defined the FHT of the uncertain process as follows:

$$t_\omega = \inf\{t_\omega \geq 0 \mid X(t) = \omega\}. \quad (9)$$

According to Theorem 3 in (Liu, 2013), the FHT of an independent increment process with a continuous uncertainty distribution at each time can be expressed as follows,

$$\Upsilon(z) = \mathcal{M}\left\{\sup_{0\leq t\leq z} X(t) \geq \omega\right\} = 1 - \inf_{0\leq t\leq z} \Phi_t(\omega). \quad (10)$$

Therefore, before deriving the reliability and lifetime distributions, we firstly need to prove that $X(t)$ in Eq.(5) is an independent increment process with a continuous uncertainty distribution at each time.

Proof:

1. From Eq.(6), it is easy to know that $X(t)$ has a continuous uncertainty distribution at each time t.
2. For each $\gamma \in \Gamma$, the uncertainty distribution of $X(t \mid \gamma)$ can be expressed as

$$\Phi_t(\gamma) = \left(1 + \exp\left(\frac{\pi(e(s)\cdot t - \ln\gamma)}{\sqrt{3}\sigma\sqrt{t}}\right)\right)^{-1}. \quad (11)$$

Eq.(11) is obvious a continuous function with respect to time t.

3. From Eq.(6), we can get the inverse uncertainty distribution of $X(t)$ as follows,

$$\Phi_t^{-1}(\alpha) = \exp(e(s)\cdot t + \frac{\sigma\sqrt{3t}}{\pi}\ln\frac{\alpha}{1-\alpha}), \ \alpha \in (0,1). \quad (12)$$

At each time t, the derivative of Eq.(12) with respect to α is

$$\left(\Phi_t^{-1}(\alpha)\right)' = \frac{\sigma\sqrt{3t}}{\pi}\exp\left(e(s)t + \frac{\sigma\sqrt{3t}}{\pi}\ln\frac{\alpha}{1-\alpha}\right) \times \frac{1}{\alpha(1-\alpha)}. \quad (13)$$

Since $\alpha \in (0,1)$, we can get that $\alpha(1-\alpha) > 0$. It is easy to prove that $\Phi_t^{-1}(\alpha)$ is a continuous and strictly increasing function with respect to α.

4. For any times $0 < t_2 < t_1$, to prove $\Phi_{t_1}^{-1}(\alpha) - \Phi_{t_2}^{-1}(\alpha)$ is a monotone increasing function with respect to α, we need to prove the following condition:

$$\Phi_{t_1}^{-1}(\alpha) - \Phi_{t_2}^{-1}(\alpha) = \exp\left(e(s)\cdot t_1 + \frac{\sigma\sqrt{3t_1}}{\pi}\ln\frac{\alpha}{1-\alpha}\right) - \exp\left(e(s)\cdot t_2 + \frac{\sigma\sqrt{3t_2}}{\pi}\ln\frac{\alpha}{1-\alpha}\right) > 0. \quad (14)$$

Since $\exp(\bullet)$ is a monotone increasing function, Eq.(14) is equivalent to the following condition:

$$e(s)\cdot(t_1 - t_2) + \frac{\sigma\sqrt{3}}{\pi}\ln\frac{\alpha}{1-\alpha}\left(\sqrt{t_1} - \sqrt{t_2}\right) > 0. \quad (15)$$

According to the given information, it is easy to prove that the condition in Eq.(15) holds. Thus, $\Phi_{t_1}^{-1}(\alpha) - \Phi_{t_2}^{-1}(\alpha)$ is a monotone increasing function with respect to α. Based on **Theorem 1** in section 2, we can prove that $X(t)$ in Eq.(5) is an independent increment process.

From the above analyses, we can get that the uncertain process $X(t)$ in Eq.(5) is an independent increment process with a continuous uncertainty distribution at each time t. Thus, the uncertainty distribution of the FHT of $X(t)$ can be expressed as follows,

$$\begin{aligned} \Upsilon(z) &= 1 - \inf_{0\leq t\leq z}\Phi_t(\omega) \\ &= 1 - \inf_{0\leq t\leq z}\left(1 + \exp\left(\frac{\pi(e(s)\cdot t - \ln\omega)}{\sqrt{3t}\sigma}\right)\right)^{-1} \\ &= \left(1 + \exp\left(\frac{\pi(\ln\omega - e(s)\cdot z)}{\sqrt{3z}\sigma}\right)\right)^{-1}. \end{aligned} \quad (16)$$

The corresponding reliability distribution is

$$R_B(t) = \mathrm{M}\{t_\omega > t\} = \left(1 + \exp\left(\frac{\pi(e(s)\cdot t - \ln\omega)}{\sqrt{3}t\sigma}\right)\right)^{-1} \quad (17)$$

where $R_B(t)$ is known as the "belief reliability" with an uncertain measure (Zeng et al., 2013).

Meanwhile, the belief reliable life, i.e. $BL(\alpha)$, can also be derived and expressed as follows

$$BL(\alpha) = \sup_{0\le t\le z} R_B(t) \ge \alpha = \Upsilon^{-1}(1-\alpha). \quad (18)$$

3.3 *Statistical analysis method for parameter estimations*

With different loading profiles, there are different kinds of ADT plans, including the constant stress accelerated degradation testing (CSADT), the step stress accelerated degradation testing (SSADT), and the progressive stress accelerated degradation testing (PSADT). Here, we provide the statistical analysis method for parameter estimations in CSADT.

Liu (2015) employed the principle of least squares for parameter estimations of uncertain variables. In this section, we also use this method to estimate the unknown parameters of the proposed model M_1.

Suppose that x_{ijk} is the k^{th} observed degradation value for the j^{th} sample under the i^{th} stress level, and t_{ijk} is the corresponding measurement time, $i = 1, 2, \ldots, K$, $j = 1, 2, \ldots, n_i$, $k = 1, 2, \ldots, m_i$, where K is the number of accelerated stress levels, n_i is the sample size under the i^{th} stress level, and m_i is the number of measurements for the j^{th} sample under the i^{th} stress level.

The unknown parameters of the proposed model M_1 is $\boldsymbol{\Omega} = \mathrm{a}, \mathrm{b}, \sigma)$. We proposed a two-step statistical analysis method for the parameter estimations: 1) Collecting belief degrees; 2) Estimating unknown parameters. The procedure of the method is shown in Figure 1 and details are shown as follows:

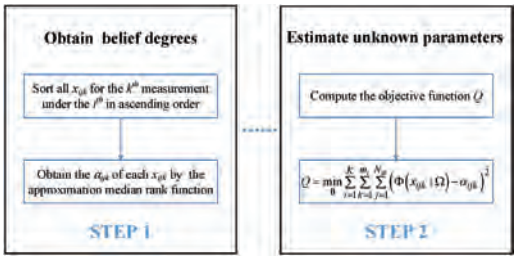

Figure 1. The two-step statistical analysis method for parameter estimations of the proposed model.

1. Obtain belief degrees

From Section 3.2, it is known that x_{ik} is an uncertain variable. All the degradation data x_{ijk} of the k^{th} measurement under the i^{th} stress level are the observations of x_{ik}, i.e., $x_{ik} = \{x_{i1k}, x_{i2k} \ldots x_{ijk} \ldots\}$, ($j = 1, 2 \ldots N_i$, and n_i is the upper boundary of N_i). Each of the element has a belief degree α_{ijk}. In this section, we use the approximate median rank functions to obtain belief degrees, which is expressed as follows,

$$\alpha_{ijk} = (j - 0.3)/(N_{ik} + 0.4),\ j = 1,2,\ldots,N_{ik}\ . \quad (19)$$

For all the degradation data of the k^{th} measurement under the i^{th} stress level, if there exist degradation data that are the same, then their belief degrees are also the same.

2. Estimate unknown parameters

According to the principle of least squares, the parameters estimations of the proposed model can be obtained by the principle of least squares, which is

$$Q = \min_{\boldsymbol{\theta}} \sum_{i=1}^{K}\sum_{k=1}^{m_i}\sum_{j=1}^{N_i} \left(\Phi\left(x_{ijk}\,|\,\Omega\right) - \alpha_{ijk}\right)^2 \quad (20)$$

4 CASE STUDY

In this section, the carbon-film resistors CSADT dataset (Meeker and Escobar, 1998) is used to illustrate the proposed methodology, and discussions are conducted for the sensitivity analysis of the proposed methodology to the sample sizes.

4.1 *The carbon-film resistors CSADT dataset*

In the carbon-film resistors CSADT dataset, there are 9, 10, 10 samples under each accelerated stress levels, which belongs to the small sample situation. Therefore, the proposed methodology can be used to this case for the reliability and lifetime evaluations under normal conditions. Details about this case is shown in Table 1.

Table 1. Basic information about the carbon-film resistors CSADT dataset.

Test information	Contents
Stress levels (temperature/°C)	83, 133, and 173
Normal conditions (°C)	50
Sample size	9, 10, and 10
Measurement times	4, 4, and 4
Failure threshold ω (%)	12

4.2 *Reliability and lifetime evaluations under normal conditions*

Since the accelerated stress is temperature, the Arrhenius model is selected as the acceleration model. Based on the proposed methodology, the parameter estimations are obtained as follows:

Taking the parameter estimation results in Table 2 into Eq.(17) and Eq.(18), the reliability and lifetime evaluations under normal conditions can be obtained. Results are showed in Figure 2.

From Figure 2 (a), it can be seen that the belief reliability changes from the initial value 1 and decreases gradually with the increasing time, which agrees with the intuitive cognition of human beings. If decision makers are interested at belief reliability $R_B = 0.9$, the corresponding belief reliable lifetime $BL(0.9) = 10181$ hours. It means that the belief degree that the products will survived at the normal conditions after 10818 hours is 0.9.

4.3 *Discussions*

For the sensitivity analysis of the proposed methodology to the sample sizes, we simulate several different situations that has different sample size, and remark each situation as ST_r (n_{r1}, n_{r2}, n_{r3}), $r = 1, 2,\ldots, 8$. ST_r represents the r^{th} situation. n_{r1}, n_{r2}, and n_{r3} represents the chosen sample size under each stress level. Details are shown in Table 3.

Table 2. Parameter estimation results.

Parameters	a	b	σ
Values	–15.18	3.975	9.060e-04

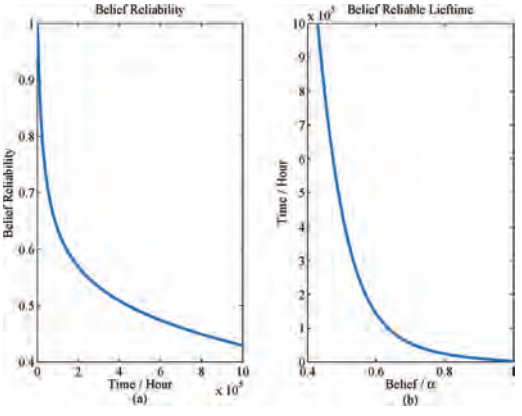

Figure 2. Reliability and lifetime evaluations of the carbon-film resistors ADT dataset under normal conditions.

As shown in Table 3, under each situation, there are many different combinations of samples, which will lead to many different reliability evaluations. To present the range of reliability evaluations under different situations, under each monitoring time t under the situation ST_r, we choose the minimum and maximum reliability evaluation results as the lower and upper boundaries of the reliability evaluations. So the lower and upper boundaries under each situation can be obtained, and results are shown in Figure 3.

Figure 3 show that with the increasing sample size, the lower and upper boundary are approaching gradually. It indicate that when there are more samples that can provide more information, the epistemic uncertainty in ADT data decreases, which will lead to more stable reliability evaluation results. In addition, the reliability evaluations

Table 3. Different situations for discussions.

Situations | Sample sizes	n_{r1}	n_{r2}	n_{r3}
ST_1	2	3	3
ST_2	3	4	4
ST_3	4	5	5
ST_4	5	6	6
ST_5	6	7	7
ST_6	7	8	8
ST_7	8	9	9
ST_8	9	10	10

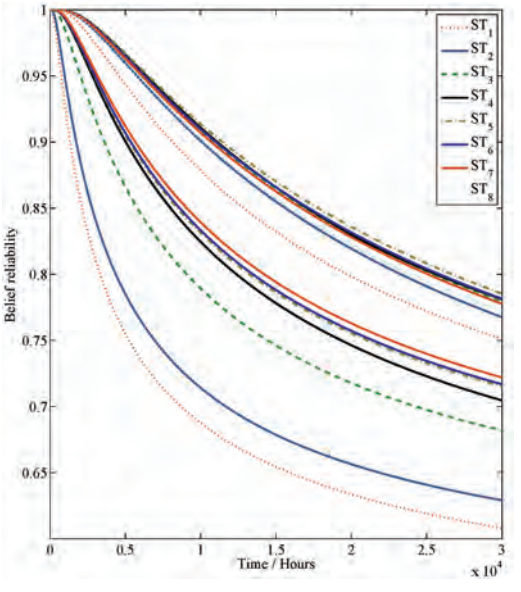

Figure 3. Lower and upper boundaries of the reliability evaluation results under different sample sizes.

results under ST_8 is included in the lower and upper boundaries under most situations (ST_3 to ST_7). As for ST_1 and ST_2, the sample size is very small, which makes the provided information too scarce to get stable reliability evaluation results.

The above analysis results show that the proposed methodology is a suitable choice for the small sample situation and can furtherly provide support for the subsequent decision making.

5 CONCLUSIONS

This paper deals with the positive degradation process with small samples in ADT, and concludes as follows,

1. Based on the uncertainty theory, the general geometric Liu process is used to conduct an uncertain accelerated degradation model, which takes the epistemic uncertainty due to small samples in ADT data into consideration.
2. The corresponding statistical analysis method with objective measures is provided for the unknown parameter estimations.
3. The application results show that the reliability evaluation results of the proposed methodology agrees with agrees with the intuitive cognition of human beings, and the discussion results show that the proposed methodology provides stable reliability evaluation results under small samples, which makes it a suitable choice for the small sample situation and can provide support for the subsequent decision making.

In addition to the work of this paper, there are other issues that are worthwhile for future researches. The proposed model is built up on the general geometric Liu process, which is a positive uncertain process. But in practical applications, there are degradation processes which are not only always positive but also strictly monotonic. It is necessary to apply other uncertain processes in ADT to model such degradation processes.

ABSTRACT: For solid state drive (SSD) with high reliability and long life, it is nearly impossible to obtain sufficient amount of time-to-failure data within acceptable testing time by testing such products under normal operating environments. Thus, accelerated degradation testing (ADT) are introduced to solve reliability modeling problems based on the products' degradation information obtained from accelerated tests. The intimate link between performance degradation data and product failures can be obtained according to the degradation threshold failure mechanism. Through the hypothetical degradation process and failure time, we can estimate the failure time with a given threshold value. However, due to diverse users, and uncertainty of what explicit level of degradation will cause a failure, a probabilistic, rather than a deterministic threshold value should be taken into account. On the other hand, complex operation environment would result in inevitable noise, so it is necessary to consider the detecting error in the reliability analysis. This paper propose a reliability assessment method based on fuzzy failure threshold and measurement errors, aiming at improving the assessment precision. We establish the degradation modeling with fuzzy failure threshold and measurement errors, and the maximum likelihood estimation method is adopted to estimate the failure time distribution parameters. Then the reliability model can be used for subsequent forecasting and decision-making. A commercial off-the-shelf SSD is shown as an example to illustrate the procedure that how to predict time to failure, of which writing current is used as a precursor parameter and directly monitored. Finally the results show the superior performance of the proposed method over traditional methods.

1 INTRODUCTION

Solid state drives (SSDs) are the most important and widely-used data storage device in space application due to their high performance, low energy consumption, small size, and shock resistance compared with traditional hard disk drives (HDDs). As the amount of data stored in SSDs keeps increasing, it is important to understand the reliability characteristics of SSD under field conditions. However, for SSD with high reliability and long life, it is nearly impossible to obtain sufficient amount of time-to-failure data within acceptable testing time by testing such products under normal operating environments and sometimes even under harsher conditions (Nelson 2008).

The accelerated degradation testing (ADT) with higher stress levels provides a method to carry out the life test within a reasonable time frame based on the products' degradation information obtained from historical data or degradation tests (YaoHsu, Chih-YenSu et al. 2014). Generally, a failure occurs when the performance degradation data exceeds a specified threshold. The reliability can be predicted by extrapolating the degradation trend to its threshold after tracking the degradation path for a while (Ye and Xie 2015). Thus, numerous failure and reliability information can be obtained in the accelerated degradation process.

Great attention have been caught in this field. Ren proposed an original approach combining ADT and physics of failure (PoF) modeling for effectively assessing connector reliability (Ren, Feng et al. 2015). González presented a complete reliability analysis including the determination of the reliability functions and parameters obtained for concentrator mutijunction solar cells (Espinet-González, Algora et al. 2015). Chang proposed a reliability qualification test method for pneumatic cylinders based on performance degradation data (Chang, Kwon et al. 2014).

The actual failure point is usually unpredictable or random in the practical engineering application because of the lack of enough empirical information and experimental data, leading to the ambiguity in failure threshold definition. Therefore, it's significant to consider the potential uncertainties in the reliability analysis.

Chen presented the reliability analysis for system with random failure threshold based on the degradation model and failure threshold probability distribution (Chen, Ma et al. 2014). Hua proposed a novel performance degradation reliability based on an adaptive failure threshold (Hua, Zhang et al. 2013).

In this paper, a reliability assessment method based on measurement errors and fuzzy failure threshold is proposed. First, the life-stress model and lifetime distribution model are established. By combining these two models, we adopt the maximum likelihood estimation method to estimate the failure time distribution parameters, and then the reliability based on fixed failure threshold can be estimated. Subsequently, we present a reliability assessment method based on fuzzy failure threshold by applying the probability formula of the fuzzy event and the convolution formula. Then the reliability assessment method is validated by a type of commercial off-the-shelf SSD to be used in the Chinese space station. In the end, we take a comparative analysis on the reliability assessment curves with fixed failure threshold, fuzzy threshold without measurement errors, and fuzzy failure threshold and measurement errors. The result shows that the proposed method has a higher assessment accuracy, and it is more flexible.

2 RELIABILITY MODELING AND ANALYSIS

2.1 *Drift degradation data analysis and model modification*

For electronic products in ADT, performance degradation is accompanied with performance drift created by accelerated stress (Li et al. 2017). The degradation path model can be described by:

$$m_i(t) = x_i(t) + \Delta x_i + \varepsilon_i \tag{1}$$

where $m_i(t)$ is the measured value; $x_i(t)$ is the true degradation value; Δx is the performance drift; ε_i the measurement error which is independent of $x(t)$, and $\varepsilon_i \sim N(0, \sigma^2)$.

2.2 *Lifetime distribution and parameter estimation with degradation data*

2.2.1 *Life-stress model*

As temperature is the acceleration variable, the well-known Arrhenius model is selected:

$$\xi(T) = Ae^{-\frac{Ea}{kT}} \tag{2}$$

where $\xi(T)$ is the performance characteristic related to life; A is a constant; E_a is the activation energy (eV); k is Boltzmann constant (8.617×10^{-5} eV/K); and T is the absolute temperature.

2.2.2 *Lifetime distribution model*

In many standard statistical distributions used to model the various reliability parameters, Weibull distribution is the most common lifetime distribution (Bertsche 2010). Because it applies well to various failure modes by adjustment of the distribution parameters. In this paper, a two-parameter Weibull distribution is selected for the degradation life distribution, whose cumulative distribution function (cdf) has the expression:

$$F(x;t,T) = 1 - e^{-\left(\frac{x}{\eta}\right)^{\beta}} \tag{3}$$

where x is the true degradation, t is the measurement time, T is the accelerated temperature stress level, β and η are shape parameter and scale parameter, respectively.

Under assumption of constant temperature, (2) can be reduced to the following power formal function related with test time and stress level (Ren, Feng et al. 2015):

$$\eta(t,T) = a \cdot e^{\frac{b}{T}} \cdot t^c \tag{4}$$

where a, b, c are the parameters to be estimated.

The scale parameter of the Weibull model (η) depends on the temperature in the Arrhenius model, and the shape parameter (β) has been assumed constant for different temperatures. Combining the life-stress model and lifetime distribution model, we can obtain the combined Arrhenius-Weibull model:

$$F(x;t,T) = 1 - e^{-\left(\frac{x}{a \cdot e^{b/T} \cdot t^c}\right)^{\beta}} \tag{5}$$

where β, a, b, c are the parameters to be estimated.

The failure probability density function (pdf) can be expressed as follows:

$$f(x;t,T) = \frac{\beta}{\left(a \cdot e^{b/T} \cdot t^c\right)^{\beta}} \cdot x^{\beta-1} \cdot e^{-\left(\frac{x}{a \cdot e^{b/T} \cdot t^c}\right)^{\beta}} \tag{6}$$

2.2.3 *Parameters estimation*

In order to estimate the best-suited parameters of the Arrhenius-Weibull model (5), the maximum

likelihood estimation method (MLE) can be utilized. The likelihood function is (Ren, Feng et al. 2015):

$$L(\beta,a,b,c)=c\cdot\prod_{k=1}^{n}\prod_{i=1}^{q}\prod_{j=1}^{m}\frac{\beta}{\left(a\cdot e^{\frac{b}{T}}\cdot t^{c}\right)^{\beta}}\cdot x^{\beta-1}\cdot e^{-\left(\frac{x}{a\cdot e^{\frac{b}{T}}\cdot t^{c}}\right)^{\beta}} \tag{7}$$

Substituting the performance degradation data into (7) and solving the MLE equation $\partial L/\partial\beta=0$, $\partial L/\partial a=0$, $\partial L/\partial b=0$, $\partial L/\partial c=0$, we can get the estimates $\hat{\beta}\ \hat{a}\ \hat{b}\ \hat{c}$. The estimated true degradation distribution is expressed as:

$$F(x;t,T)=1-e^{-\left(\frac{x}{\hat{a}\cdot e^{\frac{\hat{b}}{T}}\cdot t^{\hat{c}}}\right)^{\hat{\beta}}} \tag{8}$$

The product will not work properly when the degradation value $x(t)$ reaches the threshold level D. For a fixed failure threshold, the reliability $R(t)$ is the probability that the true degradation value $x(t)$ is larger than the fixed threshold level D. Therefore, the reliability function based on fixed failure threshold is represented by the cumulative distribution function of the true degradation value distribution:

$$R(t,T)=P(x(t)\le D)=1-e^{-\left(\frac{D}{\hat{a}\cdot e^{\frac{\hat{b}}{T}}\cdot t^{\hat{c}}}\right)^{\hat{\beta}}} \tag{9}$$

2.3 *Reliability assessment method based on fuzzy failure threshold*

The membership function is used to describe the membership between an element u and a fuzzy set on the domain U. It is assumed that the performance degradation data has an increasing trend over time in this paper. In the beginning, the membership function is equal to 1. When the performance degradation data $x(t)$ increases to the lower limit of fuzzy failure threshold ($D_{\min}$), the membership function is $\mu_A(x)$, and the performance of the product continues to degenerate gradually; When the performance degradation data $x(t)$ is larger than the upper limit of fuzzy failure threshold ($D_{\max}$), the membership function is equal to 0 (Yan 2014).

Thus, the lower semi-trapezoid distribution membership function is:

$$\mu_A(x)=\begin{cases}1 & x<D_{\min}\\ \dfrac{D_{\max}-x}{D_{\max}-D_{\min}} & D_{\min}\le x\le D_{\max}\\ 0 & x>D_{\max}\end{cases} \tag{10}$$

2.4 *Establishment and assessment of reliability function based on measurement errors and fuzzy failure threshold*

Consider the measurement uncertainty of sensors, we assume the measurement errors ε_i obey a normal distribution ($\varepsilon_i \sim N(0,\sigma^2)$). So its probability density function is

$$f_\varepsilon(\varepsilon)=\frac{1}{\sqrt{2\pi}\sigma}\cdot e^{-\frac{(\varepsilon-\mu)^2}{2\sigma^2}} \tag{11}$$

A fuzzy subset showing the good state of the product is expressed as follows:

$$A\overset{\Delta}{=}\{D\ge X(t)\}=\{D\ge Y(t)-E\} \tag{12}$$

Since the true degradation value $x(t)$ has a different distribution form with the measurement errors ε_i, the reliability function based on measurement errors and fuzzy failure threshold can be obtained by applying the probability formula of the fuzzy event and the convolution formula:

$$\begin{aligned}R_A(t)&=P(A)=\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\mu_A(t)f(y-\varepsilon,t)f_\varepsilon(\varepsilon)dyd\varepsilon\\&=\int_{-\infty}^{\infty}\int_{0}^{D_{\min}}f(y-\varepsilon,t)f_\varepsilon(\varepsilon)dyd\varepsilon+\int_{-\infty}^{\infty}\int_{D_{\min}}^{D_{\max}}\mu_A(t)f(y-\varepsilon,t)f_\varepsilon(\varepsilon)dyd\varepsilon\\&=\int_{-\infty}^{\infty}\int_{0}^{D_{\min}}\frac{\beta}{\left(a\cdot e^{\frac{b}{T}}\cdot t^{c}\right)^{\beta}}\cdot(y-\varepsilon)^{\beta-1}\cdot e^{-\left(\frac{y-\varepsilon}{a\cdot e^{\frac{b}{T}}\cdot t^{c}}\right)^{\beta}}\frac{1}{\sqrt{2\pi}\sigma}\cdot e^{-\frac{(\varepsilon-\mu)^2}{2\sigma^2}}dyd\varepsilon\\&+\int_{-\infty}^{\infty}\int_{D_{\min}}^{D_{\max}}\frac{D_{\max}-y}{D_{\max}-D_{\min}}\frac{\beta}{\left(a\cdot e^{\frac{b}{T}}\cdot t^{c}\right)^{\beta}}\cdot(y-\varepsilon)^{\beta-1}\cdot e^{-\left(\frac{y-\varepsilon}{a\cdot e^{\frac{b}{T}}\cdot t^{c}}\right)^{\beta}}\frac{1}{\sqrt{2\pi}\sigma}\cdot e^{-\frac{(\varepsilon-\mu)^2}{2\sigma^2}}dyd\varepsilon\end{aligned} \tag{13}$$

Substituting the estimators $\hat{\beta}$ $\hat{a}$ $\hat{b}$ $\hat{c}$ in (13), then we acquire the reliability assessment result. If we ignore the measurement errors, the function reduce to be:

$$R_A(t) = P(A) = \int_{-\infty}^{\infty} \mu_A(t) f(\mathrm{x},t)\,dx$$
$$= \int_0^{D_{\min}} f(\mathrm{x},t)\,dx + \int_{D_{\min}}^{D_{\max}} \mu_A(t) f(\mathrm{x},t)\,dx$$
$$= \int_0^{D_{\min}} \frac{\beta}{\left(a \cdot e^{b/T} \cdot t^c\right)^{\beta}} \cdot y^{\beta-1} \cdot e^{-\left(\frac{y}{a \cdot e^{b/T} \cdot t^c}\right)^{\beta}} dy$$
$$+ \int_{D_{\min}}^{D_{\max}} \frac{D_{\max} - y}{D_{\max} - D_{\min}} \frac{\beta}{\left(a \cdot e^{b/T} \cdot t^c\right)^{\beta}} \cdot y^{\beta-1} \cdot e^{-\left(\frac{y}{a \cdot e^{b/T} \cdot t^c}\right)^{\beta}} dy \tag{14}$$

3 EXAMPLE OF SSD APPLICATION

3.1 *SSD test plan*

SSD consists of main control unit, power supply, connector, cache, and NAND flash. Non-volatile NAND flash memory is the core component. According to Fowler-Nordheim (FN) tunneling, electrons in memory cells write in or read out data in the NAND flash memory by passing through tunnel oxide repeatedly. This process reduces the reliability of memory cells, leading to the gradual degradation of the tunnel oxide.

As the environment temperature rises, the thermal motion energy of electrons increases, accelerating the destruction of tunnel oxide in tunneling. Therefore, temperature is the sensitive stress that causes SSD's performance degradation(Li, P., et al. (2017).

According to the reliability enhancement testing, the tested SSD's temperature design limit is proved to be –40 ~ 85°C, and operating limit is proved to be –80 ~ 125°C. Thus, a step-stress temperature preliminary test has been taken firstly by testing all the 9 samples from 25°C to 125°C with the same pre-fixed stress-change time. The degradation effect can be neglected because test duration is very short.

Results of the step-stress temperature preliminary test show that the majority of performance indexes nearly remain unchanged except the read/write current and quiescent current, which rise with the increasing of temperature. Therefore, the relationship between current drift Δx and temperature T can be modeled by regression analysis:

$$\Delta x = f(T) \tag{15}$$

Nine SSD samples are randomly divided into three groups. ADT is carried out in each group for each accelerated stress levels with 80°C, 90°C and 104°C. The test duration is set to 40 days and measurements are conducted every 96 hours. During the test process, performance characteristics (read/write current, quiescent current, read/write speed, read/write response time and bad block increment) are real-time monitored. Samples continue working all along at the same time. Results of the test indicate that write current is the most suitable index to track SSD degradation.

3.2 *SSD test results and reliability analysis*

After the determination of the relationship between write current drift and temperature, the degradation path model can eliminate the drift impact.

Assume the write current at 25°C to be the initial value, and apply the least square method to fit the average measured drift data. Then the fitting curve is illustrated in Figure.1.

The fitting model is expressed as:

$$\Delta x = a \cdot \exp(b \cdot \Delta T) \tag{16}$$

where Δx is the current drift; and ΔT is the temperature rise over initial temperature T_0 = 25°C. The parameters are estimated to be $\hat{a} = 2.088$, $\hat{b} = 0.03446$.

Samples tested under 80°C are named N-0, N-1, N-2, and N-3, N-4, N-5 under 90°C, and N-6, N-7, N-8 under 104°C. After eliminating current drift impact, the true degradation path of write current can be calculated under 80°C, 90°C and 104°C, which are shown in Figure. 2.

Figure. 3 shows the variation over time of the write current degradation distribution in terms of Weibull probability plots, for different levels of temperatures. The data is proved to follow the Weibull distribution as all the scatter points are close to the reference line.

Substituting the test observations by MLE with the Arrhenius-Weibull model presented above, the estimates $\hat{\beta}$ and $\hat{\eta}$ can be obtained. Further, with

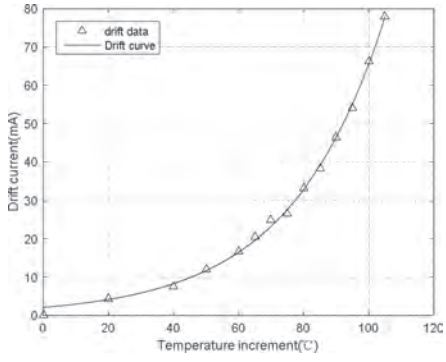

Figure 1. Regression analysis of current drift & temperature increment.

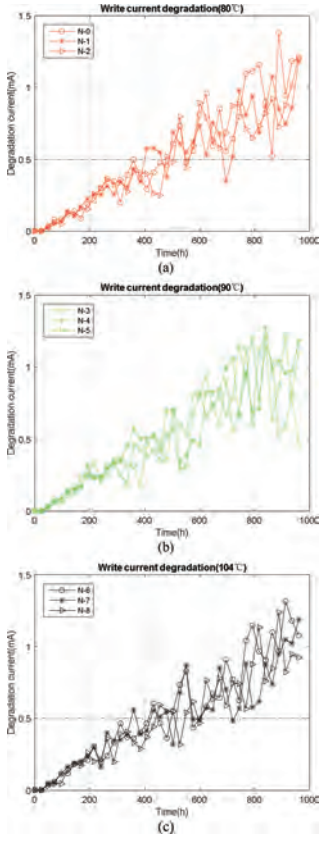

Figure 2. True degradation path of write current. (a) 80°C. (b) 90°C. (c)104°C

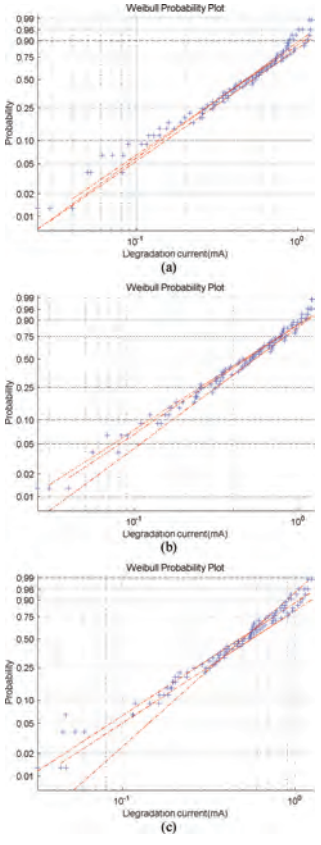

Figure 3. True degradation path of write current at different measuring time and temperature levels. (a) 80°C (N-0, N-1, N-2). (b) 90°C (N-3, N-4, N-5). (c) 104°C (N-6, N-7, N-8)

the estimates of $\hat{\eta}$ at different time points and stress levels, the parameters a, b, c can be estimated and the write current degradation distribution model is specified as:

$$F(x;t,T)=1-e^{-\left(\frac{x}{0.005e^{-350/T}\cdot t^{0.93}}\right)^5} \tag{17}$$

3.3 *Reliability extrapolation at normal working conditions*

Afterwards the Arrhenius-Weibull model is used to extrapolate the performance of SSD at normal temperature. According to the NAND flash memory manual, the failure threshold at normal temperature (25°C) is 125 mA (Isobe 2010). Then, the reliability function based on fixed failure threshold for SSD is:

$$R(t,T)=P(x(t)\le D)=1-e^{-\left(\frac{125}{0.005e^{-350/T}\cdot t^{0.93}}\right)^5} \tag{18}$$

Assuming the lower limit of fuzzy failure threshold ($D_{\min}$) to be 100 mA, and the upper limit of fuzzy failure threshold ($D_{\max}$) to be 150 mA. Besides, the variance of measurement error distribution is 0.8, namely $\varepsilon \sim N(0,0.8)$. As the integration in (13) and (14) have no explicit expressions, numerical integration method are used to solve the problems. Thus, the reliability curves based on fixed failure threshold, fuzzy failure threshold without measurement errors, and fuzzy threshold with measurement errors under normal temperature (25°C) are illustrated in Figure 4 respectively.

It can be observed that the three reliability curves are close to each other, but if we consider fuzzy threshold situation, the reliability is slightly smaller than the deterministic threshold. Moreover, the reliability with measurement errors and fuzzy threshold is the lowest. Thus, when dealing with SSD's reliability prediction, it's necessary to consider the influences of measurement errors and fuzzy threshold, which can result in a more conservative and practical value.

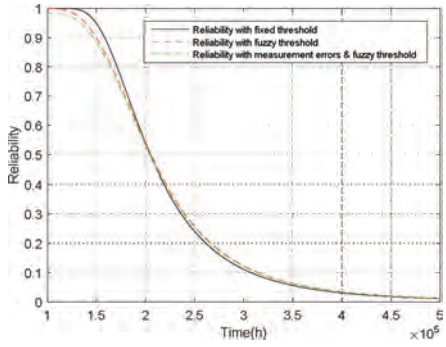

Figure 4. Reliability curve based on different assessment methods.

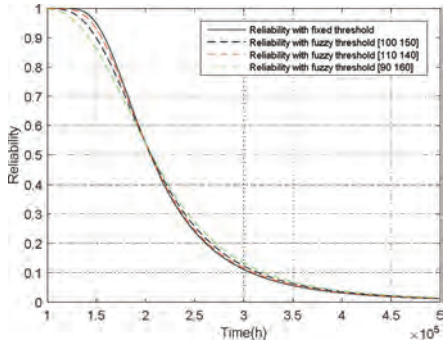

Figure 5. Reliability curve under different failure thresholds.

For further analysis, Figure 5 represents the reliability curves under different failure thresholds by changing the range of failure threshold.

It can be found that the smaller the fuzzy threshold range is, the closer the reliability assessment curve is to the reliability curve based on fixed failure threshold. The reliability comparison results show that the reliability assessment method based on measurement errors and fuzzy failure threshold is more accurate and flexible.

4 SUMMARY AND CONCLUSIONS

In this paper, a reliability assessment method based on fuzzy failure threshold and measurement errors is proposed. Firstly, we establish the life-stress model and lifetime distribution model, and then model parameters are estimated by the maximum likelihood estimation method. Secondly, we derive the reliability model based on fixed failure threshold by substituting the estimators into the combined Arrhenius-Weibull model. Thirdly, we present a reliability assessment method based on fuzzy failure threshold and measurement errors by applying the probability formula of the fuzzy event and the convolution formula. Subsequently, we take a type of SSD as an example to demonstrate the reliability assessment method. In the end, we compare the reliability assessment curve based on different situations. The comparison results show that the proposed method has a higher assessment accuracy, and it is more flexible.

Effect of load-generation variability on power grid cascading failures

R. Rocchetta & E. Patelli
Institute for Risk and Uncertainty, Liverpool University, Liverpool, UK

L. Bing & G. Sansavini
Reliability and Risk Engineering Laboratory, Department of Mechanical and Process Engineering Institute of Energy Technology, ETH Zurich, Zurich, Switzerland

ABSTRACT: Cascading failures events are major concerns for future power grids and are generally not treatable analytically. For realistic analysis of the cascading sequence, dedicated models for the numerical simulation are often required. These are generally computationally costly and involve many parameters and variables. Due to uncertainty associated with the cascading failures and limited or unavailable historical data on large size cascading events, several factors turn out to be poorly estimated or subjectively defined. In order to improve confidence in the model, sensitivity analysis is applied to reveal which among the uncertain factors have the highest influence on a realistic DC overload cascading model. The 95*th* percentile of the demand not served, the estimated mean number of line failures and the frequency of line failure are the considered outputs. Those are obtained by evaluating random contingency and load scenarios for the network. The approach allows to reduce the dimensionality of the model input space and to identifying inputs interactions which are affecting the most statistical indicators of the demand not supplied.

1 INTRODUCTION

Assure high-reliability of electric power supply is a major concern for next-generation power grid. Power grid should have the ability to withstand know threats, such as N-1 and N-2 contingencies, but also poorly understood low-probability-high-consequence events such as N-k contingencies leading to cascading sequences. Due to the inherent complexity of cascading failure events, associated mathematical models are, generally, analytically not solvable. This is mainly due to the high dimensionality of the problem and to the complex, non-linear and dynamic behaviour characterizing domino failures.

Computational models for the simulation of the cascading sequences are used to provide a solution to the cascade problem. A wide variety of models have been proposed in the past, aiming at analysing different system behaviours and with several different objectives. For instance, models employing the AC power flow (PF) equations, such as the Manchester model (Nedic et al. 2006) or the linearized AC PF model (Li et al. 2016), the ORNL-PSerc-Alaska (OPA) model (Dobson, Carreras, Lynch, & Newman 2001) and DC PF-based models have been developed to simulate realistically cascading failures sequences.

Numerical models for cascading simulation have to be adequately designed, calibrated and validated (Bialek et al. 2016). Calibration and validation should use available historical cascading data, which is (in particular for large size cascade events) quite limited (Rocchetta et al. 2018) or affected by imprecision (Rocchetta et al. 2018). Consequently, the resulting model verification and calibration is very challenging and affected by high level of uncertainty. Uncertainty will result particularly prominent when the model is used to simulate rare events leading to very severe consequences.

To increase confidence in the cascading model results and better understand the relation between its inputs and outputs, all the relevant sources of uncertainty affecting the analysis should be quantified. Dimensionality and complexity issues are often involved in cascades analysis problems and the numerical simulators generally reflect these problems. In fact, the simulators often are time costly and involve a large number of uncertain variable and parameters.

Sensitivity analysis methods are useful to deal with both dimensionality and uncertainty issues. These methods can be used to reveal which sources of uncertainty are affecting the most the model output and can be used to reduce the dimensionality of the aleatory space by prioritizing only the most important factors. This is indeed a useful information, necessary to better comprehend inputs-outputs relations otherwise hidden within the complexity of the model.

Global sensitivity analysis methods are often employed by uncertainty analysts to sharpen the

view of the problem. Sensitivity analysis is sometimes regarded as a fundamental part of works that involves the assessment and propagation of uncertainty (Borgonovo and Plischke 2016). Applying global sensitivity analysis methods, insights can be gained regarding the input-output mapping and the key drivers of uncertainty can be clearly revealed (Borgonovo and Plischke 2016).

In this paper, an integrated framework for sensitivity analysis and power grids cascading analysis is proposed. The framework can be used to identify and prioritize the most relevant uncertain input factors by revealing their effect on different cascading failures indicators. Both system-level indicators, describing the overall impact of cascading failures, and component-level indicator, focusing on a single component performance, are considered. One of the aims of this work is to provide some guidance for the application of given data sensitivity analysis and screening methods to engineering practitioners, promoting their potential.

The framework is tested on a modified version of the RTS96 IEEE system. Two uncertainty cases are analysed, first accounting for only the uncertainty in the load demand. Then, a more complex and realistic case has been considered by accounting for randomness in the generators costs, thus inflating the dimensionality of the input space, i.e. more flexibility for the generators outputs. The analysis allows to point out which among loads and generator costs uncertainties is affecting the most the outputs of cascading failures model and for a modest computational effort.

The rest of the paper is organized as follows: Section 2 introduces global sensitivity analysis and screening methods. In Section 3 the algorithm for cascading failure simulation and the performance indicators are introduced. A benchmark case study, the RTS96 system, tests the framework in Section 4, 2 uncertainty cases are analysed. Section 5 closes the paper with a discussion on the results and conclusions.

2 SENSITIVITY ANALYSIS AND SCREENING

This section proposes a concise introduction to uncertainty quantification and methods for global sensitivity analysis. Traditionally, uncertainty quantification and analysis consist in the assignment of probability distributions to the model input factors (variables and parameters). Once the uncertainty has been characterized, it is propagated into the simulation code via Monte Carlo method. First, uncertain factors are characterised by assigning probability distributions. This is an important step which has to be performed adequately to assure high quality and consistency of results (Patelli, Pradlwarter, & Schuller 2010). Then, samples are obtained from the joint probability distribution of the input factors, e.g. by Latin hypercube sampling, quasi-random sequences or crude Monte Carlo inverse transform sampling (Patelli, Broggi, Angelis, & Beer 2014). Once the i^{th} input realisation is obtained $\boldsymbol{X}_i = \left[X_i(0),..,X_i(m)\right]$, the sample is forwarded to the computational model $M(X)$. This allows obtaining information about the input-output mapping defined by the computational model as follows:

$$M : \mathcal{X} \to \mathcal{Y},\ \boldsymbol{X} \to Y = M(\boldsymbol{X}) \tag{1}$$

where Y is the model output, for simplicity assumed 1-dimensional and without loss of generality.

Global sensitivity analysis methods have been developed to identify the most and the least relevant factors and gain additional insight on the input-output mapping defined in equation 1. Several global methods have been developed in the last decades. Screening methods, such as the one-at-a-time design of Morris (Morris 1991), variance-based methods, density-based methods (Borgonovo & Plischke 2016) are some of the most intensively applied methods.

2.1 *Given data Sobol's indices*

A variance-based statistic, commonly referred as the first order sensitivity coefficient, quantifies the (additive) effect of each input factor on the model output as follows (M. Sobol 1990):

$$S_i = \frac{V_{X_i}\left[\mathbb{E}_{\mathbf{X}_{\sim i}}[Y \mid X_i]\right]}{V[Y]} \tag{2}$$

where $V[Y]$ is the total variance of the output Y, X_i is the i^{th} uncertain input factor, $\mathbf{X}_{\sim i}$ is the matrix of all uncertain factors but X_i, $\mathbb{E}_{\mathbf{X}_{\sim i}}[Y \mid X_i]$, is the expectation of the model output Y taken over all possible values of $\mathbf{X}_{\sim i}$ while removing the X_i uncertainty (i.e. keeping X^i fixed) and $V_{X_i}[]$ is the variance taken over all possible values of X_i. The indices S_i can be used to reveal the importance of the input factor X_i on the variance of the output and it is a normalized index, that is $\sum_i S_i = 1$

The main effect index reveals what is the importance of each uncertain factor on the uncertainty in the model output. It relatively cheap to obtain as it can be efficiently computed using given data methods or from a single Monte Carlo run (Plischke et al. 2013). The main drawback of the index is that interactions between input factors are not accounted for with this sensitivity measure. Higher order Sobol's effects (second and higher order interactions) compose the so-called total effect index S_{Ti}. This is a variance-based measure of the influence of an input i accounting for all the inter-

actions with other uncertain factors. It is defined as follows:

$$S_{Ti} = \frac{\mathbb{E}_{\mathbf{X}_{-i}}\left[V_{X_i}[Y \mid \mathbf{X}_{-i}]\right]}{V[Y]} = 1 - \frac{V_{\mathbf{X}_{-i}}\left[\mathbb{E}_{X_i}[Y \mid \mathbf{X}_{-i}]\right]}{V[Y]} \tag{3}$$

where S_{Ti} account for all the contribution to the total variance of the output $V[Y]$ when the first order effect of $\mathbf{X}_{-i}$ is removed.

2.2 *Elementary effects and Morris diagram*

The Elementary Effects (EEs) is a screening method used identify the effect of input factors $X(i)$ with $i = 1,2,\ldots,m$ on the output Y of a mathematical or computational model $M(\mathbf{X})$. The method consists in the calculation of m incremental ratios, also called Elementary Effects, which are used to assess the influence of the input variables and parameters. The i^{th} elementary effect of the m-dimensional input vector $\mathbf{X}_0$ is defined as follows:

$$\delta_i(\mathbf{X}_0) = \frac{Y\left(X_0(1),..,X_0(i)+\Delta,..,X_0(m)\right) - Y(\mathbf{X}_0)}{\Delta} \tag{4}$$

where the quantity Δ is a given variation in the input factor whose effect has to be evaluated. Intuitively speaking, the input factors leading to the higher incremental ratios $\delta_i(\mathbf{X}_0)$ have to be considered as the most relevant for the output quantity Y. Of curse, this relevance metric is valid only locally, in $\mathbf{X}_0$, where Y has been evaluated. Repeated One-At-a-Time (OAT) evaluations of random vector configurations provide the elementary effect method with global sensitivity analysis features (Turati et al. 2017). The mean and standard deviation of the EEs, resulting from random input vector configurations, can be plotted in the well-known $\mu(\delta) - \sigma(\delta)$ plot proposed by Morris (Morris 1991). If a factor X_i results in a small absolute value of the mean and small variance, it should be considered less relevant for the model. On the other hand, a factor X_i resulting in a high $|\mu(\delta_i)|$ has to be considered highly relevant for the model, i.e. it leads to the average higher variation in the output. Similarly, a factor X_i resulting in a high $\sigma(\delta_i)$ is also of interest for the model output. In fact, high $\sigma(\delta_i)$ probably indicate a non-linear relation between the factor i and the output and/or a relevant interaction with other factors. An example of Morris plot is presented in Figure 1 where the standard error of the mean (SEM) is used to decompose the plot in different areas.

The method has some points of strength, worth highlighting: 1) It is relatively easy to implement; 2) Computationally cheap compared to other global sensitivity methods also for high number of factors; 3) It uses a sensitivity measure which is simple to communicate (similarity between incremental rations and partial derivatives) to non-experts; 4) Compared to variance/based measures, shows if the input factors are (in average) positively or negatively correlated to the output.

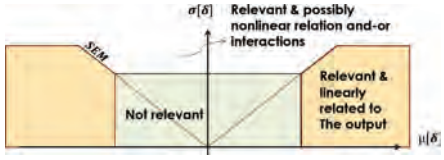

Figure 1. An example of Morris diagram and how to discern between important and non important factors.

3 THE CASCADING MODEL

A model for the simulation of steady-state operations of electric networks has been developed and calibrated in (Bing Li and Sansavini 2017). It can be used to simulate the initial contingencies that trigger the cascading events and estimate the post-contingency system states. The initial generation dispatch for each load demand is computed with a Security Constrained Optimal Power Flow (SCOPF), which takes into account the generators constraints, line flow constraints, voltage angles constraints and, optionally, the N-1 security constraints. After line tripping, DC power flow is used to evaluate the post-contingency power flow. The failures propagate in the grid through line over loading. Frequency control and protections, voltage protections and a variety of other automatic and realistic regulations and remedial actions are also included in the model.

A simplified flow chart of the cascading failures analysis is presented in Figure 2 adapted from (Bing Li and Sansavini 2017). The algorithm starts by loading power grid data, selecting the steady-state solver (e.g. DC-SCOPF) and a list of N-k contingencies. Then, for each contingency N-k, islands are identified, frequency deviation assessed and under frequency load shedding performed if necessary. Once power balance is restored, line flows are evaluated using the power flow solver and the lines exceeding their flow limit are removed from the grid topology. This process is repeated until grid stability is reached. The considered outputs are the total Demand-Not-Served (DNS) due to contingency N-k and lines failure indicator functions indicating if a line tripped during the simulation of the N-k contingency.

For simplicity, the contingency list has been obtained by random sampling N-1, N-2 and N-k line contingencies. To better identify and select

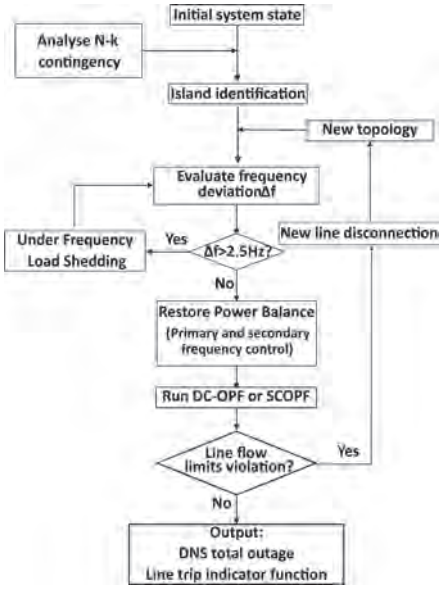

Figure 2. The flow chart of the algorithm for cascading failures analysis.

critical failure scenarios, methods such as the N-2 contingency screening, eg. the method presented in (Kaplunovich and Turitsyn 2016), could have been employed. However, a smart exploration of the contingency space was not the main aim of this work. Once the list is obtained, repeated N-k contingency analysis are performed as presented in Algorithm (Bing Li and Sansavini 2017).

3.1 *System and components performance indicators*

Several output measures can be obtained from the cascades model. In this work, we focus on 2 system-level indicators, which provide insights on the grid performance as a whole, and on N_l components performance indicators, one for each line in the system.

The indicators are the 95*th* percentile of the DNS cumulative distribution function $p_{95}(DNS)$, the average total number of lines tripped $\mu(N_f)$ and the line outage frequency $P_{f,l}$, defined as follows:

$$\mu(N_f) = \frac{\sum_{c=1}^{N_c}\sum_{l=1}^{N_l} I_{l,c}}{N_c}; \quad P_{f,l} = \sum_{c=1}^{N_c} \frac{I_{l,c}}{N_c};$$

where N_c is the total number of contingencies listed, N_l is the total number of lines in the system and $I_{l,c}$ is the indicator function for line l and contingency c. The indicator function will result 0 if the line survived the cascading propagation initiate by contingency c or 1 if the line failed, e.g. due to flows redistribution leading to an overload.

4 A CASE STUDY

The IEEE RTS96 power grid is used to test the methods and the cascading model and Figure 3 displays the grid layout. The power grid data can be found in (Grigg et al. 1999) and are not reported here for sake of synthesis. In this analysis, two representative uncertainty cases, named Case A and B, are considered. In Case A, the uncertainty associated with the load demand is explicitly modelled. In the second case, CASE B, also random generation costs are accounted for, thus introducing uncertainty in the power dispatch and increasing the dimensionality of the random input space. The DC cascading model presented in section 3, is employed for the solution of the cascading problem. A predefined contingency list is selected and includes 2444 line contingencies. The list counts the full set of N-1 and N-2 line failures and a set of 1000 random N-3 line failures. To simplify comparison between uncertainty cases and the different sensitivity analysis methods, the contingency list has been kept the same throughout all the analysis (i.e. the random set of N-3 contingencies has been sampled just once).

4.1 *CASE A: Random loads*

The first uncertainty case A assumes that uncertainty affects the 17 loads in the system due to inherent variability. The analysts lack better information regarding the variability affecting the load at each node, thus, the uncertainty in *Li* is simply modelled by assuming uniform distributions. The

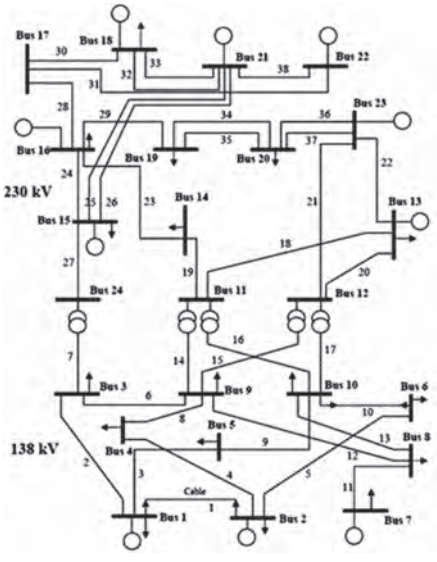

Figure 3. The IEEE RTS96 system, the connections between the 24 nodes, the lumped generators (32 generators) and the location of the aggregated loads (17 arrows).

distribution parameters have been selected to cover a range of values around the design loads and based on experts opinion:

$$L_i \sim U\left(0.5L_{d,i}, 1.2L_{d,i}\right) \quad i = 1,..,N_l$$

where $L_{d,i}$ is the design load of node i as presented in (Grigg, Wong, Albrecht, Allan, Bhavaraju, Billinton, Chen, Fong, Haddad, Kuruganty, Li, Mukerji, Pat ton, Rau, Reppen, Schneider, Shahidehpour, & Singh (1999) and the number of lines is $N_l = 17$.

Once the uncertainty sources are characterized, a preliminary uncertainty analysis is performed. Monte Carlo method is used to propagate 5e4 samples of the load profile. For each load sample, the cascading failure model is solved 2444 times, one for each contingency listed. The percentile of the demand not served, the average number of failed lines and the line outage frequencies are computed for each load sample as described in Section 3.1. The p_{95} (*DNS*) results are summarised in Figure 4. This figure presents a so-called cobweb plot, also known as parallel coordinates plot. It is a simple and effective way of visualising random input and output spaces in high dimensions. The X-axis reports the inputs loads and the percentile of the DNS (on the far right). The Y-axis reports the normalized inputs and output realisations of the Monte Carlo method. Each one of the dark dashed line in the background corresponds to one load profile realisation and corresponding The p_{95} (*DNS*) obtained through N_c model evaluations. Red solid lines are conditional samples, which highlight only the load combinations leading to the highest p_{95} (*DNS*). It can be observed, later confirmed by Morris' and Sobols' analysis, that there is a strong influence of some of the loads (e.g. in nodes 15 and 18) on the extremes of the DNS. In particular, when the power demanded in nodes 15 and 18 is small, the risk of facing severe DNS scenarios increases.

Morris and Sobol's indices have been computed aiming at better investigating which among the uncertain factors are key drivers for the output uncertainty. The Morris indices are obtained by selecting 250 random input vector realisations

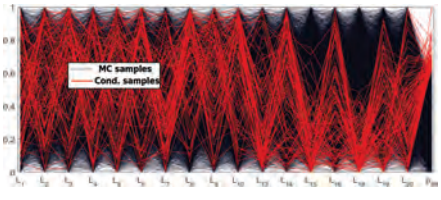

Figure 4. The parallel plot of the Monte Carlo loads and p_{95}(DNS) realizations. In red solid line the conditional samples which lead to the highest p_{95} and in the background (black dashed lines) all the MC realisations.

(saved from the MC) and computing incremental ratios δ as described in section 2.2. The Sobol's first order coefficents are obtained using given data sensitivity approaches, see ref. (Plischke, Borgonovo, & Smith 2013) for further details. This is a very convenient approach as for calculations, as the data from the MC run can be used for this and with essentially no-extra computational cost. On the other hand, total Sobol's indices require higher computational cost and in this work the Liu and Owen method (R. Liu 2006) is used for their computation.

The result relative to the DNS percentile and the average total number of line failed are presented and compared in Table 1. The Morris statistics and Sobol's main and total effect indices are also graphically presented in the $\mu - \sigma$ plot in Figure 4 and in Figure 5, respectively. Both methods identify L_{18} and L_{15} as the most influencing factors for the DNS and average number of line failures. Less relevant but, not to be neglected, is the effect of loads in nodes 8, 19 and 16. Morris analysis has the advantage of revealing an inverse relation between L_{18}, L_{15}, L_{19} and the outputs (see figure 4) which could not be revealed only using Sobol's indices. On the other hand, an increment in load 8 lead to higher risk of extreme DNS.

This result can be explained looking at the generators production profile, which is obtained solving the pre-contingency DC-SCOPF with objective

of minimizing generation costs. The generators in nodes 18, 22 are associated with lower generation costs. This lead to the maximum exploitation of their production capacity, independently from the load profile realisation. Consequently, when electrical power is consumed in loco (e.g. the loads close to these generators as in 15 and 18), less power will be flowing from the 'northern' area to the 'southern' area of the network. On the other hand, if less power is demanded in, for instance, nodes 18 and 15 (or more power in 8), this increases the risk of higher loads on line such as 24, 25 and 26 which connecting the upper part of the grid with the lower part, and with it the risk of facing more severe post-contingency scenarios.

4.2 *CASE B: Random loads and generator costs*

The second uncertainty case B extends case A by accounting for generators costs uncertainties. The generation cost variability is characterised by uniform probability distributions as follows:

$$C_{g,i} \sim U(0.9,1.1) \quad i = 1,..,N_g$$

where $C_{g,i}$ is the cost of the generating unit i and the number of generators N_g is equal to 32. By assuming costs $C_{g,i}$ distributed uniformly between 0.9 and 1.1, the economic viability of the generators drastically changes if compared to case A. This lead to a higher variability in the economic dispatch, i.e. generators in nodes from 18 to 22 will sometime produce less than their maximum capacity. This case study shows the applicability of the method to larger input spaces and larger power grids. Furthermore it shows the impact of different generation profiles, in combination with load demands, on the cascading failures.

Similarly to the uncertainty case A, a Monte Carlo uncertainty propagation is performed and the Sobol's S_i indices and Morris $\mu(\delta)$ and $\sigma(\delta)$ have been calculated. The 5 most influencing factors

5	L_{18}	L_{18}	L_7

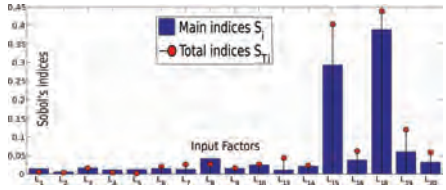

Figure 6. The Sobol s main and total effects obtained for the uncertainty case A and for the DNS percentile output.

(among the 17 loads and 32 generator costs) affecting the 95*th* percentile of the DNS are reported in Table 2. Multiple generators can be found in the same bus and to simplify the notation, the relevant costs are presented using the symbol $G_k(j)$, where j is the machine reference number within the bus k where the generator is installed. Differently from case A, load in node 8 emerged as the most relevant factor for the DNS percentile.

Uncertainty in the loads and generator costs has been propagated to the line outage frequency indicator $P_{f,l}$. The resulting MC realisations are displayed using a box plot in Figure 6. The X-axes shows the lines identification number and the Y-axes presents the $P_{f,l}$ values (red markers). Each box indicates the median (the central mark) and the bottom and top edges of the box indicate the

25th and 75th percentiles, respectively. It can be observed that the line connecting node 7 to node 8 results in the higher failure frequency and that lines in the lower voltage area of the grid (ID from 1 to 13) are more prone to failure. This result is probably due to the lower thermal limit (175 MW) and to the specific combination of grid topology, design load demanded in node 7 and 8 (125 and 171 MW, respectively) and generators in node 7 maximum lumped capacity (300 MW). Thanks to the sensitivity analysis, it has been possible to clarify which are the factors responsible for this peculiar behaviour, i.e. better understanding which are the variables which are contributing the most to $P_{f,7\text{–}8}$.

Main effect sensitivity indices have been computed for each line $P_{f,l}$ to reveal which of the input factors is affecting the most their variability. Results are presented graphically with a bar plot in Figure 8 and reported in Table 3. Table 3 presents only the factors leading to relatively high S_i, i.e.

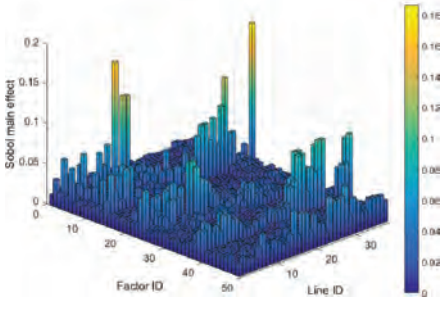

Figure 9. The $\boldsymbol{S}_i$ indices calculated for the 49 input factors and for the $\boldsymbol{P}_{f,l}$ outputs. The factors from 1 to 17 are loads at different locations and last 32 are the generator costs.

Table 3. The most influencing factors for the line failure probability. Factors leading to a $\boldsymbol{S}_i > 0.08$.

From	To node	Factors
7	8	L_7, $G_7(1)$, $G_7(2)$
8	9	L_8
8	10	L_8
15	21	L_{18}, $G_{18}(1)$, $G_{21}(1)$
15	21	L_{18}, $G_{18}(1)$, $G_{21}(1)$,
16	17	L_{18}
17	18	L_{18}, $G_{18,}(1)$, G_{21} (1)
17	22	L_{18}, $G_{18,}(1)$, G_{21} (1)
21	22	L_{18}, $G_{18,}(1)$, G_{21} (1)

greater than 0.08, and the corresponding components. It can be observed that the variability in the line 7–8 outage frequency is mainly affected by uncertainty in node 7 (generators and load). On the other hand, uncertainty in L_8 is not affecting much the variance of $P_{f,7\text{–}8}$ but it is the most relevant factor for $P_{f,8\text{–}9}$, $P_{f,8\text{–}10}$.

5 DISCUSSION AND CONCLUSIONS

In this paper, the sensitivity of a cascading failures model for power grids has been analysed. Variance-based global sensitivity analysis indices, i.e. Sobol's indices, have been computed to reveal which among the uncertainty sources is affecting the most the variances of the cascading failure model output. The Morris screening indices are also obtained and compared to variance based indices to improve confidence in the results and better understand dependencies between output and factors.

Different system-level and component-level indicators have been evaluated using the cascading model. The selected metrics were the 95*th* percentile of the DNS, the average total number of line failed and the frequency of line failure for each line. The IEEE RTS96 power grid has been selected as a representative case study and used to test the applicability of the methods to a real-world system. Two uncertainty cases (Case A and Case B) have been investigated, which were characterised by an increasing dimensionality of the aleatory space.

In the Case A, only load variability has been accounted for and the result suggested that two uncertainties in the loads in node 15 and 18 are the major contributors to the extremes of the demand not served. A similar result is obtained for the average total number of line failed. Morris had the advantage of showing a negative relationship between the DNS and loads in nodes 15 and 18. In reality prices are indeed affected by uncertainty, so a sensitivity analysis that assumes fixed prices (and therefore fixed generator dispatch) might be misleading in identifying critical components in the

power grid. Thus, in the uncertainty Case B, the variability of the generator costs and loads variability are both considered. The new economic setting changed the underling behaviour of the network and, consequently, of the cascading evaluation process. The Sobol's and Morris' analysis are fairly consistent in pointing out which among the load and generators costs are the most relevant for the system output. The results are quite different compared to case A, due to the difference in the economic setting of the generators. In addition, the sensitivity of the lines outage frequency has been computed.

This analysis was performed to investigate more in detail some cascading-relevant relationships between input loads, generators costs and line failures. The results are very interesting from an engineering perspective and at least 2 results can be highlighted which are helpful in a practical context:

- The vulnerable lines (i.e. prone to failure) and the most relevant factors affecting $P_{f,l}$ are identified (using sensitivity indices). This information can be helpful to support reliability-related decision, for instance, in deciding on weather it is better to replace the line with one having higher capacity (i.e. if $P_{f,l}$ high and is similarly affected by all the input factor), or if it may be more useful to intervene on the factors affecting $P_{f,l}$ (i.e. if $P_{f,l}$ high and sensitive to just few factors);
- When the uncertainty in the loads is identified as highly relevant for a system-level indicator, it is advisable to consider actions such as allocation of distributed generators or adopt peak-shaving (load variance reduction) control methods. This can be beneficial to reduce the uncertainty in the reliability performance of the network (reducing its variance).

The framework proved to be flexible and computationally quite cheap which is a requirement for its application to more realistic large size power networks. This will be the focus of future analysis.

Managing interdependencies in critical infrastructures—a cornerstone for system resilience

P. Ferreira

E. Bellini
University of Florence, Florence, Italy

ABSTRACT: The management of critical infrastructures is increasingly challenged by the high complex and interdependent nature of their operations. The need for methods and tools that better address these challenges has been often argued in literature. An improved access and accuracy of information on local operational conditions is referred to as one of the assets to be pursued, towards better coping with complexity. Technology currently available facilitates the access to a wide range and amount of data and information. However, putting such data and information to use as an effective support to decision making remains poorly addressed. Project RESOLUTE proposes an approach to the management, aggregation and processing of "big data" towards an enhanced adaptive capacity of stakeholders within critical infrastructures. The approach is based on the understanding of functional interdependencies between stakeholders and the use of that understanding for the tailoring of existing data to various operational contexts and conditions. A modelling of critical infrastructures was developed using FRAM. This model is then used as a basis for the development of an IT platform that supports coordination and cooperation between stakeholders.

1 INTRODUCTION

The increasing interdependent nature that spans across all industry sectors poses major challenges. While most management practices remain grounded on the control of internal processes, an increasing number of threats emanate from beyond the formal boundaries of organisations, where control based approaches reveal many shortfalls. Safety barriers that are continuously raised against threats identified based on hindsight, often show little effectiveness in the face of the variability and uncertainty that emerge from a growingly interdependent world.

Risk management remains strongly attached to the assumption that phenomena can be sufficiently known and described, so as to fully master the likelihood and means through which undesired events may occur. However, there is a growing awareness that managing and coping with uncertainty is an unavoidable consequence of the interdependent world. Singly investing on the elimination of uncertainty through hindsight-based statistical and predictive approaches is no longer sufficient. The maturity of methods and tools to effectively manage uncertainty remains unsatisfactory in view of industry needs and desires of communities at large.

This paper presents an approach to the management of uncertainty within critical infrastructures based on the experience of project RESOLUTE. Rather than attempting to eliminate uncertainty through knowledge on how and when "things might happen", the focus is set on understanding their sources as a result of highly interdependent and tight coupled operations. Project methodology is outlined and the key aspects of interdependency and uncertainty within critical infrastructures are highlighted. Main results are then presented and, given that it is an ongoing project, the paper concludes with a discussion of foreseeable achievements in terms of potential enhanced adaptive capacities and ability to cope with uncertainty for critical infrastructure stakeholders. As argued by Woods (2015), enhancing such adaptive capacities can be placed at the core of systems resilience, in particular within the scope of the resilience engineering approach.

2 COMPLEXITY, UNCERTAINTY AND INTERDEPENDENCY

The notion of complexity is widely used and yet remains difficult to define with precision. Many definitions of the concept underline that

something complex challenges the ability to describe and also to predict in terms of its states or behaviours, and of outcome of any actions taken or changes introduced to it (Hollnagel, 2012a). This feature of complexity is particularly relevant for the scope of this discussion, as it can be placed at the source of uncertainty. According to Grote (2009), uncertainty may concern the probability of an event (state uncertainty), a lack of information on the outcomes of an event and the underlying cause-effect relationships (effect uncertainty), or a lack of information about response options and their consequences (response uncertainty). RESOLUTE proposes to address the need for understanding uncertainty through the modelling of functional interdependencies. This is addressed late in this paper.

Another important aspect of complexity is the lack of linear behaviours. As pointed by Flach (2012), things like a mechanical clock can exhibit a wide range of possible states and yet, because the relations between its parts assume a linear nature, these possible states can be predicted. This however, would fit the definition of something that is complicated rather than something complex. Complexity is related to non-linearity. Describing and predicting possible states and outcomes cannot be achieved by the knowledge of individual variables or components, and of their relations. Within complex environments, a given action may lead to many different outcomes and a given state can be achieved through many different combinations of variables or parts (Flach, 2012).

Interdependency if often at the source of non-linear behaviours. Variables or components can interact and combine in many different ways, much beyond simple cause-effect relations. Interdependency has been studied for a number of decades. James Thompson (Thompson, 1967) had anticipated in 1967 the critical role that this phenomenon would play across most social endeavours.

The pursuit of multiple goals and the need to secure the access to a wider diversity of resources to respond to this pursuit generate self-reinforced cycles. The more interdependencies are generated through coalitions and exchanges of resources, the higher the number and diversity of goals that are put into play. The conflicting priorities that must be negotiated, lead to the continuous pursuit of more convenient options, which in return can be placed at the source of a search for coalitions that may potentially offer higher benefits. Thus, multiple conflicting goals produce continuous adjustments in existing interdependent relations, and also generate the potential for the expansion towards new interdependencies. As interdependencies increase in number, diversity, dynamics and complexity emerges and with it, uncertainty increases (Flach, 2012).

3 THE RESOLUTE APPROACH

Complexity and its inherent interdependent nature, poses a challenge to the management of critical infrastructures. As stated by Flach (2012), "classical hierarchical or servomechanism-type control systems are inadequate as a basis for dealing with the unanticipated variability endemic to complex work domains".

3.1 *The context of critical infrastructures*

The European Directive 2008-114-CE from the European Commission defines critical infrastructures as an "asset, system or part of which is essential for the maintenance of vital societal functions, health, safety, security, economic or social well-being of people, and the disruption or destruction of which would have a significant impact".

Critical infrastructures are particularly prone to the emergence of complexity and uncertainty related issues. On the one hand, they operate at the intersection of a wide range of stakeholders, with diverse organizational and legal status (i.e. public service, non-profit and for profit…), and with multiple operational purposes (i.e. maintenance, oversight and control, support and service delivery…). On the other hand, critical infrastructures tend to operate within many different scales, both geographically and temporally.

In addition, the critical nature of the service they provide exposes these infrastructures and their operation to a particularly strong public and political scrutiny. This kind of exposure often generates important pressures towards heightened efficiency, reliability and safety of operations. This means that critical infrastructures are expected to generate the capacity to adapt to continuously changing environments under highly complex and uncertain operational conditions. Generating such adaptive capacities is at the core of resilience (Woods, 2015) and to which project RESOLUTE aims to contribute to. The challenge then becomes how to integrate flexibility as a requirement for adaptive capacities, whilst ensuring the degrees of coordination and alignment between multiple goals necessary to respond to efficiency and safety demands.

3.2 *RESOLUTE methodology*

Project methodology was based on the functional modelling of critical infrastructures as sociotechnical systems. The modelling activities were carried out with the FRAM – Functional Resonance Analysis Method (Hollnagel, 2012b). FRAM enables modelling activities through the description of human, technical and organisational elements as functions within an interdependent system. FRAM

is essentially a tool intended for the modelling of "real work". It has been mainly applied to the modelling of operations and work on what is often considered the "sharp end" where human activity and processes tend to be more tangible. Within the RESOLUTE approach, the aim was to develop a generic functional model at critical infrastructure level. The contrast with what is normally considered the "sharp end" is that, at critical infrastructure level, interactions between human, organisational and technical elements tend to be less direct and may become more difficult to perceive and describe. Interviews with subject matter experts were used to develop the necessary insight on operations that mainly consisted of decision-making processes distributed across multiple infrastructure stakeholders. Given the broad system scale that was needed in this case (a critical infrastructure), the functions described are often imprecise in terms of their nature (human, technical or organisational). The insight obtained through the contact with experts was used to ascertain if each function was described with an acceptable level of clarity and precision.

Functions were identified on the basis of "what (actions or processes) should be carried out in order for a given critical infrastructure to achieve its operational purpose (the delivery of a given service)". Functions are then described according to six different aspects: input, output, resources, preconditions, time and controls. In order to systemise the gathering of data and information for the modelling activity, a set of triggering questions were used. These are shown in Table 1.

Table 1. Questions supporting the description of functions.

	Triggering questions
Input	• What should start the function? • What should the function act on or change?
Output	• What should be the output or results of the function? • Do you should to inform anyone? • Do you have to collect or record/report anything? If so, where? • Who needs the output? Who will use what is produced?
Precondition	• What should be in place so that you can complete the function normally?
Resource	• What resources do you need to perform the function, such as people, equipment, IT, power, buildings, etc.?
Control	• Should be any formal procedures or instructions controlling the function? • Should be people, such as supervisors, controlling the function? • Should be there any priorities? • Should be there specific constraints?
Time	• Should be there any time related to the function? • Should be a certain time where you have to perform the function?

Through the identification of these six aspects for each of the functions described, the potential couplings between functions can be identified. Except for the function output, the remaining five aspects can be considered as inputs to the function that rely on couplings with "upstream" functions. These potential couplings may then become effective, as system operation is instantiated in the model. These couplings represent the "functional points" at which critical infrastructure stakeholders generate interdependencies to ensure process flows and overall conditions necessary to service delivery. This provided an important understanding of various critical operational aspects at system level, namely how key resources are exchanged amongst stakeholders, or operational control is carried out, among others.

The main focus of RESOLUTE was urban transport systems as a critical infrastructure. The generic FRAM model developed was interpreted in the context of urban transport systems, in order to produce a more concrete understanding of the different stakeholders and their interdependencies.

RESOLUTE proposes to urban transport stakeholders a cooperation and coordination platform, aiming at generating adaptive capacities that address the specific needs to cope with complexity and the uncertainty that it generates. The platform was designated as CRAMSS—Collaborative Resilience Assessment and Management Support System, and consisted mainly on the usage of "big data" to enhance the ability of sense-making at various decision-making processes within various management and operational levels of critical infrastructures.

3.3 *From FRAM to CRAMSS*

The CRAMSS integrates real-time and historical data retrieved from a wide range of operational and environmental aspects, namely traffic monitoring, weather conditions, public transport services, and water levels in river banks, among many others.

Information is vital for every kind of decision making process. The lack of information is one of the main sources of uncertainty (Grote, 2009). Through the powerful technology currently available in most decision scenarios, access to information and data can be relatively easy and fast. However, knowing what information and where to look for it within vast arrays of big data often poses many challenges. Determining what is relevant and needed at a given level and scenario of decision requires understanding its sources of uncertainty,

based on which available data and information may be processed and/or filtered.

The FRAM model previously developed was used as guidance for the tailoring of the data gathered and fed to the CRAMSS to the potential needs of different decision makers and actors, and across the different critical infrastructure stakeholders. In a first step, the functions described in the model were associated with different roles played by stakeholders in a given critical infrastructure. For instance, the function "monitor operations" was associated with the role and responsibilities attributed to operations control rooms such as those that be found at an urban transport network. The rational of this approach is illustrated in Figure 1.

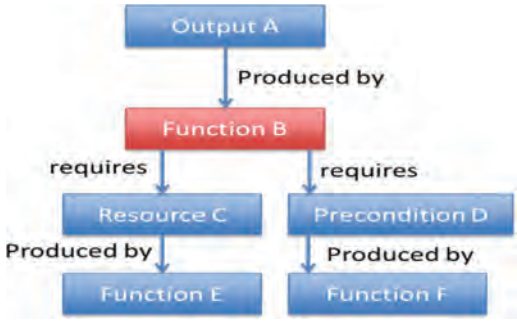

Figure 1. Structure of the analysis of function couplings.

Table 2. Functions in the FRAM model.

Function	Description
Develop Strategic Plan	Define the long-term objectives and identify critical resource needs and allocation strategy. It also involves the definition of policies, according to which all stakeholders should be strategically aligned. This is expected to take place by policy makers, regulators and with the participation of key stakeholders.
Manage financial affairs	Develop financial control and plan financial assets in accordance to financial needs of the operation and financial obligations. Often maintenance or renewal investments required by critical infrastructures greatly exceed the scope of legal ownership or responsibility of a given stakeholder. Managing such large scale projects requires detailed coordination amongst stakeholders and frequently the oversight of regulators, in particular for the oversight of financial responsibilities.
Perform Risk Assessment	Organisations carry out multiple risk assessment activities. Such activities tend to be developed within relatively limited scopes (i.e. specific tasks or projects, specific equipment…) and limited to a given domain of risk (i.e. safety, security, financial, environmental…). Assessment tools also tend to undermine risk factors that are not formally recognised and described in particular those emanating from beyond the formal boundaries of an organisation. This function should recognise the added value of integrating risk factors of diverse nature and of coordinating with multiple stakeholders, in particular along the supply chain of the service supplied by the critical infrastructure.
Coordinate Service delivery	The delivery of critical infrastructure services requires a thorough coordination amongst multiple stakeholders. Coordination activities should be carried out at various planning and operational stages of service delivery. This function contemplates operation related decision-making and activities that directly aim at keeping service delivery aligned with the strategic plan and the overall level of service in terms of quality and safety.
Manage awareness & user behaviour	As providers of fundamental public services, critical infrastructures tend to be significantly exposed to individual and collective behaviours, in many cases not just of the service end-users, but also of the wider public. Recent technological developments, in particular in relation to ICTs, offer a great potential for the enhancement of interactions with the public and the use of this potential towards an increased effectiveness in managing and deploying operational adjustments to various relevant events and circumstances.
Develop/ update procedures	The complete set of procedures forms a body of formal knowledge regarding management and operation requirements. They tend to reflect the structure of decision-making and production processes of a given organisation, so as to ensure coordination and shared understanding of operations and their goals. While this may be relatively well achieved at organisational level, amongst stakeholders of complex sociotechnical systems such as critical infrastructures, this is often very challenging. Procedures are essentially tools internal to organisations but within the scope of the function here described, to the extent possible and in addition to safety and efficiency requirements, procedures should also reflect the need for synchronisation and coordination amongst stakeholders at various CI process stages and supply chain levels. This should follow from the scope of a regulator's initiative, down to an active cooperation amongst stakeholders.
Manage human resources	Managing human resources within an organisation involves dealing with multiple relations between in-house and sub-contracting staff. The contractual boundaries may often be misaligned with real operational demands, where tight and dynamic cooperation amongst team members is required, regardless of the fact that various stakeholders are likely to be formally involved. Beyond the management of staff contractual relations, rosters and other human related operational needs, this function takes into account the need to manage the dynamics of close operational cooperation amongst multiple stakeholders and the need to align such dynamic relations with the formally established and recognised responsibilities and accountability.

(*Continued*)

Table 2. (*Continued*).

Function	Description
Training staff	In line with the principles previously outlined in relation the management of human resources, in addition to employee training needs, and their quality control, this function must also account for the need to provide and control the quality of training of staff that while working under other stakeholders, may operate on a more or less continuous basis with the premises of a given organisation such an infrastructure owner or manager. This relates to initiatives such as cross training and shared expertise programmes.
Manage ICT resources	Provide/maintain/update/develop/repair information and communications services to support critical infrastructure operation and management. Information systems may be owned and managed by a given organisation but may be strongly reliant on the operation and input from multiple stakeholders. ICT often gives shape to many interdependencies and the management of such resources should recognise this critical system role, namely by providing an overall system understanding of how these resources and made available and used by stakeholders in view of the overall service delivery (system operational purposes).
Maintain physical/cyber infrastructure	Maintenance activities require increasingly skilled and specialised staff and technical resources. Because their nature, maintenance services are often sub-contracted and providers become stakeholders with tight couplings with operational requirements. In addition to the planning, delivery and testing of maintenance activities, this function also incorporates the need to continuously assess the integration between in-house and sub-contracted maintenance resources, in view of process and technology changes, and overall operational environment demands.
Monitor Safety and Security	Integrated risk management has been recognised as a potentially valuable approach but has proven to present many managerial and operational challenges. As two of the fundamental risk domains for the operation of all critical infrastructures, safety and security should be managed in the scope of an integrating function, aiming to maximise efficiency and effectiveness of assessment and control measures and to integrate multiple interdependent risk factors that emanate from both within and beyond organisational boundaries.
Monitor Operations	The monitoring of service delivery performance is often singly based on lagging indicators and stakeholders tend to each assess their performance in reference to internal targets to be met, which may not necessarily reflect overall needs of the service delivered at critical infrastructure level. This function envisages the development of shared performance assessment practices amongst critical infrastructure stakeholders, mainly by integrating stakeholders' targets with overall service delivery needs. This becomes fundamental to generate overall system performance understanding.
Monitor Resource availability	Complex sociotechnical systems such as critical infrastructures rely on increasingly diversified and dynamic supply chains. This function focuses on generating an overall coordination of resource planning and deployment, taking into account the need to align multiple stakeholder needs with CI service delivery. This requires an understanding of resource flows and their main variability trends.
Monitor user generated feedback	Current technology provides the means to monitor service usage on a wide range of parameters and produce in real time, fundamental support to the deployment of operational adjustments. This function deals with the need for an integrated approach to the assessment of user generated feedback, mainly by placing this data and information in the context of operational monitoring. This requires the coordinated action amongst multiple stakeholders under a shared framework.
Coordinate emergency actions	The operation of critical infrastructures relies on the close cooperation amongst multiple stakeholders. Emergency response scenarios pose additional challenges, mainly by adding significant time pressure and high uncertainty (and therefore heightened risk) to this already complex operational environment. Coping with such challenges places even greater emphasis on the coordination needs and increased pressure on already limited resources. This function deals mainly with the requirements of an efficient distributed decision-making process under emergency response scenarios, namely the availability of accurate and timely information and data, and coordinated action of multiple and diverse stakeholders, often under unplanned and unforeseen circumstances.
Restore/Repair operations	Restoring operational capacities after significant damages requires much more than the re-allocation of system resources, namely those foreseen under maintenance and renewals projects. Dedicated teams are normally put in place to design, plan and execute specific projects, which in the case of critical infrastructures, in addition to the need to maintain minimum operation capabilities, is also likely to require the containment of impacts on other interdependent infrastructures.
Provide adaptation & improvement insights	With the scope of resilience, the operation of complex sociotechnical systems is challenged by two opposing needs: sustaining adaptive capacities to continuously changing operational conditions (flexibility) and the continued and coherent pursuit of goals within their own timescales (rigidity/robustness). For instance, Operation and production goals may be reassessed on an annual basis, while strategic goals may be addressed on a five year basis. Without compromising the consistency and feasibility of planned operations within each of those timescales, a given degree of flexibility must be ensured, in order to sustain the ability to respond to unforeseeable operational changes. This relates to aspects such as learning from ex-post event analysis, de-briefing, daily operations and providing insights for system capacities adaptation, keeping operations record, examining good practices, performing impact analysis of suggested actions, among others.
Collect event information	Collecting in house and external event data as good practices and/or historical data (archiving). From the perspective of resilience, this should not only address the occurrence of undesired events but most of all the understanding of factors that under highly variable circumstances become critical for achieving successful performance.

4 PROJECT ACHIEVEMENTS

The couplings described in the FRAM model were used to relate types of data to different user profiles for the CRAMSS. These user profiles were defined according to different roles and activities carried out by key stakeholders within the delivery of urban transport services. Emphasis was placed on conveying to users across multiple stakeholders, information on the conditions or operational status of other stakeholders with which relevant functional couplings had been identified through the FRAM model. The purpose was to create conditions for an improved cooperation and coordination between interdependent stakeholders. Providing information and data with a higher context and time dependent relevancy is expected to reduce uncertainty associated to decision-making and enhance the capacity to adapt to the continuously changing conditions under which such decisions are made, and their resulting actions taken.

For reasons of practicality, the complete FRAM model cannot be reproduced here in such a way that functions and potential couplings could be clearly presented. To illustrate the project outputs achieved so far based on the approach previously described, Table 2 provides a brief description of all the functions identified.

5 CONCLUSIONS

Beyond the provision of "big data" to support decision-making, the approach here outlined addresses the need to tailor a wide range of available data to different scenario and operation needs, taking into account interdependencies that are critical for process flows and the delivery of services.

The control of operations and processes remains strongly grounded on centralised mechanisms and on "top-to-bottom" procedural structures. One of the shortfalls of such approaches is the rigidity that it imposes on processes and operations, which often fails to account for the need for local adaptive capacities to uncertainty and continuously changing operational conditions (Woods, 2015). The conflicts generated by different goals and local priorities, and across multiple organisational boundaries frequently escape the prescribed work of procedures. The CRAMSS and the underlying FRAM model offers to each stakeholder an enhanced adaptive capacity. In some cases, this capacity means the ability to adjust operations and conditions in anticipation of critical events. In others, it may only provide the means for the detection of events in hindsight, but nevertheless, with an early warning and with increased precision and detail on the actual occurrence. Overall, these adaptive capacities and the ability to cope with complexity are at the core of system resilience.

Throughout the remaining duration of project RESOLUTE, the CRAMSS and the various tools on which it is build will be tested under real scenarios (a first one in the city of Florence and a second one in the city of Athens). The outcome of these testing activities will be fed back to the FRAM model, aiming to improve the understanding of stakeholder interdependencies that it provides.

ABSTRACT: The study presents an uncertainty and sensitivity analysis exercise of the security of gas supply model implemented in the probabilistic gas network simulator ProGasNet. The study showed the potential and usefulness of sensitivity study applied to the ProGasNet gas network model. It has not only identified the most important model parameters for which more attention should be paid during the estimation process of the input parameter values, but also provided useful insights into the simulation process by confirming, e.g., the heterogeneity of the network from a sensitivity analysis perspective. The model was run for four different scenarios representing different disruption situations. The study confirms the results already observed in other studies that some disruption scenarios affect only part of the network (e.g. specific countries) while other parts of the network are not affected. This clearly indicates heterogeneity of the network and the need for further infrastructure development. The most important parameters for each country are identified, and peak demand value is the main parameter for the three countries.

1 INTRODUCTION

Natural gas networks can be viewed as complex technical systems, which are exposed to various threats, for example technical failures, natural disasters and human/political uncertainties. As a consequence of these threats, a subset of network components might fail. In order to simulate security of gas supply due to component failures/attacks, the probabilistic gas network simulator ProGasNet (Probabilistic Gas Network Simulator) is being developed.

ProGasNet is able to model, in a single computer model, capacity and reliability constraints of a natural gas network. The physical model is based on graph theory (maximum flow algorithm), whereas component failures are simulated by the Monte-Carlo method. The ProGasNet simulator has been developed with the primary purpose to quantify the security of gas supply situation in probabilistic metrics (V.Kopustinskas et al., 2012). The simulator can be used to perform risk assessment of the gas transmission network as required by the EC Reg 2017/1938 (EU Regulation, 2017), formerly known as 994/2010 (EU Regulation, 2010). In addition, the simulator can evaluate infrastructure development plans and the proposed PCI projects. ProGasNet was used in vulnerability assessment which could be of interest to critical infrastructure protection policy makers (Praks et al., 2017).

The ProGasNet has been applied to gas transmission networks of several EU countries, however geographical information cannot be disclosed. Various types of analysis have been performed: reliability, vulnerability, security of supply analysis and the results have reported reliability of supply estimates under different disruption scenarios (Praks et al., 2015). The ProGasNet model also provides an indication of the worst networks nodes in terms of security of supply and their numerical ranking. The model is very powerful to compare and evaluate different supply options, new network development plans and analyse potential crisis situations.

Despite of the insightful information that can be obtained regarding the security of gas supply within European regions with this simulator, still ProGasNet remains a strong approximation of the reality of gas supply in Europe (simplified assumptions, quasi steady-state modelling, lack of knowledge about some parameter values, etc). Therefore, it is important to assess the impact of epistemic uncertainties in gas network models in order to point out those sources of uncertainty that have an impact on the model responses of interest. Identifying important sources of (epistemic) uncertainty allows to guide further investigation for possible improvements of gas network models.

In this study we analyse an EU regional network already used for other purposes and bottleneck

analysis in particular (Kopustinskas et al, 2015). The focus of this study is to perform sensitivity analysis by using Polynomial Chaos Expansion (PCE) method (Sudret, 2008).

2 PROGASNET SIMULATOR

The ProGasNet (Probabilistic Gas Network) simulator is the JRC in-house developed software tool currently in use at the Joint Research Centre. ProGasNet is used for experimental simulation-based security of supply analyses of selected European gas transmission networks. Usually, one million Monte-Carlo simulations are automatically solved within one hour on a single-core processor computer. The software tool can make use of a multi-core computer, as multiple simulations (Monte Carlo runs) can be evaluated independently. The gas transmission network model implemented in ProGasNet is based on Maximum Flow (MF) algorithm well known in graph theory (Deo, 2008). The algorithm was modified to reflect gas transport property to have lower pressure at the points far from the supply source. This means that in case of disruption and lack of gas in the network, consumers that are closer to the source have better chances to be served rather than those that are located far away. Therefore, the maximum flow algorithm was modified to distribute gas first to the consuming nodes close to the supply source and distance from the nearest source was used as a priority criteria. Although not being a model requirement, this assumption was chosen as if network operator decision on how to distribute available gas among the users is not known. No doubt that in a real crisis management situation, the network operator has more options on how to supply and distribute the available volumes of natural gas.

The model is not running physical gas pressure and flow computations, but uses available results of physical models as a set of rules to define flow limitations. The ProGasNet simulates network facility failures (pipeline ruptures, failures of compressor stations, unavailability of LNG terminals and storages) by Monte Carlo method and each different network configuration is evaluated by modified maximum flow algorithm to evaluate available gas for each network consuming node. The statistical results are obtained from 1 million of Monte-Carlo runs.

3 STUDY CASE AND NETWORK DATA

Figure 1 shows topology of the study case gas transmission network. It is based on a real regional network topology and data, however geographical

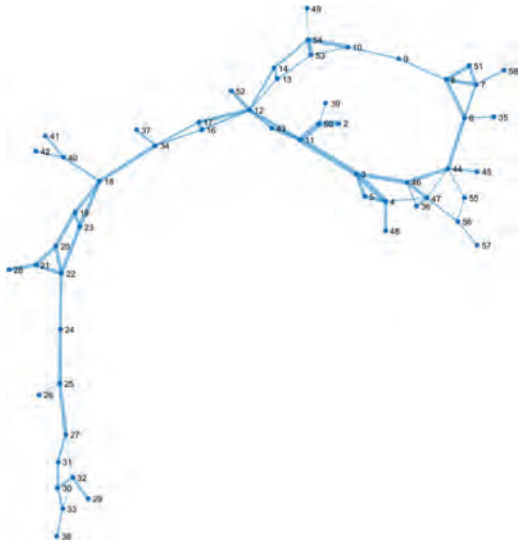

Figure 1. Topological layout of the gas network.

location is not displayed. The transmission network GIS data are converted to a graph by creating nodes and links (edges). The nodes are:

- Demand nodes (consumers connected to pressure reduction stations of the transmission network;
- Compressor stations;
- Supply nodes (storages, LNG terminals, import points at cross-borders).

The network links (edges) are typically pipelines. The model explicitly considers two parallel pipelines as two components (double links between nodes).

The basic network data are the same as already reported (Kopustinskas et al., 2015). Here we replicate only the most important network data.

The demand nodes are determined by daily demand value (Table 1). This value is a peak demand value, but it could be also average winter or summer consumption value depending on the purpose of the study.

Table 2 shows maximum capacities and type (pipeline, UGS or LNG) of input supply nodes. In case of Underground Gas Storages (UGS), also the output values of not fully loaded storages can be used.

The total maximum supply capacity is 77.5 mcm per day. The total network peak demand is 45.8 mcm/d, so the network has certain degree of spare capacity to compensate supply disruptions. The experience of different analysis already performed shows that depending on where the disrup-

Table 1. Network demand nodes, in millions of cubic meters per day (mcm/d).

Node	Demand	Node	Demand
4	0.1	34	0.5
5	3.2	35	0.1

26	0.8	48	1.8
27	3	49	0.2
28	6	51	7
30	0.5	52	0.6
33	0.5	53	0.1

Table 2. Maximum capacity of supply sources.

Node	Type	Capacity, mcm/day
2	Pipeline	31
10	LNG	10.2
11	Pipeline	7
19	UGS	30
29	Pipeline	4
38	Pipeline	1.2

tion happens, internal bottlenecks in the network prevent from full usage of this spare capacity.

For each network component, failure data must be provided. The following components (nodes) are considered for failures:

- Compressor Station (CS) failure: 2.5E-01/yr;
- Underground storage failure: 1.0E-01/yr
- LNG terminal failure: 1.5E-01/yr
- Pipeline failure: 3.5E-05 /km/yr.

The model uses annual failure data (probability of failure per year), however when simulations are performed, one month interval is considered. It is assumed that the same peak consumption in the network is constant during this one month period.

The compressor station node normally is modelled as working or failed, for each state determining the corresponding capacity of the outgoing pipelines. The capacity reduction due to compressor station failure is normally estimated by hydraulic model computations or expert evaluation. As a consequence due to a CS failure, capacity reduction by 20% of the inlet pipelines and also the outlet pipelines until the next connection node is assumed. This assumption is based on physical flow models, however is not accurate in all cases and also multiple CS failures will have more severe effects on the network operation.

The pipeline import points are not considered as failure-prone elements due to lack of upstream network model, however they are modelled as on/off elements by scenario analysis.

4 DISRUPTION SCENARIOS

In total four different gas disruption scenarios were analysed. The first scenario is the reference scenario during which the system operates under normal conditions without predefined disruptions.

Scenario 1: All available sources operate. Scenario 1 represents a basic scenario when all sources can be used for supply and the network components can fail randomly according to their reliability parameters.

Scenario 2: Node 2 disruption. In this scenario, supply node 2 (the largest gas source in capacity) is not available. This scenario can test the system for the largest source disruption which can be classified as N-1 situation looking at the network globally.

Scenario 3: Node 19 disruption. Scenario 3 runs the model with disconnected node 19, the second largest gas source.

Scenario 4: Loss of two largest gas sources (Nodes 2 & 19). The underground gas storage can be unavailable due to technical problems, failures or inability to fill it up during summer period. The Scenario 4 simulates a more challenging crisis in which the both sources of the highest capacity are unavailable. The scenario 4 is used to demonstrate vulnerability of the network, when the largest and the second largest gas sources are lost simultaneously. The network can be supplied only with source nodes 10 and 11 and small sources 29 and 38.

5 SENSITIVITY ANALYSIS METHODOLOGY

Uncertainty in model predictions stems from the lack of knowledge about the process of interest (in the present case, about the gas transport), model simplification and parameters' value. For some of the model inputs, it is possible to refine our knowledge about their probable value (that is, decreasing their uncertainty) but such a task is time consuming. Our strategy is i) to assign large but likely uncertainty ranges to the inputs of the

gas network model, ii) to check whether this yields large uncertainty in the model predictions of interest and iii) to identify eventually those inputs that are mostly responsible for the predicted uncertainty. In step iii), it is expected that only a few of the uncertain inputs are identified as influential in order to reduce the effort to pay during the subsequent input uncertainty refinement.

Twenty model inputs of the gas transmission network model have been deemed as uncertain (Table 3). It can be noted that some are assigned uniform distributions within plausible ranges while some others are assigned normal distribution. It is assumed that the model input values are independent of each other. These uncertainties reflect the experts' belief before further investigation. The prior uncertainties being large reflect the fact that the experts (here the modellers) have a vague knowledge about model inputs uncertainty.

This study has applied Polynomial Chaos Expansion (PCE) method to estimate sensitivity indices. The idea of PCE is to approximate variance decomposition terms (Sobol, 1993) by multidimensional orthonormal polynomials. The rate of convergence of such an expansion of course depends on the regularity properties of $g(\boldsymbol{x})$, the model response of interest. By exploiting the Parseval-Plancherel relationship, one obtains a standard variance decomposition equation. Therefore, we get (Wiener, 1938),

$$g(\boldsymbol{x}) = \sum_{\boldsymbol{\alpha} \in N^n} a_{\boldsymbol{\alpha}} \psi_{\boldsymbol{\alpha}}(\boldsymbol{x}) \tag{1}$$

where $\boldsymbol{\alpha} = \alpha_1 \quad \alpha_n$, with $\alpha_i \in N$, is a multi-index indicating whether $\psi_{\boldsymbol{\alpha}}(\boldsymbol{x})$ depends on x_i ($\alpha_i > 0$) or not ($\alpha_i = 0$), a_α is the polynomial coefficient associated with $\psi_{\boldsymbol{\alpha}}(\boldsymbol{x})$ which is the so-called multivariate orthonormal polynomial chaos that is written

$$\psi_{\boldsymbol{\alpha}}(\boldsymbol{x}) = \psi_{\alpha_1}(x_1) \cdot \quad \cdot \ \psi_{\alpha_n}(x_n)$$

$\psi_{\alpha_i}(x_i)$ being the α_i-th degree univariate polynomial basis element ($\psi_0 = 1$).

The expression of the univariate polynomial basis elements depends on the PDF assigned to the input variables. If $x_i \sim U(-1,1)$, $\psi_{\alpha_i}(x_i)$ is the Legendre polynomial of degree α_i, while if $x_i \sim N(0,1)$, $\psi_{\alpha_i}(x_i)$ is the Hermite polynomial of degree α_i. One can rely on the Wiener-Askey scheme to choose the appropriate polynomial family (Xiu & Karniadakis, 2002).

Once a PCE expansion such as Eq.(1) is obtained, it is straightforward to prove that the total variance of $g(\boldsymbol{x})$ is,

(1) U = Uniform distribution, $N(\mu,\sigma^2)$ = Normal distribution of mean μ and variance σ^2.
(2) E stands for epistemic uncertainty as opposed to A-aleatory uncertainty.
(3) The modellers belief regarding the assigned prior uncertainty: L = Low, M = Medium and H = High.

$$V\left(g(\boldsymbol{x})\right) = D_y = \sum_{\boldsymbol{\alpha}\in N^n} a_{\boldsymbol{\alpha}}^2 - a_{0\ldots0}^2$$

by exploiting the orthonormality property of the polynomial basis elements, that is,

$$E\left(\psi_{\boldsymbol{\alpha}}(\boldsymbol{x}) \cdot \psi_{\boldsymbol{\beta}}(\boldsymbol{x})\right) = \delta_{\boldsymbol{\alpha}\boldsymbol{\beta}}$$

where $\delta_{\boldsymbol{\alpha}\boldsymbol{\beta}}$ is the symbol of Kronecker.

Therefore, it is possible to estimate the Sobol' indices from the PCE coefficients as follows,

$$S_{i_1} = \frac{V\left(E\left(g(\boldsymbol{x})\middle|x_{i_1}\right)\right)}{V\left(g(\boldsymbol{x})\right)} = \frac{\sum_{\alpha_{i_1}\in N} a_{0\ldots0\alpha_{i_1}0\ldots0}^2}{\sum_{\boldsymbol{\alpha}\in N^n} a_{\boldsymbol{\alpha}}^2 - a_{0\ldots0}^2}$$

$$ST_{i_1} = \frac{E\left(V\left(g(\boldsymbol{x})\middle|\boldsymbol{x}_{-i_1}\right)\right)}{V\left(g(\boldsymbol{x})\right)} = \frac{\sum_{-\in N^n:\alpha_{i_1}>0} a_{\boldsymbol{\alpha}}^2}{\sum_{\boldsymbol{\alpha}\in N^n} a_{\boldsymbol{\alpha}}^2 - a_{0\ldots0}^2}$$

Hence, the issue with the PCE approach for variance-based sensitivity analysis is to assess the PCE coefficients. In this work this is achieved with the Bayesian sparse PCE developed in (Shao et al, 2017). With this approach, the variance decomposition is obtained from one single Monte Carlo sample of size N. This is very computationally cheap compared with other classical approaches (Saltelli, 2002; Saltelli et al, 1999). The cost of the analysis is a criterion to keep in mind with a long-time run model like the ProGasNet.

6 UNCERTAINTY & SENSITIVITY ANALYSIS: RESULTS AND DISCUSSION

6.1 *Model output selection*

Given the computational time required to run ProGasNet, a sample of size 512 was considered. The input sample was generated according to the probability density function of each input variable (see Table 3). The low-discrepancy LPτ sequences of (Sobol' et al. 1992) were employed. It required four days of calculation with ProGasNet to propagate the input uncertainty into the model responses for the four different scenarios under analysis.

It is possible to analyse the impact of the model input uncertainty onto different model responses. For this purpose, while propagating the input uncertainty with a Monte Carlo sample, one has to save the different model responses of interest after each model run. In the present work, we have considered 20 different model responses, namely: $\bar{S}$ the mean volume of gas supply, $P(S=0)$ the probability of none gas supply, $P(S<0.2D)$ the probability of supplyinless than 20% of the demand, $P(S<0.5D)$ the probability of supplying less than 50% of the demand, $P(S<0.8D)$ the probability of supplying less than 80% of the demand and $P(S<D)$ the probability of supplying less than the demand. Doing so for each country provided a set of $3\times6=18$ different model responses.

The different model responses are more or less sensitive to the uncertainty in the model inputs. Figure 2 shows the Monte Carlo simulation results

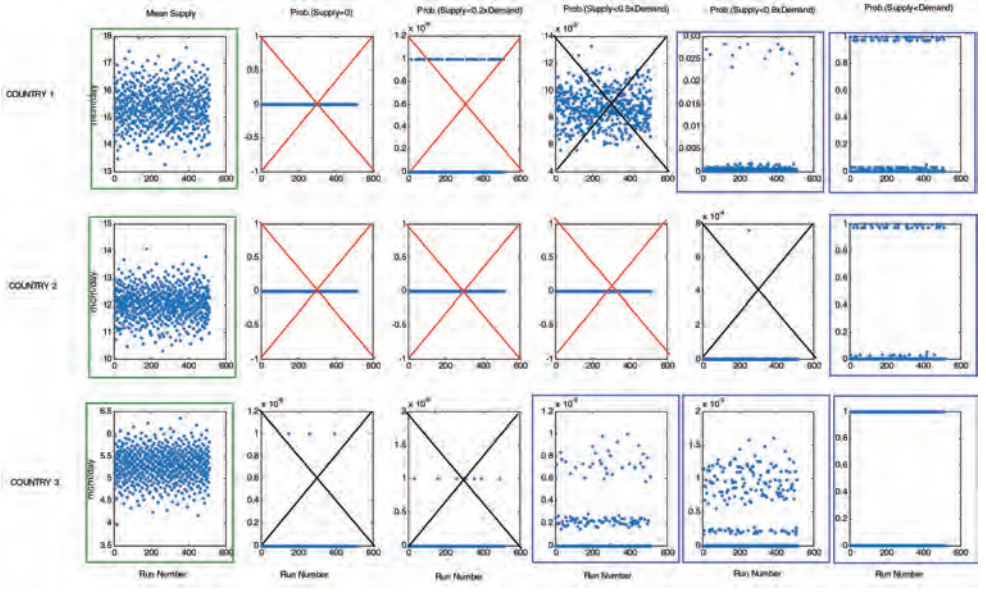

Figure 2. Monte Carlo predictions of the 18 model responses.

obtained for Scenario 2. In Figure 2 outputs with a cross do not change significantly and are not analysed. Outputs with a green frame are analysed with the PCE approach. It can be noted that some output variables do not vary at all (likewise $P(S=0)$ for country 1 & 2), some do not vary significantly (values less than 10^{-3}), some others only take discrete values (e.g. $P(S<D)$) while the averages volume of gas supply $\bar{S}$ vary continuously. Consequently, only those model responses that are significantly impacted by the input uncertainty are analysed in the sequel. Only the model responses that take continuous values are analysed with the polynomial chaos expansion.

6.2 *Results for Country 1*

In the following sections, we analyse the predictive uncertainty on the mean volume of gas $\bar{S}$ supplied by the network to the different countries. The estimated probability density functions of the mean volume of gas supply (in millions of cube meters/day) for the four different scenarios are depicted in Figure 3. We note that the PDF's are the same for scenario 1 (normal operation) and scenario 3 (Source 19 off). This means that the system is completely resilient to the failure of this important source regarding the gas supply in Country 1. When the main source of gas is off (scenario 2), the network remains quite resilient. However, as far as scenario 4 is concerned, the system completely fails at satisfying the gas demand (vertical dashed-line) although some quantity of gas is supplied.

Notably, in the first three scenarios, according to the model, the ability of the network to supply sufficient gas volume depends on the true value of some of the uncertain input variables. Indeed, Figure 3 indicates that the system might fail at satisfying the gas demand under certain uncertain conditions, linked to capacity of sources which is subject to strong aleatory uncertainty.

To guess which are the critical uncertain inputs responsible for the variability of this model response we have carried out a global sensitivity analysis for each scenario. Given that this model response takes continuous values, the PCE method

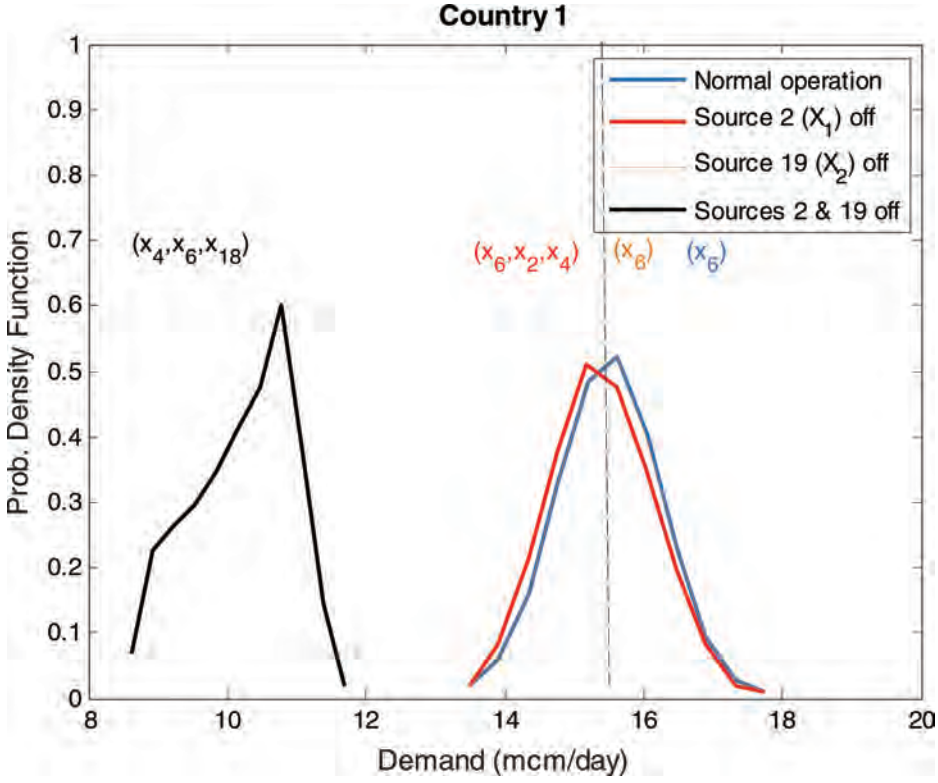

Figure 3. Predicted uncertainty of mean gas supply for country 1 with respect to the different disruption scenarios.

Table 4. Relevant inputs for the predicted mean gas supply for country 1.

Scenario	Relevant inputs	S_i%	ST_i%
1 (Normal)	X_6 = Peak demand of Country 1	100	100
2 (X_1 off)	X_6 = Peak demand of Country 1	80	85
	X_2 = Capacity of Source N19	7	16
	X_4 = Capacity of Source N11	1	9
3 (X_2 off)	X_6 = Peak demand of Country 1	100	100
4 (X_1, X_2 off)	X_4 = Capacity of Source N11	88	88
	X_6 = Peak demand of Country 1	9	9
	X_{18} = Capacity of DN400	3	3

is employed. The first-order (S_i) and total-order (ST_i) Sobol' indices are shown in Table 4. We recall that S_i represents the amount of variance of the predicted mean gas supply explained by the input variable while the difference ($ST_i - S_i$) represents the amount due to the interaction of the variable with the other ones. We note that only scenario 2 is subject to interactions.

The results indicate that the accuracy of the model to predict the mean gas supply to Country 1 heavily depends on the knowledge of the peak demand in that country. This is particularly crucial for scenarios 1 & 3. When source N2 is off, then the model response becomes more complicated involving sources N10 and N11. When both sources N2 and N19 are off (scenario 4), then the capacity of source N11 prevails for the mean gas volume supplied to country 1, the country peak demand (X_6) becoming less relevant. In summary, to predict accurately the mean gas volume supplied to Country 1 it is crucial to know accurately the value of the following inputs: X_6, X_4, X_2 (by order of importance) and in a less extent X_{18}.

6.3 *Results for Country 2*

The estimated PDF's of the mean volume of gas supply for the four different scenarios are not shown due to lack of space. Note that when source N19 is unavailable (scenarios 3 & 4), the predicted mean value of gas supply is much less than the demand of the country. This indicates that the source N19 is very important for the Country 2. However, the system is resilient to the failure of gas source N2 (recall that it is the highest capacity source in the region). This is due to the location of the Country 2 with respect to the sources and potential bottlenecks in certain connections. Another study of bottleneck analysis of this network has identified several bottlenecks in this network (Kopustinskas et al., 2015).

The most important input variable is the peak demand of the country 2 when the system operates normally and when Source N2 is off. Surprisingly, we note that when Source N19 fails, the capacity of the system to provide gas to Country 2 also depends on the peak demand of Country 3 and the peak demand of Country 1 (when both N2 & N19 are unavailable). This result is also a consequence of the priority algorithm implemented in the ProGasNet. Indeed, the latter supplies the closer demand nodes first before serving the other more distant nodes. Hence, if a country is far from the main sources of gas, it might be more subject to failure of gas supply.

6.4 *Results for Country 3*

For Country 3, the system behavior is simpler. The system is resilient to the failure of one of the main sources but it is incapable to provide gas to Country 3 when both main sources collapse (scenario 4). This is an important result, revealing the country vulnerability to crisis. However, the crisis simulated by scenario 4 is unlikely to happen. The prediction of volume of gas supply heavily depends on the knowledge of the value of the gas demand in the country.

7 CONCLUSIONS

The study presents an uncertainty and sensitivity exercise of the security of gas supply model implemented in the probabilistic gas network simulator ProGasNet. The selected network was an EU gas transmission network of several member states. It is based on realistic network topology and data, but due to sensitivity of information, the network is anonymised.

The study aims to identify and rank the model parameters that most significantly affect the security of supply. The main finding is that the risk of gas supply shortage in the three countries heavily depends on the accurate knowledge of different model inputs. In particular, the peak demand in each country is the key parameter whose precise estimation is very important for accurate model results.

The model was run for four different scenarios representing different disruption situations. The study confirms, the results already observed in other studies, that some disruption scenarios affect only parts of the network (e.g. specific countries) while other parts of the network are not affected. Even more, due to existing bottlenecks in the system, supply disruptions in one part of the network cannot be restored from the other part even if there is enough gas available. This clearly indicates heterogeneity of the network and the need for further infrastructure development.

Looking at each country, for Country 1, the peak demand is the most important parameter, followed by capacity of sources 19 and 11 and capacity of DN400 pipeline. This is important information for further development of the model and indicates where to target further research efforts.

For Country 2, again the peak demand is the most important parameter, followed by capacity of source 19, DN500 and DN400 pipelines. Interestingly, for some scenarios, peak demands of Countries 1 and 3 are identified as important. This can be well explained by the fact that in certain disruption scenarios, lower demand in neighbouring countries allows better supply to the other countries.

For Country 3, the supply is secured in case of scenarios 2 and 3, but in the case of unlikely scenario 4, the security of supply is threatened.

The study showed the potential and usefulness of sensitivity study applied to the ProGasNet gas network model. It has not only identified the most important parameters of the model for which more attention should be paid during the estimation process, but also provided useful insights into the simulation process by confirming, for instance, the heterogeneity of the network from the sensitivity analysis perspective.

ABSTRACT: This research works is focused on the analysis of Fuzzy Finite-Element Method (FFEM) with the present of uncertainties. In considering a major engineering science problems, like damage processes or loading in consequence of real incident, uncertainty are present. Uncertainty is due to lack of data, an abundance of information, conflicting information and subjective beliefs. With that reason, the present of uncertainties is needed to avoid for prevent the failure of the material in engineering. The goals of this study are to analyzed and determine the application of FFEM by taking into consideration of the epistemic uncertainties involved toward the single edge crack plate and beam. Since it is crucial to develop an effective approach to model the epistemic uncertainties, the fuzzy system is proposed to deal with the selected problem. Fuzzy system theory is a non-probabilistic method, and this method is most appropriate to interpret the uncertainty compared to statistical approach when the deal with the lack of data. Fuzzy system theory contains a number of processes started from converting the crisp input to fuzzy input through fuzzification process and followed by the main process known as mapping process. In mapping process stage, the combination of fuzzy system and finite element method are proposed. In this study, the fuzzy inputs are numerically integrated based on extension principle method. Obtained solutions are depicted in terms of figures and tables to show the efficiency and reliability of the present analysis.

1 INTRODUCTION

An uncertainty is define as a gradual assessment of the truth content of a proposition, doubt arises as to whether the truth content may be stated with sufficient accuracy using each of the data models in all cases. Also, uncertainties are defined as the vagueness and lack of the information or data, Farkas (2010). The element of uncertainty is one of the biggest challenges in the field of engineering. He (2007) mentioned that, in general, uncertainty can divided into three types, which are stochastic uncertainty, epistemic uncertainty and error. Stochastic uncertainty is due to variations in the system. For the epistemic uncertainty, it exists as a result of incomplete information, ignorance and lack of knowledge caused by the lack of experimental data. When compare to the error, this uncertainty is the uncertainty that can be identified due to the imperfections in the modelling and simulation.

For a several decades ago, uncertainty is modelled according to the theory of probability. Probability method is very effective in solving the problem of stochastic uncertainty, but this method is not suitable to be used to solve problem involving the lack of data. Some scholars hold that the use of non-probability methods are most appropriate to interpret the uncertainty compared to statistical approach when deal with the lack of data. The interval analysis (Zimmermann 2012), convex modelling (Tapaswini et al. 2012) and fuzzy set theory (Ozkoka & Cebi 2014) are the main categories of non-probabilistic methods. Specifically, fuzzy system is a system to be precisely defined and it applied all the theories that use the basic concept of fuzzy set theory. According to Savoia (2002), the main advantages of using the fuzzy set theory than the fuzzy probability theory is able to maintain the intrinsic random nature of the physical variables without the need for modeling the probability density function. The simple justification for fuzzy system theory is the real world is too complicated for precise explanation and description to be obtained. Fuzzy system theories are knowledge based or rule based systems. Fuzzy systems have been applied to a wide field.

Finite Element Method (FEM) has become a powerful tool in solving numerous complex scientific and engineering problems. By using FEM, the complicated structured of any materials can be discretized into a small finite element. All the elements are assembling then applying the respective requirement to obtain the output. System parameters such as geometry, material properties, external load or boundary conditions are considered as crisp value or can be defined exactly in the convectional FEM. However, rather than the particular value, it may have only the vague, imprecise and incomplete information about the variables being a result. The present of uncertainty is the biggest challenging in engineering in order to deal with uncertainty in designing the material and cannot be avoided.

Fuzzy Finite Element Method approach (FFEM) is present to deal with the uncertainty and it is the merger method of fuzzy approach with the conventional Finite Element Method (FEM). In FFEM approach, conventional FEM is used as a parent in order to obscure the data input mapping to the output data (Behera, 2012). In this paper, there are two illustrative examples which applied the fuzzy finite element method with considering the presence of uncertainties. The first illustrative example is the application of FFEM in single edge crack plate by considering a fuzzy variable of crack length. And the second one is to analyze the structural reliability on beam.

2 PRELIMINARIES

In the following paragraphs, some of the notation, definition and preliminaries which are used further in this paper discuss deeply.

Definition 1:

A fuzzy number is convex normalized fuzzy set of the real line such that

$$\mu_A = X \to [0,1] \tag{1}$$

Definition 2:

We can defined an arbitrary triangular fuzzy number as $\tilde{A} = [a_L, a_N, a_R]$ and trapezoidal fuzzy number as $\tilde{B} = [b_L, b_{NL}, b_{NR}, \mathrm{b}_R]$. The fuzzy number $\tilde{A}$ is said to be triangular fuzzy number when the membership function is given by

$$\mu_{\tilde{A}}(x) = \begin{cases} 0 & x \le a_L \\ \dfrac{x - a_L}{a_N - a_L} & a_L \le x \le a_N \\ \dfrac{a_R - x}{a_R - a_N} & a_N \le x \le a_R \\ 0 & x \ge a_R \end{cases} \tag{2}$$

The triangular fuzzy number $\tilde{A} = [a_L, a_N, a_R]$ can be transformed into interval form by using α-cut as Equation (3).

$$\begin{aligned} \tilde{A} &= [a_L, a_N, a_R] \\ &= \left[a_L + (a_N - a_L)\alpha, a_R - (a_R - a_N)\alpha\right] \end{aligned} \tag{3}$$

The fuzzy number $\tilde{B}$ is said to be trapezoidal fuzzy number when the membership function is given by

$$\mu_{\tilde{B}}(x) = \begin{cases} 0 & x \le b_L \\ \dfrac{x - b_L}{b_{NL} - b_L} & \mathrm{b}_L \le x \le b_{NL} \\ \dfrac{b_R - x}{b_R - b_{NR}} & \mathrm{b}_{NR} \le x \le b_R \\ 0 & x \ge b_R \end{cases} \tag{4}$$

The trapezoidal fuzzy number $\tilde{B} = [a_L, a_N, a_R]$ can be transformed into interval form by using α-cut as Equation (5).

$$\begin{aligned} \tilde{B} &= [b_L, b_{NL}, b_{NR}, b_R] \\ &= \left[b_L + (b_{NL} - b_L)\alpha, b_R - (b_R - b_{NR})\alpha\right] \end{aligned} \tag{5}$$

3 FUZZY FINITE ELEMENT METHOD

The fuzzy finite element method is a combination of fuzzy approach and conventional finite element method. Figure 1 shows a flow chart for a fuzzy finite element process which included the fuzzification process, mapping process, α-cut level process and ending with defuzzification process.

The procedure for the analysis by using the fuzzy finite element methods is started by transform the crisp input or real value for input into the fuzzy input uncertainty through the fuzzification process. The variable that have fuzzy uncertainty is probably the material properties, geometry of the materials, boundary condition or loading (Akapan 2001). Triangular fuzzy numbers are used for understanding the function of all parameters of fuzzy membership. This FFEM approach continues with the mapping process, where the fuzzy input will be used in the FEM model by using α -cut level. Vertex method is common numerical methods used in the implementation of the extension principle. Vertex method is a combination of interval arithmetic methods with α-cut method. The purpose of this mapping is to map two or more fuzzy input to the fuzzy output with binary combinations of as many as where is the number of fuzzy input parameters. Figure 2 showed the example of α-cut method for fourth level of alpha for each variable available.

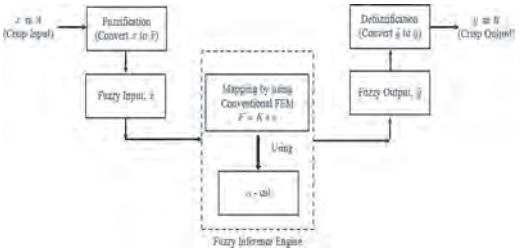

Figure 1. Flow chart for FFEM.

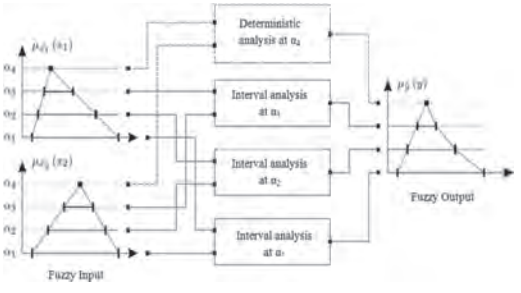

Figure 2. α- cut method for each alpha level Source: Farkas et al. (2010).

After the mapping process, the new probability distributions of the fuzzy output are created. The final stage in FFEM is defuzzification process in which stress intensity factor is the final output for this study. In defuzzification process, there are many different methods available which is center of gravity, center of area, mean of maximum, middle of maximum, fuzzy mean, fuzzy clustering defuzzification and so many. The center of gravity or centroid (COG) is the familiar defuzzification method used by many researchers and in this study. Defuzzification process is the process that transforms the fuzzy output into crisp output. This technique determines the point at which it will distribute one area into two parts which have the same value.

4 RESULT AND DISCUSSION ON ILLUSTRATIVE EXAMPLE

4.1 *A single edge crack plate by considering the fuzzy variable of crack length*

The model used in this study is Aluminium Alloy 2024-T351, since this material widely used in structural engineering such as parts of the hydraulic valve and piston, gear and shafts. In this study, three parameters that are Young's modulus, E, Poisson ratio, v and Density, ρ of Aluminium 2014-T3, are used as non-fuzzy parameters. Compare to the crack length, a is treated as a fuzzy parameter. The geometry used in this study is based on the stress analysis of crack handbook by Tada et. al (2000) as shown in Figure 3.

From analytical aspect, the stress intensity factor under mode I can be obtained by using the Equation (6) as below:

$$K_I = \sigma\sqrt{\pi a}F\left(a/b\right) \tag{6}$$

The geometry function $F\left(a/b\right)$ in equation (6) can be calculated by using the equation (7).

$$F\left(a/b\right) = 1.122 - 0.231\left(a/b\right) + 10.55\left(a/b\right)^2 - 21.7\left(a/b\right)^3 + 30.382\left(a/b\right) \tag{7}$$

where a is the crack length, b is width of the geometry, π is the constant with the value 3.1415927 and σ is the applied stress. The ratio of a/b for the geometry in Figure 3 is 0.1. The fuzzy value of crack length, a is represent in a trapezoidal fuzzy

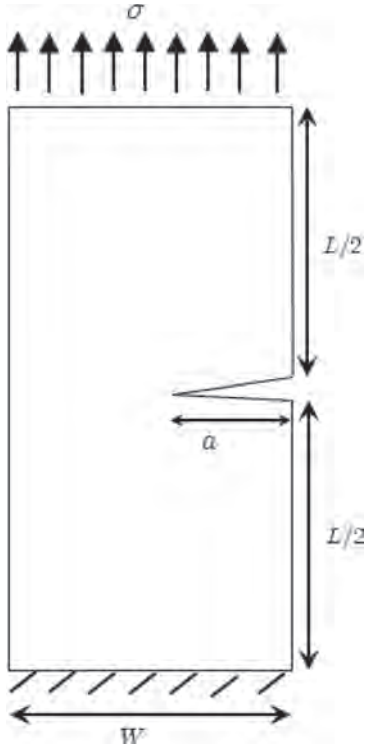

Figure 3. Two-dimensional loaded plate.

number in form as $a=(a_1,a_2,a_3,a_4)$ and written in α-cut form and finally the interval fuzzy number can written as Equation 8.

$$[a_L,a_R]=[a_1+(a_2-a_1)\alpha,a_4-(a_4-a_3)\alpha] \quad (8)$$

As mentioned early, this study only considered the fuzzy variable of crack length whereas the Young's Modulus and Poisson Ratio are considered as crisp variables.

Using fuzzy values are present the result in interval form and sketch it in trapezoidal membership function graph. The fuzzy number for crack length are $a=(0.1,0.32,0.41,0.49)$. By using Equation 6 and 7, the fuzzy intervals in term of α-cut are obtained as shown in Table 1. These fuzzy intervals are substitute into SIF formula in term of interval as

$$K_{I(R)}=\sigma\sqrt{\pi a_{(R)}}F\left(a/b\right) \quad (9)$$

$$K_{I(L)}=\sigma\sqrt{\pi a_{(L)}}F\left(a/b\right) \quad (10)$$

and continue till all SIF are obtained. Where $K_{I(L)}$) and $K_{I(R)}$) is a left and right value of interval respectively for each α-value. The output for SIF with the fuzzy crack length is shown in Table 2. Beside the result is shown in Figure 4. The cases of crack length are treating as interval at a width again increases as we increase the number of elements. In fuzzy, the large width of interval for membership functions is giving more accurate result.

The result is shown in Figure 4 depicts the SIF plot the single edge crack plate. It may be seen from the above numerical result that the natural stress (crisp values) are constant with increase in number of elements as it should be even though only two elements consider here. However it differs for values got in each element by using fuzzy method. The cases of crack length are treating as interval at a width again increases as we increase the number of elements. In fuzzy, the large width of interval for membership functions is giving more accurate result.

4.2 *Analysis on beam structure*

The analysis on structural reliability in the presence of uncertainties is performed in beam structure. In the analysis of beam structure in Figure 5, the moment of inertia and modulus of elasticity of beam are considered as fuzzy input parameters with incomplete data.

The existing data shows the moment of inertia is a normal distribution with mean value $6.58\times10^{-5}m^4$ and constant variance, COV of 0.1, while the elastic modulus has a normal distribution with mean and COV value of 0.1 and 73.1 GPa respectively. The uniformly distributed load applied to the beam is considered as an input that has no data. Thus, the opinion of an experienced

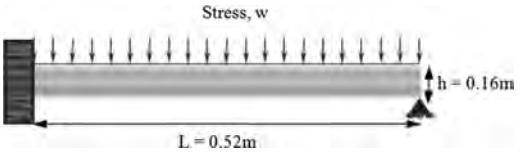

Figure 5. The geometry of the beam structure.

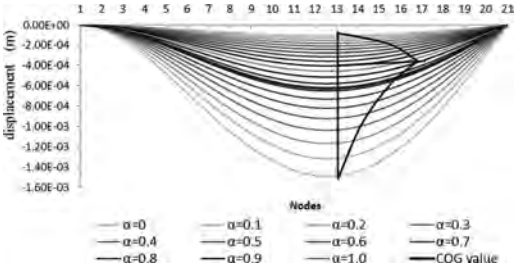

Figure 6. Fuzzy outputs of displacement using COG method.

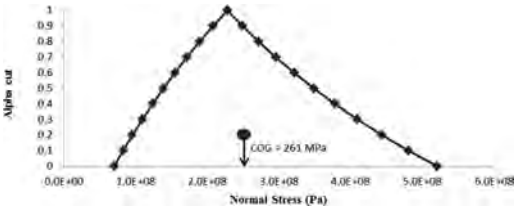

Figure 7. Fuzzy outputs of normal stress using COG method.

specialist should be considered to determine the likely distribution of that load. In this study, the distributed load is considered as a normal distribution with mean value 5.55 MN/m and COV value of 0.2. The base area of membership function for the three fuzzy input parameters considered to have the interval of 6 standard deviation and σ normal distribution, where 99% of the distribution included in the analysis.

In general, the deformation and stress in the beam plays an important role in determining the reliability of the structure. The output at each node in the FFEM is in membership function form. A COG value at each node is calculated with the centroid techniques used in the defuzzification technique. The maximum displacement is 0.00062 m at node 13. COG values in Figure 6 and Figure 7 represent the FFEM results considering uncertainties in the input parameters. In the reliability analysis of beam structures, the critical parameter is the stress. The COG value for the maximum normal stress is at node 1 with the value 261 MPa and this value is less than the yield strength of a material. The results showed that the reliability of the structure under this illustrative example is 0.9733, which mean it is close to 1. Therefore, the beam structure is still in a safe region of the elastic deformation range. Besides that, the maximum normal stress value for conventional FEM is 228 MPa. From this, it shown that the FFEM method was produced more conservative value of reliability compare to conventional FEM method.

5 CONCLUSION

Obtained solutions are depicted in terms of figures and tables to show the efficiency and reliability of the present analysis. This study shows that, the FFEM approach is conservative method to solve the uncertainties problems. One way to reduce the uncertainty in the data is by experiment. FFEM method developed does not require a large amount of data. FFEM method only required data to determine the profile or shape of membership function. The data can usually be obtained from the opinion of expert knowledgeable in the analysis associated with inductive reasoning or a genetic algorithm. Modeling input in the form of membership function, effectively involving the epistemic uncertainty in the analysis. Although both these illustrative example are based on fuzzy approach, but the presence of a finite element method in FFEM approach allows us to use easily analysis toward the complex structure or component. In addition, the factor that affects the developed simulation of FFEM is the number of fuzzy parameters. The more obscure parameters involved in the simulation, the most conservative result of the analysis. The important decision by using fuzzy approach is the large width of interval for membership functions will give more accurate in result. The trapezoidal and triangle membership function are considered for these two illustrative examples. The result is compare and it worth mentioning that by using fuzzy value given better result in term of interval width of the membership function and also reliability values.

Application of evidential network to model uncertainty in quantitative risk assessment of Natech accidents

N. Khakzad & P.H.A.J.M. van Gelder
Safety and Security Science Group, Faculty of Technology, Policy, Management, TU Delft, The Netherlands

ABSTRACT: Natech is a technological accident which is triggered by a natural disaster. Increasing frequency of natural disasters along with an increasing growth of industrial plants are bound to increase the risk of Natechs in the future. Due to a lack of accurate field observations and empirical data, risk assessment of Natechs has largely been reliant on experts opinion and thus prone to epistemic uncertainty in addition to aleatory uncertainty originating from randomness of natural disasters. Evidential Network (EN) is a directed acyclic graph based on Dempster-Shafer Theory to explicitly model the propagation of epistemic uncertainty in system safety and reliability assessment. In the present study, we have illustrated an application of EN to handling epistemic uncertainty in risk assessment of flood-induced floatation of storage tanks.

1 INTRODUCTION

Technological accidents which are triggered by natural disasters such as earthquakes, lightning, storms, wildfires, tsunamis, and floods are known as Natechs. Natural disasters have reportedly led to the release of significant amounts of oil, chemicals, and radiological substances (Showalter & Myre 1994, Rasmussen 1995, Young et al. 2004).

The occurrence of Natechs in industrial plants, particularly oil terminals, can result in catastrophic consequences in terms of large spillage of petroleum products. In 2005, the floods triggered by the Hurricane Katrina in the U.S. caused a spillage of ~ 8 million gallons of oil into the ground and waterways. In August 2017, the Hurricane Harvey in the U.S. caused damage to storage tanks in refineries and petrochemical plants, leading to a substantial release of pollutants. The structural damage caused by natural events, however, does not compare with the environmental damage and revenue losses due to interruption in production and supply chain: the Hurricane Harvey made oil refineries shut down as for safety precautions, leading to at least a loss of more than 1 million barrels of oil per day in refining capacity (CNBC, 2017).

Natechs has been recognized in quantitative risk assessment of industrial plants by many researchers (Young et al. 2004, Godoy 2007, Cruz & Okada 2008, Antonioni et al. 2009, Haptmanns 2010, Krausmann et al. 2011, Landucci et al. 2012, Necci et al. 2013, Marzo et al. 2015, Mebarki et al. 2016, Khakzad & van Gelder 2017, 2018, Kameshwar & Padgett 2018). The scarcity of historical data, especially data with sufficient resolution and accuracy, has made the majority of previous studies reliant on analytical or simulative techniques (e.g., finite element modeling) in modeling and calculating the probability of failure modes. This mostly has been carried out based on modeling the envisaged failure mechanisms as a function of loads exerted by natural disasters (e.g., impact of tsunami wave) and the resistance of impacted vessels.

The stochastic features of natural disasters as well as randomness of failure mechanisms are naturally modeled via probability density functions. Either the types or the parameters of such density functions are usually estimated based on insufficient (either amount or accuracy) objective data. This lack of objective data is usually tried to be compensated for by experts opinion based upon their experience, knowledge, and even intuition, inevitably introducing degrees of epistemic uncertainty into the analysis.

The Evidence Theory (Dempster-Shafer Theory, DST), originally initiated by Dempster (1967) and further developed by Shafer (1976), is an effective tool to handle imprecise probabilities and reasoning under epistemic uncertainty. According to DST, all the possible states (mutually exclusive and collectively exhaustive) of a system is presented in a set known as *the frame of discernment* $\boldsymbol{\Omega}$. To each subset of Ω such as $\mathbf{A}$, an evidential weight $\mathbf{m(A)}$ can be assigned to indicate the degree of evidence (based on objective data or subjective opinion) in favor of the claim that a specific state in Ω belongs to A (Rakowsky 2007). Having m(A), which is also known as belief mass, the amounts of *belief* and

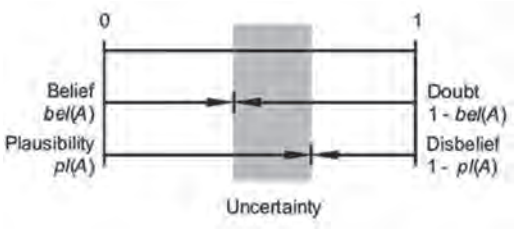

Figure 1. Quantification of epistemic uncertainty through Bel and Pls functions (Rakowsky, 2007).

plausibility of A, equivalent to lower and upper probability bounds of A, respectively, can be determined (Shafer 1976). The difference between plausibility **Pls(A)** and the belief **Bel(A)** represent the epistemic uncertainty of A (Fig. 1).

An Evidential Network (EN) is a directed acyclic graph to propagate uncertainty based on conditional belief functions (Xu & Smets 1996). Simon and Weber (2009) combined DST with Bayesian Network (Pearl, 1988) to take advantage of the junction tree algorithm developed by Jensen (1996) in propagating and computing the marginal belief functions of child nodes based upon those of their parent nodes.

The present study is an attempt to illustrate the potentiality of EN in system safety where due to lack of sufficient accurate data the analysis would be subject to epistemic uncertainty embedded in expert judgement. The application of EN will be demonstrated via safety assessment of oil storage tanks impacted by floods, with the floatation of tanks as the most common failure mode (Cozzani et al. 2010).

2 REASONING UNDER EPISTEMIC UNCERTAINTY

2.1 *Dempster-Shafer theory*

Assume that all the states of a system can be presented in a frame of discernment as Ω = {S1, S2, S3}. Accordingly, the set of all the subsets of Ω can be shown as:

$$A_i : \{\{\varnothing\},\{S1\},\{S2\},\{S3\},\{S1,S2\},\{S1,S3\},\{S2,S3\},\Omega\} \quad (1)$$

According to the available evidence (either objective or subjective), an expert may assign a belief mass to each A_i as $0 \le m(A_i) \le 1$. Each A_i for which $m(A_i) > 0$ is called a *focal set*. If all the states of the system are known, then $m(\varnothing) = 0$. Further, it must always hold that:

$$\sum_{A_i} m(A_i) = 1 \quad (2)$$

Having the belief masses determined, the belief and plausibility measures of each focal set can be defined:

$$Bel(A_i) = \sum_{B|B\subseteq A_i} m(B) \quad (3)$$

$$Pls(A_i) = \sum_{B|B\cap A_i \neq \varnothing} m(B) \quad (4)$$

$Bel(A_i)$ and $Pls(A_i)$, which are non-additive, can be taken as lower and upper probability bounds, respectively, of A_i (Simon & Weber 2009):

$$Bel(A_i) \le P(A_i) \le Pls(A_i) \quad (5)$$

$$Bel(A_i^c) = 1 - Pls(A_i) \quad (6)$$

$$Pls(A_i^c) = 1 - Bel(A_i) \quad (7)$$

where A_i^c is the complement of A_i. Having the Bel and Pls functions, the belief mass of a focal set can be determined using the möbius transformation as (Smets 2002):

$$m(A_i) = \sum_{B|B\subseteq A_i} (-1)^{|A_i - B|} Bel(B) \quad (8)$$

where $|A_i - B|$ refers to the difference between the number of elements of A_i and B.

2.2 *Evidential network*

Simon & Weber (2009) used a Bayesian network (BN) formalism to propagate imprecise probabilities using the belief mass functions assigned to the focal sets. Since the belief masses allocated to the focal sets of each component of the system add up to unity, they can be used as marginal probabilities of the nodes in the BN.

Combination of the mass belief functions of components (nodes) can readily be carried out by means of Boolean algebra. For the sake of exemplification, consider a system Z comprising two components X and Y as shown in Fig. 2.

In Fig. 2, the components and the systems are considered as binary nodes, i.e., being in one of *up* or *down* states. Thus, for instance, the frame of discernment of X and its focal sets can be presented as Ω_X = {up, down} and A_X = {{up}, {down}, {up,down}}, where {up,down} = {up}⊕{down}, respectively. Among the focal sets of X, {up,down} models the uncertainty, indicating that X can be in either up or down states. Now consider a case where

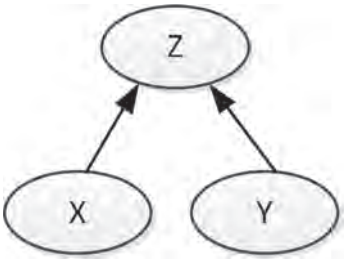

Figure 2. BN for reliability assessment of a two-component system.

Table 1. Truth table used to combine the focal sets of components X and Y via AND and OR gates (Simon & Weber, 2009).

		Z	
X	Y	AND	OR
{up}	{up}	{up}	{up}
{up}	{down}	{down}	{up}
{up}	{up,down}	{up,down}	{up}
{down}	{up}	{down}	{up}
{down}	{down}	{down}	{down}
{down}	{up,down}	{down}	{up,down}
{up,down}	{up}	{up,down}	{up}
{up,down}	{down}	{down}	{up,down}
{up,down}	{up,down}	{up,down}	{up,down}

X = {up} and Y = {up,down} are connected to Z by an AND gate; using Boolean algebra, the state of Z can be identified as {up}∩{up,down} = {up}∩{up} ⊕ {up}∩{down} = {up} ⊕ {down} = {up,down}. Likewise, in case of an OR gate, the state of Z can be identified as {up}∪{up,down} = {up}∪{up} ⊕ {up}∪{down} = {up} ⊕ {up} = {up}. The results of AND and OR gates in the form of a truth table have been presented in Table 1.

For the system shown in Fig. 2, assume that the analyst, based on his degree of belief, has assigned the marginal belief mass distributions to the focal sets of components X and Y as $m(A_X) = \{0.5, 0.4, 0.1\}$ and $m(A_Y) = \{0.4, 0.4, 0.2\}$. We in the next section will demonstrate using a case study how the belief mass distributions can be determined using Equations (2)–(8). Fig. 3 displays the resulting EN in which X and Y are connected to Z via an AND gate.

As can be seen in Fig. 3, the inference algorithm of BN can be used to calculate marginal belief mass distribution of Z based on the marginal mass distributions of X and Y and the truth table (see Table 1) as $m(A_Z) = \{0.2, 0.64, 0.16\}$. Having the belief mass distribution of Z, the belief of Z = {up} can be calculated using Equation (3):

$$Bel(\{up\}) = \sum_{B|B\subseteq up} m(B) = m(\{up\}) = 0.2.$$

This is because among the focal sets of Z, i.e., $A_Z = \{\{up\}, \{down\}, \{up,down\}\}$, only the focal set B = {up} is the subset of {up}. Likewise, the plausibility of Z = {up} can be calculated using Equation (4):

$$Pls(\{up\}) = \sum_{B|B\cap up\neq\varnothing} m(B) =$$
$$m(\{up\}) + m(\{up,down\}) = 0.2 + 0.16 = 0.36.$$

This is because among the focal sets of Z, only the intersections of focal sets {up} and {up,down} with {up} are not null. As a result: $0.2 \le P(Z = up) \le 0.36$.

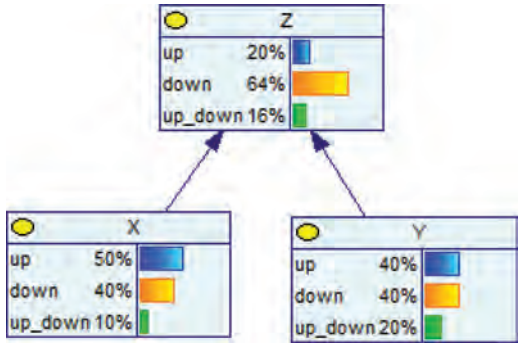

Figure 3. EN for reliability assessment of a two-component system using belief mass distributions.

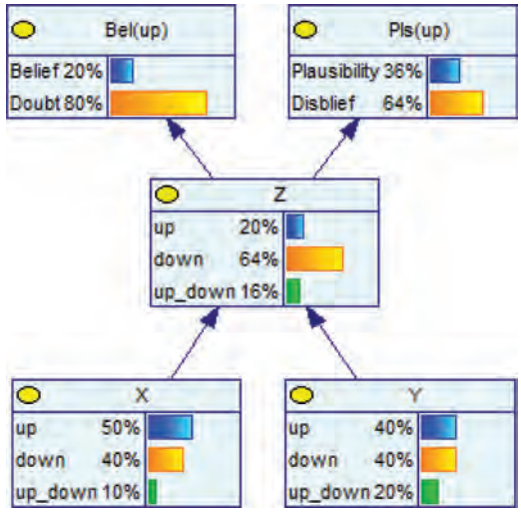

Figure 4. Adding belief (Bel) and plausibility (Pls) nodes in order to calculate epistemic uncertainty of Z = {up}.

Table 2. Conditional belief table used to calculate Bel(up) and Pls(up) of Z in Fig. 4.

Z	Bel(up)	Pls(up)
{up}	1	1
{down}	0	0
{up,down}	0	1

The procedure of calculating belief and plausibility can be carried out using the developed BN (which in fact is an EN) by adding the nodes Bel({up}) and Pls({up}) to the network (Fig. 4). The conditional belief table used to connect these two nodes to node Z is presented in Table 2. It should be noted that since Bel and Pls are non-additive (see Equations (6) & (7)), they have been presented as two separate nodes in the EN.

3 SAFETY ASSESSMENT OF STORAGE TANKS IN CASE OF FLOOD

3.1 *Floatation of storage tanks*

Floatation of storage tanks has reportedly been the most frequent failure mode during floods (Cozzani et al. 2010). Floatation of storage tanks occurs if the upthrust force of flood exceeds the bulk weight of the storage tank (weight of the tank plus the weight of its liquid containment). Fig. 5 presents the loading force (buoyancy) and resisting forces (bulk weight of the tank) contributing to the flotation of the storage tank.

When there is a lack of field or experimental data to relate the characteristics of the natural disaster to the failure modes and failure probabilities of an impacted equipment, one may choose to develop Limit-State Equations (LSE) based on influential loading and resisting forces. Development of LSEs helps the analyst combine his knowledge (though incomplete) of the influential parameters with available objective data to compensate for the inadequacy of objective data required for estimation of failure probabilities.

As for the floatation of storage tanks, the relevant LSE should take into account the weight of the tank W_T, the weight of the contained liquid W_L, and the buoyant force F_B. As can be seen from Fig. 5, we have considered a self-anchored storage tank (not bolted to the foundation) which is a common practice in case of atmospheric storage tanks. As such, the only resisting forces against the tank's floatation comprise the bulk weight of the tank. Considering the direction of the forces in Fig. 5, the LSE can be developed as:

$$LSE = F_B - W_T - W_L \tag{9}$$

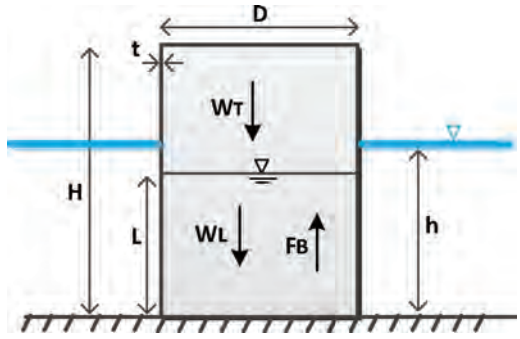

Figure 5. Schematic of the load-resistance forces considered for tank floatation.

$$F_B = \rho_w g \frac{\pi D^2}{4} h \tag{10}$$

$$W_T = \rho_s g \left(\pi DH + 2\frac{\pi D^2}{4} \right) t \tag{11}$$

$$W_L = \rho_l g \frac{\pi D^2}{4} L \tag{12}$$

where D: tank's diameter, H: tank's height, t: tank shell's thickness, L: height of liquid inside the tank, h: height of flood's inundation, ρ_w: flood water density, ρ_s: tank shell's density, ρ_l: liquid's density, and g: gravitational acceleration. Accordingly, the floatation probability of the tank can be presented as P(LSE > 0).

3.2 *Failure analysis*

For the sake of exemplification, assume that the analyst, based on objective data, would know the amounts of the tank's and flood's parameters as listed in Table 3, except the initial amount of chemical liquid (gasoline in this example).

Floatation of a storage tank due to slow submersion can result in an instantaneous release of liquid should the tank collapse, continuous release of the entire containment in a limited time in case of full disconnection of large pipelines, or a minor release in case of partial disconnection of flanges and pipelines (Cozzani et al 2010). In any of these release scenarios, if the initial inventory of the tank was not known before the floatation, the estimation of a priori inventory of the tank would be subject to uncertainty (epistemic).

Since the analyst would have doubts about the initial inventory of the tank before the flood impacted the plant, he decides to seek the opinion of two experts (e.g., operators working at the storage tank area). The first expert comes up with

Table 3. Parameters used for risk assessment of floatation.

Parameter	Value
H (m)	6
D (m)	10
t (m)	0.01
h (m)[¥]	N ($\mu = 1, \sigma = 0.2$)
ρ_s (kg/m^3)	7900
ρ_w (kg/m^3)	1024
ρ_l (kg/m^3)[§]	850

[¥] due to aleatory uncertainty inherent in flood's forecast.
[§] gasoline has been considered as the chemical liquid.

P(L = 0.5 m, L = 1.0 m, L = 1.5 m) = (0.2, 0.5, 0.3) whereas the second expert with P(L = 0.5 m, L = 1.0 m, L = 1.5 m) = (0.5, 0.3, 0.2). As such, the experts' uncertainty about the initial inventory of the storage tank can be expressed using imprecise probabilities as:

$$\begin{cases} 0.2 \le P(L = 0.5) \le 0.5 \\ 0.3 \le P(L = 1.0) \le 0.5 \\ 0.2 \le P(L = 1.5) \le 0.3 \end{cases} \quad (13)$$

According to the parameters in Table 3, the tank's weight, the weight of liquid containment, and the buoyancy force can be calculated as $W_T = 219$ (KN), $W_L = 655$ L (KN), and $F_B = 789$ h (KN), respectively. The floatation probability can thus be calculated as:

$$P(LSE > 0) = P(F_B > W_T + W_L) = P(789h > 219 + 655L) = P\left(h > \frac{219 + 655L}{789}\right) \quad (14)$$

3.3 *Uncertainty modeling*

Considering L as an uncertain variable with three states as L1 = 0.5 m, L2 = 1.0 m, and L3 = 1.5 m, its frame of discernment would be:

Ω_L = {L1, L2, L3}.

Consequently, the set of its focal sets would be:

A_L: {{L1}, {L2}, {L3}, {L1, L2}, {L1, L3}, {L2, L3}, {L1, L2, L3}}.

Using the equations in Section 2.1, the belief mass of each focal set can be determined. For example, consider the first focal set, {L1} with the lower and upper bound probabilities as shown in Equation (13). Based on Equation (5), Bel({L1}) = 0.2 and Pls({L1}) = 0.5. Since {L1} is a singleton, using Equation (8), m({L1}) = Bel({L1}) = 0.2. Similarly, m({L2}) = 0.3, and m({L3}) = 0.2.

As another example, consider the focal set {L1, L2}. Since {L1}, {L2}, and {L1, L2} are all the subsets of {L1, L2}, using Equation (8), we will have m({L1, L2}) = Bel({L1, L2}) – Bel({L1}) –Bel({L2}).

Further, based on Equation (6), Bel({L1, L2}) = 1 – Pls({L3}) = 1 – 0.3 = 0.7.

As a result, m({L1, L2}) = 0.7 – 0.2 – 0.3 = 0.2. Following the same procedure, m{{L1}, {L2}, {L3}, {L1, L2}, {L1, L3}, {L2, L3}, {L1, L2, L3}} = (0.2, 0.3, 0.2, 0.2, 0.1, 0, 0). Since m({L1, L3}) = m({L1, L2, L3}) = 0, they would not be considered as focal sets any more.

3.4 *Probability of floatation*

As can be seen from Equation (14), the only influential parameters in estimating the probability of floatation are the flood inundation height h and the liquid containment height L. To facilitate the propagation of uncertainty – aleatory uncertainty in h and epistemic uncertainty in L – the EN in Fig. 6 can be developed. It is worth noting that compared to the EN proposed by Simon & Weber (2009), in our EN both the belief and plausibility of *Floatation* have been modeled using a single node, considering the fact that:

$$Bel(A_i) + Unc(A_i) + Dis(A_i) = 1.0 \quad (15)$$

$$Unc(A_i) = Pls(A_i) - Bel(A_i) \quad (16)$$

$$Dis(A_i) = 1 - Pls(A_i) \quad (17)$$

where $Unc(A_i)$ and $Dis(A_i)$, respectively, refer to the uncertainty and disbelief about the focal set A_i (see Fig. 1).

In the EN shown in Fig. 6, the states of the node L have been represented by its focal sets with the respective belief masses as marginal probabilities (although belief masses are not probabilities, as discussed in Rakowsky (2007)). As opposed to the node L, the states of the node h are the discretized intervals of h with their (real) marginal probabilities calculated based on the normal distribution presented in Table 3. In this regard:

$$h = \begin{cases} h1 & if \quad 0 \le h < 0.8 \\ h2 & if \quad 0.8 \le h < 1.2 \\ h3 & if \quad 1.2 \le h < 1.6 \\ h4 & if \quad 1.6 \le h < 2.0 \end{cases}$$

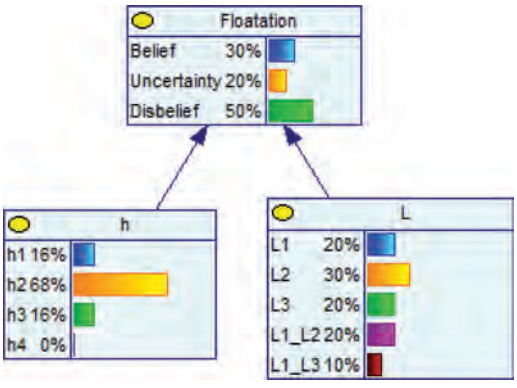

Figure 6. Evidential network to estimate the probability of floatation under aleatory and epistemic uncertainty.

The conditional belief table used to calculate the marginal masses of the node Floatation has been shown in Table 4. The conditional masses can readily be calculated using Equation (14). As an example, consider the combination of h2: $0.8 \le h < 1.2$ with the states (focal sets) of L:

- Case 1

{L1}: L = 0.5

$$P\left(h2 > \frac{219 + 655L1}{789}\right) = P\left(h2 > 0.69\right) = 1.0$$

Since h is always greater than 0.69 (note $0.8 \le h < 1.2$), the belief and plausibility of the floatation, as the lower and upper bounds of probability, are both equal to 1.0. This, in turn, yields a zero uncertainty (see Equation (16)) and a zero disbelief (see Equation (17)). See the 6th row in Table 4.

- Case 2

{L2}: L = 1.0

$$P\left(h2 > \frac{219 + 655L2}{789}\right) = P\left(h2 > 1.11\right) = P\left(1.11 < h < 1.2\right) = 0.133$$

As a result, Bel = Pls = 0.133, Unc = 0.0, and Dis = 0.867 (7th row in Table 4).

- Case 3

{L3}: L = 1.5

$$P\left(h2 > \frac{219 + 655L3}{789}\right) = P\left(h2 > 1.52\right) = 0.0$$

Since h is always smaller than 1.2 (note $0.8 \le h < 1.2$), the belief and plausibility of the floatation, as the lower and upper bounds of probability, are both equal to 0.0. This, in turn, yields a zero uncertainty and a disbelief of unity (8th row in Table 4).

- Case 4

{L1, L2}: L = 0.5 or 1.0

From Case 1 (L = 0.5) and Case 2 (L = 1.0), the probabilities of floatation were calculated as 1.0 and 0.133, respectively. Accordingly, the lower probability can be taken as Bel = 0.133 whereas the upper probability as Pls = 1.0. This in turn will result in Unc = 0.867 and Dis = 0.0 (9th row in Table 4).

- Case 5

{L1, L3}: L = 0.5 or 1.5

From Case 1 (L = 0.5) and Case 3 (L = 1.5), the probabilities of floatation were calculated as 1.0 and 0.0, respectively. Accordingly, the lower probability can be taken as Bel = 0.0 whereas the upper probability as Pls = 1.0. This in turn will result in Unc = 1.0 and Dis = 0.0 (10th row in Table 4).

As can be seen from Fig. 6, given the marginal and conditional probabilities and belief masses, the lower bound probability of floatation has been calculated as Bel = 0.3. Similarly, the amount of uncertainty has been calculated as Unc = 0.2, which together with the amount of belief results in an upper bound probability of floatation as Pls = 0.3 + 0.2 = 0.5.

Modeling the uncertainty of the floatation in a single node instead of two nodes (cf Fig. 4) comes

Table 4. Conditional belief mass distribution for the node Floatation in Fig. 6.

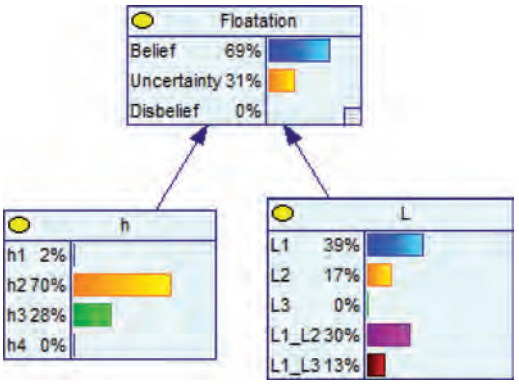

Figure 7. Updated belief masses by means of Disbelief = 0 as soft evidence.

in handy in reasoning about a priori inventory of the storage tank via belief updating. For instance, in case the storage tank is believed to have lost some of its containment as a matter of floatation, the initial belief masses assigned to L can be updated by instantiating the amount of Disbelief to zero (Fig. 7).

The updated belief masses have been depicted in Fig. 7, where L1 (i.e., L = 0.5 m) is believed to be the likeliest amount of initial inventory before the floatation.

4 CONCLUSIONS

In the present study we examined the applicability of evidential networks to system safety under both aleatory and epistemic uncertainties.

Modeling epistemic uncertainty of a parameter in a single node as an aggregation of the degrees of belief, uncertainty, and disbelief, makes it possible to perform belief updating by using a variety hard and soft evidence. We demonstrated the application of evidential networks to assess the vulnerability of storage tanks against flood-induced submersion. However, the methodology, without a loss of generality, can be applied to system safety and reliability assessment in a wide variety of domains.

Towards an online risk model for dynamic positioning operations

Anna Yining Dong, Jan Erik Vinnem & Ingrid Bouwer Utne
Department of Marine Technology, NTNU, Norway

ABSTRACT: Automation and increasing complexity mean that operators have to handle data and alarms and emergent decisions under the pressure of unexpected and rapidly changing hazardous situations. Position loss during marine operations may lead to serious accidents, such as collision, loss of well integrity, etc. An online risk model aims at assisting operators in dynamic positioning operations to successfully recover the vessel's position in a good timing. The objective of this paper is to identify generic scenarios of position loss during operational phase and the information that is needed for successful recovery action. The results show that position loss normally involves of complex human machine interactions, generally in two patterns. Based on the findings, it has been recognized that risk model considering time aspect is of vital importance to develop an online risk model for DP operations.

1 INTRODUCTION

A dynamically positioned (DP) vessel is by the International Maritime Organization (IMO) defined as a vessel that maintains its position and heading (fixed location or pre-determined track) exclusively by means of active thrusters (1994). A DP system generally consists of three main subsystems, i.e., the power system, thruster system and DP control system. To further measure the designed equipment redundancy of the DP system, the IMO MSC Circ. 645 (1994) defines three classes, i.e., DP 1, DP 2 and DP 3. For DP class 1, position loss may occur given a single failure event of an active component. For DP class 2, position loss should not occur given a single failure, and for DP class 3, position loss should not occur given a single failure, including fire and flooding of watertight compartment or fire subdivision.

Based on more than two-decades of experience with safety management of DP marine operations, it has been shown that risk of position loss is intrinsic to all DP vessels (Chen and Nygård 2016). A position loss may happen on DP 1 vessels, as well as on DP 2 and DP 3 vessels. Meanwhile, offshore exploration and exploitation of hydrocarbons have opened up an era of DP vessels. There are wide applications of DP vessels in the offshore oil and gas industry, e.g., diving support vessels, pipe-layers, heavy lifting vessels, drilling rigs, subsea construction vessels, platform support vessels, shuttle tankers, etc. The focus of this paper is on offshore loading operations using DP shuttle tankers.

Nowadays, most liquid products (i.e., stabilised crude oil, condensate, liquefied petroleum gas, liquefied natural gas, etc.) from oil and gas fields in the North Sea are transported to refineries and terminals by DP shuttle tankers (ST). These large vessels with high thrust and power capacity may pose a significant collision risk to an adjacent offshore installation in case of position loss. Since 2000, there have been two collisions between shuttle tankers and facilities on the Norwegian Continental Shelf (NCS). In addition, there have been four near misses (collision events) and seven incidents related to loss of position, with varying degrees of severity.

There are two generic failure modes of position loss, i.e., drive-off and drift-off. The primary concern in this paper is on the drive-off scenario. The term *drive-off* is defined as a tanker moving away from its own target/desired position by its own power in off-loading operations. It might occur in different phases during offloading operations, i.e., approach, connection, loading and disconnection. Excessive relative motions between the FPSO (floating production storage and offloading) and tanker, categorized in surging and yawing modes, have been identified as the failure prone situations (drive-off) in tandem offloading (Chen 2003). Several recommendations have been given by (2003) regarding how to reduce the occurrence of excessive surging and yawing events. For instance, the coordination of mean heading control between the FPSO and tanker is important to minimize the probability of excessive yawing.

A recent review of DP accidents and incidents by the Petroleum Safety Authority in Norway (PSA) has shown that there is an increasing tendency in the number of DP drive-off accidents and incidents during offshore loading with shuttle tankers on the NCS in the past fifteen years (Kvitrud, Kleppestø

et al. 2012). Vinnem et al. (2015) indicate the need for new risk reduction measure and outline an overall concept for online risk management. A research project has been initiated by the Department of Marine Technology in the Nowegian University of Science and Technology (NTNU). The main goal of the project is to develop an online risk monitoring and decision support system.

An analysis was performed on DP accidents and incidents with emphasis on root causes and barrier failures (Dong, Rokseth et al. 2017). One of the major conclusions was that the most recently drive-off accidents and incidents on NCS involve both technical and human/operational failures. The development of DP operator (DPO) decision support should focus on reducing the combination of causes. Five design principles for the online risk model, including complementarity, integration, early detection, early warning, and transparency were proposed by Hogenboom et al. (2017). Moreover, it is likely that an online risk management system may reduce the risk due to human machine interface (HMI) failures. Automation and increasing complexity mean that DPOs have to handle data and alarms and take safety-critical decisions under the pressure of unexpected and rapidly changing hazardous situations. A previous study shows that human error is the most complex and least understood factor in the failures of complex systems, accounting for as much as 60% to 80% of complex system failures (Sudano 1994). As an additional barrier function (Vinnem, Utne et al. 2015), the new decision support system should aim at supporting information to operators, reducing the potential for catastrophes induced or exacerbated by human errors. The complex HMI determines the importance of information support for operators' decision-making.

The objective of this paper is to identify the human action and types of technical failures in the initiating event of drive-off. The purpose is to find out the challenges and problems for early detection during DP operations, which online risk model and decision support system can provide the information to contribute to improve DPOs' situation awarness and decision making, and understanding of system performance as well.

The paper is structured as follows: the challenges of DPO decision-making are stated in Section 2, where classifications of decision and risk information are also introduced. In Section 3, human actions in the initiating event of drive-offs and classifications of failures are presented, following by the description of analysis and result in Section 4. Based on the analysis and result, discussions are given in Section 5. Lastly, conclusions are summarized in Section 6.

2 DP OPERATOR DECISION-MAKING, CHALLENEGES, TYPES OF DECISION AND RISK INFORMATION

An information-decision-execution model (Figure 1) for DPO reaction in a drive-off scenario was introduced by Chen (2003). One important factor and dimension that needs to be under control is the *time*. As illustrated in Figure 1, the model is presented with the time reference. It is worth noting that the three stages (Ta; Td; T1) do not happen in a purely linear, sequential manner. The estimation of the DPO action initiation time (T1) is, accordingly, based on an estimation of the following three characteristic time interval values, as shown in Figure 1:

- Information time: 0-Ta
- Decision time: Ta-Td
- Execution time: Td-T1

Chen (2003) states that the challenge of human intervention is that the DPO needs to make a decision within typically 45 seconds to avoid a collision in the case of drive-off, given that the typical distance between vessels is 75 m. Some previous studies show that DPOs when collisions occurred, used about 3 minutes before taking manual evasive action.

Loss of situation awareness has been recognized as the main reason for no early detection (Chen 2014). Situation awareness (SA) is defined as "the perception of the elements in the environment within volume of time and space, the comprehension of their meaning and the projection of their status in the near future" (Endsley 1995). Moreover, Endsley (1995) developed a three-level model to describe the different levels involved in the formation of SA. Level 1, perception, refers to the perception of attributes and dynamics of elements in the environment. Level 2, comprehension, refers to the integration and understanding of the information, i.e. it involves the human operator's sense-making to establish what is happening in the situation. Level 3, projection, refers

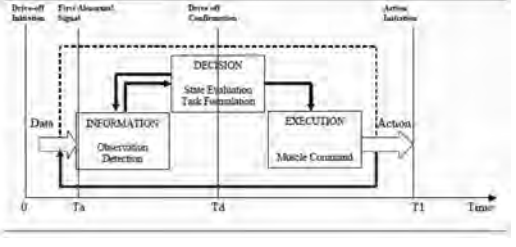

Figure 1. Information-Decision-Execution model for DP operator reaction in drive-off scenarios, adopted from (Chen 2003).

to the operator's estimation of future states of the system. The results of the assessment of the current situation can be utilized to determine future courses of action, thus supporting decision-making. However, Kjell et al. (2015) argued that the process of gaining SA does not follow sequentially from level 1 SA to level 2 SA, as set out by Endsley's model, but rather the build-up seemed to be adaptive and related to the work system's higher level goals, such as to avoid collision. He also found that in a majority of DP accidents and incidents, DPOs didn't expect the occurrence of an accident or incident. Some of the DPOs were not able to identify the relevant initiating events (lack of level 1 SA), or to understand the relevance of the initiating events (lack of level 2 SA) in DP accidents and incidents (Øvergård 2015). *Initiating event* is an identified event that upsets the normal operations of the system and may require a response to avoid undesirable outcomes (Rausand 2011). The initiating events that were used in the study include environmental impact, DP reference, human error, component failure, power management system, DP software failure (Kjell I. Øvergård 2015).

To avoid a collision and mitigate the consequence of position loss, successful human intervention has been considered as the main risk reduction measure, while efforts should be made on bridge ergonomics, HMI, alarm system, procedures and training. Meanwhile, it also needs to improve DPO's decision-making for gaining and maintaining situation awareness.

From a risk assessment perspective, decisions can be classified into planning decisions and execution decision. *Planning decision* is the decision made by blunt-end decision maker and middle level decision makers, such as operational managers. The time lag between decision and action is relative long. Enough time systematically identify and evaluate different alternatives. *Execution decision* is made by sharp-end personnel, who monitor or control ongoing operation and emergency response teams. The time lag between decision and action is much less. When DPO is in charge of making execution decision (illustrated in Figure 1), it can be further divided into *instantaneous decisions* and *emergency decisions*. Instantaneous decisions are taken spontaneously by sharp-end operators, e.g. to follow or deviate from procedures; ignore or react upon deviations in normal working conditions. The decision-making emphasizes situation assessment and pattern matching. This type of decision is normally taken quickly, although not necessarily. Emergency decisions are taken in emergencies to avoid or adapt to hazardous situations. Time dynamic is often so fast that pattern matching may not match the development of the situation. Decisions have to be made fast.

Furthermore, Yang and Haugen (2015) identify six different risk types to make the different operational decisions. To support execution (instantaneous and emergency) decisions, time-dependent action risk information is proposed. The time-dependent action risk can be estimated or predicted based on the margin between the performance of parameters in the current situation and operational limits.

In terms of early detection, focus should be on signals of deterioration of position to strengthen situation awareness during the monitoring (boredom) phases. Early warning including indicators derived from operating parameters against operating limits should faciliate early detection and reflect the operating limits and capabilities.

2.1 *Human actions in initiating event of drive-off*

To study the HMI in initiating event of drive-off, human action is used instead of human error. *Human error* is defined by Reason (1990) as all those occasions in which a planned sequence of mental or physical activities fails to achieve its intended outcome, and when these failures cannot be attributed to the intervention of some agency. Reason (1990) emphasizes that the notion of intention and error are inseparable. Human action can be categorized as intentional action and nonintentional action. Reasons argues that human error is only associated with the intentional action, and it has no psychological meaning in relation to nonintentional behaviour. This view is also accepted in paper, although nonintentional human behaviour may contribute to system failure from safety point of view.

The human actions and their interations with technical failure events have been categorized into initiating action, response action and latent action:

- *Initiating action* is an action that initiates a failure event in the system.
- *Response action* is an action that responds to the system demands, typically under technial failure events or special external situations. Chen (2003) points out that the response action may save or worsen the situation or cause a transition to another event.
- *Latent action* is an action that influences (but does not directly initiate) the technical failure, e.g. maintenance action, and/or the above two types of human actions.

2.2 *Types of failures*

With respect to the performance of an item, it is necessary to explain the difference between failure, fault and error, a relationship between failure, fault

and error is given as follows (Rausand og Høyland 2004):

- A failure is an event that occurs at a specific point in time.
- A fault is the state of an item characterized by inability to perform a required function. While a failure is an event that occurs at a specific point in time, a fault is a state that will last for a shorter or longer period.
- The error is a discrepancy between a computed, observed, or measured value or condition and the true, specified, or theoretically correct value of condition. An error is present when the performance of a function deviates from the target performance (i.e., the theoretically correct performance), but still satisfies the performance requirement. An error will often, but not always, develop into a failure.

An illustration showing the relationship can be found in Figure 2. A failure may originate from an error. When the failure occurs, the item enters a fault state. A failure mode is always related to a required function and the associated performance requirement. A failure mode is a description of a fault (i.e., a state) and not of a failure (i.e., an event). A correct term would, therefore, be a fault mode.

In addition, failures may be classified according to their causes, effects, detectability and several other criteria. It is worth to mention a special category of cause is common-cause failures (CCFs). According to the effect of the failure, IEC 61508 (2010) classifies failures as follows:

- *Safe failure:* failure which does not have the potential to put the safety-related system in a hazardous or fail-to function state.
- *Dangerous failure:* failures has the potential to put the safety-related system in a hazardous or fail-to function state.
- *Non-critical failure:* failures where the main functions of the item are not affected.

Safe and dangerous failures may be classified further as either detected (by diagnostics) or undetected (not detected by diagnostics).

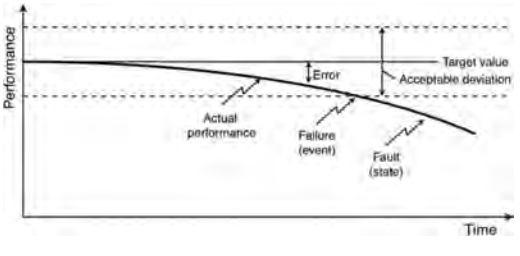

Figure 2. Difference between failure, fault and error (Rausand og Høyland 2004).

3 ANALYSIS AND RESULTS

The analysis is performed by reviewing the incident investigation reports of recently occurred DP accidents and incidents (a detailed overview can be found in (Dong, Rokseth et al. 2017)). According to the classifications of human action and failures that are stated above, the following keywords are used to analyse the accidents and incidents:

- Performance deviation
- Initiating event
- Failure (event), particularly technical failures
- Human initiating action
- Human response action

The result shows two identified situations regarding performance deviations.

Situation 1: Deviation is observed. Normal operational activity is required to perform.

Situation 2: Deviation is observed. Deviation represents the abnormal performance of the technical system.

For each situation, operator tasks, HMI, type of human action and typical technical failures are summarised in Table 1.

For the first situation (shown in Table 1), the operator needs to interact with the techncial system to perform operation activity when they observed deviations in normal working conditions. When performing the task, this situation mostly involved human initiating action. In addition, DP control logical failure has been identified as a typical technical failure that is initiated by the human action. For instance, the DPO might need to adjust ST heading to return backloading hose during disconnection. When giving the new setpoints, DPO initiated the software logic failure. However, it is challenging for the DPOs to identify the DP logic failure, since it is a type of undetected dangerous failure. Technical failures can be classified into (dangerous or safe) undetected and (dangerous or safe) detected failures. Dangerous Undetected (DU) failures are preventing activation on demand and are revealed only by testing or when a demand occurs. Sometimes, it is also called dormant failures (61508 2010).

The drive-off involving human initiating action also shows DPO lacks information for performing their task. A task analysis is conducted based on a case study of adjusting shuttle tanker position to return loading hose during disconnection. It is illustrated in Figure 3. The task analysis is made according to a six-step decision-making process (D. Husjord 2015) using in navigational training and practice. As shown in Figure 3, the main task is to adjust ST position to return loading hose

Table 1. Identification of situation that contributed to human action in DP accidents and incidents.

Situation	Description	Operator task	HMI	Type of human action	Identified technical failures	Type of technical failures
1	Deviation is observed. Normal operational activity is required to perform.	Interact with technical system to perform operation activity. i.e., adjust ST heading to return backloading hose during disconnection.	– Select an operation mode – Give new setpoints in user menu – Select DP reference orgin	Initiating action, i.e., DPO gives new setpoints.	– DP control logic failure. – Sensor failure.	Dangerous undetected
2	Deviations represent abnormal performance of technical system.	Interact with technical system to keep ST position.	Interaction depending on the type of technical failures (i.e., safe failures or dangerous failures) and causes of the technical failures.	Response action, i.e., DPO performs position drop-out to calibrate PRS	Inaccurate DP offset (s) for PRS (s) and/ or gyros deviating from true north	Safe detected

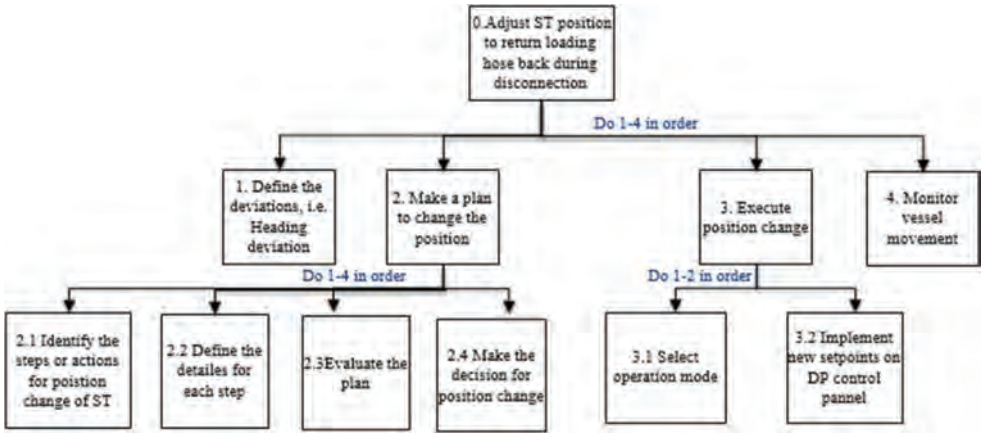

Figure 3. Task analysis of adjusting ST position to return backloading hose during disconnection.

during disconnection. To achieve it, there are a couple of steps, which are listed as follows:

Step 1: Define the heading deviations;
Step 2: Make a plan for changing the position;
Step 3: Execute the action for a position change;
Step 4: Monitor the movement of the vessel.

The operator should follow the Step 1-4 in order. However, this is not just a human task. It demands a human-machine collaboration to change the heading. While the operator decides whether the heading should be changed or not, execution of the position change needs thrust allocation, which is implemented by the DP control system. The problem is the DP control system might have limitations that are not stated in the user manual or hidden failures. Therefore, the operators need information about the real-time performance of the DP control system to avoid undesired outcome from the command they give to the control system. By referring to real-time, it means the weather conditions at the moment is also taken into account.

Regarding the second situation in Table 1, it is normally associated with technical failures. While

technical failures appear, the DPO identifies the deviations. To ensure safe operation, the DPO further identifies the risk that can be caused by the technical failures so that they can take action to respond to the failure. Nevertheless, they might misunderstand the technical failures, which means they should be able to distinguish between dangerous and safe detected failures.

- Dangerous detected failures (DD): dangerous failures that are detected immediately when they occur, for instance by an automatic built-in self-test.
- Safe detected failures (SD): Dangerous failures that are detected (normally by automatic self-testing).

The detection of technical failures and identification of dangerous or safe failures have been mainly given as the task of the automation, which is performed by *diagnostic self-testing* (Rausand og Høyland 2004). Therefore, the increasing trust of the reliability of the automatic function (i.e., automatic self-testing) may result in loss of skill of human operators. The operator needs information support for being aware that the actual performance of DP system is within acceptable deviation even though a deviation is observed.

4 DISCUSSION

Based on the classifications of human actions, initiating action and response action are identified from the recently occurred DP accidents and incidents. First, it shows that the initiating event of drive-off does have to be a technical failure. It can be a human initiating action that triggers a failure in technical system with the purpose to perform a normal operational task. While lack of information support during performing the task is identified, it also represents the deficiency of proof testing to detect dangerous undetected failure (i.e., DP control logic failure). DPO needs information for evaluation before executing the decision when time is available. Lack of information may result in loss of situation awareness and *overconfidence* of the DP system performance. Sometimes, overconfidence is referred to as *complacency*, and can have severe negative consequence if the automation is less than fully reliable (Wickens, Gordon og Liu 1997). The cause of complacency is probably an inevitable consequence of the human tendency to let experience guide our expectancies. When DP systems are marketed as quite reliable, we should avoid that the DPOs perceive the device to be of "perfect reliability". Otherwise, it becomes a natural tendency for the operator to cease monitoring its operation or at least to monitor it far less vigilantly than is appropriate. One implication of automation for human intervention related to situational awareness is that people are better aware of the state of processes in which they are actively participating in than when they are passive monitors of someone (or something) else. If they are carrying out those processes to detect a failure in an automated system, they will be less likely to intervene correctly and appropriately if they are out of the loop and do not fully understand the system's momentary state. All of this information will be essential in order to develop the risk model, which the on-line monitoring will be based on.

In addition, a drive-off event can also be triggered by an observed technical failure with interaction of human response action. Indeed, it requires the DPO to be able to analyse if it is a safe or dangerous failure. The operator needs information support for being aware whether the actual performance of DP system is within acceptable deviation or not.

To avoid DPO overconfidence in the automation and imporve their understanding of actual system performance, it is necessary with an additional supervisory system to assist operators in detection, situational awareness and skill loss.

One of the purposes for such a system is to support the DPO in two situations described in Section 4 to avoid initiating action and response action during DP operations. The information support should help DPOs to have the reference for the following questions:

- Will the action initiate a dangerous undetected failure?
- Is it a dangeorus technical failure? Will the action worsen the situation?

For the first question, the system aims to support the operator in the situation that they face deviations in normal working condition and need to perform an operational action about the deviations. For instance, if the DPO needs to adjust ST position to return loading hose during disconnection if heading deviation has been observed. This information will be used in the forthcoming development of a risk model which will be the main basis of the online risk modeling tool.

Initiation of action is a decision-making process. Therefore, we can call the new system an online decision support system. It will support operator aiming to reduce initiating action and response action. Based upon the findings, the online decision support system should address two types of information support. An illustration is given in Figure 4 to demonstrate the online decision support system will support the two types of information.

1. Support information for DPO in the task planning in the situation that DPO encounters

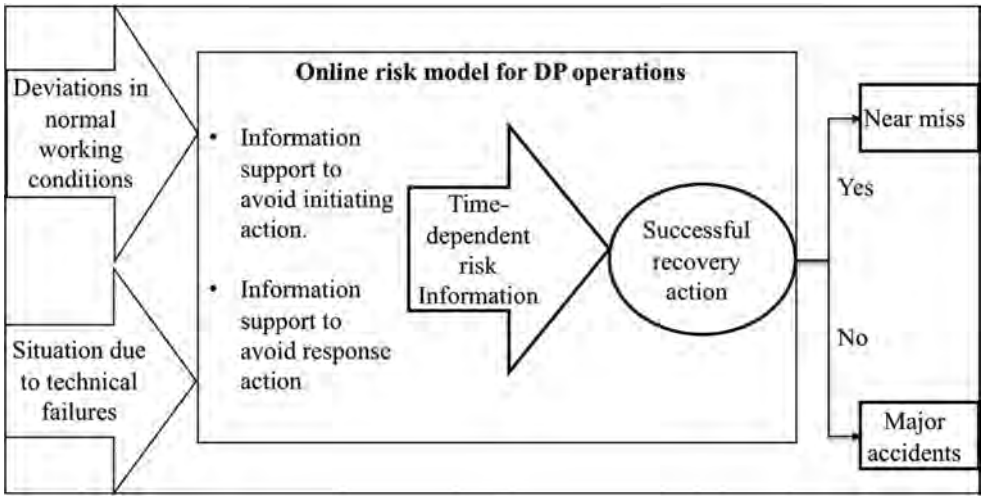

Figure 4. Two types of information support in an online decision support system.

deviations in normal working condition. The operator needs to be aware of whether their planned action will initiate a dangeorus undetected failure. This information support should avoid initiation of drive-off involving human initiating action.

2. Support information for DPO to analyse the actual system performance. The information is to help operator to be aware of whether their response action will make worse the situation leading to a drive-off.

Meanwhile, the importance of the time aspect should be emphasized, since responses may develop so fast in a drive-off situation that it might develop to a severe consequence, such as collision, within a very short time. Operator has to maintain awareness of the situation and catch the development of the situation.

5 CONCLUSIONS

Due to the nature of DP operations and human machine dynamics, loss of situation awareness has been recognized as the main reason for no early detection. One of the reasons is that the initiating event of position loss involves a complex HMI. Tanker drive-off potentially involves not only DP hardware and software, position reference systems, and vessel sensors and local thruster control system, but also the DP operator.

To improve DP operator's situational awareness and understanding of system performance, it is necessary to study the human machine interaction based on classification of human action and types of failures. It has been found that many DP accidents and incidents are involved human initiating action and response action.

Two situations are identified from the DP accidents and incidents involving initiating action and response action. First, DPO encounters the situation that is associated with deviations in normal working conditions (ST keeps its position within operating limits). Drive-off is initiated due to the interaction between human initiating action and dangerous undetected failures. Second, DPO faces a situation given by technical failures. The operator needs information support for being aware whether the actual performance of DP system is within acceptable deviation or not.

Based on the situations, some challenges are pointed out:

Challenge 1: In the first situation, the DPO should evaluate if their action will initiate a dangerous failure which has not been detected. It indicates the need for information support concerning the deficiency of proof testing, which should be supported operator' evaluation of planning a decision for the normal operational task.

Challenge 2: In the second situation, the DPO should analyze the detected failure if it is a safe failure or dangerous failure and if their response action will worsen the situation. Therefore, it is of vital importance for the operator to be aware of the actual system performance is acceptable deviations.

An online decision support system will be an advisory tool concerning the listed challenges to support the DPO to improve situation awarness and decision

support. A benefit of introducing the system is to avoid DPO overconfidence in the DP system.

Development of dynamic safety envelopes for autonomous remotely operated underwater vehicles

J. Hegde, E.H. Henriksen, I.B. Utne & I. Schjølberg
NTNU Center of Autonomous Marine Operations and Systems, Norwegian University of Science and Technology (NTNU), Trondheim, Norway

ABSTRACT: This paper describes the implementation of dynamic safety envelopes for Autonomous Remotely Operated Vehicles (AROVs). A safety envelope is defined as a three-dimensional spatial area around the AROV, which forms a virtual protective barrier against collision with known and unknown obstacles in the subsea environment. The Octree method is used to setup the cuboidal shape of the proposed safety envelope. A Fuzzy Inference System (FIS) is modeled to derive the size of the dynamic safety envelope. The three inputs of the proposed FIS are vehicle velocity, probability of acoustic sensor failure and time to collision risk indicator. A user interface allows for verification and visualization of the resulting dynamic safety envelope during live laboratory tests. The results show that similar to vehicular envelopes in other industries, dynamic safety envelopes can be implemented on AROVs. The proposed dynamic safety envelope may be used to model the behavior of AROVs when confronted with different collision scenarios.

1 INTRODUCTION

Globally, numerous research initiatives are investigating the use of autonomous remotely operated underwater vehicles to perform subsea inspection, maintenance, and repair (IMR) operations (Jamieson et al. 2012, Furuholmen et al. 2013, Mai et al. 2016, Gancet et al. 2016, Schjølberg et al. 2016). Autonomous remotely operatedc underwater (AROVs) are tethered/untethered underwater vehicles, which can independently control manipulator functions, permit shared control between the vehicle and the human operator. AROVs can navigate autonomously, perform self-diagnostics, and be equipped with remotely operated tool systems requiring limited operator control (Hegde et al. 2015). However, the introduction of autonomy in subsea IMR operations may also result in emerging risk factors. One such risk factor is the risk of collision posed by the use of AROVs (Hegde et al. 2016, Utne and Schjølberg 2014). Delayed IMR operations, loss of vehicle, loss of structural integrity may be some of the severe consequences of AROV collisions with the subsea structures, other AROVs and the seabed. Safeguarding the functions of subsea infrastructure and the AROVs is vital to ensure safe and cost efficient autonomous subsea IMR operations.

Studies to identify, assess, and avoid collision risk of vehicles are paramount for all vehicular systems. In the early 1970s, an increase in maritime traffic and need for safe envelopes around the marine vessel was highlighted by Fujii and Tanaka (1971). Influenced by the collision avoidance procedures in the aviation industry, Goodwin (1975) coined the term "*ship domain*". Goodwin (1975) defined "*ship domain*" as the "*sea around the ship, which the navigator would like to keep free, with respect to other ships and fixed objects*". Over the years, the size, shape, and the area covered by the ship domain has evolved continuously (Pietrzykowski and Uriasz 2009, Tam et al. 2009, Lewison 1978, Davis et al. 1980). Currently, in the automotive, maritime (surface vehicles), aviation and space industries, different forms of vehicular safety envelopes are utilized during operations. The primary aim of these vehicular envelopes is to suggest or autonomously modify the behavior of the vehicle when obstacles are detected inside the vehicular safety envelope.

Hegde et al. (2017) utilize the Octree method to design a static safety envelope for AROVs. The term safety envelope can be defined as *a 3D spatial area around the underwater vehicle forming a virtual protective barrier (in space and time) against collision with known and unknown obstacles in the subsea environment, influencing the behavior of the AROV* (Hegde et al. 2017). In a static safety envelope, the size of the envelope is constant and does not change during live IMR operations. This approach is valid when the AROV is in close proximity to the subsea equipment. However, when the AROV is moving from one location to another, a dynamic safety envelope may assist the AROV

and the human operator to adapt and react to different collision scenarios. In addition, a dynamic envelope can reduce the need to detect obstacles by decreasing the area of the envelope. This can result in decreased data processing requirements for the on-board collision detection module. At this time, such dynamic vehicular envelopes do not exist for AROVs (Hegde et al. 2015).

The objective of this paper is to develop dynamic safety envelopes for AROVs, i.e., the size of the safety envelope changes depending on operational parameters of the AROV.

This paper is organized as follows: Section 2 presents the design of safety envelope. The elements of the proposed fuzzy inference system is described in Section 3. Section 4 describes the laboratory setup used to test the dynamic safety envelope. The results from the laboratory tests are presented in Section 5. The findings are discussed in Section 6. Section 7 presents the conclusions and future work possibilities.

2 DESIGN OF DYNAMIC SAFETY ENVELOPES

An Octree is used to generate the dynamic safety envelopes. Octree is a recursive tree data structure, which consists of spatial cubes named Octants. Each Octant can further be divided into eight child Octants. Figure 1 illustrates the Level 1 and the Level 2 Octree rendering with the AROV in the center of the Octree. In the Level 1 Octree, eight cubes surround the AROV and in the Level 2 Octree sixty four cubes surround the AROV. Each of the cubes are allocated an unique identifier and linked to a safe subsea traffic rule. The subsea traffic rule aims to maximize the horizontal and vertical seperation from the identified obstacle. If an obstacle is detected in one or more Octants, a suitable subsea traffic rule is suggested to the AROV or the human operator.

According to Hornung et al. (2013), there are four main reasons to use the Octree method for robot applications.

1. Octrees can establish virtual spatial grids around the robot, which can be used to check for collisions with the obstacles in all three axis.
2. The resolution of Octrees can be increased or decresed, which can result in detailed obstacle tracking, if required.
3. Measurement data from multiple sensors can be probabilistically represented using Octrees.
4. Both active and passive sensors can be used to check for collisions in known and unknown environments.

AROVs are also exposed to collisions with obstacles. Data from multiple active and passive sensors can be used to detect obstacles in the subsea enviornment. Therefore, use of the Octree method as highligted by Hornung et al. (2013) can also be extended to underwater vehicle applications.

In addition, the size of the of the Octree can increase or decrease the computational load in detecting the obstacle. If the safety envelope is static, the constant computations required may consume battery power by the AROV even when there are no obstacles in the vicinity. A dynamic safety envelope may lead to decrease in the computations required by limiting the collision detection module to an optimized Octree area. The next section explores the use of fuzzy logic to derive the size of the dynamic safety envelope.

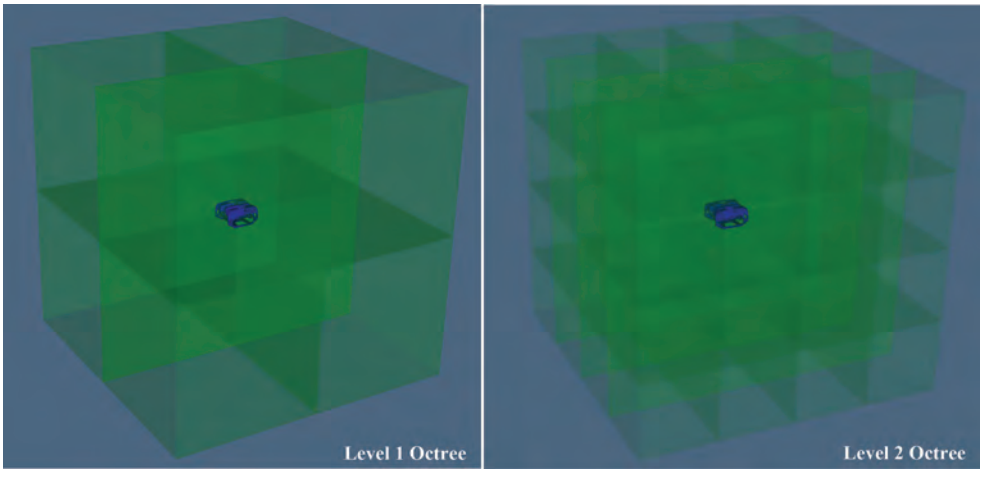

Figure 1. Rendering of static safety envelope for AROVs as proposed by Hegde et al. (2017).

3 FUZZY INFERENCE SYSTEM

Fuzzy logic delivers precise outputs from imprecise inputs. Input values are assumed to vary within a given range of values, which resembles real-life scenarios. Figure 2 is adapted from (Zadeh 2002, Zadeh 1996) and describes the overall methodology of a fuzzy inference system (FIS). In a FIS, input and output variables can contain n number of fuzzy sets with shared memberships among other fuzzy sets. This process of converting the crisp input to range values is known as fuzzification. A fuzzy operator is used to connect the antecedent (fuzzy inputs) to a consequent (crisp output) through an if-then logic. Defuzzification is achieved by calculating the membership of input variable fuzzy sets against the output variable fuzzy sets. Defuzzification results in a crisp value that can further be used as input to make decisions. Fuzzy inference systems are useful in two main use cases: first, to model systems that are highly complex and when the systems behavior is vaguely understood; and second, where an approximate, but quicker solution is acceptable.

Scikit Fuzzy, a fuzzy logic module in Python programming language is utilized to set up the proposed FIS (Warner et al. 2017). Figure 2 provides an overview of the proposed FIS, which has three input variables and one output variable.

3.1 *Fuzzification of variables*

Three input variables (operational performance indicators of the vehicle) are identified to influence the output variable i.e., the size of the safety envelope. This means that it is assumed that the vehicle performance influence the safe operation. This subsection describes the fuzzification of the input and output variables.

3.1.1 *Vehicle velocity*

Considering the kinetic energy of a moving vehicle, the velocity at which the vehicle moves can influence collision detection and avoidance ability of the underwater vehicle. An AROV traveling at high velocity can result in a faster approach to a potential obstacle. This means that the time needed to detect and avoid the collision scenario is inversely related to the velocity of the underwater vehicle. Therefore, vehicle velocity (vv) is used as one of the inputs in the proposed FIS. Three membership functions for the vehicle velocity input are assumed, namely low, medium and high.

The FIS was modeled according to the technical specifications of the Blue Robotics BlueROV2. The maximum achievable velocity of the BlueROV2 vehicle is 1 m/s (Blue Robotics 2017). Figure 3 illustrates the resulting membership functions (MFs) for vehicle velocity input. The three MFs are low, medium and high. The low velocity MF ranges from 0 to 0.4 *m/s*. The medium velocity MF ranges from 0.2 to 0.8 *m/s* and high velocity MF ranges from 0.8 to 1 *m/s*.

3.1.2 *Probability of acoustic sensor failure*

Stovner et al. (2017) demonstrate use of underwater acoustic sensor grid to aid localization capabilities of the AROVs. A grid of acoustic sensors is used to communicate with and track the position of the AROV during IMR operations. However, failure of one or more subsea acoustic sensors may result in inaccurate position, orientation and velocity estimates. Reliable measurements of vehicle position, orientation, and velocity are important to safely navigate in the subsea enviornment. Failure of acoustic sensors may lead to increased risk of collision or loss of the AROV. It is therefore, important that AROVs use the available acoustic sensor information to make informed decisions.

In this paper, the acoustic grid consists of four acoustic transducers on the bed of the pool and two acoustic transducers on the AROV as illustrated in Figure 7. Acoustic transducers placed on bed of the pool can communicate with the transducers

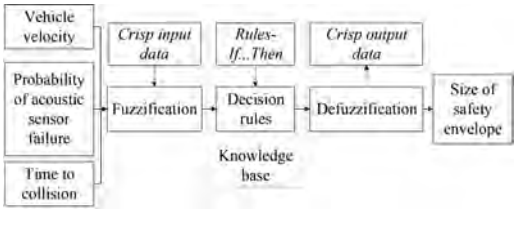

Figure 2. Overview of the proposed fuzzy inference system.

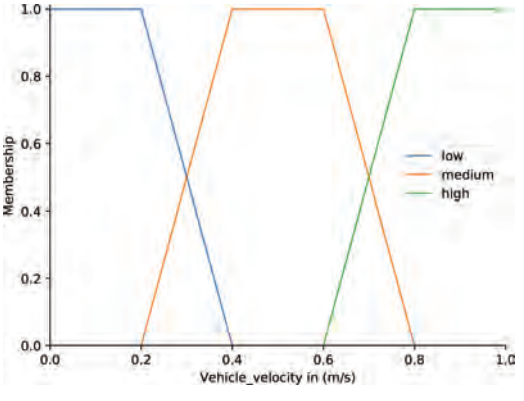

Figure 3. Membership functions for vehicle velocity (m/s).

on the AROV. This results in an acoustic network with eight possible range (distance) measurements. A minimum of four range values are needed for the acoustic positioning system to be classified as reliable. If there are fewer than four range measurements, the resulting estimates (position, orientation and velocity) are assumed to be unreliable. In such scenarios, the acoustic localization system is categorized as failed i.e., the probability of acoustic sensor failure is 1. Failure is defined as the termination of the ability of a functional unit to provide a required function or operation of a functional unit in any way other than as required (IEC 61508 2009). Therefore, the acoustic sensor voting scheme is 4*oo*8 (four out of eight). In a failed state, it is vital that the safety enelope around the AROV increases in size.

Figure 4 illustrates the membership functions of the probability of acoustic sensor failure. A trapezoidal membership function (TRAMF) is used to signify that at certain range of input values the membership is unity (1). As shown in Figure 4, the probability of the acoustic sensor failure variable consists of three MFs, namely low, medium and high. The low MF ranges from probability 0 to 0.3. The medium MF ranges from probability 0.2 to 0.7 and the high MF ranges from probability 0.6 to 1.

3.1.3 *Time to collision*

In the automotive and aviation industry, the time remaining for the vehicle to collide with an obstacle is used to suggest collision avoidance maneuvers. The term time to collision (TTC) is used to convey the criticality of the collision scenario. The lower TTC, the greater the risk of collision with the obstacle. In the Traffic Collision Avoidance System (TCAS), the value of TTC is utilized to calculate the criticality of the obstacle (US Department of Transportation and Federal Aviation Administration 2011).

Hegde et al. (2016) apply the TTC as a risk indicator that can indicate risk of collision in a given AROV path. The TTC can be classified as an operational parameter, in that it can change as the vehicle velocity and the distance to the obstacle varies. As AROVs are required to navigate through the subsea infrastructure, they may face many obstacles in their path.The TTC risk indicator can aid in classifying critical obstacles by monitoring continously. TTC is calculated by using Equation 1

$$Time\ to\ collision = \frac{Distance\ to\ obstacle}{Resultant\ velocity\ of\ \ AROV} \tag{1}$$

A recommended standard for autonomous subsea IMR also highlights the need for monitoring all existing obstacles in the vicinity of the subsea production system (Germanischer Lloyd Aktiengesellschaft 2009). Therefore, the inclusion of the TTC indicator in the proposed FIS allows the AROV to not only monitor the obstacles, but also devise collision avoidance behavior if they are under a threshold value. In the proposed FIS, the threshold values relate to the MFs. Three MFs are determined for the TTC input variable, namely low, medium and high. The low MF of TTC ranges from 0 to 3 *s*. The medium and high MF range from 2 to 5 and 5 to 10 *s* respectively.

3.1.4 *Size of safety envelope*

The output variable in the proposed FIS is the size of the safety envelope. The safety envelope is realized in form of a cuboid. Therefore, the FIS output: size of the safety envelope will increase or decrease uniformly along all three axes *North, East and Down*. The size of the safety envelope is proportional to the velocity of the vehicle and

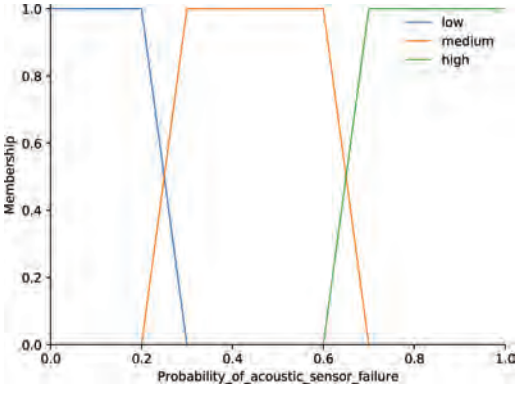

Figure 4. Membership functions for probability of acoustics sensor failure.

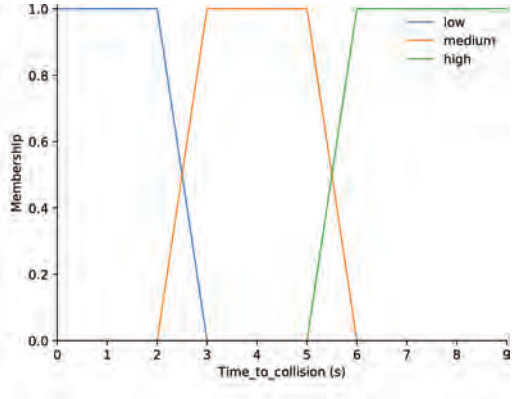

Figure 5. Membership functions for time to collision (s).

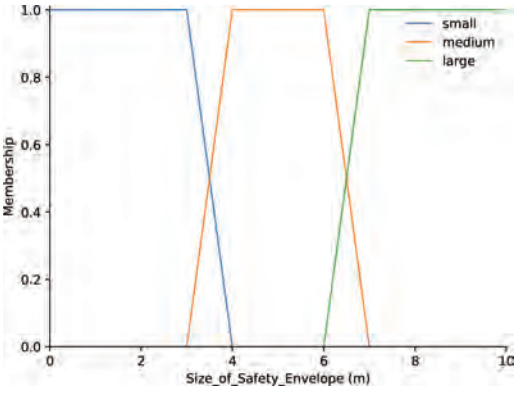

Figure 6. Membership functions for size of safety envelope (m).

probability of acoustic sensor failure (PASF) and inversely proportional to the time to collision input. In short, the safety envelope size increases when vehicle velocity and PASF increase and decreases when TTC value increases. A large safety envelope reflects a low safety margin whereas a small safety envelope reflects high safety.

Figure 6 illustrates the MFs for the FIS output variable. The size of the safety envelope is classified into three MFs, namely small, medium and large. The MF for the small safety envelope ranges from 0 to 4 *m*. The MF for the medium safety envelope ranges from 3 to 7 *m* and the MF for the large safety envelope ranges from 6 to 10 *m*.

3.2 *Fuzzy rule set*

Once the fuzzy sets of input and output variables are determined, the next step is to define fuzzy rules by combining the input and output variables using logic statements. Table 2 lists the twenty seven fuzzy rules resulting from the three input variables. The fuzzy logic operator AN D is used to derive the inference from input variables.

It has to be noted that the input variables and their influence on the output variable is different. For example, a low TTC is not favorable as this would mean that the obstacle is in close proximity to the AROV. On the other hand, low vehicle velocity and PASF are favorable. Relative importance of inputs are not considered in this paper. Weights are not allotted to the input variables and therefore the fuzzy rule set do not favour certain rules over others. All rules are given equal importance.

3.3 *Deffuzification*

The process of obtaining crisp values from fuzzy inputs is known as defuzzification. The Scikit Fuzzy library supports numerous defuzzification methods, such as centroid, bisector, mean of maximum (mom), min of maximum (som) and max of maximum (lom) (Warner et al. 2017). Centroid defuzzification method is used in this paper because it provides conistent crisp output values when compared to other deffuziffication methods within the uncertainty constraints. The centroid defuzzification method aggregates the total area under the membership functions of the input variables and calculates the centroid of the combined area (Sivanandam et al. 2007).

Table 1. Rule sets in the fuzzy inference system. vehicle velocity (VV), probability of acoustic sensor failure (PASF), time to collision (TTC).

4 LABORATORY SETUP AND TESTING

Figure 7 illustrates the laboratory setup to test the dynamic safety envelopes. The Mission Orientated Operating Suite (MOOS) middle-ware (Newman 2006) stores and retrieves information from the AROV. Four acoustic sensors are installed on the bed of the pool and two on the AROV. The acoustic

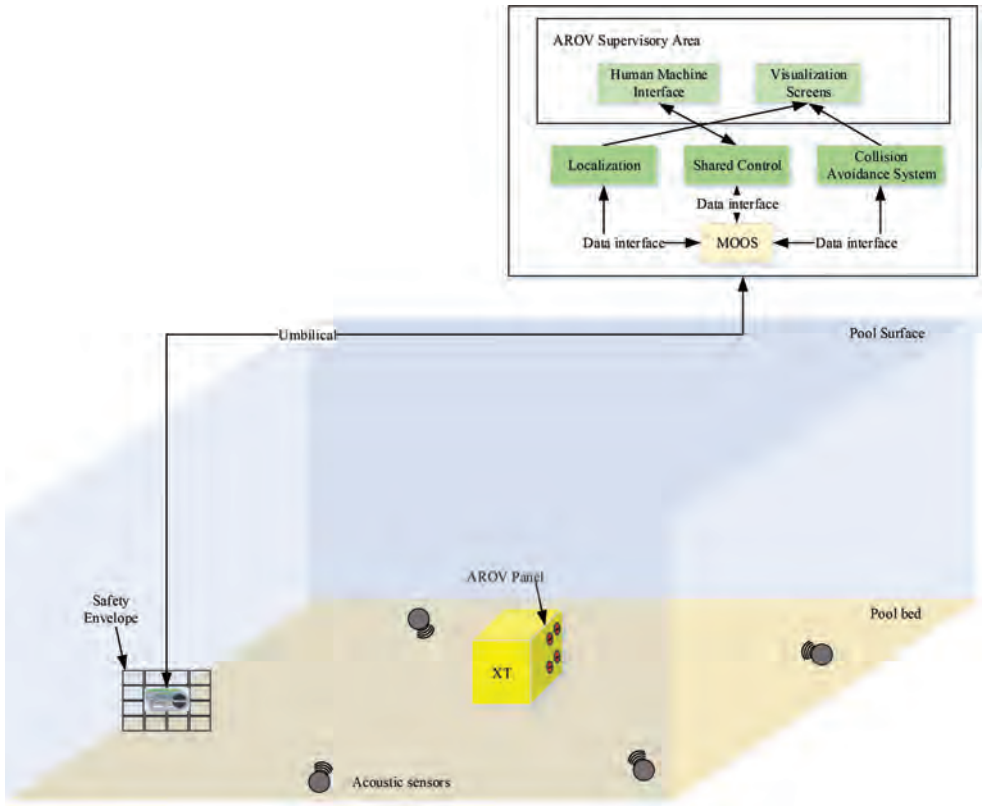

Figure 7. Laboratory setup to test feasibility of dynamic safety envelopes.

sensors provide the localization measurements, such as position of obstacle and AROV, velocity and orientation of the AROV. The localization module shares the data with MOOS. The shared control module retrieves data from the localization module via MOOS and utilizes it to control the AROV either autonomously or via shared control between the AROV and the AROV supervisor. The communication to the AROV is established through an umbilical.

The collision avoidance module posts and retrieves collision data to and from MOOS. The two parts of the collision avoidance module are the dynamic safety envelope and the subsea traffic rules. The subsea traffic rules are set of assigned safe navigation maneuvers that can be performed by the AROV to increase the vertical and/or horizontal separation (distance) from the obstacle (see Section V of Candeloro et al. (2016)). The subsea traffic rules are developed based on the rules from collision regulations (COLREGs) in the maritime and from the TCAS in the aviation industry. Each Octant in the Level 2 Octree in Figure 1 is assigned a subsea traffic rule to maximize vertical and/or horizontal separation from the obtascle.

The pseduocode implemented to derive the dynamic envelopes from the proposed FIS is as listed in Listing 1. The first step is to retrieve the velocity and position variables from MOOS followed by the distance to the potential obstacle. Then the available acoustic ranges are counted and a sensor voting scheme of 4oo8 is used to derive the PASF. The velocity of the AROV, distance to the obstacle are used to calculate the TTC. When the input data are collected, they are routed to the FIS as described in Figure 2.

The FIS computes the new size of the safety envelope and publishes the new size of the safety envelope to MOOS. The 3D renderer updates safety envelopes to the new size and the detection algorithm updates the potential detection volume.

5 RESULTS

In Figure 8, the Vehicle velocity is 0.02 m/s (MF = low) and PSAF is 0 (MF = low) and TTC is 391.01 s (MF = high). These inputs result in application of Rule 6. The resulting size of safety envelope is 1.76 *m* (MF = small). In Figure 9, the Vehicle velocity is 0.03 *m/s* (MF = low) and PSAF is 0.38 (MF = medium) and TTC is 391.01 *s* (MF = high). These inputs result in application of Rule 6. The resulting size of safety envelope is 5.00 *m* (MF = medium). Observations from the laboratory tests are as listed in Table 2.

6 DISCUSSION

This section discusses the learnings from the process and the impact to industrial applications through the development of the proposed dynamic envelopes.

The key drivers in development of safety envelopes in the aviation and maritime industries (TCAS, Ship Domain) are asset/personnel safety and ability to design an intelligent collision avoidance systems. By fusion of both active and passive sensor technologies, the safety envelopes in the aviation, maritime (surface vehicles) and automotive industries currently utilize dynamic safety envelopes. In comparision, current remotely operated vehicles are controlled by human operators. In the future, AROVs will also need to be able to make decisions both in presence or in absence of the human operators. Development of dynamic safety envelopes can be seen as the first step towards ensuring asset safety of AROVs by identifying, assessing, and mitigating the risk of underwater collisions.

As applications of AROVs to inspect and repair subsea production systems, offshore aquaculture systems, offshore wind turbines and facilitate subsea mining, asset safety of AROVs is vital. The proposed process to build dynamic safety envelopes using fuzzy logic allows the system developers to tweak the membership functions and fuzzy rule sets according to their respective industrial requirements. This allows for application specific dynamic safety envelopes. For example, requirements for dynamic safety envelope for subsea

IMR operations and subsea mining operation may vary as the later is more vulnerable to seabed collisions than collisions with the man-made subsea structures.

Use of fuzzy logic (expert-based systems) ensures that the system developers can understand the inherent behaviour of the system under different input conditions. However, two limitations of fuzzy logic in engineering applications can be highlighted. First, fuzzy logic is a form of deductive reasoning i.e., to conclude on a specific truth by using generic inputs (Ross 2009). An example for deductive reasoning is the ground is wet (input) therefore, it must be raining (truth). Second, the subjective nature of defining the membership functions of the fuzzy variables and deriving fuzzy rule set can be challenging. This is true for any technical system where experts are needed to provide input and they can disagree with each other's judgment. For example, in the proposed fuzzy rule set, weightage to different inputs are not implemented. All rules and input values are given the same importance. In the future, a modification may be necessary to include the relative importance of input variable. Is the TTC more important than PASF and VV or vice-versa?

The proposed dynamic safety envelopes are highly dependent on availability of reliable sensor measurements. The laboratory setup used in this paper consists of a grid of six acoustic sensors providing eight range measurements. Measurements from the acoustic sensors were used as the primary input to calculate the orientation, velocity and position of the AROV and the obstacle (passive sensor grid). However, the advantage of the proposed dynamic envelopes is that it can be easily modified to include input from either passive or active sensors. For example, active sensors, such as sonar and LiDAR can detect both known and unknown obstacles. This is possible because of the underlying architecture of the implemented 3D rendering program, which allows for scalability. In addition, if the sensor module comprises of redundant sensors, failure of one sensor type can be tolerated by the overall collision avoidance system. For example, if the acoustic position sensor fails to measure the depth of the AROV, measurements from a dedicated depth sensor can still provide a reliable source to the proposed FIS.

7 CONCLUSIONS

This paper proposes a novel approach to developing dynamic safety envelopes for autonomous remotely operated vehicles (AROVs). A proof-of-concept of the dynamic safety envelope is presented in this paper.

The proposed dynamic safety envelope was developed by using a fuzzy inference system (FIS) to adapt the size of the safety envelope. Three fuzzy input variables were used in the FIS, namely vehicle velocity, probability of acoustic sensor failure and time to collision. A FIS was implemented in an existing underwater collision avoidance system. Observations from the laboratory tests performed to verify the feasibility of dynamic safety envelopes are presented. Results show that the AROV safety envelope can increase or decrease in size depending on the three input variables. This allows the AROV to decrease or increase the obstacle detection area in a highly uncertain and sensitive subsea environment.

In presence of uncertainty, visualizations of obstacles that pose the risk of collision to the AROV may aid situation awareness of human operators. The size of the safety envelope can be used to make decisions related to maneuvering of the AROV either autonomously by the AROV or remotely by the human operator. To safely maneuver the AROVs during collision scenarios, further development and testing is required to implement dynamic safety envelopes together with the subsea traffic rules.

ABSTRACT: The urgency of applying a more ethical approaches to get to a sustainable low-carbon economy by 2050 requires to implement a model of sustainable mobility, which embraces social, economical and industrial activities. In this horizon, behavioral change can produce considerable benefits whose effects are distributed on wider period. In this direction, the GamECAR project aims at provoking a change in driver style towards a more sustainable and efficient use of private cars by applying gamification. However, safety must not be affected by the introduction of new technologies, tools or systems, which are not essential for the driving task. This paper presents a methodology for the control of the inference of a smart-phone application suggesting eco-driving hints to the driver, on the basis of the dynamic assessment of the risk exposure embedded in the current situation. Real-time measurements of physiological, behavioural and car performance parameters are combined with data-driven driver models to determine the safe communication of eco-driving suggestions to the driver. The methodology builds upon the structured approach to operational safety initially applied in aviation and its adaption to the road environment during the XCYCLE Project (Funded by the Horizon 2020 Framework Programme of the European Union – Grant n° 635975).

1 INTRODUCTION

Road transport is troubled by two major issues: environmental pollution induced by cars and serious injuries to people from traffic crashes. The common denominator between these problems can be found in the aggressive driving style. Studies found that fuel consumption can be affected by the driver's style up to 35%. Hard acceleration and braking, excessive speed, open windows results in higher emission rates from a vehicle compared with a more calm driving style.

We are now in a transitional phase, where electric and hybrid vehicles are becoming more popular, but they are still not sufficiently distributed to generate a significant effect. Eco-driving can become an intermediate tool for inducing a more sustainable and effective use of current private vehicles, carbon fuelled, but it can also inspire a behavioural change, that will be beneficial across generations.

Eco-driving has been defined as a decision making process that significantly affects the fuel economy and emission intensity of a vehicle, reducing its environmental impact. Ecological, economic, but also road safety and social benefits can be derived from adopting eco-driving conduct. However, changing the behaviour of a driver seems to be a challenging task. For example, the social context in which the driver is operating can result a mediating factors of behaviour.

In the context of the GamECAR Project (Funded by the Horizon 2020 Framework Programme of the European Union—Grant n°732068) a Decision Support System module embedding personalized driver models will combine the calculus of an eco-driving score with the dynamic evaluation of the risk associated to the context where the action is conducted. The most appropriate eco-related, personalized suggestion will be communicated to the driver if the operational risk results acceptable. This paper will present the methods adopted to combine real-time measurements of physiological, attitudinal and car performances parameters with data-driven driver models, to determine the safe communication of eco-driving suggestions to the driver. The methodology builds upon the structured approach to operational safety initially applied in aviation and its adaptation to the road environment during the XCYCLE Project (Funded by the Horizon 2020 Framework Programme of the European Union—Grant n° 635975).

2 THE FOUNDING CONCEPTS

Some keywords inspired the creation of the model.

Dynamicity: the road is, by nature, an ever-changing, dynamic environment. In such contexts, the discrepancy between the time available and time required to make a decision generates time pressure. Unfortunately, cognitive models of driving behaviour still fail to take into account the dynamic context that the road environment offers. GamECAR focuses very much on real-time and context dependent information, through which it can suggest new modelling parameters for a more realistic scheme.

Change: dynamicity causes revolution. Managing dynamic traffic scenarios is a complex exercise and the actual task of management is dynamic itself, according to the increase or decrease of the situation. Driver's capability also varies and affects the driver state. For example, the variety of stimuli could affect the driver's attention by causing distraction or by numbing his/her reaction times. Moreover, an impaired or fatigued driver may not be sufficiently responsive to the changing surrounding conditions.

Change is also an innate element of the social context in which the driver operates and can represent a mediating factor of behaviour.

Change is a key word for the GamECAR project itself, as one of its most important objectives is to provoke a behavioural revolution towards more sustainable driving style and general attitude.

Interactive: the traffic system is composed of three main actors, namely road users, vehicles and road environment. This frequent and heterogeneous interactions introduced by traffic impose demands on drivers, increasing the complexity of the activity. Considering road transport, at least three elements compose the scenario: different road users, their transport means and the environment in which the driving task is conducted.

Safety & Ecology: previous researches demonstrated that adopting eco-driving behaviours not only induces economic paybacks, but also contributes to road safety. Among these, it is essential to ensure that any just-in-time feedback must not compromise the safety of its user, by increasing his/her cognitive workload and shifting attention from the actual driving act.

3 A NEW USE FOR DYNAMIC RISK ASSESSMENT OUTCOMES

An adequate, modern and complete risk model for the road transport must include all the above elements as well as their mutual conditionings.

Beyond facing the challenge of designing a risk model capable of representing all members and their interactions through a sufficiently lean structure, thanks to the GamECAR project's requirements, the proposed model adds a significant novelty in the exploitation of risk assessments. In fact, traditionally, results from risk analysis, either dynamic or not, either proactive or retrospective, served to inform the user about the undesirable situation just experienced or possibly to encounter, in order to highlight the need for mitigation actions. In GamECAR, the output of the risk analysis will feed information to the platform, so as to decide whether it is appropriate or not to present the eco-driving information to the driver. The statement depends on the context in which the driving action is conducted, the driver's current state and personal traits, and the driving performances expressed by vehicles parameters. The results of the risk analyses aim at avoiding that new tools, such as the GamECAR display, despite their noble intentions, could overload the driver with unnecessary information and distract him/her from the primary task. The user will not be warned about the fact that s/he is going to experience a hazardous situation (e.g., a risk indicator, whose colour communicates the level of risk), neither about what this circumstance is (e.g., hazard's name and description), nor about the consequences s/he might face (e.g., icon depicting the possible negative outcome). S/he will not be conscious that a risk analysis is performed, but the effects of these background operations will be essential to maintain his/her focus on the primary task and to induce his/her behavioural change through a safe process.

4 STARTING POINTS

The GamECAR risk model builds upon the research conducted in previous EU projects, namely A-PiMod (FP7/2007–2013, contract number: 605141) and XCYCLE (H2020/2015–2018, contract number 635975). The former, through the design of a new adaptive automation concept based on a hybrid of three elements: a multi-modal pilot interaction, an adaptive distribution of tasks between flight crew and automation and real-time risk assessment, aimed at supporting flight management when hazards and unexpected conditions are encountered. The latter focuses on the development of technologies to improve active and passive detection of cyclists, as well as systems informing both drivers and cyclists of a hazard at junctions.

From the progressive experiences and breakthroughs in the aviation domain, in which a structured approach to safety has been applied for decades, and from the adaptation of such approach

in a different sector, such as the road transport one, the GamECAR model is sketched.

5 RISK MODEL COMPONENTS

The GamECAR model is constructed by three components: a LUT (Look Up Table), a calculus engine and a risk matrix (Figure 1).

The LUT represents a database containing static data, such as driver's name, age, residence, driving experience and eco-attitude, but also the list of hazards characterizing road types, such as straight lines or T-junctions.

Personal information can be inserted by the driver in the Profile section of the GamECAR system, either via the application or via the web platform. His/her eco-attitude is assessed through specifically designed questionnaires, which attempt to deduce also other personality traits, such as driver aggressiveness. The driver can decide to refill a questionnaire, updating his/her profile, while the GamECAR developers could add new questions to refine the user modelling.

The list of hazards is generated by GamECAR researchers on the basis of retrospective analysis of incidents and accidents related to specific road layouts as well as through expert judgment.

For example, some inputs may derive from the study of pre-fatal crash manoeuvres identified in the early stages of the XCYCLE project (Fruhen, L., et al. (2015). Threats and consequences are the other elements attached to the hazards and they contribute to improving the description of the situation (event) under exam with potential harm.

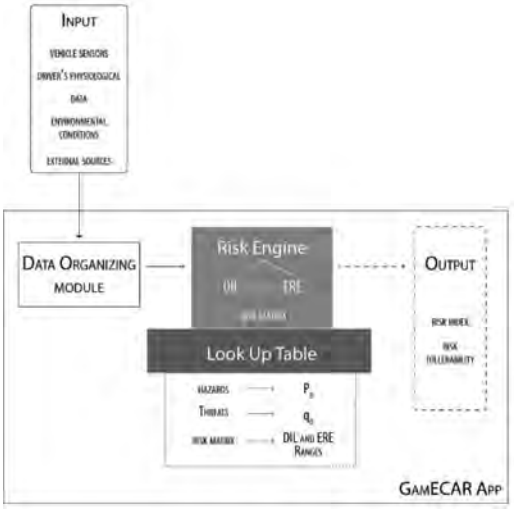

Figure 1. GamECAR risk module's component.

A threat is an external element that may generate or increase the effects of hazards, thus affecting the margins of safety and impacting on the development of incidents and accidents. A consequence is any possible measurable outcome, whether adverse or beneficial, resulting from the evolution of threats and hazards. Each element is represented in the LUT by variables, which are quantifiable by measurable parameters, in order to calculate the probability of occurrence or the weight of the influencing factors in the current situation. Every combination of threat(s), hazard and consequences generates a single incident sequence, which is expressed through its probability of occurrence, of risk.

Even if it the LUT contains only static data, its content can be updated periodically thanks to new research findings, newly discovered hazards or edited personal data.

The assessment engine runs two distinct functions, named DIL (Driver Impairment Level) and ERE (Environmental Risk Exposure). These functions are embedded in the GamECAR application. Therefore, every time a driver activates the GamECAR app and monitors h/her eco-driving performances, these dynamically evaluate the risk associated to the driving task. Their inputs derive both from the LUT as well as from the data measured in real time through the GamECAR sensors, such as a wearable device for the monitoring of physiological parameters and the OBD-II (On-Board Diagnostics) device reporting on vehicle performances.

By being two independent functions, modelling two different aspects of the overall driving activity, in order to obtain a single outcome, they must be combined into a specific matrix where the riskiness of distracting the driver by adding information emerges, together with its tolerability level.

The following three sections will provide more insight into: 1) the human factors aspects, through the evaluation of the Driver Impairment Level; 2) the driving context, i.e., the mean of transport and the surrounding environment; and 3) the matrix, discussing the meaning of its cells and how the tolerability level could be used to tailor the eco-message to display to the driver.

5.1 *The DIL function*

As stated before, the major peculiarities of the road environment are represented by three specific elements, namely: the driver in control of the action, the context in which the driving action is conducted and the transport mean. The DIL function deals with the first one, i.e., the person controlling (driving) a technological tool (i.e., the vehicle). According to Carsten (2007), two broad

types of models of behavior of the human-in-control can be distinguished in the literature. The first type is defined as "descriptive model" and it attempts to describe parts or the whole of a task in terms of what the operator has to do. The second one is named "motivational model" and it aims to describe how keen the operator is in managing risk or abnormal situations.

In GamECAR we concentrate on the second type, by developing a predictive and context-aware model, able to reproduce the effect of a dynamic environment on the driver's performance capabilities. In fact, if task demand exceeds the driver's capabilities, task overload is experienced, resulting in high workload (e.g., De Waard, 1996). Given that driving task difficulty fluctuates in a dynamic environment, instantaneous driver workload also fluctuates. As driving demand changes, driver capabilities also varies with driver state (for example, impaired, fatigued or distracted).

The model is based on five categories of driver capability, performance and behavior, which are related to safety. The outcome is the probability of error making generated by human related factors and possible operational conditions.

The Driver Impairment Level (DIL) focuses on the human related aspects and environmental dynamic circumstances that favour the possibility of error making. Five parameters have been selected as the most essential quantities that influence people's motivational aspects. They are not claimed as representing neither an exhaustive nor an independent set of quantities that characterizes human behaviour. However, they are a first instantiation of several theoretical and applied research studies and the main characteristics of this modelling approach will not be altered by the implementation of different sets of parameters.

The mechanism to describe DIL attempts to combine dynamic changing conditions expressed via Driver State (DS), Situational Awareness (SA) and Environmental Conditions (EC) and more static quantities that reveal the driver Experience/competence (EXP) and Attitudes/personality (ATT) (Cacciabue, P.C., 2010).

More in details:

- Experience/competence (EXP). This parameter enables to consider age and the number of years of driving license. Skills can be developed through practice; when a skill becomes automatic it is consciously controlled and more cognitive resources may be devoted for managing unanticipated events (such as emergency events) (static parameter);
- Attitudes/personality (ATT). Attitude and personality are typical individual traits that result in interpersonal differences and specific behavior. In the context of GamECAR it refers to the ecological and sustainable approach the driver applies not only in driving, but in his/her everyday life. The value is derived from a specifically designed questionnaire and it is updated through the averaged eco-score calculated by GamECAR over the different trips the driver has played. The driver would be asked to fill the form at his/her first access to the application and s/he will have the opportunity to edit the responses anytime. His/Her eco-score will be measured every time s/he performs a trip with the GamECAR App on and it is stored in his/her personal section of the Virtual Community Platform (quasi-static parameter);
- Situation awareness (SA). SA is a very important parameter, as it represents "the perception of the elements in the environment within a volume of time and space, the comprehension of their meaning and the projection of their status in the near future" (Endsley 1994) (dynamic parameter);
- Environment Conditions (EC). Since the surrounding conditions might affect efficiency also at cockpit level, environmental characteristics should not be entirely disregarded, but included as describers of the operational contest. Inputs can come either from sources external from the GamECAR system (e.g., weather applications) or from GamECAR sensors, such as the vehicle OBD-II (dynamic parameter);
- Driver state (DS). The Driver State refers to those psycho-physiological variables that may affect task performance either permanently (e.g. physical/cognitive impairments) or temporarily (e.g. impaired performance due to fatigue or drowsiness) (dynamic parameter).

Driver's bio signals are monitored via wearables devices that provides measurements for heart rate, respiration rate and muscle activity, and transmit them to the GamECAR App via Bluetooth technology. The physiological data are correlated to the driver's psychological parameters, such as SA and DS. For example, by the detection of the heart rate and the setting of proper thresholds, we can derive the driver's level of anxiety or calm. Such data source and quantification process are some of GamECAR's main innovation.

Apart from the Environmental Conditions parameter, all others reflect individual traits.

All parameters vary between 0 and 1 with the meaning expressed as follows:

From a purely logical reasoning, the DIL is assumed to depend these five parameters as follows:

$$DIL_{(Driver,t)} = 1 - e^{-[\varphi+(2-\lambda)/4]}$$

Table 1. DIL parameters and their ranges.

	Novice	Low	Medium	High
EXP	0	0.25	0.5	1
	Bad	Poor	Medium	Good
ATT	0	0.25	0.5	1
	Full	Slightly degr.	Degraded	Loss
SA	0	0.25	0.5	1
	Good	Regular	Poor	Bad
EC	0	0.25	0.5	1
	Very good	Slightly degr.	Degraded	Bad
DS	0	0.25	0.5	1

where:

$$\varphi = \Sigma SA, DS, EC$$

$$\lambda = \Sigma ATT, EXP$$

Note that:

- best driver dynamic conditions = > φ = 0
- best driver static conditions = > λ = 2
- if ATT = EXP = 1 (best static pilots condition), and SA = DS = TD = 0 (best dynamic conditions) then DIL = 0, i.e., Driver Impairment Level is null.

The simple, basic hypothesis is that at the increase of a parameter corresponds an increase in the DIL value.

5.2 *The ERE evaluation*

The Environmental Risk Exposure (ERE) analysis mainly takes into account the other two elements of the road environment, i.e., the scenario and the transport mean. For each one of them, it retrieves inputs from external sources and merges them into a safety assessment of the situation. This data extraction is fulfilled by the sensors utilized in the GamECAR project, which are on-vehicle, in the smartphone, and worn by the driver. With regard to the vehicle, its data are provided via an OBD-II device connected directly to the CAN bus of the car. Real time information includes: active transmission gear, fuel type, consumption and tank level, throttle position, engine RPM, vehicle speed, and other data.

Moreover, the sensors integrated inside any modern smartphone, such as the linear accelerometer and the GPS receiver, enables to collect essential information on the location of the vehicle (i.e., longitude and latitude) and also about its acceleration.

Finally, other meaningful information about the environment are gathered from cloud services, e.g., streets maps, traffic, and climatic conditions.

The ERE builds upon an internal database, i.e. the LUT, a Data Organizer module that retrieves and manages the raw external inputs, and a Risk Engine, which performs the dynamic calculus for evaluating the exposure to hazards in a particular, forthcoming moment of time.

Standard incidental sequences, based on previous retrospective analysis are stored in the LUT. They are described by the well-known Bow-Tie logic, where to a central hazard the threats (or factors) leading to it are linked to its left inside, and the consequences representing the final result of the possible incident sequence are connected from its right inside. At the beginning, an absolute probability value is given to each hazard; moreover, static default values are allocated to each factor representing the baseline for the successive calculation steps. Due to the scarcity of recorded data about road transport, compared to the potential availability, these values have been assigned on the basis of the literature available and, mostly, through expert judgment.

In order to find a suitable trade-off between the theoretical framework, which sustains that more consequences can derive from the same hazard, and the practical real life, where possible incidental sequences share many commonalities and it is complicated to differentiate among them with a sufficiently accurate proves, we decided to link to each hazard only one direct consequence.

Another important database section includes a list of the road types, and a more detailed mapping of the roads sections and junction types, exploiting open source maps. To each element, a value expressing its harmfulness potential is assigned, determined from retrospective evaluations of incidents occurred in that particular spot. Hazards are linked to specific crossroads or streets on the basis of the possible occurrence of the associated direct consequence.

In case the user sets in advance the itinerary of the trip s/he is going to take, the Risk Engine would be able to analyse the specific road path with higher discretization, thanks to the pre-load of the needed information due to a more intense usage of the map info, thus providing more frequent and more refined outcomes.

Data in the LUT are static, but their quality can be refined and the dataset could be enriched with the scope of covering previously unforeseen scenarios.

The preparation of the database is executed offline and when completed becomes the baseline for the real time calculus. The Data Organizer module collects as many inputs possible among those previously described from the on-vehicle sensors and the external sources, and it serves them to the Risk Engine. The online risk calculus

dynamically modifies the values in the LUT, transforming the basic probability of each hazard $P_{0,i}$ into an adapted value $P_{1,i}$, which represents the exposure to risk the user suffers while s/he is driving. The Risk Engine is supported by a function eta (η) that is responsible to update the probability in accordance with the characteristics of the current action scenario.

$$\eta_i(\gamma) = \frac{c}{1 + b * e^{-\gamma}}$$

where:

$$\gamma = \frac{\sum_{i=1}^{n_f} \left(q_{j,i} * l_{j,i}\right) * \mu}{nn_f}$$

c and b are two constants that keep the function from exceeding the range's limit when multiplying it for the hazard probability value;

- $l_{j,i}$ is a vector containing the dynamic values calculated by exploiting the data received from the Data Organizer;
- $q_{j,i}$ is a matrix containing the weighting values for each specific factor$_j$ linked to the hazard$_i$;
- n_f is the number of evaluated factors, while nn_f is the number of not null factors calculated during the real time assessment;
- μ considers risk of each specific hazard, and to personalize the weight of the factor for different road configuration.

In order to transform the basic probability of the hazard$_i$ into a contextualized one, the following formula is applied:

$$P_{1,i} = P_{0,i} * \eta_i(\gamma)$$

This final outcome is a value included between 0 and 1. This is combined with the DIL value into a Risk Matrix designed for the purpose.

6 RISK MATRIX

Given that DIL and ERE are two independent functions, they must be combined into a matrix in order to obtained a single, merged "risk" value. The basis is the well-known risk matrix proposed by ICAO Doc. 9859 (Third Ed.), improved by assigning to each cell a numerical index, enabling to compare among hazards associated to the same location and to range them.

The tolerability range is also assigned by a five-colour code, in order to avoid the risk index to fall too often into a critical area, which might induce misunderstanding or overestimation of the situation. This reasoning arises from the experience of the use of risk matrices in dynamic and proactive assessments, in contrast to retrospective analyses, where a three-colours code could be sufficient.

The major difference relies in the meaning of the Severity. In GamECAR, the Severity is not represented by the potential harm of the consequences, but by the level of impairment of the driver, thus by his/her capacity to promptly react to abnormal situation. Instead of an esteem on the effects of a consequence, the attention is shifted towards the measurement of human performances.

7 CONCLUSIONS

The GamECAR model is still in its designing version since the project is currently at its mid-term. A dedicated software solution is under development and it will be integrated in the project App, linked to the shared database and providing inputs to the display function. This activity is scheduled for Spring 2018 and the so called Evaluation Phase will run in Summer 2018. For this reason, this paper could not present a practical case study where the full methodology has been experimented. Tests will be very significant in relation to the fine tuning of threats' weighting factors. At first, the travelling path will be pre-defined, thus allowing the researchers to fill the LUT with information, such as hazards, road types and harmfulness potential, etc. with more peculiar and accurate data. In the meantime, thanks to the experiences lived during the test-drives, the hazards list, as well as the threats list, can be increased, refined and improved, in order to better represent the complexity of the driving reality.

The possible exploitation opportunities of such model are various. In the GamECAR project framework, it determines which visualization option is more appropriate for the scenario in which the driving task is conducted, in order not to jeopardize safety in benefit of ecology. The same scope could be exploited by other functionalities, technologies, or tools the vehicle is equipped with. Generally, these functions support or customize the driving action, but they are not essential for its core fulfilment.

The main advantage of this model, and the main difference with the ones usually applied in other domains with high automation, such as aviation, is that the information is not presented to the final users, but it becomes a controlling input for another background service(s). This implies that the user does not have to be trained on risk principles, risk variables, index and colour meaning and that the system is suitable for drivers of any experience levels.

ACKNOWLEDGMENT

The outcomes described in this document arise from the activities conducted in the GamECAR project. The project has received funding from the European Union's Horizon 2020 research and innovation programme under grant agreement N°732068.

What could adaptive risk management look like in practice?

J.M. Nisula
Risk in Motion and ICS-IRIT, Université de Toulouse III, France

ABSTRACT: Complex adaptive systems pose challenges for risk management, e.g. due to the difficulty to forecast evolutions in the system and to predict system responses to different interventions. Due to the complex cause-and-effect relationships, straightforward actions would often fail to produce the desired effects in the system. A more adaptive approach is required. This paper focuses on the challenges of adaptive risk management and especially adaptive risk treatment. Key features of complex adaptive systems are described, as well as the consequences of these features for risk management. Different types of possible interventions are introduced, including simple actions, adaptive policies and portfolios of experiments. Advantages and challenges of adaptive risk treatment strategies are discussed and some examples are provided. It is argued that the scientific community should promote the use of adaptive approaches compared to the older less dynamic approaches which are not well-adapted for complex systems.

1 INTRODUCTION

Examination of the features of a complex adaptive system leaves no doubt that in our everyday lives we are more and more exposed to—or rather agents within—complex systems. These would include the various social networks, so much accelerated by social media; logistics systems like the transport system in a city; political systems such as the system of governance for a country or a company; and so on. Complexity makes risk management more difficult, especially when a modern risk perspective is adopted, putting a lot of emphasis on the knowledge dimension behind the assessments (see e.g. Cox 2012, Aven 2013, Bjerga et al. 2016).

It is argued that the very dynamic nature of complex systems requires dynamic risk management techniques. Adaptive risk management has been introduced in literature, see e.g. Cox (2012) and Bjerga & Aven (2015). The current paper tries to take a rather practical perspective to how adaptive risk management techniques could be used. Both risk assessment and risk treatment are discussed but the main focus will be on risk treatment.

Examples are picked from the challenging domain of managing transport safety risks.

2 COMPLEX ADAPTIVE SYSTEMS AND RISK MANAGEMENT

2.1 *Features of complex adaptive systems*

Cilliers (1998) presents the following 10 characteristics of complex systems:

1. Complex systems consist of a large number of elements.
2. The elements interact dynamically.
3. The interaction is fairly rich, i.e. any element in the system influences, and is influenced by, quite a few other ones (but there can be large differences between elements in this respect).
4. The interactions are often nonlinear. This means that small inputs in one part of the system can have large results in other parts of the system.
5. Each element is mainly dealing with its immediate neighbors in its local context. However, due to the interactions, influences can propagate through the system, while possibly getting modulated (enhanced, suppressed or altered).
6. There are feedback loops. Any feedback can be positive (enhancing, stimulating) or negative (inhibiting, dampening).
7. Complex systems are usually open systems, having live interactions with the environment and there is a multitude of influences between the system and its environment. The system borders could be defined in many ways depending on the purpose and the position of the observer.
8. Complex systems operate under conditions far from equilibrium being highly dynamic and constantly evolving.
9. Complex systems have a history and their past is co-responsible for their present behavior.
10. Each element in the system is ignorant of the behavior of the system as a whole, responding only to information that is available to it locally.

Reiman et al. (2015) summarize the key features of a Complex Adaptive System in the following way:

> "A complex adaptive system is a collection of individual agents with freedom to act in ways that are not always predictable, and whose actions are interconnected so that one agent's actions change the context for other agents. These agents interact in a non-linear way creating system-wide patterns and higher and higher levels of complexity. The agents differ from each other and none understands the system in its entirety. This diversity is a source of invention and improvisation. As the agents are interdependent of each other, relationships among agents can be considered to be the essence of a complex adaptive system. Understanding a complex adaptive system requires understanding of patterns of relationships among agents."

Complex systems can also be associated with the following concepts (Reiman et al. 2015):

- *Emergence*: properties and behaviors which cannot be deducted from the individual system components appear spontaneously in the system. Consequently, the properties of the whole can be significantly different from the properties of the parts, and the outcomes are not predictable, even when the initial conditions are known.
- *Self-organization*: agent interaction and connections lead to new structures, patterns and new forms of behaviors. Emergence, feedback and non-linearity contribute to self organization.
- *Nested systems*: complex systems are typically part of larger complex systems, thus the expression *system of systems*.

Meadows (2008, p. 11) argues that a system consists of *elements*, *interconnections* and a *function* or *purpose*. To these can be added the more visible aspects: *events* (Senge 2006 p. 21) and system *behavior* (Meadows 2008, p. 88). Senge points out that people are naturally drawn to events and their alleged causes, failing to see the longer-term behavior of the system. The system behavior and the resulting events are visible but from the system point of view they are consequences of the purpose, interconnections and elements. Consequently, the following hierarchy can be established:

- Purpose
- Interactions
- Elements
- Behaviors
- Events

This hierarchy is helpful both for understanding behaviors in complex systems and for guiding interventions. As Dekker (2011, pp. 130–133) points out, understanding a complex system requires going "up and out" (synthesis) rather than following the typical "down and in" (analysis) approach of the Newtonian-Cartesian worldview.

2.2 *Challenges for risk management in complex adaptive systems*

A complex adaptive system introduces many challenges for risk management, affecting both risk assessment and risk treatment.

Knowledge is a key aspect of new risk perspectives. Obtaining precise and comprehensive knowledge in a complex system is particularly challenging. On one hand, knowledge is spread all over the system and cannot be centralized in one place (cf. point 10 in Cilliers' list above). This makes gathering comprehensive knowledge about the system and its behavior virtually impossible. On the other hand, due to the *unpredictability* of the system, many things are simply unknowable in advance. The nonlinearity of the system also reserves potential *surprises* in terms of emerging phenomena and their magnitude. These challenges related to knowledge affect the capability for risk assessment.

Risk treatment suffers from the same unpredictability that affects risk assessment. One may have a good idea of the desired change in the system, however, it may be very difficult to establish an action plan which would achieve the desired outcomes with some level of certainty or repeatability. Methods, tools and techniques which work in simple and complicated systems are not adapted for complex systems (Kurtz & Snowden 2003). Modeling the system would almost certainly cover only some parts of the system behavior and any models would by definition not reproduce the full complexity of the real system. Controlled experiments are not possible because the system is open and keeps changing all the time whether or not this is desirable (Sterman 1994). When a specific intervention is introduced, nobody can predict with certainty what the various consequences within the system will be. Not only can an intervention fail to reach its desired outcomes—it could have different unwanted consequences, some of which may remain difficult to detect.

For example, a new strict rule introduced by the regulator in order to eradicate common shortcuts in aviation maintenance procedures may seem like the typical easy solution from the point of view of the regulator. However, if it misses the true reasons for the shortcuts it may be fairly inefficient. Moreover, the additional negative consequence could be loss of respect and faith in the regulator by maintenance professionals when they perceive that the regulator has not addressed the real problem but only opted for an apparent solution which, to make things worse, threatens them with punitive actions.

3 ADAPTIVE RISK MANAGEMENT

The classical way to act in trying to change a system is often a specific action at a specific point in time. This could typically be a new working method, new procedure, a new piece of regulation, or a reorganization. Such interactions are not adaptive, i.e. they cannot adapt to changing conditions after the implementation.

The main focus in this paper is on adaptive interventions in the context of risk treatment. Especially two types of adaptive interactions are discussed: adaptive policies and experiments.

3.1 *Adaptive policies*

The main idea behind adaptive policies is to develop policies that are not targeted to be optimal for a best estimate future, but which could be robust across a range of futures. Swanson et al. (2010) argue that policies designed for a certain range of conditions often face unexpected challenges outside of that range and this leads to unintended impacts and failures in accomplishing the original goals. Instead of being forced to change policies on an ad hoc basis repeatedly, adaptive policies have a built-in capability to adapt to new conditions. Such an approach is particularly suited for highly complex, dynamic and uncertain settings—so typically for complex adaptive systems.

Another key feature of adaptive policy making is that all major uncertainties do not need to be tackled prior to the implementation phase. As new knowledge is gained during the implementation, the policy is gradually adapted accordingly (Marchau et al. 2010).

Swanson et al. (2010) propose "seven tools for adaptive policymaker", which can be summarized as:

1. *Integrated and forward-looking analysis*. The idea is to try to identify the key success factors for the policy in advance, anticipate problems and to mitigate the foreseeable unintended impacts in advance.
2. *Built-in policy adjustment*. If the future needs for policy adjustment can be anticipated, fully or semi-automatic adjustment mechanisms can be built in the policy.
3. *Formal review and continuous learning*. Ideally a policy is introduced in a phased manner, using so-called policy pilots allowing early testing and adjustments.
4. *Multi-stakeholder deliberation*. Volunteers are used in a very structured manner to get valuable feedback from stakeholders.
5. *Enabling self organization and social networking*. Policies should promote self organization and networking so that local solutions can be discovered without external input.
6. *Decentralization of decision-making*. Both formal and informal feedback gets faster and better when the decision-makers are closer to the people affected.
7. *Promoting variation*. This can be achieved either by several parallel experiments, facilitating an environment where variation can occur, or by using feedback to create variation.

Going from simple one-shot actions to adaptive policies can already be a significant step in embracing the complexity of the surrounding system and creating more suitable solutions for that environment.

Adaptive policy making could very naturally be adopted by regulators and other administrative agencies. However, the same philosophy can also be applied in private companies (and various other types of organizations) in trying to replace company policies, rules and procedures by more adaptive alternatives.

3.2 *Experiments*

As the heart of the problem with complex systems is that any intervention could have unpredictable consequences, the most natural course of action is to organize probes, i.e. set up experiments and use the results to improve the next round of experiments. As Sterman (1994, p. 310) states, effective learning in the world of dynamic complexity and imperfect information can be based on continuous experimentation and feedback. The final aim is to gradually find the most effective solutions through trial and error.

By definition many experiments will fail. It is therefore important that the various cost dimensions (e.g. time, financial cost, potential damages) of the experiments are very limited.

Other key requirements for experiments are:

- Clear criteria for success and failure are necessary; otherwise the iteration towards better experiments will be too slow.
- It must be possible to stop the failing experiments rapidly.
- There must be a way to scale up the successful experiments.

The whole point of experiments is that many diverse strategies can be experimented with. Therefore, a thorough pre-screening of proposed experiments is not necessarily recommendable. A lot of different experiments may be ran, as long as they are safe-to-fail. Experiment proposals should not need to be convincing, they just need to have a certain level of coherence, showing that they *could* possibly work.

In designing experiments, it is good to keep in mind the hierarchy of elements within complex adaptive systems (see above, section 2.1), i.e. modifying the *purpose* or the *interconnections* within a system will probably bring a more tangible and durable change than working at the level of *elements* and *behaviors* (Meadows 2011, pp. 16–17).

3.3 *Example: Adaptive risk treatment based on experiments*

Let's use as an example the problem of high road accident rates of young drivers. The challenge from a transport safety agency's point of view is to find effective interventions to reduce this particular risk.

Instead of trying to figure out a single preferred solution, the solution could be built through experimentation with different types of interventions. It would be important to involve different types of people in creating the experiments, including people outside the typical group of transport safety experts. In particular, it would be valuable to involve some young drivers who are themselves part of the risk group. In this way, different perspectives to the problem can be included and relevant knowledge from the real-life context can be made available.

The working group creating the experiments might come up, for example, with the following experiments:

1. Adding a specific short training which highlights the limits of the driving skills of the young drivers. Typically, the drivers could learn about the speeds and conditions at which they no longer can control the car in a curve or stop the car by breaking. Rationale: reduce the overconfidence of young drivers by illustrating the limits of their skills, thereby achieving a more cautious driving style.
2. Introduce specific driving limitations for young drivers: forbid driving 10 pm-6 am on Fridays and Saturdays and forbid transporting more than one young person in the car, unless if at least one adult is present. Rationale: reduce exposure to dangerous driving situations at nighttime and under negative influence of peers.
3. Introduce specific driving limitations II: require that no weekend driving can take place without an adult present in the car. Rationale: eliminate risky driving during weekends.
4. Expose young drivers to their peers who have suffered a serious accident. Young drivers would be meeting face-to-face one or more people who have had serious consequences after a road accident as a young driver. Rationale: the encounter would give an emotional lesson that carelessness in traffic could have very serious and long-lasting consequences, and the encounter would contribute to a better driving style.
5. Oblige young drivers to take care of potential victims of their careless driving style. Typically, during several weeks the young drivers would be taking young children to school both by using their own car and also as pedestrians. Rationale: young drivers will experience the vulnerability of these people in a very tangible way and also create an emotional link with such potential victims. Being a pedestrian may create situations where the young drivers can observe other drivers' dangerous behavior threatening the safety of the school children that they are now responsible for.

The first experiment is close to what a regulatory action could be even without experimentation. The next two experiments are a little bit more creative but still within the regulatory domain. The last two experiments propose approaches that regulators would typically not use as a part of their interventions. All rationales can be considered coherent and the costs (in the large sense) are small, thus all five experiments can be considered valid.

From the practical point of view, each experiment could be running in a different region or city within the state in question. Probably the most challenging aspect would be to measure the impact of these experiments. Ideally, if one wants to get results in a short time it is not enough to wait for accident data. One should be able to capture feedback for all kinds of safety related problems and also comments from the drivers themselves as well as from any other key stakeholders depending on the experiment. It should be possible to adapt the course of action after a few months of experimentation.

It could happen that one or two approaches turn out to be the most effective ones, perhaps depending on certain conditions (e.g. big city vs. small town). Additionally, it could be that some experiments could be combined or their lessons learned could be fed into the winning strategies as additional elements. For example, it could be decided that all young drivers should "meet" previous young drivers who have had serious accidents, but that this could be made virtually through a film.

Once the winning strategies have been implemented it is important to keep in mind that some fresh experiments should be run in the not-too-distant future.

3.4 *Resilience as a risk treatment strategy*

It is difficult to talk about risk management within complex systems without touching the concept of resilience. Woods (2015) gives four separate interpretations for the concept of resilience:

1. *Rebound*: recovering the functional state after a major disturbance.
2. *Robustness*: increased ability to absorb perturbations.
3. *Graceful extensibility*: the capability to extend adaptive capacity in the face of surprise.
4. *Sustained adaptability*: being able to sustain adaptability over longer periods of time.

Resilience is a valid concept at different scales: e.g. one could talk about the resilience of a *crew* or an *organization* or even the resilience of a specific *system*.

From risk management point of view, a highly resilient organization could cope with virtually any kind of surprising disturbance without losing the operational capabilities. Therefore, building high resilience in an organization could be a preferred strategy compared to having to predict all possible failure scenarios and getting prepared for them. Moreover, for some types of risks—e.g. low-probability scenarios, including black swans—working at the level of individual scenarios is not even feasible due to their almost infinite number.

Achieving higher levels of resilience could also be taken as an objective within an adaptive risk treatment approach, i.e. one of the key goals for various experiments could be to increase the organizational resilience level. An innovative approach would be to use an inverse logic for such experiments: take the increased resilience as a given based on a robust scientific reasoning and use the experiments rather to test how well the organization can cope with the new constraints which come as the downside of the resilience-increasing measures.

3.5 *Dynamic risk assessment & treatment*

In the previous example, the experimental iteration took place within the risk treatment domain. However, it is possible to stretch the loop back to risk assessment and create a risk management process where both risk assessment and risk treatment are part of the adaptive approach.

Risk assessment is based on assumptions. Experiments can produce valuable feedback on the validity of the assumptions and lead to iterative corrections to the risk assessment. In this case, is not only the risk treatment for a given set of risks which may change—the priority to treat various risks may also change.

A very dynamic risk management response can be achieved, if the operational people are fully involved in the assessment and management of risks, and are empowered to take real-time decisions based on the understanding of risks, assumptions and the alternatives for action. This type of dynamic risk management requires an excellent cooperation between the risk management experts and the operational people.

For example, imagine that an airline has made a risk assessment but about its operation to a specific airport. It may have deemed the operational risks acceptable based on several assumptions, one of which could be certain acceptable weather conditions. If the pilots flying to the destination are aware of the risk assessment and the assumptions behind it, they are able to compare the real-world conditions of the day to the assumed ones and detect any mismatches. If the crew one day is faced with weather conditions different from the assumed ones, it would immediately know that the risk assessment is no longer valid. Different alternative courses of action could have been prepared in advance, and the crew could now take the most suitable one of them, for example divert to a close-by airport from which ground transportation to the final destination could be arranged.

Ideally, instead of having a one-time risk assessment produced before the operation, the dynamic approach creates an active risk management tool/process, engaging the expertise both from the risk management experts and the operational people.

3.6 *Macro-view to adaptive risk management*

It is easy to see that adopting an adaptive risk management approach replaces a one-time exercise by a dynamic activity where interventions are iterated continually based on feedback from the system.

Instead of having to make one or two big decisions, smaller decisions are taken, and they are taken more frequently.

Applying adaptive risk treatment techniques also means that at any point in time there will be several portfolios of experiments ongoing. One needs to develop skills to manage such portfolios. Attention may also have to be paid on adaptive policies if they are used.

Based on the results of the individual experiments, some would be expanded, others would be terminated, and some experiments could be merged together.

Like explained in the previous section, the process can be made even more dynamic if risk assessment becomes part of the adaptive loop and if operational people are engaged in a shared risk management and decision-making process together with the risk analysts.

4 ADVANTAGES OF ADAPTIVE TECHNIQUES

The main advantage of the described adaptive techniques should be better effectiveness due to the use of techniques which are better adapted to complex systems than less dynamic alternatives: as

it is very difficult to predict future evolutions and system responses to interventions, instead of trying to model the system it is better to use probes. Also, in a system which is in constant change, it is better to base decisions on fresh feedback from a recent experiment rather than follow a plan made several months or years ago.

As a positive spin-off from frequent experimentation, there is an opportunity to start gradually learning interesting aspects of the system behavior. This type of learning can be helpful in designing future experiments and interventions.

Finally, big decisions may be risky and frightening because of the potential losses if the intervention fails. In addition to the lost improvement opportunity and incurred costs, the failure may be damaging to the image and credibility of the organizations and people involved. The smaller decisions within the adaptive approach are much less frightening as the stakes will be smaller each time, and as the whole context is explicitly a context of experimentation where *graceful failure* is an acceptable option.

5 CHALLENGES OF ADAPTIVE TECHNIQUES

There are systems and phenomena which do not easily lend themselves to experimentation. First, by their nature some systems do not produce enough feedback so that the success of the experiment can be assessed. For example, a very safe system does not produce much feedback in the form of events where safety was compromised. Trying to test interventions aiming at further safety improvement will therefore suffer from the fact that there is not going to be enough feedback within a reasonable time period.

Secondly, one also has to accept that running a specific experiment successfully in a specific place at a specific time does not necessarily mean that scaling up the same idea in the same or in a different place, will again be a success. One has to remember that these experiments are not controlled experiments where various parameters can be frozen—because in a complex system, key parameters cannot be frozen.

Third, there may be man-made restrictions for experimentation. For example, it may be very difficult to set up experiments in a tightly regulated system. Work may be highly proceduralized, and testing new procedures in real working conditions may be judged too risky.

Finally, moving from traditional working methods to adaptive risk management is a significant change and brings with it several psychological barriers. Accepting the features of complex systems means also accepting the associated unpredictability and uncertainty. Both the people carrying out the risk management and the public might perceive admitting the uncertainty negatively. As Tickner & Kriebel (2006) point out, acknowledging uncertainty can weaken agency authority by creating an image of the agency as unknowledgeable and by threatening the objectivity of science-based standards.

The experiment-based working method itself might not look very controlled or scientific either, and could further deteriorate the credibility of the organization implementing it.

The challenge grows even bigger if one wants to explore unconventional interventions. This would typically require testing some very surprising and "crazy" ideas. It would also require involving people who are not experts in the subject matter or at least not perceived as experts. All such factors raise the bar higher for organizations to start applying modern adaptive approaches.

6 CONCLUSIONS

This paper has described typical features of complex adaptive systems and discussed the challenges that such systems pose to risk assessment and risk treatment.

It is argued that adaptive risk management is better adapted to complex systems than other classic approaches. The principal aim of this paper has been to illustrate how adaptive risk management and especially adaptive risk treatment could be used in practice. Three different approaches have been promoted: adaptive policies, experiments, and enlarging the adaptive iteration to cover also the risk assessment part of the process. The theoretical content has been complemented with a concrete example from the domain of road safety.

The key argument for promoting the use of adaptive risk management is the expectation of reaching better results in managing risks in the complex system.

However, several important challenges in implementing adaptive approaches have also been identified.

It is proposed that the scientific community should help promote adaptive risk management as a respected method which could be implemented in different organizations—including governmental agencies—without the fear of losing credibility in the eyes of peers or the public.

Risk indicators for safety performance assessment of crane-operations in the chemical industry

G. Ancione & M.F. Milazzo
University of Messina, Messina, Italy

N. Paltrinieri
Norwegian University of Science and Technology NTNU, Trondheim, Norway

ABSTRACT: In recent years, new risk analysis approaches have been developed to be applied in major hazard establishments. Amongst these, approaches associated with the overall concept of dynamic risk are the most relevant. The main reason for the diffusion of Dynamics Risk Analysis (DRA) is the need to integrate new notions, accounting for dynamics of phenomena and information on system changes over the time and/or the impact of innovative technologies, within risk assessment procedures. DRA approaches are particularly useful when assessing the risk due to the lifting of load, especially when hazardous substances are handled or in major hazard industries. The reason is the potential for loss of containment, which could be followed by catastrophic scenarios (such as fires, explosions and toxic dispersions). When carrying out a crane operation, a common hazardous situation, leading to accidents, is associated with the hindered view of the workspace for the crane-operator. At this regard, a recently developed real-time monitoring tool, named *Visual Guidance System* (VGS), can be used to assist the worker during the load lifting. It gives back an alarm, when a potential impact between the handled load and any obstacle in the workspace is occurring. Data's collection, through the feedback provided by the VGS, allows deriving appropriate indicators correlated to the safety of crane operations in chemical industry. These indicators are continuously updated; therefore, they are useful parameters to be integrated within DRAs. This work aims at the definition of *risk indicators* for lifting and handling operations; the methodology to derive such indicators is described and an application is also given.

1 INTRODUCTION

Safety in crane-related operations is a complex issue, especially in the chemical industry, where an accident, due to a wrong load lifting or handling, could lead to severe incidental scenario (Milazzo et al., 2016). In this context, Dynamics Risk Analysis (DRA) approaches can be particularly useful in managing the risk. Crane accidents can be the cause of losses of containment, which can be followed by events, such as fires, explosions and toxic dispersions. More generally, approaches for dynamic risk assessment are based on the use of models integrating parameters that change over the time. Dynamic factors impact on both frequencies and consequences of incidents and, thus, on final risk results. Moreover, it is well-known that the integration of real-time monitoring data offers the opportunity to achieve a more effective control of activities, carried out in the workplace in view of worker safety, by allowing the prevention of accidents and the timely implementation of protective actions. Currently the use of DRA is becoming more widespread, some examples from the literature are given in the following: Eide and co-authors carried out dynamic environmental risk assessment for oil tankers, sailing along the North Norwegian coast (Eide et al, 2006; Eide et al. 2007); Milazzo et al (2009) made use of the concept of *dynamic geoevent* to represent a dynamic evolution of toxic dispersions. As pointed by Paltrinieri and Reniers (2017) and Paltrinieri and Khan (2016), DRA allows improving decision-making and supporting critical risk communication; it can also be used to describe the impact of innovative technologies on the overall safety.

In the chemical process industry, risk arises from complex systems and their management requires a large number of control measures (De Rademaeker et al., 2014). In this context, a common practise is to track performance of activities by using *indicators*, in order to continuously improve the safety and the operability. As defined by Øien (2001a), an *indicator* is a measurable/operational variable that can be used to concisely describe a broader phenomenon occurring when a plant is operating.

A small number of *key indicators* can monitor the status of whole systems. In the chemical industry, the most relevant *indicators* are those used to appraise safety or risk performance of systems. The terms *safety indicator* and *risk indicator* are distinguished by Øien et al. (2011). A *risk indicator* is a risk influencing factor, i.e. an event/condition that affects the risk level of a system/activity; whereas a *safety indicator* is a factor that has an effect on safety as it is related to some measures, different than risk metrics (as number of accidents or incidents or other). Thus, *risk indicators* are derived from a risk-based approach (Øien, 2001b), whereas *safety indicators* may be developed from a safety performance-based approach. *Indicators* are also distinguished as *leading* and *lagging indicators* (HSE, 2006): *leading indicators* represent a form of proactive monitoring of the effectiveness of a Risk Control System (RCS), by providing feedback about safety outcomes before an incident occurs; whereas, *lagging indicators* represent a form of a reactive monitoring of the effectiveness of a RCS, given that they provide feedback after the occurrence of a negative event.

Approaches to develop *safety* and *risk indicators* are grouped in two perspective typologies by Øien et al. (2011), i.e. *technical-human-organisational perspective* and *predictive-versus-retrospective perspective*. The first perspective allows developing *safety indicators* as it searches for causes of accidents occurred in the past, starting from technical to human and further to organisational causes (Leveson, 2004). The second one gives *risk indicators* and aims at predicting potential accidents by including all possible causes or by trying to establish the causes after the event (according to a retrospective point of view); this approach requires the use of quantitative risk models.

The above brief review underlines that the prevention of major accidents can benefit from both the use of dynamic risk analysis techniques and *safety/risk indicators*. The application of dynamics risk assessment techniques based on proactive indicators is suggested by Paltrinieri et al. (2016), it brings additional benefits, since the risk analysis is supplemented by information related to the early warning, which supports to manage in advance unwanted events. The integration of a set of collected indicators provided the risk assessment with dynamic and proactive features. Data collection and processing, for the purpose of such a DRA, take advantage of information technology supporting real-time data collection, sharing, processing, visualization, etc. According to Paltrinieri et al. (2016), dynamics risk assessment techniques based on proactive indicators can be classified in four levels by referring to the basic theory and provided results. The first level concerns to the use of *safety indicators*, it takes into account the effect of technical, human and organization factors; the second one is related to the use of *risk indicators;* thus, the application of risk models is needed; the third level refers to the application of techniques for frequency updating; finally, the forth level concerns the use of techniques for the aggregation of information, which are provided by indicators. This aggregation allows an accurate assessment of the variation of overall risk, also based on real-time data.

This work aims at the derivation of *risk indicators* for the load lifting and handling in chemical industry, to be integrated into the dynamic risk analysis procedure. The paper is structured as follows. Section 2 shows the methodology for the derivation of these indicators based on the approach proposed by HSE (2006); some indications are given on how *indicators* could be integrated into the dynamic risk analysis. Section 3 shows the description of a case study in which the application and validation of the indicators is carried out. Section 4 comments about the results obtained from this study. Finally, in Section 5 the conclusions of the work are presented.

2 METHODOLOGY

To derive *risk indicators* for the purpose of this study, the HSE approach (HSE, 2006) has been used. Figure 1 shows a simple scheme of the main steps of this general procedure, which is usually used to develop indicators related to processes. It is based on the development of *lagging* and *leading indicators* for the facility, related to each Risk Control System (RCS) and associated with a previously identified hazardous event, the aim is to prevent, control or mitigate major accidents.

2.1 *Identify the scope of indicators*

According to this methodology, to develop key indicators of a facility, preliminarily, it is fundamental to define the scope of such indicators. This allows selecting the proper information about the adequacy of safety controls. It is important to focus on a few critical indicators, giving a sufficient overview of the performance of systems and/or a more detailed picture in a hierarchical form.

To develop facility level indicators, major accidents that could involve the equipment have to be identified. Each indicator should refer to a RCS of the facility, then, it can be weighted to reflect its importance in guaranteeing the safety at that facility. Different weights will reflect criticalities of such RCS on that equipment, e.g. plant design might be the most critical RCS on Facility 1 in

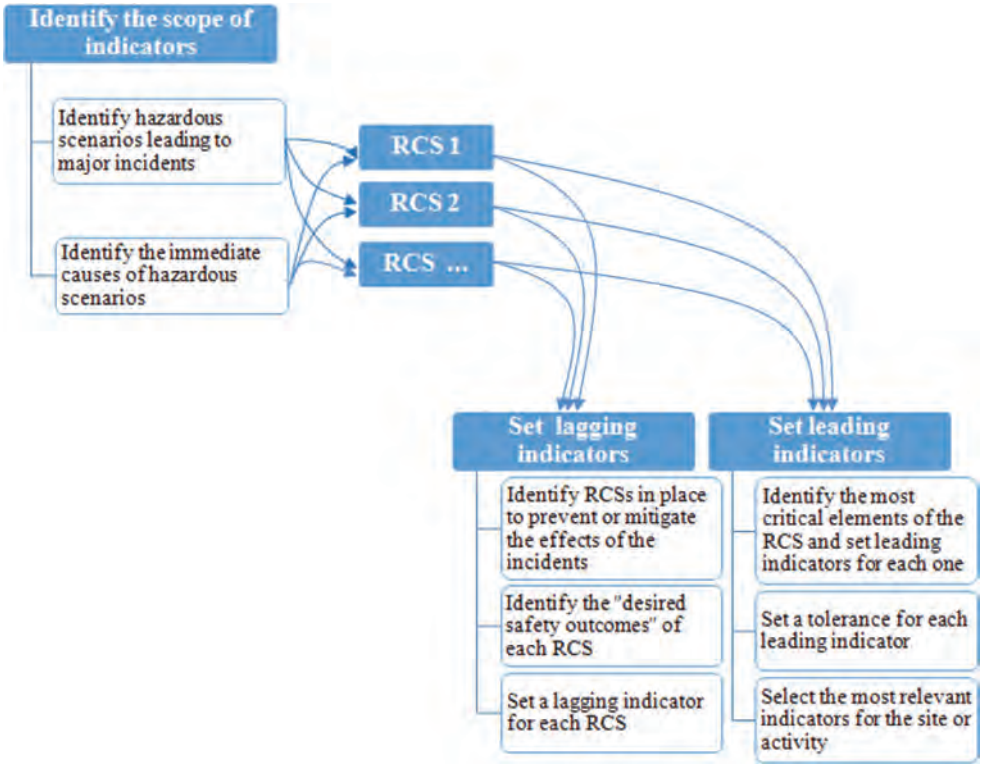

Figure 1. Main steps of the HSE approach for the development of risk indicators.

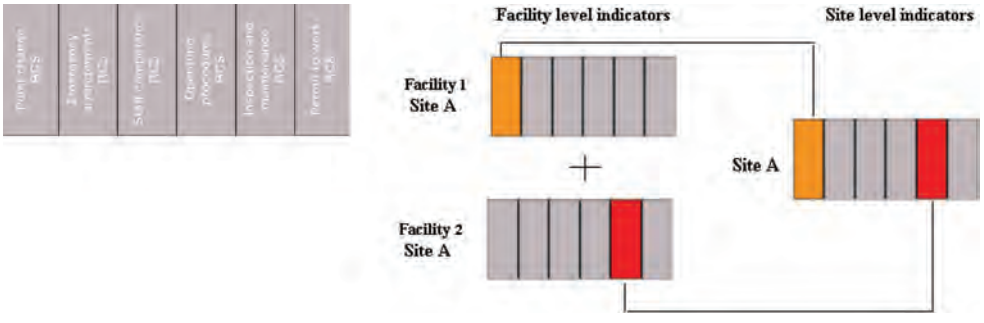

Figure 2. Development of facility level indicators.

Figure 2, whereas inspection and maintenance could be the most important RCSs at Facility 2.

2.2 *Set lagging indicators*

The identification of the hazard scenarios and the description of how these events can be generated help the analyst to focus on the most relevant activities and to identify which indicators should be set. The HSE methodology suggests considering the primary failure that gives an incident. Furthermore, attention must be given to areas where potential criticalities are present, i.e. where near-misses or past incidents have already occurred and where information from audits and inspections have collected.

Next step is to provide a list of RCSs, needed to prevent or mitigate the consequences of each hazardous scenario; the starting point is to identify their primary cause. Therefore, related safety

outcomes should be defined by means of the description of these hazard scenarios. The desired safety outcome represents the success for each RCS. For this reason, the safety outcomes must be clearly identified in term of "success/failure", otherwise it will be impossible to classify properly related indicators. At this moment, a *lagging indicator* for each RCS should be defined to highlight whether the desired goal is actually achieved.

2.3 *Set leading indicators*

After the identification of proper *lagging indicators*, the HSE approach suggests setting *leading indicators* for each critical element of all risk control systems (i.e. those actions or processes that must function correctly to deliver the outcomes). These indicate whether the RCSs provide the designed safety outcomes. The following factors must be considered to identify what are the most important critical aspects that the RCSs should cover to deliver the desired outcome:

- activities that must always be performed correctly;
- elements of the system that are susceptible of deterioration over time
- activities that are most frequently performed.

A range of tolerance for each *leading indicator* should be set. This is important, to permit to capture the analyst attention if deviations in performance are flagged up. Relevant information from *indicators* must be readily obtained, as well as the presentation of data collected should be as simple as possible to permit a prompt comprehension of them.

Finally, a review of all *indicators* implemented should also be executed, with the aim to highlight poor performance of them or just of a part of them. This means that if *leading indicators* of a RCS show poor performance, whereas *lagging indicators* give back satisfactory results for the same system, there is clearly a discrepancy. In this case, a system reviews are recommended to understand the reason of such discrepancy, because to improve the performance of the facility, or activity and so on, each deviation from the intended outcome or failure of a critical part of a RCS must be followed up. Each occasion to review provides an opportunity to consider whether improvements should be made.

2.4 *Indicators measuring the safety in load lifting and handling in chemical industry*

This paper focuses on major accidents due to use of equipment for the lifting and handling of loads in chemical industry, which involves the load and objects located in the workspace, i.e. workers or other equipment (Cheng and Teizer, 2014, Spasojević Brkić et al., 2015). In conducting such operations, there could be situations in which the operator does not have an entire visibility of the workspace. In these cases, a widespread practice is to be supported by an intermediary, which usually gives a guide to the crane-operator to correctly navigate the load. Under this condition, the crane-operator is subject to a high level of stress, as he/she has to trust in the judgment of others in order to carry out an operation for which he/she is absolutely responsible for. Indeed, one of the most important causes of accidents is the human error, which is underlined under one of the following forms distraction, wrong communication, inexperience, etc. For this reason, this contribution includes planned operator activities to control risk within the group of RCSs.

To avoid the cause of accidents associated with a partial or a total hindered view of the workspace, a real-time computer-aided visual guidance system has been recently developed, which is simply indicated as VGS (Ancione et al. 2017). This safety device is composed by hardware and

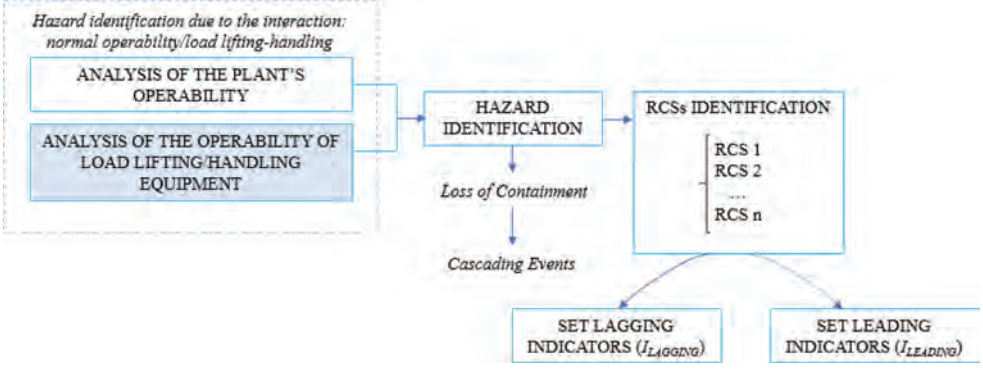

Figure 3. Methodology for the development of indicator for load lifting/handling in chemical industry.

software; it was designed to provide support to crane-operators in navigating the load. The use of the VGS for the execution of a load lifting or handling represents a supplementary RCS, aiming at the prevention of the release of hazardous substances, caused by collisions between the load and the equipment containing them. To identify the safety-related parameters for the activities associated with the crane operability, the HSE method has been adapted as shown in Figure 3 by including the investigation of the hazards due to the interference between the plant normal activity and the operations carried out with the crane.

3 CASE STUDY

The case study, analysed in this paper, is a reconstruction of an alkylation unit of a refinery, where a crane accident occurred. This event happened in 1987 in Texas (USEPA, 1993); it caused the release into the atmosphere of hydrofluoric acid, an extremely corrosive substance, forcing the authorities to evacuate thousands of people from their homes in the surrounding the refining plant. Due to the toxic dispersion more than 800 people were sent to the hospital.

The crane was lifting a multi-ton heater, which was accidentally dropped onto the top of a hydrofluoric acid storage vessel. This facility was being moved for repair and maintenance during a general plant turnaround. The dropped heater severed a 4-inch acid loading line and an inch pressure relief line causing the hydrofluoric acid to be released. Figure 4 shows the layout of the hydrofluoric acid service in the alkylation unit, where the crane that was temporary installed, and the trajectory for the load handling. All major equipment is labeled. The bulk of the acid was located in the storage drum, the settler, the acid cooler and the piping between the settler and cooler. Smaller volumes were contained in the fractionator, the fractionator accumulator, the splitter column and the acid rerun column. The acid unloading equipment was in southern boundary of the overall unit.

The event was investigated by OSHA (USEPA, 1993), which concluded that various causes contributed to the accident:

- not instituting accepted engineering control measures to prevent the release (i.e. emptying hydrofluoric acid vessel before hoisting a heavy load over it and not hoisting a heavy load over a hydrofluoric acid tank);
- the crane was not properly blocked (wooden blocks supporting crane outriggers were crushed);
- crane inspection documentation was not prepared;
- the crane safety devices were not inspected prior to use and a malfunction occurred.

It is also possible that, due to the evidence of an anomaly, which forewarned the accident, the crane operator decided to drop part of the moving system, in order to avoid a major accident due to impact with the vessel and, therefore due to the limited visibility and the complexity of the unit, he dropped it in the wrong place.

In general, the risk control system adopted by company to prevent a loss of containment and/or mitigate its risk, are: operational procedures, emergency procedures, training of workers, periodic inspection and scheduled manutention. The presence of the VGS, in that context, would have assisted the crane-operator in the navigation of the load by indicating where he would have dropped it, thus avoiding the chain of events that led to the release of the toxic cloud.

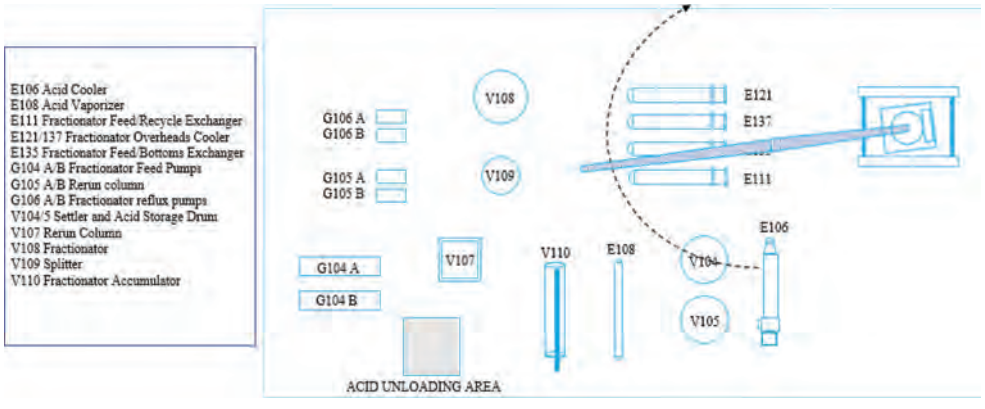

Figure 4. Layout for the hydrofluoric acid service in the alkylation unit.

4 RESULTS

The methodology described in the Section 2.4 has been applied to the case study. Initially, hazard scenarios and initial causes, which can lead to a major accident, have been defined. Then, all RCSs, that are in place to prevent or mitigate the effects of major accidents, have been identified.

Figure 5 shows a logic scheme for the identification of the incidental sequence that could occur during the crane activity. On the left side the initial cause for the hazard scenario is given, this represents what can go wrong when the crane is operating. Amongst various causes of failure for this activity, one appears associated with the hindered view and potentially leads to a major accident. It is represented by a dropped load and could be the cause of a loss of containment (hazard scenario), from which a toxic dispersion of hydrofluoric acid is originated.

The risk control systems, adopted by the Company, for the prevention and mitigation of losses of containment due to crane-related operations, are:

- Plant operating procedures (if these are not correctly followed, facilities age and, due to impacts, LOCs are more likely)
- Crane operating procedures
- Inspection and Maintenance procedure
- Work permit procedure
- Emergency procedure
- VGS

Compared to the use of traditional RCSs (considered in the case of the accident described in Section 3), the installation of the VGS has been included in the assessment.

Table 1 lists all relevant traditional RCSs that usually are adopted by the Company to prevent, control and mitigate the loss of containment. For each of them the desired outcomes are indicated, as well as the *lagging indicator* controlling the achievement of the related desired outcome. Then, critical elements of each RCS have also been

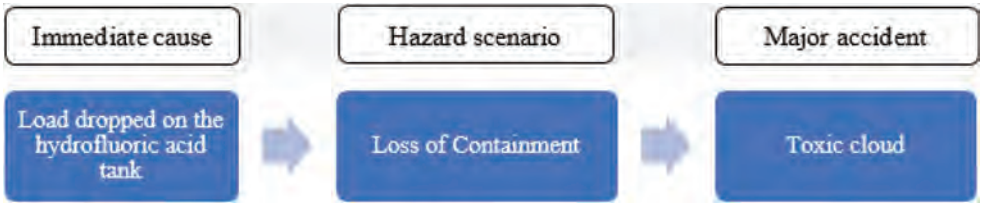

Figure 5. Schematic view of the identified hazard scenario for the case study.

Table 1. Lagging indicators.

RCS	Desired outcome	Selected lagging indicator
RCS1: Operating procedures	– Correct tank selection and operating the substance transfer – Correct cleaning, isolation and emptying	– No. of times the substance transfer does not proceed as planned
RCS2: Inspection and maintenance procedures	– No unexpected loss of containment due to failures of the crane or a not correct handling of the load or failure of the control instrumentation. – No fires or explosions caused by faulty or damaged electrical elements.	– No. of unexpected LOCs due to failures of the crane or a not correct load handling or failure of the control instrumentation.
RCS3: Crane operating procedures	– Correct execution of the load lifting/handling – Identification of lifting restriction areas – No involvement of escape route in the load trajectory – No interference with other equipment operations	– No. of times the load lifting/handling does not proceed as planned
RCS4: Work permit procedure	– High-risk maintenance activities are undertaken in a way that will not cause damage/injury	– No. of incidents due to error during maintenance
RCS5: Emergency procedures	– Minimum consequence in case of LOC	– No. of elements of the emergency procedures that fail
RCS6: VGS	– Full view of the working area and warning in case of approaching collision between load/crane and any obstacle in the workspace	– No impacts load/crane-obstacles

identified in Table 2 with the aim to define the potential *leading indicators*.

The most relevant indicators (a *lagging indicator* and one or two *leading indicators*) for the activity under analysis have been selected; this selection has been made by referring to the criterion that the most relevant criticality per RCS has to be represented.

Table 2. Leading indicators.

RCS	Critical elements	Selected leading indicator
RCS1: Operating procedures	– Procedures contain all elements (key actions, tasks including emergency actions – Procedures are clearly written and easy to be understood – Procedures are kept up to date	– Percentage of procedures reviewed and revised within the reference period
	– Information and training covering: hazardous properties of products, communication systems pre-transfer checks, load transfer controls and monitoring, post-transfer checks and emergency actions	– Percentage of staff attending safety courses within the reference period.
RCS2: Inspection and maintenance procedures	– Scope and frequency of the inspection and maintenance – Failures of critical elements of the crane and identified malfunctions	– Percentage of critical elements of the crane inspected and repaired
RCS3: Crane operating procedures	– Procedures contain all elements (key actions, tasks including emergency actions) – Procedures are clearly written and easy to be understood – Procedures are kept up to date – Execution of risk analysis for crane-operation	– Percentage of procedures reviewed and revised within the reference period – Percentage of activities covered by a preliminary risk assessment
	– Training covering: hazardous-properties of products handled, communication systems, load transfer controls and monitoring, and emergency actions	– Percentage of staff trained within the reference period.
RCS4: Work permit procedure	– Scope of activities, covered by the permit-to-work is clearly identified – Permits specify hazards, risks and control measures – Permits are only issued according to proper authorisation procedures – Duration of the permit – Work is conducted as per permit conditions, including demonstration of satisfactory completion of work	– Percentage of permits to work issued where the hazards, risks and control measures are adequately specified – Percentage of work conducted in accordance with permit conditions
RCS5: Emergency procedures	– Emergency plan covers all relevant elements (testing of emergency plan, raising alarm, shutdown/isolation procedures, firefighting, communication, evacuation	– Percentage of elements that have not failed – Percentage of staff/contractors who take correctly emergency actions
RCS6: VGS	– Device correctly shows the workspace and including elements – Alarm activated at the desired set points – Knowledge of tasks and relevant experience about substances, work processes, hazards and emergency actions	– Percentage of correct indication of the view – Percentage of warning at the set point – Percentage of staff having at least 10 years of experience

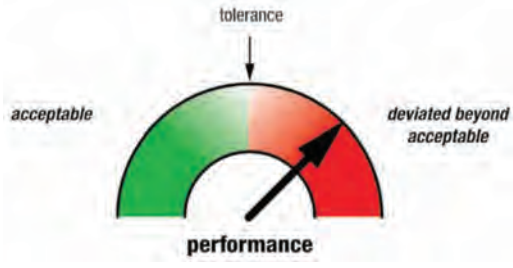

Figure 6. Example of tolerance set (source: HSE, 2006).

The HSE approach suggests that, after the definition of indicators, a tolerance value for each *leading indicator* has to be assigned with the aim to observe any deviation in performance, with respect the related RCS. This allows the plant management deciding the actions to be taken to restore the system from its deviation. For instance, for the indicator "*Percentage of elements that have not failed during simulation*", selected for the RCS "*Emergency procedures*", the tolerance may be set as zero, which means that 100% of actions must be correctly performed. Alternatively, it could be accepted a certain degree of failure if it has previously been highlighted to by the management team, this means that the tolerance of the indicator could be set below 100%.

Figure 6 shows an example of tolerance set for a *leading indicator*. However, the aim of this paper is the definition of *risk indicators* for lifting and handling operations and then, the assignment of tolerance levels for each leading indicator is objective of future study.

As underlined above, the choice of *indicators* that provide a warning when collisions could lead to LOCs, is based on the ability to monitor if RCSs are operating as desired. Moreover, the use of a proper set of *risk indicators*, which have to be collected, processed and evaluated on a regular basis, represents the fundamental for the integration of dynamic features in risk assessment and carrying out a Dynamic Risk Assessment.

5 CONCLUSION

Risk indicators for the load lifting and handling in chemical industry have been developed, according to the HSE methodology, which has been properly adapted with the aim to be integrated into the dynamic risk assessment procedure.

The application and validation of such *indicators* has been made by referring to a case study of an alkylation unit of a refinery. Firstly, the hazardous scenario (loss of containment from a hydrofluoric acid tanks), that can lead to a major accident (toxic dispersion), and its initial cause (dropped load) have been identified. This preliminary analysis allowed identifying RCSs in place to prevent or mitigate the effects of the dispersion. For each RCS, *lagging* and *leading indicators* have been defined.

Resulting indicators highlighted criteria for optimize the process by accounting for the proper safety levels. The use of a safety device, such as the VGS, could be an effective solution to control crane-operations, to guarantee the safety with respect to LOC initiated by a hindered view of the workspace and, finally, to integrate dynamic parameters within risk models in view of the execution of a DRA.

A multidimensional risk evaluation framework for managing floods in urban areas

L.B.L. da Silva, R.P. Palha, M.H. Alencar & A.T. de Almeida
Center for Decision Systems and Information Development (CDSID)—Universidade Federal de Pernambuco (UFPE), Recife-PE, Brazil

ABSTRACT: The increasing migration of people to urban areas around the world contributes to increasing man's adverse impact on the environment and therefore on climate change which is an issue that presents one of the most important challenges of modern civilization. In urban areas, this impact leads to the occurrence of many extreme events, which means multidimensional losses. Over the decades, hydrological catastrophes, especially floods, have been studied so as to control and monitor risks. However, this type of risk assessment has to meet multiple objectives that often conflict with each other. This paper proposes a multidimensional framework which allows researchers to use approaches that support decision makers in the modelling and analysis of the risk of flooding in urban areas. This includes rating risk while considering multiple factors and to responding to risk using actions, such as mitigation measures, which prioritize preventive actions to combat disasters throughout a cyclical process. Some potential benefits of using this approach are discussed.

1 INTRODUCTION

Ever since human beings first formed communities, they have felt the need to interact with each other and to be in harmony with the environment. In fact, living in isolation is not conducive to creating a common culture, to using language or to exercising the human mind (Chatfield 2016). This means not only that people are interdependent—which they rarely admit—but also that it is interdependence which underpins the progressive development of technology which is used to adapt this environment so as to bring comfort to a social group. A look at several points in history confirms this behavior, thereby revealing why human beings have needed to harness and exploit the natural resources at their disposal and how they have done this.

Thus, society has a cyclical co-dependence on technology; in other words, they cannot be separated. This reality in post-modern society has become much more apparent, for example, in terms of communications, forms of transport, modes of learning and doing business or of the artefacts of comfort. Relevant tools or practices have been developed which simplify the way humans do things.

In spite of technology in itself not being harmful to society, its use to achieve specific goals can give rise to negative impacts on human life.

As to the environmental dimension, some features of technology are, in fact, designed to control and monitor natural phenomena. However, the growing dependence on technology in all spheres of life has nevertheless led to global pollution levels increasing because of human behavior. This has had an impact on climate change which coupled with other negative human behavior has caused natural disasters (Merchant 2014).

When the focus of attention turns to urban areas, it is apparent that the unrestrained urbanization of cities has created fragmented spaces into which people have been segregated, thus making cities more vulnerable not only to social inequality but also to the consequences of environmental degradation. As a result, several natural problems adversely affect, in particular, people who suffer from social and economic disadvantages. Natural catastrophes which are considered to be geophysical, meteorological, hydrological and climatological events—such as landslides, hurricanes, floods, and fires—have affected more than one billion people, in this century alone, and caused US$ 2,512 billion in economic losses worldwide (MunichRe 2017).

With this in mind, hydro-meteorological phenomena deserve special attention, since they reinforce the impact of climate changes brought about by human activities. For example, these have caused increases beyond tolerable proportions in the emission of carbon dioxide, deforestation, the growth of metropolises and the manipulation of river basins, all of which have played a part in there being more flood events in urban areas.

In this context some studies have been developed to reach a more specific understanding of the relationship between the risk of floods—which have occurred more and more frequently over the decades—and changes in the climate. In the urban context, some research studies seek to improve prevention and emergency plans in large cities in order to strengthen urban resilience and reduce vulnerability (Ke et al. 2012, Kourgialas & Karatzas 2016, Piloneet al. 2017, van Wesenbeeck et al. 2016).

Thus, by considering climate change issues that affect the environment of urban cities, this article sets out to analyze how to control and mitigate floods by implementing strategic projects.

Assessing the risk of floods, which are extreme events, and the policies used to mitigate them have to take account of multiple strategic objectives that are often conflicting and integrate three dimensions: social, economic and environmental. That is why some researchers, on seeking approaches to support decision makers (DMs) in their decisions, have applied multi-criteria methods.

This study proposes a multi-criteria framework to model and analyze the risks of flooding in urban areas that take human, social and environmental factors into account. In addition, this framework seeks to make a contribution towards aiding public policy to prioritize preventive actions so as to combat disasters. It does so by setting out a detailed classification of risk.

The present paper is structured as follows: Section 2 presents a literature review on the impacts of climate change on urbanization, in order to justify what prompted this paper. Sections 3 and 4 present research that addresses mitigating the risk of disaster, a review of the literature on risk and multidimensional analysis for decision support. Section 5 describes the proposed framework for flood risk management in urban areas, while Section 6 makes some final remarks and suggestions for future studies on the subject.

2 IMPACTS OF CHANGES IN THE CLIMATE ON URBANIZATION

Although the issue of climate is one of the most important challenges of modern civilization, studies undertaken in the twentieth century pointed out that urbanization was one of the main factors driving global growth and this had the potential to cause natural disasters (Mitchell 1993).

In fact, the ever greater migration of people to urban areas around the world changed the interaction between man, natural resources and the environment as a whole—the Earth and the atmosphere. People's behavior led to their actions having an increasing impact on the environment and thereby contributed to climate change.

Chen & Frauenfeld (2016) investigated what the impact on the climate of urbanization in China might be in the future. They used a model to project what China's climate could be by 2050 and found it would be drier and warmer, thus indicating that human activity will have catastrophic effects.

It needs to be borne in mind that there is considerable uncertainty associated with climate changes, and therefore it is a challenge to establish secure projections that can be used to inform the management of risk. This is because projections about extreme weather events and changes in the climate are forecasts of their frequency, intensity, duration, and month or season of occurrence, which, by definition, cannot be estimated with certainty.

Studies published by IPCC—about global temperature increase—suggest that, on analyzing different scenarios, global temperatures will increase by about 1 degree Celsius between 2000 and 2040 (IPCC 2012).

O'Brien & O'Keefe (2014) assert that while such studies indicate that there is enough time to develop mitigation actions, this may be misleading because there is little "wiggle room" and decisions on mitigation trajectories and deadlines need to be made soon.

In addition, the interference of political factors contributes to the complexity of managing risks. Giddens (2009) affirms through his paradox that governments will not act until something really goes wrong by which time it is too late to take corrective actions. The explanation for this is that politicians keep postponing making difficult decisions if they believe this could be to their electoral disadvantage and therefore would lead to their not staying in power. Examples include the need to increase taxes significantly to pay for major projects such as protecting coastal cities; causing large-scale unemployment as a result of introducing stringent pollution controls or running down extractive industries; and building new nuclear power plants near heavily-populated areas.

Given this set of circumstances, little progress has been made in international climate negotiations and planning preventative and mitigating actions for both long-term and extreme events are needed urgently.

Therefore, effective management strategies for managing risk are needed to counter-act the increasing occurrence of natural disasters in the urban environment.

As an example, NATECH events have, to date, had huge impacts worldwide, and consequently, modern society has started to pay great attention to them and to call for appropriate actions.

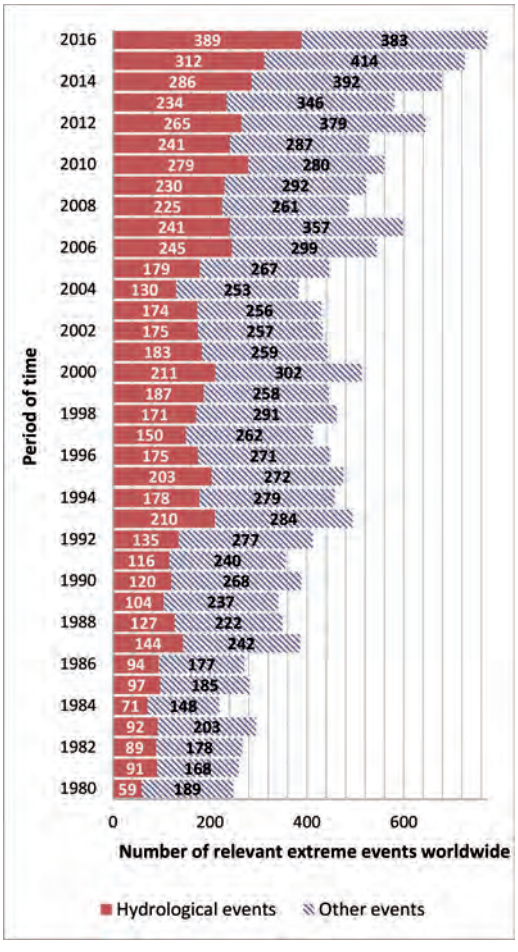

Figure 1. Number of relevant extreme events worldwide from 1980 to 2016. Source: MunichRe (2017).

Thus, Nascimento & Alencar (2016) made a systematic review of the literature on these events because of their great impact and due to their high level of complexity in terms of risk management. Their study revealed the surge in seeking improved scientific knowledge on how to mitigate extreme events, due to their occurring more and more frequently, year after year.

However, the nature and severity of the extreme impacts on climate cannot be assessed only by their intensity, but must also include assessing the exposure and vulnerability of the areas most likely to be affected (IPCC 2012).

Therefore, there is an urgent need to understand how natural disasters, which are increasing in intensity, impact the critical infrastructures of urban centers. These infrastructures have very often been integrated and this is essential for the maintenance of community life so if any break down, the impact on the rest of the system is all the more severe and potentially catastrophic.

Due to this need, the literature now contains a growing number of studies on how to tackle this problem, an example of which is et al. 2017). They propose that urban infrastructure systems be improved by structuring the problem in detail, and do so by involving a wide range of specialists including those from the areas of energy, drainage, transportation, and sanitation. Their model sets out how to conceptualize projects, actions and policies in order to reduce the exposure of areas in urban centers to extreme events.

Figure 1 illustrates the occurrence of relevant events, which have been officially registered since 1980, worldwide. The statistics show that the frequency of hydrological events, of which floods are predominant, has grown dramatically (MunichRe 2017).

The proportion of hydrological events as measured against all other extreme events has grown from 50% in the 80s, to about 80% in the 2010s and, moreover, in 2016 they were nearly equal in number to all other events. In view of this, the authors were prompted to undertake the research that led to producing this article.

3 FLOOD RISK MANAGEMENT AND THE DECISION MAKING PROCESS

Adverse impacts are considered disasters when they produce widespread damage and cause serious changes in the normal functioning of urban societies. Such events may occur because of extremes of climate and the exposure and vulnerability of places to these. Changes in climate can arise from a wide range of factors, including anthropogenic climate change, natural climate variability, and socioeconomic development (IPCC 2012).

That is why research studies seek to investigate how risk management can be used to reduce exposure and vulnerability and increase resilience to the potential adverse impacts of extreme climates, even if risks cannot be completely eliminated. As a result, ways to adapt to and mitigate these events can complement each other and together can dramatically reduce the risks that arise from climate change.

As to the context of floods, however, the qualitative and quantitative evaluations of these factors are subject to various uncertainties (Aven 2012). Therefore, it must be understood that the context of risk and hydrological uncertainty are important concepts that need to be addressed to support decision making in many situations.

The challenge is to know how to describe, measure and communicate risk and uncertainty.

This involves economic factors, including potential financial losses, and environmental and social impacts, such as estimating the number of fatalities and the impact on health services and the sanitation systems of large cities.

Several papers in the literature seek to quantify and analyze risks for which various tools are used, such as decision analysis (Cuellar & McKinney 2017) and Hydro-Meteorological analysis (Patra et al. 2015). However, this paper tackles the multi-objective point of view as a motivator to analyze in an integrated manner the dimensions involved, should an extreme event occur. This is set out in the following section.

4 MULTIDIMENSIONAL RISK EVALUATION

The multi-objective feature of a problem that a risk mitigation policy should reveal can be used in multicriteria analysis.

The application of Multiple Criteria Decision Making/ Aiding (MCDM/A) methods seeks to establish preference relations to evaluate several alternatives against various previously determined criteria during the decision process.

Due to the plurality of points of view that directly influence the decision, de Almeida et al. (2015) pointed out that the methods developed seek to translate the way people have always made their decisions. Despite the diversity of existing methods, the basic elements are simple: a set of undominated actions evaluated by considering at least two criteria that cannot be translated into economical evaluation and a decision maker.

Thus, several studies over the decades have allowed great advances in modelling problems, using multicriteria aggregation methods even more closer to the reality of their applications. Koksalan et al. (2011) and Edwards et al. (2007), for example, analyzed the evolution, history and perspectives of MCDM/A area over time and emphasized this fact.

Such advances leaded researchers to apply MCDM/A methods in many areas: water distribution networks (Fontana & Morais 2017), research and development (R&D) projects (Karasakal & Aker 2017), cleaner energy and electricity market (Cucchiella et al. 2017), civil construction (Miniotaite 2017), financial sector (Ferreira et al. 2018), among other applications.

In the risk management context, there are studies in the literature that integrate multicriteria analysis with environmental risk. Medeiros, et at. (2017) enhance previous suggestions for a multicriteria decision model that evaluates the multidimensional risks of gas transportation by pipeline.

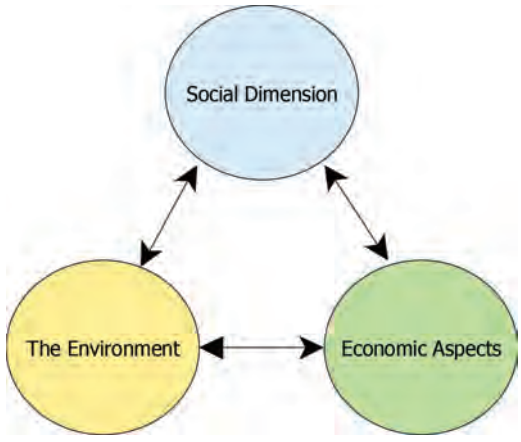

Figure 2. Integration of dimensions for evaluation. Source: This paper (2017).

Their model offers tools that help to prioritize maintenance efforts, and therefore to optimize the use of human, financial and other resources.

In fact, MCDM/A methods have been used in many risk management contexts, and a systematic literature review made by de Almeida et al. (2017) identified research trends in dealing with multicriteria models. These include that they offer a multidimensional view of problems and take into account a DM's preference structures.

By choosing, ranking or sorting actions, these methods can make recommendations on how a DM should analyze results. Thus, multi-dimensional methods admit subjectivity as part of the decision process, and support DMs by using algorithms and methodologies that aid them to build their preference structure. This way, the DMs are able to obtain more robust and reliable results, which might be submitted to sensitivity analysis.

Thus, a multidimensional risk assessment can be carried out in order to incorporate subjective and elements in the social environment that have hitherto been less exploited as presented in Figure 2. This leads to putting forward a framework for flood risk management in urban areas, in Section 5.

5 A FRAMEWORK PROPOSAL FOR MANAGING RISK FROM FLOODS

In this research study, a decision support framework was developed not only so as to understand the risks from floods and to integrate the dimensions of risk, but also so as to use this information to improve how projects are selected and portfolios of projects are managed, where a DM faces uncertainty.

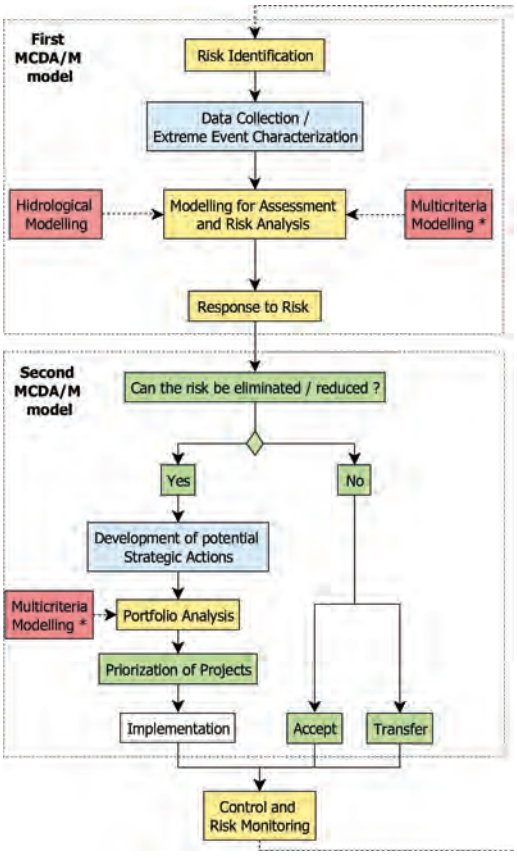

Figure 3. A framework proposal for managing flood risk. Source: This paper (2017).

The framework presented in Figure 3 is divided into 5 steps. It starts by collecting data to provide the model with enough parameters to model the problem.

Broadly speaking, the framework proposes using a multidimensional evaluation for rating risk, which has already been developed, to define possible actions to avoid risk. In this context, when this risk can be eliminated or mitigated, the framework then leads to a way to model multicriteria that will be used to manage projects that combat risk. These projects are held in a portfolio and include alternatives that perform effectively with regard to avoiding the impacts of an extreme event.

The framework proposal conducts the multidimensional flood risk analysis step by step, as described below:

5.1 *Risk identification*

This step corresponds to the initial stage of understanding the problem. A detailed characterization is made, in addition to which data is collected on important parameters which will be used as input for the risk modeling (considering the inherent probabilistic character).

Flood risk identification covers (Rausand 2011):

- Identification of all flood events that are relevant throughout the area to be studied;
- Describe characteristics such as the way, the type, the volume, when and where the flood was present in the system under study;
- Identify possible related triggering events;
- Assess if flood hazards could cause potential hazardous events; and
- Collect hydrological data, such as historical series, return time and characteristics of the hydrographic basin under analysis, and climatological/natural data, such as climate, humidity of the air, wind and soil characteristics.

If social and economic data, such as fatalities, economic losses, devastated areas, are available, it is important to take them into account and this could be done in this step (Steijn et al. 2017).

5.2 *Modelling for assessment and risk analysis*

This stage comprises the process of modeling the problem using the data collected in order to quantify the flood risk in the area of study by considering the influence and interaction of natural, social and economic aspects of floods. Thus, a multicriteria model is used along with the hydrological model to analyze and determine this measure of risk, using methods that are appropriate to the problem of risk rating in the area of study.

Thus, several procedures have been presented in the literature to support DMs in constructing a model. For example, de Almeida et al. (2015) divide the procedure into 3 phases—in successive refinements:

a. A preliminary phase, in which the decision makers, the objectives, the criteria used to model these objectives, the space of actions and the problematic are defined. In addition, uncontrolled factors are identified.
b. The modelling of preferences phase is developed by choosing what MCDM/A method will be used in addition to modelling the DMs' preferences; and
c. The finalization phase, during which the evaluation of alternatives and recommendation are presented, and the decision is implemented.

This way, building MCDM/A models to represent real problems can be faced as a creative process, which intellectual and cultural background of DMs are important for understanding its complexity.

However, an analyst help decision makers in all phases mentioned previously, giving factual information about the problem. Through the interaction of all actors of this process, DMs increase their perceptions about objectives, criteria, space of actions, what indeed enrich the model to the evaluation and implementation of the decision.

In the context of risk identification, in general, this step

- estimates unknown parameters of the model;
- uses an MCDM/A approach to generate an estimate of the risk indices and considers a broad range of different aspects.

It should be noted that the elements of a decision model, such as objectives, criteria and preferences, are constructed in order to promote a realistic assessment of the flood risk. This includes making recommendations that arise from rating the risks and establishing what the response to the risks should be.

5.3 *Response to risk*

As to disaster risk management, several procedures, which were divided into stages, have been developed in the literature, among which O'Brien & O'Keefe (2014) divides it into 4 phases in a cyclical process.

Figure 4 shows that the disaster management function is focused on preparedness for an event and then responding to that.

The authors commented that the recovery stage is often treated as the responsibility of other bodies. Mitigation efforts are dealt with similarly, but typically there will be linked with the disaster management function about the type of mitigation measures; for example, the scale and location of flood defenses.

Figure 4. Disaster management cycle. Source: O'Brien & O'Keefe (2014).

In the context of MCDM/A methods (de Almeida et al. 2015), categorizing risk based on disaster management cycle allows DMs to respond to risk in three ways:

- Accept: there is no action to be implemented, since it takes a lot of time to prepare a strategy to manage risk or high-cost actions will be needed to deal with it;
- Transfer: outsource or share risk to a third party or parties that can manage the outcome;
- Eliminate/mitigate: action is taken to eliminate the causes of threats wherever possible or reduce the likelihood of occurrence of the risk or resulting consequences.

Therefore, if the assessed risk can be eliminated / mitigated, then potential flood control alternatives can be established, while taking the critical infrastructures that are affected by it into account. This creates a discussion among scientific communities, companies, local population and public administration to help DMs to generate a portfolio to be analyzed in a later stage.

5.4 *Portfolio analysis*

As a set of projects or programs and other activities, gathered for effective management, the portfolio constructed from the risk analysis of the delimited area should be managed in order to select the set of projects that maximize satisfaction in social (such as risk by population), economic (loss reduction), and natural (environmental preservation) ways.

However, it is known that they often conflict with each other, which prompts the application of multicriteria decision support methods in this problem.

Since DMs seek to prioritize their strategic goals, which demonstrates what really matters to the organization, a portfolio needs financial and human resources but, generally speaking, the amounts required exceed the limits available (Larson & Gray 2011), and the support of MCDM/A methods is necessary for its resolution.

In addition, the interaction process of all actors is similar to the first MCDM/A model (second step), and which contributes to better results.

Broadly speaking, the portfolio problem consists of choosing, within a set of actions, a subset that meets the objectives and constraints. This results in prioritizing projects and then implementing them.

5.5 *Control and monitoring*

This is the last step of the framework and it allows a monitoring plan to be implemented. It might not only record the risks to be addressed, but also the approval of required projects and the results of the actions developed to mitigate floods. Thus, the step promotes a continuous improvement:

- to design and execute projects;
- to assess the risk and its implications;
- to understand the problem and to model the DM's preferences more coherently;
- to learn and exploit opportunities to benefit affected populations.

This stage is required to:

- Ensure the implementation of risk plans and assess their effectiveness in reducing risk.
- Follow the identified risks, including the watch list.
- Monitor residual risks and identify new risks arising from project implementation.
- Assess the perception of risk by the population;

Thereafter, a cyclical process is implemented for continuous risk assessment, which involves updating the framework and generating new input data.

It needs to be pointed out, however, that this paper seeks to propose a framework, the consolidation of which will be based on a careful analysis, step by step, of the modeling to be done, in order to correctly evaluate the problem, according to the simplifications, specifications and constraints of the model.

6 FINAL REMARKS AND FUTURE STUDIES

Combating and preventing flood risks requires a broad and integrated view of the social, economic and environmental dimensions involved. The development of risk responses in urban areas requires a multi-dimensional analysis of flood risk. Thus, the framework presented seeks to include multivariate elements to control risk in a more balanced and coherent way, thereby making cities less vulnerable and less exposed to extreme events, while their resilience grows due to efficient urban planning.

Some final considerations can be made:

- When implementing this framework in practice, it may contribute to diagnose the resilience of urban areas;
- The multicriteria analysis can give balanced and coherent recommendations, in order to increase the perception of the risk and reduce exposure and vulnerability;
- The cyclical analysis can be understood as a learning process and new information of parameters and modelling can be inserted as procedures. In addition, elements of the decision model—objectives, criteria and evaluation—can be better estimated. Thus, it can promote better portfolio management.
- The modeling of preferences becomes a challenge for DMs. Thus, prior support is required from analysts to understand not only the problem but also the MCDM/A method used. Thus, knowledge of the multidimensional problem makes the process more reliable when implementing the decision.

As future studies, we intended to apply this framework to cities around the world where floods have a considerable impact on critical infrastructures as well as on citizens. Therefore, accurate data need to be collected so that there will be enough parameters to guarantee the benefits mentioned previously, on applying this approach.

Once the decision environment of this problem is dynamic, the framework can be extended for group decision analysis. The aim is to translate strategic objectives of public power into effective actions in the fight against urban floods in order to reduce the damage caused by this natural disaster worldwide.

ABSTRACT: Risk analysis has been widely used in climate adaptation practice. However, traditional probabilistic risk analysis methods are not capable of tackling the unavailability or incompleteness of climate risk data. To deal with such challenges, this paper further applies an advanced Fuzzy Bayesian Reasoning (FBR) model for climate risk analysis of railways system in the UK. Its novelty lies in the realisation of climate risk ranking under high uncertainty in data and its practical contribution on the risk perception of stakeholders in the UK railway systems. To test the feasibility of the developed model in the transport industry, a large scale of surveys are conducted to collect data, regarding the timeframe of climate hazards, likelihood of occurrence, severity of consequences, and infrastructure resilience for the analysis of climate risks threatening British rail systems. The findings will provide transport planners with useful insights on the identification of climate hazards of high risks to facilitate the development of cost-effective climate adaptation strategies.

1 INTRODUCTION

Current variability in climate poses a challenge for rail infrastructure and operation. In the majority of countries, the related activities of transport systems are sensitive to different weather extremes, which include but are not limited to, changes in temperature, precipitation, thunderstorms, winds, visibility and sea level (e.g., Love et al. 2010).

Risk analysis as a critical element in climate change adaptation has been widely utilised through a variety of approaches and techniques. The selection of cost-effective climate adaptation measures requires systematically analysing risk reduction combining with the associated costs due to the implementation of these measures. A variety of methods in risk quantification have been proposed (Wilby et al. 2009). However, their availability and effectiveness of common-used methods are challenged in existing climate risk studies (Yang et al. 2015). One of the main challenges is that the unavailable or incomplete objective data fails to precisely evaluate the risk reduction and costs on many occasions, resulting in difficulties to assess risk and costs. Owing to the high level of uncertainties in this data, many conventional risk assessment approaches (e.g., Quantitative Risk Assessment (QRA)) which have been widely applied to conduct risk analysis in many sectors become unsuitable (UNCTAD 2012).

Fuzzy set methods have been applied to climate risk assessment on ports in several pioneering studies to deal with this challenge (i.e., Ng et al. 2013, Yang et al. 2015, 2016, 2017). In assessing climate change risks on ports, linguistic terms were regarded as variables, namely, the stakeholders' perceptions of the impacts of climate change (Yang et al. 2015). Through modelling subjective input data (linguistic terms) on climate risk evaluation based on the stakeholders' perceptions collected from their current interpretations of the frequencies, severity of consequences and timeframes of climate risks where they occur. By these studies, this paper develops a new Fuzzy Bayesian model by dividing the risk parameters into two levels. The junior-level parameters are "*Timeframe (T)", "likelihood*

(L)", "Severity of Consequences (C)" and add the fourth one "*Climate resilience (S)*". In particular, three sub-parameters of *"Severity of Consequences (C)"*, namely, "*Damage to Infrastructure (INF)*", "*Injures and/or Loss of Lives (INJ)*" and "*Damage to Environment (ENV)*" are added to extend and specialise the risks parameters. As a result, this Fuzzy Bayesian Reasoning (FBR) approach in which subjective evaluations by domain experts enables to complement the unavailable objective data to realise climate risk ranking more precisely under high uncertainty in data.

This paper aims to achieve two primary objectives. Firstly, it develops a new FBR model by subdividing and adding new parameters to quantify the risk perception of the stakeholders towards climate threats s. This new development will offer a notable foundation for further adapting to climate risks and tackling the uncertainties in climate risks. Most importantly, this FBR model is exemplified by the British rail system through conducting a nation-wide survey amongst 21 major rail stakeholders in the UK. This applicability will contribute to reveal the real climate risks on UK rail from the perspective of both industry and academia. We believe that the outcomes of this study will be of considerable value to rail planners, decision makers and industrial practitioners, helping them to create and implement adaptation plans, strategies and practices.

The rest of the paper is structured as follows. The critical review of the risk analysis for climate change is presented in section 2. The FBR methodology including a step-by-step risk analysis framework is given in section 3. In section 4, climate risks and adaptation on UK rail systems, as well as the data collection through a survey amongst the 21 rail stakeholders across the UK, are described. Finally, the discussion and conclusion implying the contribution and revelation for further research can be found in section 5.

2 CRITICAL REVIEW: RISK ANALYSIS FOR CLIMATE CHANGE

Current research on climate-related risk analysis have commons on interpreting and identifying the existing and future risks, estimating the level of risk as well as determining the level of uncertainties (Yang et al. 2015). A variety of methods in risk quantification have been proposed which can be categorised into three methods: methods requiring limited resources (i.e., sensitivity analysis), methods with modest resource needs (i.e., empirical downscaling) and methods with high resources needs (i.e., dynamical downscaling) (Wilby et al. 2009). However, traditional Probabilistic Risk Analysis (PRA) methods sometimes are unable to tackle the unavailability or incompleteness of climate risk data (i.e., Yang et al. 2015). Fuzzy set and Bayesian Networks (BNs) have been applied to climate risk assessment on ports in several pioneering studies to deal with this challenge. In this section, we review the development of fuzzy theory and BNs, as well as their applications in risk analysis.

2.1 *Fuzzy set and fuzzy logic*

Mathematically, a fuzzy set can be defined by assigning to each possible individual in the universe of discourse a value on behalf of its grade of membership in the fuzzy set (Klir & Yuan, 1995). One of main approaches to reasoning under uncertainty is possibility theory, which is called fuzzy logic (Jenso, 2001). It is the logic of classes with unsharp boundaries and has been widely utilised to cope with the problem of computer understanding of natural language (i.e., Zadeh, 1992; 2010).

In recent decades, fuzzy set and fuzzy logic have been widely accepted tools in risk assessment, providing a theoretical framework of expert decision making under uncertainty (i.e., Sii et al., 2002; Andrews & Moss, 2002). For instance, Singh & Benyoucef (2011) utilised F-TOPSIS to the solution of MCDM problems in selection of supply chain coordination. Yang et al. (2011) employed F-TOPSIS for vessel selection under uncertain environment and Yazdani-Chamzini (2014) applied F-AHP and F-TOPSIS for selection and evaluation of available handling equipment.

Fuzzy set methods had made successful attempts in climate risk assessment for climate change in recent years (Yang et al. 2015). For example, in assessing the climate risks on ports, linguistic terms were regarded as variables, namely, the stakeholders' perceptions of climate impacts (Ng et al. 2013, Yang et al. 2015, 2016, 2017). On the basis of the stakeholders' perceptions collected from their interpretations of climate risks' frequencies, consequences and timeframes in which they occur, these subjective input data were modelled to estimate climate risks. The fuzzy risk score R was defined by using a discrete fuzzy set, $R = C \circ (L \times T)$ (Ng et al. 2013) or a fuzzy set manipulation approach, $R = T \otimes C \otimes L$ (Yang et al. 2015). Nevertheless, these methods could neither avoid the loss of useful information in fuzzy operations nor deal with a huge amount of risk input data (Yang et al. 2016). A novel fuzzy-Bayesian model proposed by Yang et al (2017) overcame these issues by taking advantages of fuzzy rule bases (i.e., IF-THEN rules) in modelling non-linear relation between risk parameters and output and BN in realising fuzzy rule integration and risk inference. Employing fuzzy IF-THEN rules in Fuzzy logic theory allows the

antecedent and conclusion parts containing linguistic variables model the qualitative features of experts' knowledge and reasoning process when there is lack of precise quantitative analysis.

2.2 *Bayesian networks*

When multiple sets of data (from different experts) are employed, it is difficult to use normal fuzzy rule inference mechanisms as the calculation could take a long time. Bayesian Networks (BNs) is a sound mathematical method in minimising the uncertainties and increasing knowledge. These are achieved by combining probability distributions or functions of different parameters and updating their probabilities when new information emerges (Wang, 2003).

Bayesian modelling is a proven inter-disciplinary tool (Tebaldi et al. 2005). There are a variety of benefits with BNs including integrating different types of variables and data within a framework, and efficiently being updated when new information and knowledge become available (Castelletti & Soncini-Sessa, 2007, Cinar & Kayakutlu, 2010). In particular, BNs are capable of compensating the absence of historical statistics and handling incomplete uncertainty through combining various pieces of information and making use of expert judgments (i.e., Tighe et al., 2007). BNs has achieved a wide range of application in multiple fields, such as safety assessment, intelligent decision making and computer network diagnosis, which involve uncertainty due to incomplete data and limited cognitive capacity (Zhang et al., 2013). It is employed for the estimation of future climate change conditions, such as precipitation mean state and seasonal cycle in South Africa (Boulanger et al., 2007) and quantitative prediction and assessment of long-term shoreline change associated with sea level rise and its uncertainty (Gutierrez et al., 2011). Bertone et al. (2015) integrated BNs into participatory modelling to develop a risk assessment tool for managing water-related health risks associated with extreme events by combining System Dynamics.

Nevertheless, a major disadvantage of BNs in incorporating expert judgements is that it may fail to probabilistically forecast subjective fuzziness in a precise way as it lacks understanding of probability theory. Bayesian approaches were criticised as they often requires too much information regarding prior probabilities which are hard to receive in risk analysis. Also, this information mainly relies on subjective judgments such as provided by experts' knowledge, which might result in unexpected bias into BNs (i.e., Tversky & Kahneman, 1975; 1990). BNs might become computationally inefficient when models have a large number of variables (Liang & Lee, 2008). It cannot process time-series data and address feedback regulations (Ristevski, 2013).

To compensate these disadvantages of BNs, some theoretical research and applications have identified the benefits to combine fuzzy logic and Bayesian reasoning especially in the applications of Fuzzy-Bayesian approaches to safety and reliability (Bott & Eisenhawer, 2002). However, more advanced and capable methods are required to enhance structure learning algorithms, allowing for constraints based on expert knowledge, with precise rules for interventional risk management and decision making (i.e., Zhou et al. 2014, Constantinou et al. 2016).

Overall, the evaluation of climate change risks on the rail systems in this paper may contain various types of uncertainty. Similarly, due to the scarcity of historical/statistical data (UNCTAD, 2012), is carried out by subjective judgments. Thus, combining fuzzy set theory and BNs is appropriate to model subjective linguistic variables and cope with the discrete problem, handling incomplete uncertainty and complicated calculation.

3 A NEW FBR RISK ANALYSIS FRAMEWORK

In Section 3, it indicates a step-by-step risk analysis framework by utilising FBR approach. The proposed framework for modelling climate change risks consists of four main steps, which outlines each step required for risk estimation and assessment.

3.1 *Identify environmental drivers*

Based on previous literature review, we investigated four primary environmental drivers due to climate change affecting on the British railways: 1) temperature increase, 2) intensive rainfall/flooding, 3) increased intensity and/or frequency of high wind and/or storms, and 4) sea level rise. Hence, this risk analysis is made for each of these environmental drivers to evaluate the risk level of their corresponding potential climate threats.

3.2 *Identify fuzzy input and output variables*

To define the subjective risk estimates, five threat-based risk permeants are identified which include at both the senior and junior levels respectively. The senior-level parameter is "Risk Level (RL)". Refer to the definition of RL used in the FBR climate risk analysis on port systems (i.e., Ng et al. 2013, Yang et al. 2015, 2016), it expresses such linguistic variables as "Very High", "High", "Medium", "Low" and "Very Low".

Three junior parameters closely associated with climate change risks have been identified in previous studies, namely "Timeframe (T)", "likelihood (L)" and "Severity of Consequences (C)" based on the FMEA approach (Yang et al. 2008, 2009, Ng et al. 2013, Yang et al. 2016). Especially, in this paper, "Severity of Consequences (C)" is divided into three subcategories, namely, "Damage to Infrastructure (INF)", "Injures and/or Loss of Lives (INJ)" and "Damage to Environment (ENV)". At the meantime, "Climate resilience (S)", designed as the fourth important junior parameter in assessing climate risks in railways, is characterised in Table 1.

Table 1. Climate resilience.

Grade	Linguistic terms	Description	Fuzzy memberships
1	Very Weak (VW)	Very weak (0–20%) capacity of the transportation system to anticipate, absorb, accommodate, or recover from the effects of a climate event and requiring a very long period (a year) and very high cost of recovery (£10 million above)	(0, 0, 0.1, 0.3)
2	Weak (W)	Weak (20–39%) capacity of the transportation system to anticipate, absorb, accommodate, or recover from the effects of a climate event and requiring a long period (a month) and high cost of recovery (£1 million above)	(0.1, 0.3, 0.5)
3	Average (A)	Average (40–59%) capacity of the transportation system to anticipate, absorb, accommodate, or recover from the effects of a climate event and requiring certain length of time (a week) and cost of recovery (£100, 000–£1 million)	(0.3, 0.5, 0.7)
4	Strong (S)	Strong (60–80%) capacity of the transportation system to anticipate, absorb, accommodate, or recover from the effects of a climate event in a relatively timely and efficient manner (a day) and requiring some cost of recovery (£10,000–£100,000)	(0.5, 0.7, 0.9)
5	Very Strong (VS)	Very strong (80% above) capacity of the transportation system to anticipate, absorb, accommodate, or recover from the effects of a climate event in a very timely and efficient manner (12 hrs) and requiring slight cost of recovery (0–£1,000)	(0.7, 0.9, 1, 1)

3.3 *Establish a fuzzy rule-base network with the belief structure*

Fuzzy system theory, through collecting fuzzy IF-THEN rules from experts or domain knowledge and combining the rules into a single system, offers a systematic procedure for transforming knowledge bases to non-linear mappings (Sii & Wang 2002, Yang 2006).

While in some real cases, subjective degrees of belief (DoBs) are assigned to the linguistic variables used to express the conclusion attribute (RL) for modelling the incompleteness of expert judgments. Refer to the climate risk models on ports by Yang et al. (2016, 2017), in the fuzzy rule-base network of this study, four junior-level fuzzy input parameters including 20 (5+5+5+5) linguistic variables are assembled to generate 625 (5*5*5*5) antecedents with a rational degree of belief (DoB) distribution. Simultaneously, we constructed a secondary level network between the three subcategory parameters (INF, INJ and ENV) and junior-level parameter C, containing 15 (5+5+5) linguistic variables assembling to create 125 (5*5*5) antecedents.

3.4 *Conduct risk inference by BN techniques*

The constructed belief structures can be used to conduct risk inference using BN techniques. First of all, the rule base with belief structures is expressed in the form of conditional probabilities. Through utilising a BN technique, the FBR constructed can be modelled and converted into a five-node converging connection. It includes four parent nodes, NT, NL, NC and Ns (Nodes *T, L, C* and *S*); and one child node NRL (Node *RL*).

The prior probabilities of NT, NL, NC and Ns can be achieved through questionnaire surveys (i.e., on rails). The prior profanities of NT, $p(Li)$, for example, can be obtained through asking the question, "using the defined linguistic variables (i.e. VH, H, A, L and VL), how likely the effect will occur when you expect first to see this climate threat poses impacts to the rail your organisation associated with?", to collect the data from domain experts' risk perception. Through analysing all the prior probabilities of the four nodes, the marginal probability of NRL can be computed as (Jensen, 2001):

$$p(RLh) = \sum_{i=1}^{5}\sum_{j=1}^{5}\sum_{k=1}^{5}\sum_{l=1}^{5} p(RLh \mid Ti, Lj, Ck, Sl) \; p(Ti)p(Lj)p(Ck)p(Sl)$$
$$(h = 1, \ldots, 5) \quad (1)$$

To prioritise the climate risks, RLh (h = 1, …, 5) requires the assignment of appropriate utility values URLh. The linguistic description can then be converted into a crisp value using a centroid defuzzifcation method (Yang et al. 2009). Accordingly, RLh (h = 1, …, 5) = {0.11, 0.3, 0.5, 0.7, 0.89}. Hence, a new risk criticality ranking index can be developed as follows:

$$RI = \sum_{h=1}^{5} p(RLh)U_{RLh} \quad (2)$$

where the smaller the value of RI is, the higher the risk level of potential climate threats.

4 CASE STUDY: RISKS ANALYSIS OF CLIMATE CHANGE ON UK RAILWAYS

4.1 *Climate risks and adaptation on UK rail systems*

In the UK, the transport sector has been recognised as one of six key sectors which will be most vulnerable to the impact of climate change (McKenzie Hedger et al. 2000). The predicted climate impacts on rail transport in the UK include an increased number of hot days, a decreased number of cold days, increased heavy precipitation, drought, sea level change, seasonal change, extreme events and wind (i.e., Jaroszweski et al. 2010, Peterson et al. 2008, Hooper & Chapman. 2012).

The extreme events posed the most devastating impacts (e.g., heat waves and storms) on rail transport. Higher temperatures in summer will cause rail buckling as well as decreased thermal comfort; more intense precipitation in winter will result in flooding, landslips and bridge scour. However, this might be beneficial for lower winter maintenance. Flooding was regarded as one of the significant impacts on the rail network (EPA 2009). The damage caused by climate change on railway networks took into account approximately 29% to 71% of the total (Chatterton et al. 2010). Dora (2012) investigated the leading climate change impacts to infrastructure operations on UK rail transport systems as a result of the projected changes in temperature and precipitation. This report stressed the effects, including the increases in track buckling, days of track maintenance and exposure of staff to hear the stress and overhead power cables sagging in hot weather. Some issues included air quality in urban areas and remarkable differences between the North and South in the UK owing to the growth temperature, the increased possibility of track inundation and of scouring affecting river bridges' stability and incidence of landslips due to heavy and extreme precipitation. Overall, although there have been widespread effects on diverse transport modes, it is only recently that more attention has been given to the impacts of climate change on British railways (Hooper & Chapman 2012).

The lack of data on the impacts of climate change, as well as cost-benefit analysis for climate change pose a significant challenge for transportation planners, which also results in the failure of adaptation strategies in the transport sector (i.e., Koetse & Rietveld 2012). Owing to high uncertainties related to the future climate, adaptation measures should be robust to retain the option value of the portfolio of measures. Hence, through conducting a nation-wide survey of UK rail systems, this paper examines the new risk analysis model in Section 3 which overcomes the shortage of data and the uncertainty of climate risks to reveal the real climate risks for British rail.

4.2 *A nation-wide online survey on climate risks assessment*

To validate the efficiency of the FBR model, a nation-wide survey was conducted to collect the first-hand data through examining the perceptions of rail planners and stakeholders on the impacts of climate change within the rail systems.

This survey aims to illustrate the general situation of climate risks in UK rail systems and to justify the necessity of adaptation planning. Four main environmental drivers due to climate change were identified: temperature increase, intensive rainfall/flooding, increased intensity and/or frequency of high wind and/or storms and sea level rise. The specific potential climate threats and corresponding adaptation measures were summarised according to the Network Rail's adaptation framework (Network Rail 2015). To guarantee the validity and feasibility of questionnaire designing, a pilot study was conducted in April 2017 by inviting ten professional rail experts and academics in the UK. From May to September 2017, a nation-wide online survey was conducted amongst the 21 British rail stakeholders to assess their perception of climate change risks, including specific impacts on their operation, performance and infrastructure.

The population of this survey is all the rail stake-holders in the UK who are from rail companies and authorities, governmental departments, academics and NGOs etc. The databases of the national rail networks were chosen from the national maps to be used to select the transportation entities (Network Rail 2016). The participants in the railway survey were mainly chosen from

members of the Railway Industry Association (RIA) and the Rail Freight Group (RFG) representing major UK-based suppliers of the world's railways and the leading body for rail freight in the UK (RIA n.d., RFG n.d.). Over 200 member companies crossing the whole range of railway supply with diverse skills and resources are the typical rail entities of UK national railway.

Considering the uniqueness and complexity of climate change issues (i.e., the characteristics, geographic distribution, types and levels of risks posed by climate change on rails), non-probability sampling, including a combination method of judgment sampling and snowball sampling, was utilised in this survey. Some small entities in remote regions might lack necessary knowledge or experience of climate change issues and the representativeness of the samples is more critical than its generalisability in judgment sampling (Vogt et al. 2012). Consequently, a sample of 30 administrators representing the most critical transport institutions in different regions of the UK (e.g., Network Rail, Transport for Greater Manchester, AECOM UK, etc.) was selected to assess their perceptions of climate change risks. Snowballing was utilised via one or two key informants at each entity from the targeted population.

The 30 questionnaires were distributed online through BOS Online Survey (BOS 2017). E-mails and phone calls were used to contact all the respondents during business days. In the end, 21out of 30 effective responses were received with a high response rate 70%. The questions were divided into two types: closed-end questions, which utilise multiple choices and a linguistic evaluation approach to quantify responses; open-ended questions, which provide more freedom to respondents and produced more precise data.

Data screening was conducted to eliminate missing and ineffective data such as incomplete input information and insane responses. Accordingly, 4 out of 21 feedbacks became invalid after the screening process. The consistency of the remaining 17 sets of data was addressed through the comparative climate risk analysis. Finally, associated data from the first 11 questions from the questionnaire were inputted in this FBR model to rank and analyse the top potential risks posed by climate change.

Table 2. Questionnaire results of climate risk analysis on UK railways.

Environmental driver due to climate change	Potential climate threat on the railway	Result of risk level	Utility value	Ranking
Temperature increase	A1. Track buckling causing derailment risks & reducing opportunities for track maintenance	{0.1154, 0.1808, 0.3003, 0.1922, 0.2116}	0.54	6
	A2. Unreliable signalling, power line side systems, failure of temperature controls and overheating of electronic equipment	{0.8580, 0.2016, 0.3228, 0.2116, 0.1783}	0.54	6
Intensive rainfall/flooding	B1. Bridge foundations damaged leading to bridge collapse and derailment risk	{0.1083, 0.3299, 0.2613, 0.2109, 0.0896}	0.47	1
	B2. Landslips caused obstruction in increasing derailment risk	{0.1590, 0.2313, 0.2406, 0.2700, 0.0991}	0.48	2
	B3. Heavy rain affect visibility, scheduled work may have to be rescheduled for safety and welfare reasons	{0.0621, 0.1617, 0.2115, 0.3192, 0.2455}	0.6	7
	B4. Track drainage overloaded leading to flooding of the track	{0.0927, 0.2874, 0.2502, 0.2716, 0.0981}	0.5	3
Increased intensity and/or frequency of high wind and/or storms	C1. Trees falling onto the line	{0.1138, 0.2045, 0.2863, 0.2944, 0.1010}	0.51	4
	C2. High winds affect visibility and scheduled work may have to be rescheduled for safety and welfare reasons	{0.0997, 0.2689, 0.2229, 0.1833, 0.2252}	0.53	5
	C3. Instability of structures	{0.0500, 0.1482, 0.4197, 0.1832, 0.1899}	0.56	8
Sea level rise	D1. Breach of sea wall, flooding and derailment risk	{0.0830, 0.2974, 0.3390, 0.2142, 0.0663}	0.48	2
	D2. Reduced maintenance opportunities, bridges/sea walls may not be safely inspected	{0.0156, 0.2488, 0.3305, 0.2458, 0.1594}	0.56	8

Based on the fuzzy Bayesian approach in Section 3, the climate risk results of each potential climate threat of environmental driver related to UK rails were calculated and elaborated in Table 2. For instance, the impacts of temperature increase were divided into two potential threats, namely, "A1. Rack buckling is causing derailment risks & reducing opportunities for track maintenance" and "A2. Unreliable signalling, power line side systems, failure of temperature controls and overheating of electronic equipment". Then, the evaluations of the two threats were based on the four aforementioned risk parameters: Timeframe (T), Likelihood (L), Severity of occurrence (C) and Climate Resilience (S).

Utilising Equation (6) and Hugin software (HUGIN v.8.5 2017), the risk results of "A1. Rack buckling causing derailment risks & reducing opportunities for track maintenance" and "A2. Unreliable signalling, power line side systems, failure of temperature controls and overheating of electronic equipment" can be calculated as {11.54% RL1, 18.08% RL2, 30.03% RL3, 19.22% RL4, 21.16% RL5} and {8.58% RL1, 20.16% RL2, 32.28% RL3, 21.16% RL4, 17.83% RL5}, respectively. According to Equation (7) and Hugin, their risk index values are calculated both as 0.54.

Based on the ranking in Table 2, the highest potential climate threats to British rail are "B1. Bridge foundations damaged leading to bridge collapse and derailment risk", "B2.Landslips caused obstruction in increasing derailment risk" and "B4.Track drain-age overloaded leading to flooding of the track" due to the intensive rainfall/flooding, as well as"D1.Breach of seawall, flooding and derailment risk" due to sea level rise. Interestingly, all the top potential climate threats are attributed to the intense rainfall/flooding. However, the lowest threats are "C3.Instability of structures" owing to the increased intensity and/or frequency of high wind and/or storms, and "D2.Reduced maintenance opportunities, bridges/sea walls may not be safely inspected" posed by sea level rise.

5 DISCUSSION & CONCLUSION

This paper presents an innovative mathematical FBR model to quantify the risks posed by climate change and applied to the British rail system through conducting a nation-wide survey. Fuzzy Bayesian Reasoning (FBR) approach, in which subjective evaluations by domain experts, enables to complement the unavailable objective data to realise climate risk ranking under high uncertainty in data. Based on the previous modelling research of climate adaptation in ports (e.g., Ng et al. 2013, Yang et al. 2015, 2016, 2017), this Fuzzy-Bayesian Network is innovated by employing the climate resilience (S) as the fourth most important junior parameter in assessing climate risks taking, as well as dividing the Severity of consequences (C) into three subcategories ("Damage to Infrastructure (INF)", "Injures and/or Loss of Lives (INJ)" and "Damage to Environment (ENV)"). We believe that this new risk analysis model will offer a more precise and effective tool for researchers and rail stakeholders to tackle the uncertainties in responding to climate risks.

To test the feasibility of the model and provide the empirical evidence on its applicability in the transport industry, a large scale of surveys were conducted to collect data for the analysis of climate risks threatening the rail systems in the UK. Through previous literature reviews, we identified four primary environmental drivers due to climate change. The risk level for each potential climate threat was evaluated by the timeframe of climate hazards, likelihood of occurrence, severity of consequences, and infrastructure resilience. Unsurprisingly, the top potential climate threats to British rail are highly related to the occurrence of intensive rainfall/flooding, which is also consistent with the current priorities of adapting to flooding issues in climate change adaptation planning in the UK. It is noticeable that the research presented is part of an ongoing project and further activities and data collection (i.e., a second-round survey and in-depth interviews) are expected. Nevertheless, the outcomes of this study will provide policy makers and transport planners with useful insights for the identification of climate hazards of high risks to facilitate the development of cost-effective climate adaptation strategies before the final implementation of the relevant infrastructure.

One of the current dilemmas in climate risk assessment is that traditional probabilistic risk analysis (PRA) methods usually pay insufficient attention to a particular type of climate change event or transportation assets. This study focuses on primary impacts of climate change on British rail systems, to provide region-specific customisation and ongoing trend observation. Further research on other transport modes (e.g., road and air) and multiple regions (i.e., developing countries) is vital to establish a practical and robust adaptation framework on climate change. Hence, the present preliminary analysis that this study makes will be incorporated into a comparative study of climate risks and adaptation in the rail and road systems on the next stage. Also, it is suggested that there are more quantitative estimates, cost-effectiveness evaluations and more complex decision models to increase the robustness of the risk model (Adger et al. 2007, Walker et al. 2011, Wu et al. 2013). Accordingly, the next step of this

research is to investigate the relationship between climate change risk reduction and the costs of adaptation measures. A new economic model will be constructed complementary with the current FBR model and evidential reasoning techniques to enhance data consistency and credibility to the overall modelling.

ABSTRACT: The Florida Public Hurricane Loss Model (FPHLM) is a catastrophe model, which estimates hurricane damage. The FPHLM team has access to three main sources of exposure and claims data: county tax appraiser databases, National Flood Insurance Program (NFIP) portfolios, and private wind insurance portfolios. These databases were processed and cross-referenced at the county level. The FPHLM hazard team assigned estimates of surge and wave height, or fresh water inundation height, to each NFIP claim, as well as estimates of wind speed to each wind claim. The paper shows how combinations of more accurate building descriptions and cause of loss facilitates FPHLM flood model development, calibration and validation. The reliability evaluation, cleaning, geocoding, alignment, and integration of the different datasets, as well as the methods for the development, calibration and validation of the model are described. This is a work in progress and the paper presents some preliminary vulnerability curves.

1 INTRODUCTION

The purpose of catastrophe models such as the Florida Public Hurricane Loss Model (FPHLM) is to estimate the potential damages caused by hurricane events, including coastal flood (storm surge), inland flood, and wind. Cat models have three main components: a hazard component, which models the hurricane hazards; a vulnerability component, which model the effect of the hazard on the buildings; and an actuarial component, which translates the damage into insured losses.

Calibration and validation of the FPHLM wind and flood models outputs are conducted in part by comparisons against historical National Flood Insurance Program (NFIP) and wind insurance claims data. These comparisons require that different kinds of information are available including: 1) actuarial claim data, like values, and cause of loss; 2) building claim data, like location, elevation, age, and building characteristics; and, 3) hazard data, like date and type of event, and hazard intensity.

Once this information has been gathered for all claims in a portfolio, the teams can use the data for model development, validation and calibration. In the first case, vulnerability curves can be derived based on direct or indirect regression analysis techniques on the enhanced claim data. In the second case, empirical vulnerability curves, obtained through regression analysis of the claim data vs. hazard intensity, are compared to the corresponding model vulnerability curves. The empirical and modeled vulnerability curves are then compared to validate the FPHLM flood and/or wind models.

A challenging aspect of this methodology is that, very often, the building data in the insurance portfolios are incomplete, missing, or erroneous, and the hazard intensity data is not provided. The purpose of this paper is to describe the process for gathering missing information, and the methodology for associating that information with a specific claim. Aspects of the subsequent model development, validation and calibration processes are then described.

2 FLORIDA PUBLIC HURRICANE LOSS MODEL

The Florida Office of Insurance Regulation (FLOIR) sponsored the development of the Florida Public Hurricane Loss Model (FPHLM) as a tool for insurance regulation in the state of Florida (FPHLM, 2016; Hamid et al., 2011). The FPHLM originally analyzed portfolios of single family homes, including manufactured homes, subject to wind hazard only. Currently, the scope includes commercial residential buildings (either apartment or condominium buildings), as well as inland and coastal flooding. The purpose of the model is to predict aggregated insured losses for residential properties in the form of annual expected losses (AEL) and probable maximum losses (PML). Such loss estimates are used by insurance companies and state regulators to help evaluate rate filings. The model can also be used to conduct scenario analyses to estimate losses for hypothetical events and historical storms.

Under the sponsorship of FLOIR, the FPHLM team has recently expanded the previously wind-only scope of the FPHLM to include coastal and inland flood hazards (Baradaranshoraka et al., 2017). Their strategy was to adapt the large body of tsunami related building fragility curves, especially the work of Suppasri et al. (2013), to coastal flood, and to adapt the work of the USA Corp of Engineers (USACE, 2006, 2015) for inland flood. In all the models, building vulnerability curves provide estimates of mean building damage ratio as a function of hazard magnitude (wind speed in the case of wind, and inundation height in the case of coastal or inland flood) (Pinelli et al., 2011). The damage ratio is the cost of repair of a damaged building divided by the replacement value of the building. Paramount to that effort is the validation and calibration of the building vulnerability curves.

In addition to building damage, which includes the damage to both the exterior and interior of the building, insurance companies cover the contents damage. Contents is anything inside the building but not attached to the building (e.g. furniture, rugs, appliances, etc.). These contents vulnerability curves are being developed based on regression techniques using the flood claim data, as described in this paper.

3 DATABASES

The FPHLM teams use three primary sources of exposure and claim data

- The National Flood Insurance Program (NFIP) database: exposure files, and a claim files
- Twenty three wind insurance companies: exposure files and claim files
- County tax appraiser databases: building descriptors

Exposure files include all the policies insured by a given company, while the claim files include only the policies that suffered a loss for a particular event. The datasets provided by these sources are briefly summarized below.

3.1 *NFIP database*

The NFIP claims and exposure portfolios were provided to the FPHLM by FLOIR. The claims database contains 153,751 claims between July 1975 and January 2014 for 126 different flood events. The exposure portfolios were provided by year from 1992 to 2012. A combined portfolio was created containing all policies between 1992 and 2012. The hazard team analyzed the claims data locations and dates to associate a specific hazard to a given claim. From these datasets, a trial dataset of 43,552 claims from the eight storms with the most claims was chosen for validating the FPHLM. The eight storms are listed in Table 1.

The NFIP claim files contain information such as the date of loss, policy number, physical address, cause of damage, total property value, financial damage to building and contents, and replacement cost. Fields are present in the files for structural information such as exterior wall type and foundation type, but do not contain values for 97% of the claims. The exposure files contain policy number, flood zone, address, original construction date, base flood elevation, and more, but no structural building information.

3.2 *Tax appraiser databases*

Tax appraiser (TA) datasets have been collected for a total of 51 counties and comprising approximately 97% of Florida's population. However, the Miami-Dade TA database contains virtually no information useful for the purposes of FPHLM calibration and validation.

An ideal TA dataset would include all building properties and components that are damageable by a hurricane: interior and exterior wall composition, roof shape, roof covering, floor covering,

Table 1. Hurricane events currently included in the claims trial dataset from NFIP and wind portfolio databases.

Storm ID	Storm name	Storm year
AL041992	Andrew	1992
AL071998	Georges	1998
AL032004	Charley	2004
AL062004	Frances	2004
AL092004	Ivan	2004
AL112004	Jeanne	2004
AL042005	Dennis	2005
AL252005	Wilma	2005

year built, and number of stories. In addition, the building location, elevation, footprint area, and the number of apartment units per building is desired. However, there is no uniform format or content standard across the different county TA databases, and the amount and quality of data collected by each tax appraiser differs from county to county.

The TA databases typically consist of data tables, which contain the building attribute information, and GIS shapefiles, which typically contain the polygons defining the geographic boundaries of each parcel, and the unique parcel identification number in a linked database file. Some counties did not provide GIS shapefiles, or the shapefiles did not contain parcel identification numbers that matched any unique identifiers in the data tables. When that occurred, GIS shapefiles were sourced from the Florida Department of Revenue which contained parcel identification numbers matching those provided by the county.

3.3 *Wind insurance portfolios*

The wind insurance claim datasets represent 23 different wind insurance companies and nine hurricane events. There are 667,573 claim records among all the insurance portfolios and hurricane events. The data contained in the claim files varies by company and event, but generally include the policy ID, zipcode, county, year built, construction type, and loss to structure, contents, appurtenant structures, and time related losses (additional living expenses). The exposure portfolios also vary in details provided, but generally include policy ID, zip code, county and construction type (frame or masonry). A few companies provided more detailed exposure files that included roof shape, number of stories, roof cover and opening protection. In all, the exposure files contain 13.5 million policies. The latitude and longitude values and/or addresses are provided in the 2012 exposure files for the location of the individual building, and in the claim data files for some of the 2004 and 2005 hurricanes. The precise locations of the buildings in the 2012 exposure portfolios makes it possible to relate the exposure information to NFIP or tax appraiser databases, which is the grand challenge for integrating these datasets. It makes it also possible to identify the location of some claim records, based on the policy ID.

4 PROCESSING OF THE DATABASES

4.1 *Reformatting*

The first step in processing the databases was to reformat the building attribute data contained within the exposure, claims and TA databases into a consistent nomenclature. The standard nomenclature for the main building attributes are provided in Table 2. For each attribute within each database, a link table was developed to relate the unique values for a given attribute within the database to a value matching the common nomenclature provided in Table 2. This process is illustrated in Table 3, where unique values of exterior wall type from the Martin County TA database are recorded to match the standard nomenclature. Generating the link tables was intuitive for most counties and attributes, but documentation on the exact definition of attribute values were generally not available from the counties, which introduces uncertainty in the link tables. For example, in Table 3 it is unclear what type of structural system "Fire Resistant" actually refers to, and so without any other supporting documentation, it is coded as "other" .

Table 2. Common nomenclature for primary building attributes.

Building use	Building category	Roof shape	Roof cover	Exterior wall
RES	PR	Gable	Shingle	Timber
MANUF	LR-CR	Hip	Tile	Masonry-unreinforced
RENTAL	MHR-CR	Other	Metal	
CONDO			Other	Masonry-reinforced
COM				
Other				Other

Table 3. Example link table to reformat attributes into common nomenclature.

TA-Assigned exterior wall	Common nomenclature
Wood frame	Timber
Concrete block	Masonry
Fire resistant	Other
Conc block 12	Masonry
Concrete	Masonry
Reinforced concrete	MasonryR
Fireproof steel	Other
Metal	Other
6 Concrete block	Masonry
Stone local cut	Other
8 concrete block	Masonry

4.2 *Geocoding and integration of the databases*

For a given building with a claim due to flood-induced and/or wind-induced damage during a hurricane, the following data sources can be joined: 1) standardized building attribute infor-

mation from the county TA database, 2) the wind insurance exposure portfolios, 3) the NFIP exposure portfolio, 4) the NFIP claims portfolio, 5) the wind claims portfolios, and 6) the hazard model output. Combined, this will allow for the classification of the claims by building type and hydrological states in the case of flood hazard, where 4 different flood condition states were defined by via the relationship between the wave height to inundation depth. This will facilitate the development of semi-empirical vulnerability curves, as explained in the next section, as well as the comparison of empirical vulnerability curves against the engineering model curves, to facilitate validation and calibration.

The various databases are joined by specific links as illustrated in Figure 1. The links can broadly be classified in two ways—spatial joins and table joins. In table joins, a common field between two fields was used to link different databases together. Table joins based on policy number were used to join the NFIP claims and exposure portfolios, and table joins based on a unique parcel identification number were used to join the tax assessor data tables and shapefiles containing the individual parcel polygons. Two methods of spatial joins were used. For generating the hybrid database linking the hazard model outputs with the NFIP claim portfolio, first the physical address contained in the NFIP exposure database was geocoded to obtain a GPS coordinate. Then the hazard model generated coastal flood heights and/or inland flood heights at the geocoded location for each claim, and the outputs were joined by matching the GPS coordinates (match-spatial-join). Finally, for combining the TA database with the hybrid hazard-NFIP database and, if necessary, the wind exposure or claim

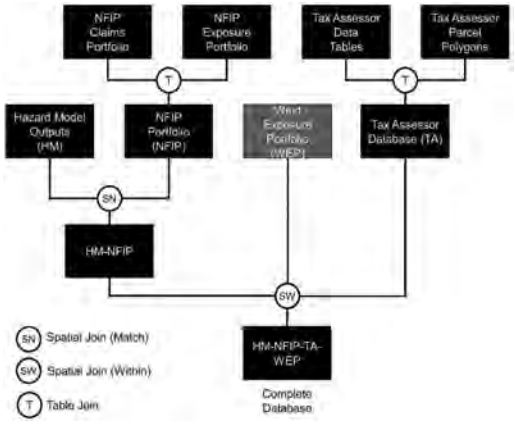

Figure 1. Process for linking hazard model output, NFIP claims and building attributes.

portfolios, a within-spatial-join was used. This was accomplished by coding a graphical user interface (GUI) in Matlab (Mathworks, 2016a) that reads in the county shapefiles and finds any elements (using the GPS coordinates obtained from geocoding the physical address) of the hybrid hazard-NFIP database or wind exposure or claim portfolios that fell within a parcel polygon. For each claim that fell within a parcel polygon, the associated building attributes from the TA database and the wind exposure portfolio were appended to the hybrid hazard-NFIP database, providing a combined dataset linking claims, hazard intensities and building attributes.

4.3 *Hazard information*

The NFIP claims data contains several attributes which can link the loss to a hazard event for each claim. Among these attributes are the "catastrophe number", "cause of loss", "date of loss" and property location. However, upon close examination of the data the FPHLM team found that the information provided by these attributes are not always complete or accurate, and do not provide sufficient detail pertaining to the hazard event. For example, the catastrophe number is often missing, or multiple hazard events may be assigned the same number if they occur around the same time period. The cause of loss often appears to be incorrect. The team found cases where the loss was listed as "Tidal Water Overflow", even though the property was too far from the coast for such an event to occur. In addition, the claims data do not provide important hazard information, such as the flood elevation or wave conditions.

In order to remedy the above issues, algorithms based on observed hazard information from a variety of sources associated hazard event information to each claim. New attributes appended to the claims data provide this information. When no observations are available, such as the case for flood elevation or wave conditions, models provided these estimates. The paragraphs below describe the new attributes.

Distance to coast is the distance of each property to the nearest coast. This information is useful to determine if coastal flood was likely to occur. The team computed the distance using the 2011 Multi-Resolution Land Characteristics Consortium (MRLC) National Land Cover Database (NLCD) (Homer et al., 2015). The NLCD has approximately 30 meter resolution and has a classification for water body. A heuristic algorithm distinguishes coastal waters from inland bodies of water.

Distance to nearest body of water. This information was computed similarly to the distance to

coast, but computes the distance to nearest body of water, regardless of type. This can help determine if the flooding could be due to river, stream or lake overflow.

Precipitation maximum. This data was derived from the high resolution (4 km) PRISM daily rainfall database (Daly et al, 2008). The team selected the largest precipitation amount that occurred with +/– 1 day and within 10 km of the property location. This information helps determine if the cause of loss could be due to accumulation of rainfall.

Storm identification. Many of the claims are due to tropical storms or hurricanes. The HURDAT2 database, from the National Hurricane Center, determines if a storm was in the vicinity of the property during the claimed date of loss. An additional attribute is also provided to include an indication of the storm intensity level (depression, tropical storm or hurricane).

Flood elevation and wave height. Since observed flood elevation data is generally not available, a coastal flood model provided an estimate of the flood elevation due to surge, and an inland flood model in the case of flood due to the accumulation of rainfall. The coastal flood model is based on the CEST model (Zhang et al, 2008), and was driven by estimated observed winds from the H*Wind analyses (Powell et al., 1998). The inland flood model is based on the SWMM model and was driven by observed NEXRAD rainfall data. A simplified wave model developed at the University of Notre Dame was used to provide an indication of wave conditions in the case of coastal flood.

The above information from these new attributes lead to a revision of the cause of loss. If the original cause of loss was tidal water overflow, but the distance to coast was greater than 20 km, the team then checked the precipitation maximum. If it is greater than 1 inch, the cause was revised to be accumulation of rainfall, otherwise it is designated as questionable. If the original cause of loss was accumulation of rainfall, but the precipitation maximum was less than 0.2 inch, then the cause of loss is marked as questionable. For hurricane events, if the original cause of loss is unknown for a property that is less than 20 km to the coast and the precipitation maximum is greater than 1 inch, then the cause of loss is marked as undetermined but is either tidal water overflow or accumulation of rainfall, and further review is needed. Otherwise the cause of loss is marked as tidal water overflow.

The end result is that each claim in the NFIP portfolio can be assigned to one of four hydrological states: inland flood with no waves; coastal flood with minor waves; coastal flood with moderate waves; and, coastal flood with severe waves.

A similar process assigns wind speed to each claims in both the NFIP and wind insurance portfolios but is not reported here.

5 DEVELOPMENT, VALIDATION AND CALIBRATION OF FLOOD VULNERABILITY CURVES

5.1 *Introduction*

The processing of the data is still in progress and will result in enhanced NFIP and wind claims subset that contains loss, value, hazard and hazard intensity, and structural characteristics. When complete, the enhanced NFIP claims data will be used for the development of the flood content vulnerability curves, and the validation and calibration of the FPHLM flood building vulnerability curves.

The model building or content vulnerability curves output are the expected damage ratios (mean damage over replacement value), where the replacement value is the cost to replace the property with a new item of like kind and quality. In the claim data, building and content coverage are used as proxies for the respective building and content replacement values. In the case of the NFIP data, there is no reliable replacement value data provided, and the coverage limits in the NFIP policies are not a true measure of the value of a building or its content. In the future, this issue will be solved through a triangulation between the TA databases, the NFIP exposure files, and the wind insurance exposure files. The idea is to use the coverage limits of the wind policies (which is a better measure of the true value of building or contents) as a proxy for the replacement values of the building and contents in the NFIP claims and exposure portfolios.

Another issue is that extreme hazard events have very large return periods and are underrepresented or altogether absent from the historical claim data. For example, the number of NFIP claims within the State of Florida with a hazard intensity of more than 1.5 m (5 ft) is not significant, and this problem becomes more pronounced as the flood height increases. Hurricanes such as Katrina produced storm surges more than 20 feet (The maximum high water mark observation was 27.8 feet at Pass Christian, MS) (NOAA, 2006), however the storm surge height for the State of Florida only reached up to 5 feet and the FPHLM is constrained to claims in the State of Florida. The result is that any validation and calibration of a vulnerability model based on claim data is more applicable to lower hazard intensities.

This last issue also complicates the development of vulnerability models based on simple regression over the claim data, since not only the assignment of hazard intensity to the claims is subject

to caution, but there might be no data to regress upon for higher hazard intensities. To resolve this problem, the FPHLM team developed the method for the creation of contents vulnerability curves.

5.2 *Development and calibration of contents vulnerability curves for coastal and inland flood*

The FPHLM team used the NFIP claim data in the development of the coastal and inland flood model content damage component. The building vulnerability curve are converted into a content vulnerability curve using a relationship derived from the NFIP claim data. To derive this relationship, the building damage ratio (building damage to building coverage) and content damage ratio (content damage to content coverage) are calculated for each claim.

Figure 2 shows a plot of content damage ratios vs. building damage ratios for a subset of the NFIP claim data of personal residential buildings that have a masonry structure, are not elevated, and are one or two stories. The data is from 16 counties, where the structural information and number of stories have been added (around 6000 of the 43,500 paid claim data for the eight hurricane events stated in Table 1). The 16 counties are spread throughout the State of Florida and contain more than half of the NFIP claim data for the entire state. The NFIP claim data does not provide information regarding the structure type or the number of stories and these were added by matching the NFIP claim data with the tax appraiser databases.

A statistical analysis using a two-way histogram defines the relationship between building damage and content damage ratios. Figure 3 shows a plot of the content damage ratio vs. the building damage ratio relationship derived using statistical analysis with the corresponding curve fit.

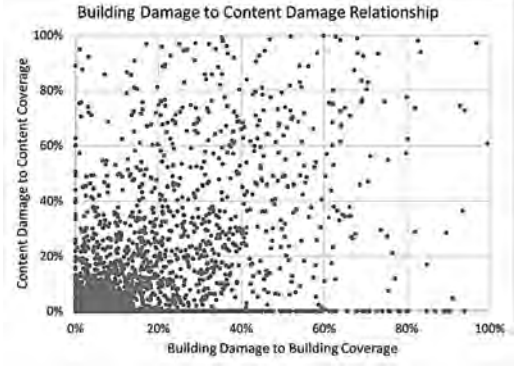

Figure 2. Example of building damage ratio to content damage ratio relationship.

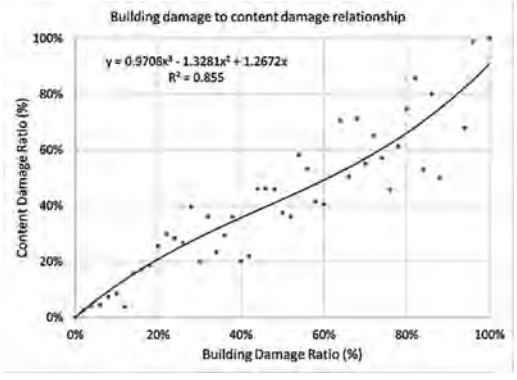

Figure 3. Example of the plot of the building vs. content damage ratios and the polynomial line fitted to the mean values.

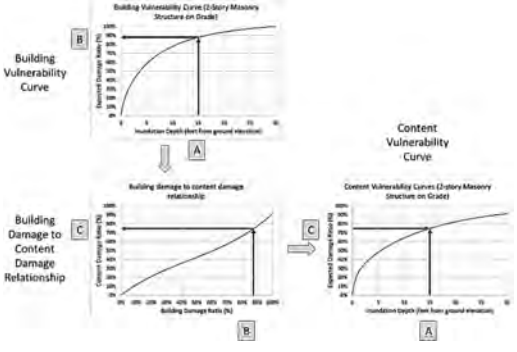

Figure 4. Converting the building vulnerability curves into content vulnerability curves using the building and content damage ratios relationship.

Figure 4 illustrates the process of converting the building vulnerability curves into content vulnerability curves for a two-story on grade masonry structure susceptible to coastal flood with *severe* waves.

The process starts with the building vulnerability curve. For specific hazard intensity ("A" box on the top left graph of Figure 4) we identify the building damage ratio ("B" box on the top left graph). Then, we move to the building and content damage ratios' relationship curve. For the specific building damage ratio found in the first curve ("B" box on the lower left graph), the content damage is identified ("C" box on the lower left graph). Now, for the specific hazard intensity ("A" box on the lower right graph) we know what the equivalent content damage is ("C" box on the lower right

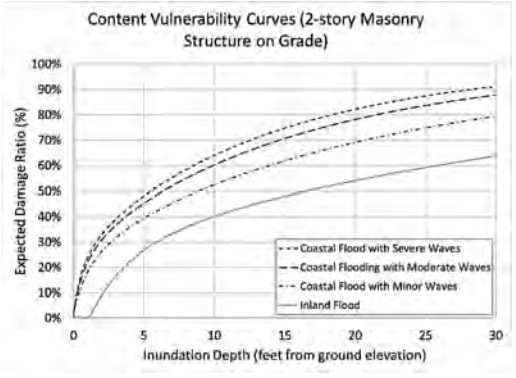

Figure 5. Example of content vulnerability curves. (1 ft = 0.305 m).

graph). This will give a point in the content vulnerability curve. Repeating this process for different hazard intensities will result in the content vulnerability curve.

This methodology resolves the issue of the uncertainty attached to the assignment of a specific hazard intensity to each claim. Instead the claims are simply grouped, according to their appurtenance, to one of the 4 hydrological states. It also resolves to a certain extent the lack of claim data for higher hazard intensities, by combining the claim data with the building vulnerability model, which extends to the whole range of hazard intensity. Finally, it ensures the compatibility between both the building vulnerability model, the claim data, and the resulting content vulnerability model.

Figure 5 shows an example of content vulnerability curves for different hydrological states of a two-story on grade masonry structure. These results are preliminary and intended for the development of the methodology. Significant refinements to the building vulnerability curves are in progress, and the resultant content vulnerability will differ from that shown in Figure 5.

6 CONCLUSIONS AND RECOMMENDATIONS

The analysis of insurance claims data provides a way for developing, validating, and calibrating hurricane risk model outputs. However, before they can be used they need to go through extensive processing and interpretation. This paper describes some of the challenges risk modelers face while handling insurance claims data.

The paper presents a methodology to convert building vulnerability curves into content vulnerability curves using the building damage to content damage relationship derived using NFIP insurance claims data. This method produces contents vulnerability curves compatible with both the claim data and the building vulnerability models.

This is a work in progress. Additional work includes: the validation of the building vulnerability curves, within the limitations of the data; the validation of the wind model; and, the validation of the combined wind and flood model

In addition, the merging of tax appraiser databases with the wind and flood insurance portfolio has the potential of increasing the accuracy of the portfolio analyses, since more data will be available during the analyses.

ACKNOWLEDGEMENT

The Florida Office of Insurance Regulation provided financial support for this work. The opinions, findings, and conclusions presented in this article are those of the authors alone, and do not necessarily represent the views of the FLOIR. Special thanks to Yuepeng Li from Florida International University, and Andrew Kennedy from University of Notre Dame, who provided hazard information

Optimizing warnings for slippery runways based on weather data

Arne B. Huseby
University of Oslo, Oslo, Norway

Marit Rabbe
Air Navigation Services, Avinor, Norway

ABSTRACT: Slippery runways represent a significant risk to aircrafts especially during the winter season. In order to apply the appropriate braking action, the pilots need reliable information about the runway conditions. Unfortunately the accuracy of runway reports can sometimes be unsatisfactory. In order to obtain more precise and up-to-date information about the current conditions, a warning system based on various types of weather data was suggested by Huseby & Rabbe (2012). See also Huseby & Rabbe (2008) and Huseby et al. (2010). The system is based on a set of scenarios known to cause slippery conditions. By monitoring meteorological parameters like air and ground temperature, humidity, visibility and precipitation, and comparing these to the given scenarios, the system can issue warnings to the ground personnel. This system is currently being used on 16 Norwegian airports. In the present paper this warning system is reviewed. Ideally, the warning system should issue warnings whenever the estimated runway conditions are medium or worse. At the same time the system should not issue warnings when the runway conditions are good. Thus, there are two types of errors we need to take into consideration. Type 1 errors occur when the system does not issue a warning even though the conditions are medium or worse, while Type 2 errors occur if a warning is issued when the conditions are good. When designing the system, we need to find the optimal balance between these types of errors taking into account that a Type 1 error to a certain degree is considered to be worse than a Type 2 error. The paper describes how the system can be optimized using a combination of weather data and flight data.

1 INTRODUCTION

Slippery runways represent a significant risk to aircrafts especially during the winter season. Accidents, such as the Southwest Airlines jet skidding off a runway at Chicago Midway Airport in December 2005, as well as the similar accident with the Delta Connection flight at the Cleveland Hopkins International Airport in Ohio in February 2007, show that this is indeed a serious problem. More recently, an aircraft skidded off the runway at Oslo Airport in May 2015 due to wet conditions. Fortunately this accident only caused minor damages.

In order to apply the appropriate braking action, the pilots need reliable information about the runway conditions. Unfortunately the accuracy of runway reports can sometimes be unsatisfactory. During the Southwest Airlines accident the pilots based their landing on an assumption that conditions were fair. However, computer calculations after the crash showed that the actual conditions were in fact worse than poor. Given the correct information about the landing conditions, including a significant tailwind of 8–9 kt, the flight should in fact have been diverted. For more details about this accident see Rosenker et al. (2007). For a discussion of the effect of contaminated runways on aircraft braking performance see Giesman (2005).

Having reliable methods for identifying slippery runway conditions is very important. However, measuring the runway friction with a satisfactory precision is very difficult. There are two main reasons for these problems. Firstly, measuring the runway friction with a satisfactory precision is very difficult. While many different measurement devices have been developed, it is hard to find equipment that produces stable and consistent results. The second problem is that in order to measure friction, the runway needs to be closed for traffic. Thus, in order to avoid severe delays, such measurements cannot be carried out too frequently. As a result the runway reports are not as useful as one could hope. This is especially true during heavy snowfalls, or when the temperature suddenly drops below the freezing point, where the conditions change very rapidly.

Rosenker et al. (2007) discusses the difficulties with assessing runway condition, and notes that

no standardized and universally accepted correlation exists to define the relationship between the runway surface condition, using any of the available runway surface assessment methods, and an airplane's braking ability.

In Haugen et al. (2002) an alternative approach to this problem was developed. Contaminated runways were characterised in terms of a function of local weather parameters. The main idea was that this function would be easier to update compared to friction measurements which are based on the last runway report. Thus, by using weather data one could bridge the gaps between the runway reports.

Based on a large-scale study of runway conditions carried out during two winter seasons at two Norwegian airports the ideas suggested in Haugen et al. (2002) were developed further. A complete report from this project, referred to as the SWOP-project, is given in Aarrestad et al. (2007). The study was carried out by *Avinor*[1] with contributions from the three airlines SAS, Norwegian and Widerøe. As in Haugen et al. (2002) the main goal was developing methodology for predicting runway conditions utilizing weather data in addition to runway reports. Throughout the two seasons various kinds of weather data were collected, such as air and surface temperature, humidity, precipitation, visibility and wind. Using these data a scenario based weather model for slippery conditions was developed. At a given point of time, the weather model compares the current conditions to a set of different scenarios. If the conditions match any of these scenarios, the model classifies the runway conditions as *potentially slippery*.

Using the experiences from the SWOP-project, an integrated runway information system, called IRIS, has been developed. This system is now implemented on 16 Norwegian airports. For a description of this system see Søderholm et al. (2009). This system consists of three parts: a *weather* model, a *runway* model and a *development* model. The weather model uses a scenario approach to identify slippery conditions. A description of an early version of this model can be found in Huseby & Rabbe (2008), while a revised version is presented Huseby & Rabbe (2012). The weather model currently in use is yet another revision based on more recent data. The runway model uses mainly runway report data and assesses runway conditions on a five level scale ranging from *poor* to *good*. This model is discussed in Huseby et al. (2010). See also Klein-Paste et al. (2012). The development model combines runway report data and precipitation and temperature data in order to issue warnings when the runway conditions appear to be deteriorating.

In the present paper we focus on the weather model and show how this model can be optimized. In order to analyze and optimize the model, a large data set including weather data, runway report data and flight data has been collected. The full data set consists of data from 16 Norwegian airports. In the present paper, however, we only consider data from the airports at Oslo and Tromsø. For both airports we have observations from *9 winter seasons* starting at the winter 2008/2009. The weather observations are sampled every minute starting at midnight November 1 and ending at midnight April 30. The flight data sets are provided by Scandinavian Airlines Services (SAS) and Norwegian Air Shuttle AS. In this paper, however, only the flight data sets from SAS are used. At Oslo airport there are two runways, *West* and *East*. In the analysis these runways are treated separately.

2 FRICTION LIMITED LANDINGS

In order to optimize the weather model, flight data was obtained from the Quick Access Recorder of Boeing 737-600/700/800 NG airplanes. The data was provided with approval of the Pilots Associations of the cooperating airlines. Starting at the time of touchdown, a 60 seconds record was taken including among others the following main parameters:

- Airplane weight
- Longitudinal acceleration
- Airspeed
- Ground speed
- Flaps settings
- Spoiler settings
- Engine rotational speed
- Brake pressures
- Auto brake settings
- Longitude and latitude positions

The flight data was analyzed using the *Boeing Airplane Performance model* which is based on general equations of motion for airplane, along the length direction of the runway. The model gives an *airplane braking coefficient*, denoted by μ_B. This parameter is used to represent the contribution of the wheel brakes to stopping the airplane. The coefficient μ_B is the ratio of the stopping force contribution of the wheel brakes to the average airplane weight on wheels. In general μ_B will include both the wheel braking and the effect of contaminant drag force.

A key concept when analysing flight data is the notion of *friction limited landings*. Unless the pilot challenges the runway friction during the

1. Avinor is a state owned limited company that operates most of the civil airports in Norway.

landing, the maximum friction available will not be utilized. In this case μ_B reflects the amount of tire-pavement friction that was used. When wheel brakes are applied fully or to a high degree on a slippery runway, the maximum attainable friction from the runway is used during the stop. In this case the airplanes deceleration and stopping capability is limited by the friction available from the runway. The obtained μ_B will then reflect the amount of tire-pavement friction that was available. It is therefore crucial to determine whether or not the stop was limited by the friction available from the runway. A landing where this is the case, is said to be *friction limited*. For more details about the Boeing Airplane Performance model see Klein-Paste et al. (2012).

Given the airplane braking coefficient μ_B it is possible to obtain the socalled *runway braking action* (BA) associated with the landing. This is a simplified measure given according to a five level scale randing from *poor* to *good*. The relation between μ_B and BA is given Table 1.

In the validation of the weather model only the friction limited landings are used. In Table 2, Table 3 and Table 4 the total number landings as well as the number of friction limited landings for the three runways are listed. In the same tables we have also included the number of landings with braking action level less than or equal to 3 (i.e., *medium*).

Table 1. The relation between μ_B and runway Braking Action (BA).

μ_B	BA-level	BA
[0.000, 0.050]	0	NIL
(0.050, 0.075]	1	Poor
(0.075, 0.100]	2	Medium to poor
(0.100, 0.150]	3	Medium
(0.150, 0.200]	4	Medium to good
(0.200, ·]	5	Good

Table 2. Number of friction limited landings at Oslo West.

	Count	Percentage
Total number of landings	57324	100.0%
Friction limited landings	997	1.7%
Landings with BA ≤ 3	845	1.5%

Table 3. Number of friction limited landings at Oslo East.

	Count	Percentage
Total number of landings	54794	100.0%
Friction limited landings	981	1.8%
Landings with BA ≤ 3	764	1.4%

Table 4. Number of friction limited landings at Tromsø.

	Count	Percentage
Total number of landings	12362	100.0%
Friction limited landings	2214	17.9%
Landings with BA ≤ 3	1866	15.1%

3 THE WEATHER MODEL

In this section we review briefly the scenario based weather model which is a central part of the runway condition prediction methodology. This model is based on the work in Rabbe (1974), and includes eight different scenarios which are known to cause slippery runway conditions. In this context we will not describe all these scenarios in detail. Instead we refer to Huseby & Rabbe (2012) for a more complete description.

All scenario evaluations are typically done relative to a given point of time T representing the touchdown point of time for a given flight. In order to describe the weather conditions and check whether or not any of the scenarios has occurred at T, weather data from two time intervals $[T - S_2, T - S_1]$ and $[T - S_1, T]$ is used. In our study $S_1 =$ 1 hour, while $S_2 = 4$ hours. The length of the first interval is $(T - S_1) - (T - S_2) = S_2 - S_1 = 3$ hours, while the length of the second and most recent interval is $T - (T - S_1) = S_1 = 1$ hour. Thus, the two intervals represent a total of 4 hours of observations. Throughout this period the different weather parameters are ideally sampled once every minute, so given the four hours of observations, each weather parameter is sampled 180 times during the first interval and 60 times during the last interval. In real life, the number of observations is typically slightly less than this, but still there is more than enough of data for the model calculations. We assume that all the data are indexed, and let I_1 and I_2 denote the index sets corresponding to the first and second interval respectively. Moreover, for $i \in I_1 \cup I_2$ we introduce:

- p_i = the ith precipitation type,
- t_i^a = the ith air temperature,
- t_i^r = the ith runway temperature,
- h_i = the ith relative humidity,
- v_i = the ith horizontal visibility,

The scenarios are divided into two groups, where the first group includes three scenarios with precipitation, while the second contains the remaining three scenarios with no precipitation.

3.1 *Scenarios with precipitation*

The following five scenarios are all characterized by the presence of some sort of precipitation.

Scenario 1. *Dry snow*
Dry snow is usually not so dangerous as wet snow. However, if this condition persists over some time, the runway may become polished by the snowflakes, which can result in slippery conditions.

Scenario 2. *Snow*
Snowfalls can have dramatic effects on braking performance. Falling snow is typically a mixture of ice crystals and water with a temperature close to 0°C. Dry snow containing less water is less slippery than snow with a higher water content. This scenario is defined to occur when the air temperature is between –6°C and +2°C. Severe conditions occur with heavy snowfalls, temperatures close to the freezing point, and relative humidity close to 100%.

Scenario 3. *Freezing rain/drizzle*
Freezing rain or freezing drizzle occurs when warm air tries to replace cold air from above. If rain or drizzle falls from the warm layer through the cold layer, it will be supercooled on its way down. When these supercooled drops hit the frozen ground, they will freeze immediately, and as a result the runway becomes extremely slippery. The weather sensor can sometimes identify this condition as a specific type of precipitation. However, in our scenario definition, we also include another set of conditions based on the precipitation type *rain*.

Scenario 4. *Freezing fog*
When temperatures at ground level drop to or below freezing, the water droplets making up fog often freeze on contact. This condition is called *freezing fog*. The result can be black ice, which makes the runway very slippery and dangerous.

Scenario 5. *Rain or drizzle on ice-coated or supercooled runway*
When rain or drizzle falls on an ice-coated or supercooled runway, some of it will start freezing. As a result the braking actions will be reduced to a minimum.

3.2 *Scenarios without precipitation*

The scenarios included in this subsection does not involve precipitation, at least not during the most recent interval, $[T - S_1, T]$.

Scenario 6. *Wet runway, clearing sky*
This scenario occurs when the weather is clearing after overcast and rain. Due to the outgoing radiation, the temperature both in the air and in the runway surface gradually drop below zero. The water left on the runway, will then start to freeze, and the friction coefficient may drop quickly.

Scenario 7. *Stratus/fog, air temperature below* 0°C
When a low stratus cloud or a fog layer at freezing temperatures flows into the airport, small drops will settle on the cold runway surface and partially freeze. As a result the runway becomes slippery.

Scenario 8. *Rime, sublimation, ice crystals*
In clear autumn and winter nights the temperature in the air and on the ground can fall below zero. At the same time the humidity increases towards 100%. Sometimes this results in fog, while other times moisture may settle on the runway as rime. When water vapor sublimates on solid objects, the result is ice crystals. Some of this may melt under the wheels of the aircrafts, and create a slippery ice-coat on the runway.

In the analysis the weather model is calculated each minute throughout the 9 winter seasons based on the data from these seasons. As as result we have as many as 2348640 realizations of this model for the three runways in our data set. Figure 1, Figure 2 and Figure 3 show the rates of occurences of the eight scenarios (denoted $S1$, …, $S8$ in the diagrams). We have also included the null-scenario (denoted $S0$ in the diagrams) representing the fraction of the realizations with no identified scenarios. Note that the scenario definitions allow several scenarios to occur at the same time. Thus, the sum of the rates of occurences (including the null-scenario) is greater than 100%.

We observe that the two dominating scenarios are $S2$ (*snow*) and $S8$ (*Rime, sublimation, ice crystals*). Scenario $S2$ is relatively easy to identify. Thus, we will not discuss this scenario further here. Scenario $S8$, on the other hand, is much more difficult to identify. The scenario definition depends

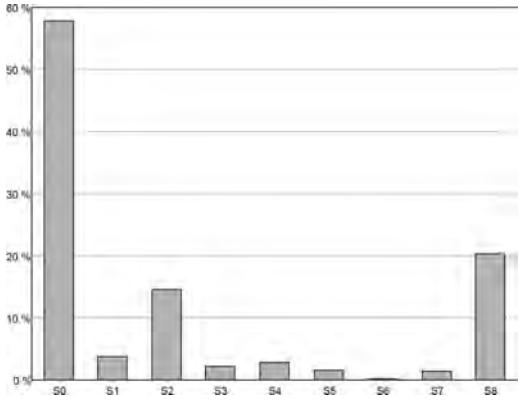

Figure 1. Rates of occurences of the weather scenarios at Oslo West.

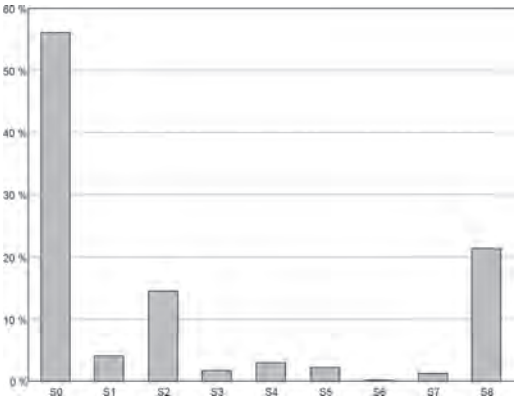

Figure 2. Rates of occurences of the weather scenarios at Oslo East.

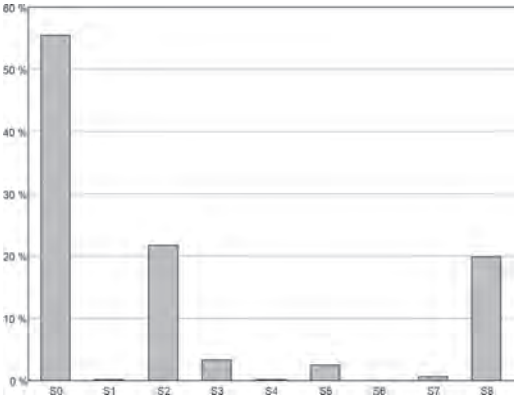

Figure 3. Rates of occurences of the weather scenarios at Tromsø.

on several parameters which need to be finetuned in order to optimize the results. In the next section we show how this problem can be attacked.

4 OPTIMIZING THE RIME SCENARIO

In this section we show how to optimize the rime scenario, i.e. scenario $S8$. We say that this scenario has occurred if the following conditions hold:

- The number of minutes with precipitation[2] during the last 4 hours should not exceed 10.
- The air temperature is decreasing during the last 4 hours, and last value is less than or equal to α°C,

  OR

  The air temperature is less than or equal to 0°C during the last hour
- The runway temperature is less than or equal to 0°C during the last hour
- The relative humidity is in the interval [β%, 100%] at least half of the time during the last four hours

The quantities α and β mentioned in the conditions, are parameters which will be subject to simultaneous optimization. Based on meteorological insight, however, it was decided that the parameters should be chosen within the following intervals: $\alpha \in [0, 3]$ and $\beta \in [70, 85]$. As a *base case* we let $\alpha = 2$ and $\beta = 75$. In the optimization only the parameters α and β will be considered here. However, as scenario $S8$ is only one out of eight scenarios, the contributions of the other scenarios need to be taken into account as well.

One of the difficulties with optimizing the weather model is the lack of precision with respect to the response. Even when the runway is very slippery, this does not need to be reflected in the flight data if the pilot does not challenge the runway friction during the landing. On the other hand even when no weather scenario is identified, the flight data might indicate slippery conditions if this is due to the presence of older contamination on the runway. Thus, when the weather model is applied, a substantial number of both Type 1 and 2 errors are to be expected. Still, finding the best balance between the two types of errors is important.

We now consider an arbitrary point of time t, and introduce the following events:

A = A scenario is identified at time t

B = The true BA-value is 3 or less at time t

A Type 1 error corresponds to the event $A^c \cap B$, while a Type 2 error corresponds to the event $A \cap B^c$. In order to balance the two types of errors, we introduce a loss function L defined as follows:

$$L = \begin{cases} K_1 & \text{if } A^c \cap B \text{ occurs} \\ K_2 & \text{if } A \cap B^c \text{ occurs} \\ 0 & \text{otherwise} \end{cases}$$

The expected loss is then given by:

$$\mathrm{E}[L] = K_1 \mathrm{P}(A^c \cap B) + K_2 \mathrm{P}(A \cap B^c)$$

The constants K_1 and K_2 are relative numbers chosen in order to reflect that a Type 1 error is usually much worse than a Type 2 error. In the analysis we have chosen to let $K_1 = 25$ and $K_2 = 1$.

2. In this context *mist* is not considered as precipitation.

The probabilites $P(A^c \cap B)$ and $P(A \cap B^c)$ are easily estimated based on the available data, and depend on the values of the parameters α and β. In particular the event A is identified using the weather data, while the event B is identified using flight data.

In particular, by using the data in Table 2, Table 3 and Table 4 we get the following estimated probabilities for the event B:

$$P(B) = \begin{cases} \frac{845}{57324} & = 1.47\% \text{ at Oslo West} \\ \frac{764}{54794} & = 1.39\% \text{ at Oslo East} \\ \frac{1866}{12362} & = 15.09\% \text{ at Tromsø} \end{cases}$$

It is easy to see that $P(A)$ is increasing in α and decreasing in β. Hence, the Type 1 error probability, $P(A^c \cap B)$ is decreasing in α and increasing in β, while the Type 2 error probability, $P(A \cap B^c)$ is increasing in α and decreasing in β. Moreover, for the base case where $\alpha = 2$ and $\beta = 75$, we get the error probabilities and expected losses listed in Table 5.

In order to optimize the weather model we run it for all the relevant combinations of the parameters α and β. The resulting expected losses are shown in Table 6, Table 7 and Table 8. The parameter combinations yielding the minimum losses are indicated in bold face.

For Oslo West and East we observe that the optimal values are $\alpha = 0$ and $\beta = 85$. This is the most restrictive combination which implies that the probability of a Type 1 error is at its maximum while the probability of a Type 2 error is at its minimum. From a meteorological perspective, these parameter values are hardly realistic. The reason why this combination still comes out as the best, is due to the fact that Oslo Airport has a fairly proactive runway maintenance strategy which prevents the different scenarios from causing problems. As a result $P(B)$ is relatively small for this airport. Thus, if we use $\alpha = 0$ and $\beta = 85$ instead of the base case values $\alpha = 2$ and $\beta = 75$, the Type 1 error probability increases slightly from 0.23% to 0.24%, while the Type 2 error probability decreases significantly from 31.01% to 26.06%.

For Tromsø we have the opposite situation where the optimal values are $\alpha = 3$ and $\beta = 70$. This is the least restrictive combination which implies that the probability of a Type 1 error is at its minimum while the probability of a Type 2 error is at its maximum. At this airport it is more common to have a contaminated runway during parts of the winter season. As a result avoiding Type 1 errors are more important.

Table 5. Type 1 and Type 2 error probabilities and expected losses.

Runway	$P(A^c \cap B)$	$P(A \cap B^c)$	$E[L]$
Oslo West	0.23%	31.01%	0.367
Oslo East	0.29%	44.70%	0.520
Tromsø	3.37%	28.87%	1.132

Table 6. Expected losses for various combinations of α and β at Oslo West. Optimal combination is indicated in bold face.

	$\beta = 70$	$\beta = 75$	$\beta = 80$	$\beta = 85$
$\alpha = 0$	0.3685	0.3586	0.3431	**0.3204**
$\alpha = 1$	0.3741	0.3634	0.3477	0.3245
$\alpha = 2$	0.3782	0.3668	0.3508	0.3265
$\alpha = 3$	0.3792	0.3674	0.3513	0.3268

Table 7. Expected losses for various combinations of α and β at Oslo East. Optimal combination is indicated in bold face.

	$\beta = 70$	$\beta = 75$	$\beta = 80$	$\beta = 85$
$\alpha = 0$	0.5310	0.5155	0.4973	**0.4716**
$\alpha = 1$	0.5351	0.5188	0.5004	0.4742
$\alpha = 2$	0.5362	0.5195	0.5007	0.4748
$\alpha = 3$	0.5370	0.5203	0.5012	0.4752

Table 8. Expected losses for various combinations of α and β at Tromsø. Optimal combination is indicated in bold face.

	$\beta = 70$	$\beta = 75$	$\beta = 80$	$\beta = 85$
$\alpha = 0$	1.1044	1.1446	1.2399	1.4198
$\alpha = 1$	1.0980	1.1370	1.2369	1.4185
$\alpha = 2$	1.0929	1.1320	1.2369	1.4175
$\alpha = 3$	**1.0857**	1.1264	1.2330	1.4175

Table 9. Expected losses for various combinations of α and β at Tromsø given that $K_1 = 10$. Optimal combination is indicated in bold face.

	$\beta = 70$	$\beta = 75$	$\beta = 80$	$\beta = 85$
$\alpha = 0$	0.6312	0.6265	0.6405	0.6906
$\alpha = 1$	0.6320	0.6262	0.6412	0.6916
$\alpha = 2$	0.6330	0.6260	0.6423	0.6919
$\alpha = 3$	0.6306	**0.6240**	0.6408	0.6919

It should be noted that the optimal parameter values depend on the choice of the loss factors K_1 and K_2 also. If more less weight is put on Type 1 errors, i.e., if K_1 is reduced, the optimal parameter values will change accordingly. As an illustration we have computed the expected losses for Tromsø airport given that K_1 is reduced to 10. The results are shown in Table 9. In this case the optimal parameter combination is $\alpha = 3$ and $\beta = 75$.

5 CONCLUSIONS AND FUTURE WORK

In the present paper we have reviewed the weather model used in the integrated runway information system IRIS. We have shown how the model can be optimized by using a combination of weather data and flight data. The methodology is demonstrated on a simplified problem with only two parameters. In a full scale analysis, a multidimensional optimization must be carried out. Furthermore, the model needs to be finetuned in order to work in combination with the other models in the system. In order to carry out such a complex optimization it is important to screen the parameters and choose the relevant ranges carefully. Moreover, in order to handle the enormous amount of data, an efficient database structure must be applied.

This work is just a small part of a much larger study which includes all the weather scenarios, the use of all available flight data as well as separate analysis for all 16 airports where the IRIS system is installed. A more extensive report from this analysis will be available later.

Risk management for natural hazards based on reliability analysis: A case study of landslides

Jongook Lee
Interdisciplinary Program in Landscape Architecture, Seoul National University, Seoul, South Korea

Dong Kun Lee
Research Institute of Agriculture Life Science, Seoul National University, Seoul, Republic of Korea

ABSTRACT: To cope with natural disasters, it is necessary to establish a strategy for adaptation after analyzing the risk originating from natural hazards. When conducting risk analysis, the first step is estimating the frequency of occurrence, followed by calculating the probability of occurrence. This study aimed to estimate the frequency of landslide occurrence, using the correct units, and to present how the probability of occurrence can be calculated utilizing the concept of reliability, which corresponds well to the outcomes obtained when a Poisson distribution is employed. For the analysis, a pixel unit of GIS-based spatial information was considered as a component to denote the unit for the frequency of landside occurrence, and the equation for the probability of occurrence was derived from the definition of reliability. As a result, the frequency of landslide occurrence in the study region was demonstrated, and a sample calculation of the probability of landslide occurrence is presented.

1 INTRODUCTION

Disasters caused by natural hazards are especially dangerous because they affect larger areas, with greater intensity, than disasters caused by human activities. In addition, the frequency of natural disasters has increased in recent years due to climate change (IPCC, 2013). In order to cope with natural disasters, it is necessary to establish a strategy for adaptation after analyzing the risk originating from natural hazard, to mitigate the risk below acceptable criteria, and to manage it constantly to prevent unwanted loss of life, property, or environment. Landslides are a type of natural disaster that frequently have caused significant damage, especially near mountainous regions (Guzzetti, 2000). Thus, risk analysis for landslides was conducted in this study, utilizing the concept of reliability.

The first step in conducting risk analysis is to estimate the frequency of occurrence (Corominas et al., 2014), followed by calculating the probability of occurrence. However, estimating the frequency can be challenging because of the long interval between relevant events over time, and the lack of accumulated inventory information available in a study region (van Westen et al., 2006, Jaiswal et al., 2010). In addition, frequency units considering spatial and temporal probability are often applied in misinformed ways in risk analysis. Regarding the probability of natural dis-aster occurrence, calculations are often based on a Poisson distribution, sometimes without a clear explanation.

The objective of this study was to estimate the frequency of landslide occurrence, using the correct units, and to present how the probability of occurrence can be calculated utilizing the concept of reliability. For the analysis, a pixel unit of GIS-based spatial information was considered as a component to denote the unit for the frequency of landside occurrence, and the equation for the probability of occurrence was derived from the definition of reliability (Lee et al., 2017).

To estimate the frequency of landslide occurrence, the point locations where landslide events have occurred were considered as failed components, and the other areas, in which no landslide has occurred, were regarded as surviving components. To find the specified time between landslide events, a rainfall threshold was established to estimate the frequency of landslide occurrence due to the limitation of landslide inventory data. A number of methodologies for setting the rainfall threshold have been examined (Frattini et al., 2009, Polemio and Sdao, 1999, Caine, 1980, Aleotti, 2004); however, the validity of those methods are pertinent only with the local geo-spatial properties (Martelloni et al., 2012, Jakob et al., 2006). Therefore, the rainfall threshold value for this study was deter-mined based on local research.

To express the equation of the probability of landslide occurrence, the reliability function, which was derived from the definition of reliability, was used. The equation derived from the concept of reliability has the same outcomes as those reported by Crovelli (2000) based on a Poisson distribution model, which is commonly employed to model the random disastrous events caused by natural hazards over time.

As a result, the frequency of landslide occurrence was determined, and a sample calculation for the probability of landslide occurrence is presented for the study region, Gangwon Province in South Korea, from which landslide inventory data and a landslide hazard map were available for the analysis. The resulting model can be used for risk management of landslides, and also can be extended to assess various mitigation measures to handle the risk from natural hazards.

2 METHOD

2.1 *Study site and inventory data*

Gangwon Province is well known as the region where Pyeongchang County, the host of the 2018 Olympic Winter Games, is located. The province includes high mountainous regions in its boundaries, as shown in Figure 4. The elevation of its northeast area is higher than other parts of the country, and the area has steeper terrain. Due to its topographical features, Gangwon Province is prone to landslides. The population of Gangwon Province is currently growing, reflecting the high demand for leisure activities and property investment. Consequently, housing is expanding, both for permanent residences and for tourism, into mountainous areas that are susceptible to landslides.

The landslide inventory data were provided by the local government of Gangwon Province. The inventory was conducted when devastating damage was reported after Typhoon Ewiniar brought heavy rainfall to the region in July 2006. The damage and losses caused by the typhoon were recorded as a historic natural disaster, as it caused 62 casualties in total, and the loss of property was estimated to be over 1.5 billion USD (N.E.M.A., 2007). The landslide inventory data used for the study were part of the second and third rounds of data collection after the field survey that covered the overall region of Gangwon Province, and the inventory data contained a summary of observed landslide events, with information about the location and damaged area. The survey results were recorded in a polygon-type file in a GIS system and plotted on a 1:25000 scale, including the GPS location data and the areas affected by landslides.

2.2 *Landslide hazard map*

In order to differentiate the frequency of landslide occurrence, we adapted the landslide hazard map produced by the Korea Forest Service in 2012, which was made based on logistic regression analysis considering the following nine factors of mountain properties: slope inclination, slope orientation, slope length, slope curvature, topographic wetness index, the type of forest, the age of the forest, soil depth, and bedrock (Korea Forest Service, 2012). The map classified the analyzed area into five hazard classes, from grade 1 (the highest) to grade 5 (the lowest), with pixel units sized 10 m × 10 m, and the map was projected on a 1:25000 scale. Grade 5 was excluded from our analysis because those pixel data were marked with a null value, including areas of water and flat land with no hazard of landslides.

2.3 *Frequency of landslide occurrence*

Landslide risk can be briefly expressed by an equation in which the probability of a hazardous event is multiplied by the probability of loss of life or property (A.G.S., 2000). For risk analysis, the frequency of landslide occurrence must be identified prior to calculating the probability of landslide occurrence. To estimate the frequency of landslide occurrence, a unit pixel of GIS-based spatial information was considered as a component item to denote the unit for the frequency of landside occurrence. The frequency of landside occurrence can be interpreted as the instantaneous failure rate, presented in terms of the number of failures per unit time, and it is based on measurements of the quantity of components exposed to a stressful environment (Goble and Cheddie, 2005).

Based on the assumption above, the frequency of landslide occurrence can be derived from the concept of the failure rate as below:

$$\lambda = (N - Ns)/(Ns \times \Delta t) \quad (1)$$

where λ = the failure rate of the pixel components, which corresponds to the frequency of landslide occurrence; N = the number of total items; Ns = the number of surviving items; and Δt = the time between landslide occurrences.

Given that Ns is defined as the number of pixel components with no landslide initiation, subtracting Ns from N in Formula 1 can be considered as a measure of the number of landslide events because the point locations of landslide initiated were regarded as the failed components. Time to fail, which refers to the time to landslide reoccurrence, is given by Δt in Formula 1, and it expresses the probabilistic period between landslides. It can be estimated by establishing the rainfall threshold.

More information is provided below regarding the rainfall threshold for landslide initiation.

As per Formula 1, the units for the frequency of landslides can be expressed quantitatively as below, provided that the unit pixel (10 m × 10 m) is obtained from the data of a landslide hazard map:

$$F_L = \text{landslide event} \times \text{pixel}^{-1} \times \text{year}^{-1} \quad (2)$$

where F_L is the frequency of landslide occurrence and the area of a unit pixel corresponds to 100 m^2.

Meanwhile, Corominas and Moya (2008) described two separate approaches to the spatial probability and temporal probability of landslide occurrence. The relative frequency is the ratio of the number of landslides recorded to the unit area, which allows multiple regional landslide events to be described. The units for the relative temporal frequency are the same as those given in Formula 2. The relative temporal frequency of landslides could be identified in this study because the landslide inventory data included multiple landslide events in the province region that were triggered by a heavy rain event.

The overall procedure for analyzing the frequency of landslide occurrence based on the concept of the failure rate in the reliability study and the differentiated frequency according to landslide hazard grades is shown in Figure 1.

Notably, when the number of landslide events is classified by the landslide hazard grade, the maximum landslide hazard grade was assigned to each landslide event with an overlay of the inventory polygon data and landslide hazard map on the GIS platform. Moreover, in a conservative approach to risk analysis, the area where landslides did not occur was measured when determining the total area corresponding to each landslide hazard grade. It should also be noted that the estimated value of the frequency varies depending on the size of the area. The frequency units for this study are only representative of Gangwon Province.

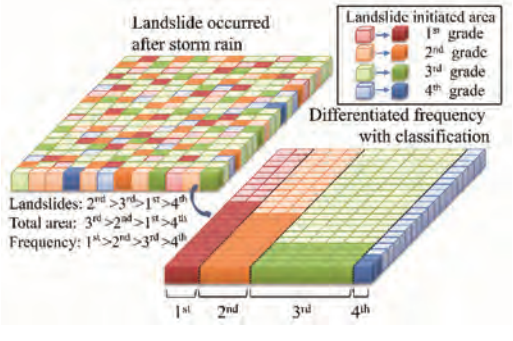

Figure 1. The frequency of landslide occurrence based on the concept of the failure rate.

2.4 *Probability of landslide occurrence*

To estimate the probability of random disastrous events caused by natural hazards over time, a Poisson distribution is often employed. Crovelli (2000) presented a Poisson distribution model to express the probability of landslide occurrence in continuous time in natural environments, as below:

$$P\{N(t) = n\} = e^{-\lambda t} \frac{(-\lambda t)^n}{n!} \quad (3)$$

where n = 1, 2, 3…; λ = the rate of occurrence of landslides; t = the specified time; and N(t) = the number of landslides that occurred during time t.

The probability of one or more landslides occurring in time t, which is referred to as the exceedance probability, is expressed as below, when λ is much less than one (λ<<1):

$$P\{N(t) \geq 1\} = 1 - e^{-\lambda t} \quad (4)$$

This model of the probability of landslide occurrence can also be presented using the definition of reliability. The definition of reliability usually contains four basic elements: probability, adequate performance, time, and operating conditions (Billinton and Allan, 1992), and one of the definitions in general terms can be introduced as follows: the probability that an item will perform a required function without failure under stated conditions for a stated period of time (O'Connor and Kleyner, 2012). The reliability function R(t) in mathematical terms is expressed as follows (Kapur and Pecht, 2014):

$$R(t) = \frac{Ns(t)}{N} \quad (5)$$

where Ns = the number of surviving items; and N = the number of total items.

Unreliability, F(t) is given as:

$$F(t) = 1 - R(t) = \frac{N - Ns(t)}{N} \quad (6)$$

and,

$$f(t) = \frac{dF(t)}{dt} = -\frac{1}{N}\frac{dNs(t)}{dt} \quad (7)$$

When the hazard rate h(t) is normalized with its surviving items Ns(t) instead of the total number

of items N from the unreliability rate f(t) equation, we obtain the hazard rate h(t), as shown below, with a more conservative meaning:

$$h(t) = \frac{f(t)}{R(t)} \tag{8}$$

The integral of the hazard rate h(t) over the time from 0 to t is:

$$\int_0^t h(\tau)\, d\tau = -\ln R(t) \tag{9}$$

Then, R(t) is:

$$R(t) = e^{-H(t)} \tag{10}$$

where H(t) is the number of hazards in time t and can be expressed as $H(t) = \lambda t$.

Finally, we obtain F(t) as:

$$F(t) = 1 - R(t) = 1 - e^{-H(t)} = 1 - e^{-\lambda t} \tag{11}$$

By using Formula 11 above, the probability of landslide occurrence can be calculated using the frequency of landslide occurrence estimated from the concept of the failure rate, as expressed in Formula 2.

2.5 *Time period estimation by Rainfall threshold*

In order to estimate the time period between landslide occurrences, a rainfall threshold was established, since the mechanism of landslide occurrence is triggered by the increase in pore water pressure and rain water seepage forces (Cullen et al., 2016). Since Caine's research (1980) examined the relationship between the minimum rainfall duration and intensity required to cause a landslide, a number of methodologies to identify the rainfall threshold have been examined, with the goal of finding the most suitable correlation with landslide initiation (Aleotti, 2004).

However, the examined proposals are valid only with the local geo-spatial properties (Martelloni et al., 2012, Jakob et al., 2006). Thus, domestic research results were applied to reflect the features of local geology, vegetation, and topography. Kim and Chae (2009) reported that landslides tend to occur in South Korea when the consecutive rainfall is over 200 mm for 48 hours. Based on their results, cumulative precipitation of more than 200 mm for 48 hours was adopted as a criterion for the rainfall threshold.

To determine the daily rainfall intensity, which was another factor used to determine the threshold, daily precipitation records were reviewed from when Typhoon Ewiniar caused heavy rainfall in July 2006. This decision was based on the assumption that landslides are likely to occur in the future in similar environmental conditions. Despite the lack of continuous landslide inventory data, this method provides a basis for estimating the frequency of landslide occurrence. Rainfall data from the Automatic Weather Station (AWS) located in the center of Gangwon Province were adopted as a representative sample to estimate landslide frequency, considering the geographic location and the high severity of damage caused by the typhoon.

The daily rainfall records in the region for the last 10 years are plotted in Figure 2. The graph shows that daily precipitation exceeded 150 mm on both July 15 and July 16, 2006, and it is possible to assume that landslides occurred after the rainstorms on those dates.

Therefore, a daily rainfall of more than 150 mm was set as another factor contributing to the rainfall threshold. As a result, the rainfall threshold was established as including both 48-hour cumulative precipitation over 200 mm and daily precipitation over 150 mm.

By screening using the rainfall threshold, as shown in Figure 3, the average landslide occurrence interval was estimated by counting the dates

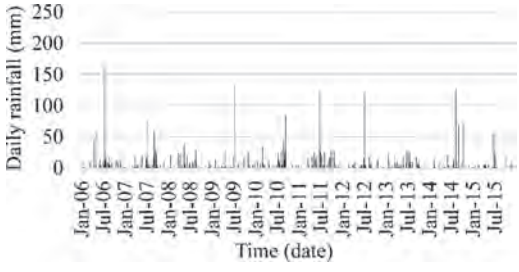

Figure 2. Sampled daily rainfall in Gangwon Province for 10 years (2006–2015).

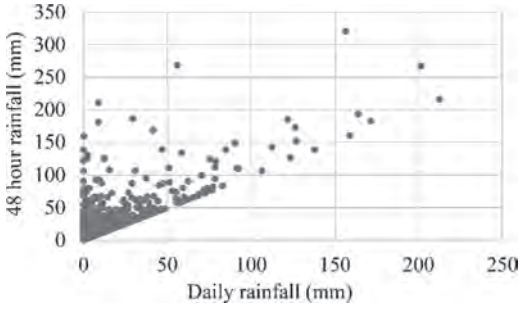

Figure 3. Scatter diagram of daily rainfall and 48-hour cumulative rainfall showing that 3 events exceeded the rainfall threshold in 10 years (2006–2015).

that satisfied these criteria, which resulted in 3 events during the reviewed 10-year period. Thus, the probabilistic period of landslide occurrence was estimated as 3.3 years for the analysis of the probability of landslide occurrence in this study.

3 RESULT

3.1 *Estimation of landslide frequency*

The locations in the inventory data where landslides have occurred in Gangwon Province are presented in Figure 4.

An analysis of the landslide hazard map of Gangwon Province shows that grades 2 and 3 predominated throughout the study region, while grade 1 areas were sparsely scattered near mountainous areas. The resulting estimation of the frequency of landslide occurrence is summarized in Table 1. The total areas of the each landslide hazard grade are shown, except for grade 5, which had null data, and it is shown that grade 3 occupied the largest area of 5815.2 km^2, followed by grade 2 (4611.6 km^2), grade 4 (250.0 km^2), and grade 1 (186.5 km^2).

When the number of landslide events was counted and classified along with the landslide hazard grades, a total of 72 landslide events were found in grade 1 areas, followed by 700 landslides in grade 2 areas, 433 in grade 3 areas, and 8 landslides in grade 4 areas.

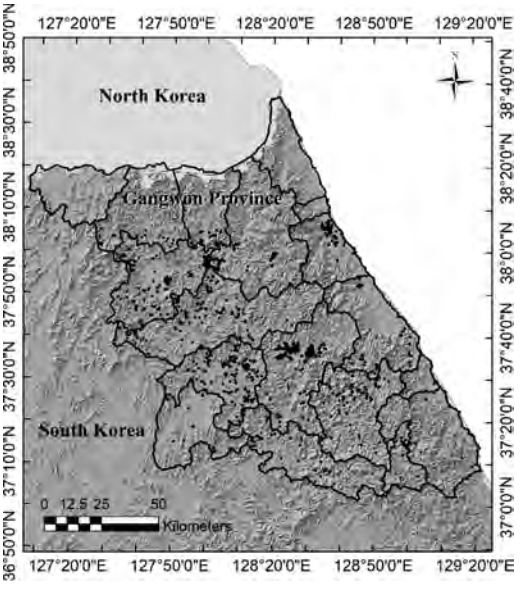

Figure 4. Locations of landslide occurrence in the study area.

Table 1. The analyzed frequency of landslide occurrence.

Landslide hazard grade	No. of Landslides	Total area * (km^2)	Landslide occurrence frequency (λ)**
1	72	186.5	1.17E-05
2	700	4611.6	4.60E-06
3	433	5815.2	2.27E-06
4	8	250.0	9.70E-07

*The unit pixel (10 m × 10 m) is used for frequency estimation.
**The unit of landslide occurrence rate (λ) is landslide event × pixel −1 × year −1.

The most landslides occurred in grade 2 areas because they accounted for the most area. However, if we examine the occurrence ratio, which is defined as the number of landslide events divided by the total area, it can be seen that the highest number of landslide events per area occurred in grade 1 areas.

Thus, our results indicate that areas with a landslide hazard of grade 1 had the highest value of landslide occurrence frequency (1.17E-05 landslide events × pixel^{-1} × year^{-1}). The frequency decreased from grade 2 to grade 4, which had the lowest value of landslide occurrence frequency (9.70E-07 landslide events × pixel^{-1} × year^{-1}). It should, however, be kept in mind that the estimated landslide occurrence frequencies are only valid for Gangwon Province area.

3.2 *The probability of landslide occurrence*

Given the estimated frequency of landslide occurrence along with the landslide hazard grades, the probability of landslide occurrence was calculated following Formula 11 and plotted with a logarithmic scale on the Y-axis. The graph in Figure 5 shows an increase in the overall probability of landslide occurrence over time, as well as presenting discrete curves according to the landslide hazard grade. The resulting graph indicates that grade 1 areas had the highest value of probability of landslide occurrence, followed by grade 2 areas, grade 3 areas, and grade 4 areas, sequentially.

Our results indicate that locations with different grades of landslide hazard are exposed to different risk levels, which can be analyzed by calculating the probability of landslide occurrence. The probability of a landslide, which is a disaster caused by a natural hazard, can be estimated based on the concept of reliability. The calculated probability value can be used as a basis for landslide risk management.

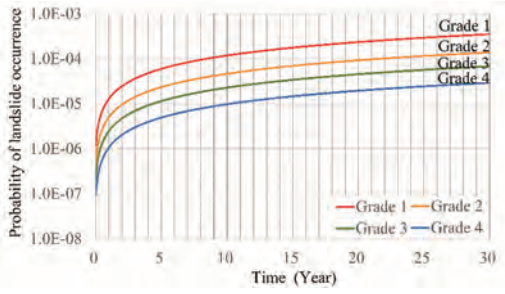

Figure 5. Increases in the probability of landslide occurrence depending on the landslide hazard grade.

4 DISCUSSION

In this study, it was shown the frequency of landslide occurrence can be estimated and the probability of landslide occurrence can be calculated using the concept of reliability analysis, which is commonly used in mechanical studies and other engineering fields. Since the occurrence of disasters due to natural hazards is affected by numerous environmental variables, estimating their frequency and calculating the probability of their occurrence are usually difficult tasks. However, when we consider a pixel unit of spatial information in a GIS platform as the component for reliability analysis, it becomes possible to calculate the frequency of occurrence with correct units and to calculate the probability of occurrence.

A set of cross-sectional inventory data obtained after the destructive damage caused by a typhoon was used due to the lack of landslide inventory data in this study. Therefore, continuous data collection in accordance with appropriate landslide inventory frameworks should be implemented, and updating landslide event observation data is important to maintain valid data regarding the frequency of occurrence.

To cope with natural disasters, it is necessary to establish a strategy for adaptation after an analysis of the risk originating from natural hazards. The method presented in this paper for estimating the frequency and the resulting probability value can be used as the basis for landslide risk analysis and management. After baseline risk analysis is conducted, various safety barriers for risk reduction can be applied to manage the risk quantitatively within acceptable criteria. Monitoring of potentially unstable slopes is a potential safety barrier serving as a preventive measure to reduce the likelihood of landslide occurrence (Uhlemann et al., 2016). Adopting an early warning system is a safety barrier to prevent unwanted loss by timely detection (Sättele et al., 2015). Major engineering work to reinforce an unstable slope with a retaining wall or to install a fence or net can be a mitigation measure to reduce the severity of the consequences of a landslide (Dai et al., 2002). Safety barriers are associated with specific magnitudes of risk reduction, and the appropriate level of risk reduction through the use of safety barriers can be decided by quantitatively considering the exposed risk, which is estimated from the probability of landslide occurrence.

Analysis of the risk originating from natural hazards through the concept of reliability can be considered a convincing approach to manage risk. Landslide risk management based on reliability analysis can be also actively applied with local frequency data that are suitable to other regions in order to prevent unwanted loss of life, property, or environment.

5 CONCLUSION

In this study, the frequency of landslide occurrence was estimated by reliability analysis and a sample calculation of the probability of landslide occurrence was presented for Gangwon Province in South Korea, from which landslide inventory data and a landslide hazard map were available. For the analysis, a pixel unit of GIS-based spatial information was considered as a component to denote the unit for the frequency of landside occurrence.

It was found that more landslide events were initiated in areas with a hazard grade of 2 or 3 than in grade 1 areas because of their greater total areas; however, the most landslide events per area occurred in grade 1 areas. It was shown that areas with a greater landslide hazard had higher values of the landslide occurrence frequency in the study region, and the estimated frequency data were used to calculate the probability of landslide occurrence in an analysis based on the concept of reliability.

By examining natural hazards through reliability analysis, we have ascertained that the estimated frequency and the resulting probability value can be used as the basis of landslide risk analysis and management. This technique can also be extended to assess various mitigation measures to handle the risks that stem from natural hazards.

Probabilistic seismic hazard assessment for offshore structures in Andaman Sea

T. Ornthammarath
Department of Civil and Environmental Engineering, Faculty of Engineering, Mahidol University, Thailand

ABSTRACT: A set of probabilistic seismic hazard maps for Offshore structures in Andaman sea has been derived using procedures developed for the latest US National Seismic Hazard Maps. In contrast to earlier hazard maps for this region, which are mostly computed using delineated seismic source zone, the presented maps are based on the combination of smoothed gridded seismicity, crustal-fault, and subduction source models. The ground motion hazard map is presented over a 10 km grid in terms of peak ground acceleration and spectral acceleration at 1.0 undamped natural periods and a 5% critical damping ratio for 10 and 2% probabilities of exceedance in 50 years, which have generally been used for Seismic Analysis and Design of Offshore Structures.

1 INTRODUCTION

The Andaman Sea is situated in an active back-arc basin lying above and behind the Sunda subduction zone, which is the Indo-Australian and Eurasian boundary zone comprise the convergent margins, including the Burma oblique subduction zone, Andaman thrust and Sunda arc, to the North West, west and south, respectively. Within Andaman Sea, several earthquakes with magnitude greater than 4 have been observed during the years 1964 to 2017. However, the earthquake activity rate is much lower than those occurred near plate boundary. For this study, the southern part of Andaman Sea (Blue dash line and the study area is bounded latitude 5° to 10° and longitude 94° to 98°, Figure 1) is of special interested due to ongoing human activities for gas pipeline and offshore facilities, several platforms and subsea gas pipelines have been developed offshore. In addition, onshore supports such as control and maintenance centre along with gas metering stations have been developed in this region. The largest instrumental earthquake within this zone is Mw 6.3 on 16 May 1933 at 10 km depth. In addition, this region is situated about 200 and 300 km from the Sumatran faults and Sumatra subduction zone, respectively. And these seismic active structures have historically produced moderate to large earthquakes with long-period ground motions that were felt in high-rise buildings in Singapore and Malaysia (Pan and Sun, 1996; Pan, 1997; Pan et al., 2001). A probabilistic seismic hazard assessment for offshore structures located in this area has been carried out.

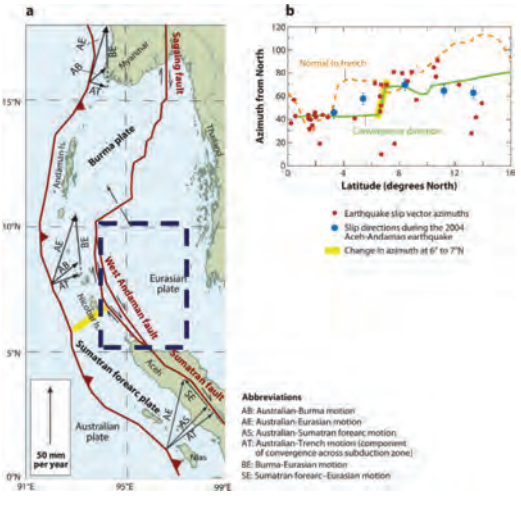

Figure 1. (a) Map showing possible relative motions of the Sumatran and Burma forearc plates relative to adjacent Indian-Australian and Eurasian (Sunda) plates. Adapted with permission from Curray (2005). The vector diagrams show the partitioning of the total convergence of Australia relative to Eurasia (vector AE) into components of subduction (vectors AS and AB) and strike-slip (vectors SE and BE). (b) Plot of earthquake slip vector azimuths (red dots). Blue dash line showing the area of current study.

The main objective of this work is to determine appropriate earthquake ground motion parameters for the seismic design of offshore structures based on available scientific information. These

ground motion parameters include: horizontal Peak Ground Acceleration (PGA) and Spectral Acceleration (SA) values at the project site with the return periods of 475 and 2475 years.

2 SEISMOTECTONIC SETTINGS

The Indo-Australian and Eurasian boundary zone comprise the convergent margins, including the Burma oblique subduction zone, Andaman thrust and Sunda arc, to the North West, west and south, respectively. The plate kinematics of the Sumatran region is, in a broad sense, the simple interaction of the Indian-Australian and Eurasian plates (Figure 1). However, in detail it is much more complex than that. Deformation rates across these plate boundaries are variable. The observed seismicity and seismotectonic settings of these plate boundaries clearly indicate the capability of producing large events, where the 26 December 2004 earthquake occurred. A convergence rate of 65–70 mm/year as a result of Australia moving toward South East Asia is reported by McCaffrey (1996).

Deformation of the overriding plate leads to larger complexities in plate motions. Sumatra sits at the southwestern edge of the Sunda plate (Bird 2003), which moves at a few millimeters per year to a centimeter per year eastward relative to Eurasia (Chamot-Rooke & Le Pichon 1999, Bock et al. 2003) (Figure 1). The resulting convergence between the Sunda plate and the oceanic plates to the southwest is somewhat slower than it would be relative to Eurasia. The rate and direction of subduction of the lithosphere under the Sunda forearc, however, are further modified by the independent motion of the forearc. Fitch (1972) explained the presence of the Sumatran fault and other similar faults inboard subduction zones by the process now known as slip partitioning. That is, in some cases of oblique subduction where the two plates do not converge at a right angle to the strike of the trench, it requires smaller overall shear force to share the shearing (trench-parallel) component of the relative motion between two separate faults instead of on one fault. In the case of partitioning, one fault is the subduction thrust, which takes up all of the trench-normal slip (the dip-slip component) and some fraction of the trench-parallel slip (the strike-slip component). A second fault, within the overriding plate and commonly strike-slip in nature, takes up a portion of the trench-parallel motion. The subduction thrust and strike-slip fault isolate a wedge of forearc called the sliver plate. The slip rates on the separate faults can be inferred from their geometries and knowledge of the overall convergence.

The motion of the Sunda forearc (sliver plate) is not known well, particularly in the Andaman section, and hence the subduction vector is highly uncertain. Earlier estimates of the relative motions assuming a rigid forearc sliver plate failed to predict convergence in the Andaman section of the trench, which probably indicates, as is now accepted, that there is extensive internal deformation within the forearc. One possibility, evident in the change in earthquake slip directions along the margin, is that the Andaman section (called the Burma plate) and Sumatran sections of the forearc move independently with a break near 6° to 7°N (Subarya et al. 2006).

3 EARTHQUAKE CATALOGUE

The earthquake catalogue for current study is composed of instrumental earthquake records from different international earthquake observatories including:

1. International Seismological Centre-Global Earthquake Model (ISC-GEM) (1907–2009),
2. Engdahl (EHB)'s earthquake catalog (1960–2007),
3. USGS/NEIC preliminary earthquake database (1900–2013), and
4. Global centroid moment tensor (GCMT) (1976 – December 2010),

The compiled instrumental earthquake catalog is covered from 1900 to 2013 (Figure 1). All reported event magnitudes have been converted to moment magnitude by using Scordilis (2006) relationship for mb-Mw and Ms-Mw. Subsequently, all duplicated events have been removed, and earthquake magnitude and location correction have been performed manually to remove any obvious errors. The largest earthquake magnitude 9.2, Great Sumatra-Andaman earthquake in northern Sumatra on 26 December 2004 at 0 7.58 local time.

3.1 *Magnitude conversion*

In the final updated earthquake catalogue, several different magnitude scales are used to define the earthquake magnitude. For example, the 20-s surface-wave magnitude (M_S) and the short-period P-wave magnitude (mb) are commonly used in the data from USGS, ISC, and other international database sources, and the moment magnitude (M_W) is reported in the Global Centroid Moment Tensor catalogue. It is necessary to convert all these different magnitude scales into a single magnitude scale. In this study, the moment magnitude scale is chosen as the single representative scale. Since the accuracy of reported magnitudes is dependent on magnitude definitions, the more reliable magnitude

is then preferred for using in magnitude conversion as follows: M_w, M_S,mb, and M_L Conversions between magnitude scales are made using the equation provided in Table 2 in Ornthammarath et al. (2011). After the magnitude conversion, we merged duplicate entries (from different data sources) into a single entry for each earthquake event.

3.2 *Declustering*

One basic assumption of the adopted seismic hazard assessment methodology is that earthquake occurrences are statistically independent (the Poisson assumption). Therefore, the earthquake catalogue to be used for seismic hazard assessment must be free of dependent events, such as foreshocks and aftershocks. The process to eliminate dependent events from earthquake catalogues is called "declustering". Gardner and Knopoff(1974) declustering algorithm, is chosen for the present study. This approach states that foreshocks and aftershocks are dependent (a non-Poissonian process) on the size of the main event, and these earthquake events need to be removed in accordance with space- and time- windows. Normally, a large main earthquake event leads to larger aftershocks over a larger area and for a longer time. Therefore the time- and distance-window parameters for larger main events are greater than those for smaller events. Declustering eliminates about 60% of the 64,866 events in the catalogue. The final declustered catalogue includes 25,654 earthquake events (4218, 7585, and 13851 events for shallow, intermediate, and deep earthquake, respectively) with M_W greater than or equal to 3.0 in the study region from 1900 to 2013.

3.3 *Catalogue completeness*

It is recognized that earthquake data in the catalogue are not complete, and that failure to correct for the data incompleteness may lead to underestimation of the mean rates of earthquake occurrence. The correction can be made by identifying the time period of complete data for prescribed earthquake magnitude ranges. Reliable mean rates of earthquake occurrence for the given magnitude ranges can then be computed from the complete data.

Two methods were employed for completeness analysis of the catalogue: (a) the Visual Cumulative method (CUVI) and (b) Stepp's method. Both algorithms provided a similar result; hence, the former technique was adopted. We divide the study region into three zones, i.e., shallow, intermediate, and deep earthquakes (BG-I, BG-II, BG-III, respectively). The data completeness analysis is carried out separately for each of these zones, and the results are presented in Table 2 in Ornthammarath et al. (2011).

4 MODELING OF EARTHQUAKE SOURCES

To properly describe the complex earthquake environments in the region, they are modeled as a mixture of background seismicity, subduction area sources, and crustal faults. These are described in more detail below.

4.1 *Background seismicity model*

The background seismicity model represents random earthquakes in the whole study region except the subduction zones. The model accounts for all earthquakes in areas with no mapped seismic faults and for smaller earthquakes in areas with mapped faults. In this approach, it is not necessary to divide the region into many small areas. One large area may be used, but the rate of seismicity is assumed (or allowed) to vary from place-to-place within the area. The rate of seismicity is determined by first overlaying a grid with a given spacing, in the current case 0.10° in latitude and 0.10° in longitude, approximately 10 by 10 km, onto the study region, and counting the number of earthquakes with magnitude greater than a reference value (M_{ref}) in each grid cell. The rate of seismicity is computed by dividing the number of earthquakes by the time period of earthquake data. The rate is then smoothed spatially by a Gaussian-function moving average and comparing with the observed seismicity. By this approach, the spatially-varied seismicity can be modeled with confidence relating to source uncertainty.

In hazard calculations, earthquakes smaller than magnitude 6.0 are characterized as point sources at the centre of each grid cell, whereas earthquakes larger than magnitude 6.0 are assumed to be hypothetical finite vertical or dipping faults centered on the source grid cell. Lengths of finite faults are determined using the Well and Coppersmith (1994) relations. Consecutively, the pre-calculated average source-to-site distance from virtual faults with strike directions uniformly distributed is employed (Petersen et al. 2008).

The whole study region is divided into 6 source zones: BG-I, BG-II, BG-III, SD-A, SD-B, SD-C, (see Fig. 3). The zones SD-A, SD-B, and SD-C are subduction zones, which will be described in detail below. The zone BG-I is a background seismicity zone covering the whole study area excepting subduction zone, and the zone BG-II and BG-III are background seismicity zone for intermediate and deep earthquake except subduction

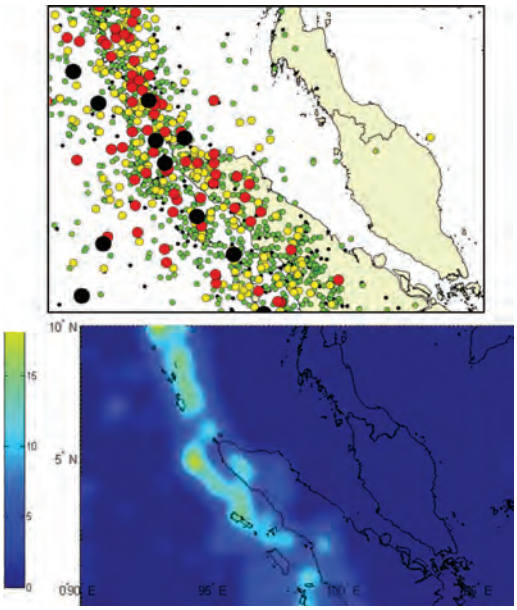

Figure 2. Observed shallow seismicity Black circle represent magnitude greater than 7.0, Red circle represent magnitude between 6.0–7.0; Yellow circle represent magnitude between 5.0–6.0; Green circle represent magnitude between 4.0–5.0 (Upper) and the smoothed activity rate 10^a value of BG-I for shallow earthquake (Lower).

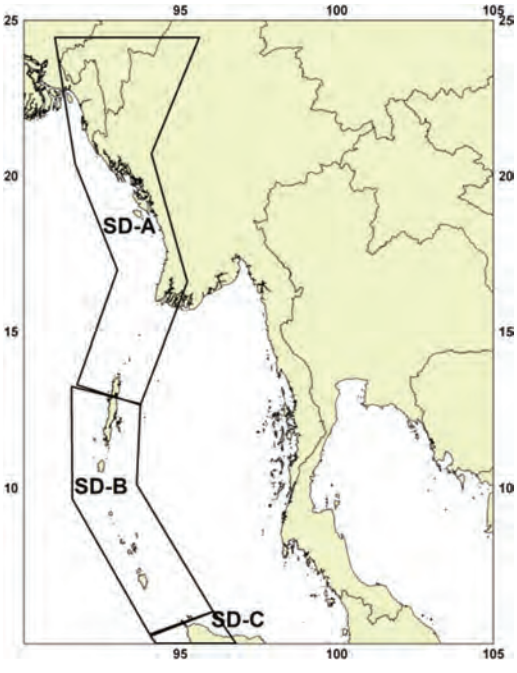

Figure 3. Subduction zones SD-A, SD-B, and SD-C considered in this study.

zones. Earthquake data, particularly greater than magnitude 3.0 earthquakes, in BG-I, BG-II, and BG-III could be reliably recorded since 2004 due to the high earthquake detection capability of a fairly dense seismograph network in Malaysia and surrounding region. Hence, the accuracy of the estimated seismicity rate in BG-I can be significantly improved by including small earthquakes ($3.0<M_W<5.0$) in the seismicity rate calculation

Furthermore, this activity rate computation is also based on the observation that moderate earthquakes generally occur in areas where there have been a significant number of magnitudes 3 events. On the other hand, in BG-II and BG-III earthquake data with $M_W > 5.0$ can be used for computing the seismicity rate due to the incompleteness of small earthquake data. Nevertheless, a lack of small earthquake data is not a major problem because the seismicity rate in these zones are relatively high; thus, the rate can be reliably estimated from moderate-sized earthquakes. In addition, the overall influence of BG-II and BG-III on the seismic hazard in Andaman sea is lower than that of BG-I. We model the magnitude-dependent characteristic of the seismicity rate in each background seismicity zone by a truncated exponential model (Gutenberg-Richter model):

$$\text{Log10}\,(N(M_W)) = a - bM_W \qquad (1)$$

where $N(M_W)$ is the annual occurrence rate of earthquakes with magnitude greater than or equal to M_W, and a and b are the Gutenberg-Richter model parameters. The b-value is assumed to be uniform throughout the whole background region. Hence, we used complete earthquake data with magnitude greater than 4.0 in current study area to compute a single regional b-value. The obtained regional b-value is 0.90, and this value is used for BG-I BG-II and BG-III. The a-value varies from place to place within each zone. It is computed by using a grid with spacing of 0.10° in latitude and longitude and is spatially smoothed using a two-dimensional Gaussian moving average operator with a correlation distance parameter C (Frankel 1995). Earthquake data with $M_W > 3.0$ and C = 50 km are used for BG-I, while earthquake data with $M_W > 5.0$ and C = 50 km are used for BG-II and BG-III. The correlation distance is chosen based on Frankel (1995) and it is comparable to earthquake location error. Note that at present there are no fixed rules or guidelines to determine an appropriate C value. If the value of C is too small, the resulting smoothed seismicity will be concentrated around the epicenters of past recorded earthquakes. On the other hand, if the value of C is too large, the resulting smooth seismicity will be blurred and will not reflect the true spatial variation pattern of seismicity. The chosen C values are believed to suitable as the computed smoothed rate 10a values

(presented in Fig. 2) are in agreement to observed spatial pattern of seismicity.

In the truncated Gutenberg-Richter models of BG-I, BG-II, and BG-III, the minimum earthquake magnitude is set equal to 4.5 because earthquakes with smaller magnitude than this are judged not to cause damage to buildings and structures. The maximum (upper bound) magnitude is set to 7.0 for BG-I and 8.0 for BG-II and BG-III to account for the largest earthquake magnitude that have been observed in these zones, as shown in Fig. 2. The average depth used in the model for BG-I, BG-II, and BG-III are 20, 75, and 120 km, respectively.

4.2 *Subduction zone model*

As explained earlier, the megathrust Sunda subduction zone is divided into seven sub-zones based on seismicity characteristics: the Burma zone (SD-A), the Northern Sumatra-Andaman zone (SD-B), and the Southern Sumatra zone (SD-C). Each sub-zone is modelled as a seismic area source with a uniform rate of seismicity (the traditional area source model), and the magnitude-dependent seismicity rate is modeled by a truncated Gutenberg-Richter relation. The geometry and recurrence times of large earthquakes associated with these active tectonic structures are largely based on available paleotsunami and seismic history studies (Jankaew et al., 2011), summarized geodetic data reported in, Berryman et al., (2013).

The calculated Gutenberg-Richter model parameters (a and b values) are shown in Table 3 in Ornthammarath et al. (2011). The minimum earthquake magnitude in the Gutenberg-Richter model is set to 6.5 as the subduction zones are very near to studied area and hence large earthquakes are also important for long period structures in southern Andaman Sea. The maximum magnitude for each zone is set to the maximum observed magnitude plus 0.5 magnitude units. The maximum magnitude for zone SD-B and SD-C is set to 9.2 as the 2004 Sumatra earthquake and the 2005 Nias earthquake

4.3 *Crustal fault source model*

Two different approaches are employed to model the magnitude-dependent characteristic of the seismicity rate of these crustal faults: the Gutenberg-Richter model and Characteristic Earthquake (CE) model. In the Gutenberg-Richter model, a magnitude-frequency distribution for crustal fault model is assumed from the minimum magnitude of 6.5 to the upper-bound magnitude (Mmax). To account for the uncertainty in estimating Mmax, we consider three different cases with Mmax set equal to MC – 0.2, MC, and MC + 0.2. The probabilistic weights of 0.2, 0.6, and 0.2 are assigned to these cases, respectively. In each case, theb-value is set equal to the regional b-value of 0.90, and the a-value is determined from the seismic moment rate, which is computed from the fault slip rate.

In the characteristic earthquake model, three characteristic earthquake magnitudes (M_C) are also considered: M_C – 0.2, M_C, and M_C + 0.2. The probabilistic weights of 0.2, 0.6, and 0.2 are assigned to these cases, respectively. In each case, the earthquake occurrence rate is computed from the characteristic magnitude and the fault slip rate (to match with the seismic moment rate of the fault). The recurrence interval for the characteristic model is determined from:

$$\text{Recurrence Interval} = \mu u LW/M_{0C} \quad (2)$$

where is μ shear modulus, 3.0×10^{11} dyne/cm^2, L is rupture length, and W is rupture width, u is the fault slip rate, M_0C is the characteristic earthquake moment, which is calculated from:

$$\log(M_{0C}) = 1.5M_C + 16.05 \quad (3)$$

and the magnitude is assumed to be normally distributed around the characteristic value with a standard deviation of 0.12. The properties and parameters of Sumatra faults considered in this study are shown in Table 2 in Petersen et al. (2007).

5 GROUND MOTION PREDICTION EQUATIONS (GMPES)

In this study, three Next Generation Attenuation (NGA) models were developed for shallow crustal earthquakes in the Western United States and similar active tectonic regions were applied for background earthquakes in BG-I and for earthquakes from crustal faults in the study region. These NGA models were developed by Boore and Atkinson (2008), Campbell and Bozorgnia (2008), and Chiou and Youngs (2008) during the NGA project.

In addition, based on comparison of several different Ground Motion Prediction Equations (GMPEs) with recorded ground motion from interface subduction earthquakes by Ornthammarath et al. (2014), it has been decided that three subduction GMPEs could be used for probabilistic seismic hazard analysis in this region, and probabilistic weights assigned to these models are 0.25, 0.25, and 0.50 for Atkinson and Boore (2003; 2008), Youngs et al. (1997), and Zhao et al. (2006), respectively. These weights are relatively consistent with residual of observed recorded data and estimated values of three selected GMPEs. To calculate ground motion for intermediate-and deep-depth earthquakes, the equations of Young et al. (1997) and Atkinson and Boore (2003) are considered with equal weights.

6 PROBABILISTIC SEISMIC HAZARD ANALYSIS

The PSHA results for southern Andaman Sea, Figure 4 and 5, are presented in terms of seismic hazard maps at 475- and 2475-year return periods at bedrock condition. For southern Andaman Sea, the observed seismicity in and around Sumatra subduction zone and Sumatra faults control the hazard for most considered structural periods. Estimated bedrock PGA near subduction zone at 2475-year return period range between 0.6g to 1.0g; however, for area near coast of Thailand and Myanmar, estimated bedrock PGA at 475-year return period are relatively less intense varied from 0.05g to 0.15g. This is primarily due to its location which is far removed from any major active structure in augmented with low observed seismicity rate of background seismicity.

For long structural period (Figure 5), large part of southern Andaman Sea is subjected by moderated long period ground motion due to lower attenuation rate of long periods. Subduction zone earthquakes contribute high seismic hazard to long period offshore structure in southern Andaman Sea. Estimated bedrock SA (T = 1s) near subduction zone at 2475-year return period range between 0.4g to 1.0g; however, for area near coast of Thailand and Myanmar, estimated bedrock PGA at 2475-year return period are relatively less intense varied from 0.10g to 0.20g. The suitable ground motion records for performing time history analysis of long period structures in southern Andaman Sea should be selected for large earthquake at long distance. In addition, the computed ground motions are comparable to those in Petersen et al. (2007) with minor different in short period ground motion near subduction zones.

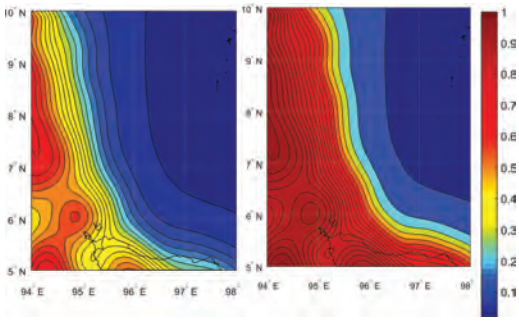

Figure 4. PGA (g) map for southern Andaman Sea at 475 - (Left) and 2475 - (Right) year return period.

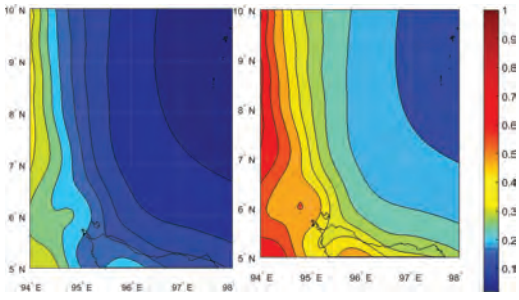

Figure 5. SA (T = 1s) (g) map for southern Andaman Sea at 475 - (Left) and 2475 - (Right) year return period.

Power outage forecasting: Methods, results, and uncertainty

S.D. Guikema
University of Michigan, Ann Arbor, Michigan, USA

ABSTRACT: Power outage forecasting for severe events such as hurricanes provides valuable information to those managing power systems and those dependent on electric power such as other utilities and individuals in society. A number of different approaches to power outage forecasting have been developed. This paper provides an overview of different approaches with a focus on how these approaches work in practice. It then focuses on the role and representation of uncertainty in power outage forecasts. What are the sources of uncertainty? How do different outage forecasting approaches handle these sources of uncertainty? How is uncertainty represented in the resulting forecasts?

1 INTRODUCTION

Sever weather is a major cause of power outages and expensive restorations associated with these outages. A critical aspect of managing weather-induced power outages for a utility is being prepared to restore power quickly and cost-effectively. Power outage forecasting models are an important part of this process, providing estimates of both total outages and the spatial distribution of these outages in advance of a storm. An increasing number of utilities are reportedly using power outage forecasting models. For example, approximately 85% of utilities responding to a recent benchmarking survey reported that they have some sort of storm power outage prediction model (Guikema et al. 2017).

A number of different approaches for predicting weather-induced power outages have been developed. The two primary approaches are fragility-based models and statistical models. Fragility-based models (e.g., Winkler et al. 2010) take as input estimates of key aspects of the weather hazard, such as gust wind speeds, and they then estimate the probability of damage at the level of individual assets via a fragility function, a mathematical function that translates the value of a hazard parameter (e.g., gust wind speed) into a damage probability. These asset level damage probabilities are then used to simulate a number of replications of sets of damaged assets. For each simulated set of damaged assets, a power flow or connectivity model is used to estimate which customers have power and which do not. This provides the overall estimate of power outages together with its spatial distribution.

A statistical power outage forecasting model (e.g., Han et al. 2009a, 2009b, Guikema et al. 2010, Nateghi et al. 2011, Guikema and Quiring 2012, Guikema et al. 2014, Nateghi et al. 2014a, 2014b, Quiring et al. 2014, McRoberts et al. 2017, He et al. 2017) uses data about the performance of power systems during past storms such as the number of meter outages in defined geographic areas together with data about the utility system, environmental conditions, and the weather conditions. These data are used to train and validate a model that can predict the impact of future weather events. The types of statistical models used vary widely, from simple linear regression models to more advanced ensemble data mining methods.

Statistical power outage forecasting models are in much wider use within electric power utilities. Based on conversations with utility personnel, many U.S. utilities have at least an Excel-based linear regression model that they use in house. It should also be noted that to date, statistical outage forecasting models have shown substantially better predictive accuracy that fragility-based models. Because statistical outage forecasting models are both more widespread and, to date, more accurate, they will be the focus of this paper.

In this paper I focus not on the technical details of statistical outage forecasting models. Rather, I take a perspective grounded in Bayesian probability and risk analysis and provide a critical assessment of the foundations of these models. To the degree possible, I use models that I have developed as the basis for the critiques. The goal here is to suggests ways in which the approaches underlying outage forecasting can advance. It is important to note that the focus here is not the meteorological side of the problem. That is, I focus on the modeling approach, not on which additional weather parameters might be helpful to include, though there is potentially substantial merit to exploring a wider array of weather variables.

This paper is structured as followed. The second section summarizes some of the practical limitations of the current approaches, drawing on the discussion in Guikema et al. (2017), laying the foundation for the following sections. The third section then focuses on discussing how these models conceptualize risk and how this is reflected in the estimates. The fourth section focuses in particularly on how uncertainty is treated in outage forecasting models. The fifth concluding section presents some suggestions for paths forward.

2 PRACTICAL LIMITATIONS

Note, this section is a summary of the discussion in Guikema et al. (2017).

The first limitation is that nearly all of the existing models in the academic literature are for a single hazard. That is, they were developed and validated for a single type of weather event, such as a hurricane (e.g., Han et al. 2009a, 2009b, Guikema et al. 2014, Nateghi et al. 2014a). The two exceptions to this that I am aware of is the model presented in Guikema et al. (2017), where an "all weather" model (wind storms, rain storms, lightening events, heat events, and to a limited extent mountain snow events) is presented and the model presented in He et al. (2017) where a model for hurricanes, thunderstorms, and blizzards is presented.

A second limitation is that the data used as input to the models can vary significantly, with some models leaving out potentially important explanatory factors. For example, our previous work suggests that variables such as the duration of strong wind, soil moisture levels, and soil type play an important role in predicting the impact of high wind events (e.g., Quiring et al. 2011, Nateghi et al. 2014a, 2014b,). For high-temperature events, the variable set becomes challenging in other ways because the duration of high temperatures and nighttime lows may be particularly important. Predictive accuracy is limited if an incomplete set of explanatory variables are used.

A third limitation is that many of the models we have seen in use within utilities vary greatly in the rigor with which they were developed and validated. It is a possible to train a statistical model that fits an outage data set extremely well, but offers poor predictions for new events. Careful validation testing, using out-of-sample holdout testing is critical for properly balancing the trade-off between bias and variance, maximizing prediction accuracy for future storms.

A fourth limitation is that most of the available models, with a few notable exceptions, provide point estimates of impacts and do not represent the uncertainty inherent in any prediction of the impacts of hazard weather events on power systems. This point will be discussed further below.

3 CONCEPTUALIZATION OF RISK AND TREATMENT OF UNCERTAINTY IN POWER OUTAGE FORECASTING MODELS

3.1 *Background*

Risk has been conceptualized and measured in many different ways. Here I draw on Aven (2012) and Guikema and Aven (2015) and focus on three conceptualizations of risk: (1) risk is an expected value, (2) risk is a function of probabilities, consequences, and outcome scenarios, and (3) risk is a function of uncertainties, consequences, and outcome scenarios. These conceptualizations can be summarizes as: (1) $R = E$, (2) $R = f(S,P,C)$, and $R = f(S,U,C)$.

The first approach to risk assumes that risk can be summarized by an expectation. This could be expected outcome, with outcome measured in financial terms or some other measure appropriate for the situation, or it could be expected utility, converting the outcomes of the different scenarios into utility. The different possible outcome scenarios are accounted for, but the risk measure is condensed down to a single measure by summing probability multiplied by the consequence measure over all possible outcome scenarios. In this sense uncertainty is included in the measure, but only to the degree the probabilities over the scenarios are included in calculating the expectation. This approach implicitly assumes a fixed value function, either through assuming risk neutrality (for an expected outcome) or a fixed risk attitude and utility functional form. This approach also assumes that uncertainty can be fully represented by probability, with a Bayesian perspective typically adopted.

The second approach is different in that rather than summarizing the probabilities and consequences by a single expected outcome measure, the full probability distribution is presented. Kaplan and Garrick (1981) is arguably the paper that originated this approach, though it was used in the earlier WASH 1400 nuclear reactor study as well. It is widely used within many areas of risk analysis. The results are often given in the form of a F-N (Frequency-Number) curve, a special case of an inverse cumulative distribution. This approach allows decision-makers to consider more than just a point estimate given that the full probability distribution is available to them. It also does not assume a fixed value function. This means that the decision maker(s) are able to obtain the probability-consequence pairs for all scenarios and

using them in their own utility function should they wish to. This approach does still assume that uncertainty can be adequately represented by probabilities. Typically, a Bayesian perspective is taken with regard to the probabilities.

The third approach is similar to the second, except in how uncertainty is treated. Probabilities are often still provided, again sometimes in the form of an F-N curve. However, additional qualitative descriptions of the information underlying those probabilities is provided. Flage and Aven (2009) provide approaches for doing this in an organized, grounded manner. This approach is fully Bayesian and focuses on describing the background state of knowledge underlying any probability assignment made within a Bayesian framework. As such, this approach provides substantially more information to decision-makers, particularly information that would allow them to judge how much confidence to place in the assessed probabilities.

3.2 *How do outage models conceptualize risk and treat uncertainty?*

Power outage forecasting models deal with an inherently spatial process. That is, they provide spatial estimates of power outages. For example, Figure 1 below shows examples of predicted and actual outages for the hurricane power outage forecasting model of Nateghi et al. [2014a] for Hurricane Ivan.

In these types of forecasts, predictions are given as spatial point estimates. For example, in the model output shown in Figure 1, a prediction consists of an estimate of the number of power outages in each 12,000 ft. by 8,000 ft. (3.66km by 2.43 km) grid cell.

How does such a model conceptualize risk? The predictions are not probabilistic in any sense. One could argue here that the predictions are intended to represent a "best estimate" with one interpretation of this being that point estimate is intended to be a represent the mean, mode, or some other measure of central tendency of the unknown, unestimated underlying distribution. This, however, is reading more into these models than is actually there. Many of the current generation of outage models (e.g., Nateghi et al. 2014a, 2014b, Guikema et al. 2014, McRoberts, 2017) use distribution-free ensemble data mining methods such as Random Forest. These types of models do not directly estimate distributions, and they lack asymptotic approximations of distributions as one would have with generalized linear models. It is thus problematic to say exactly what the point estimates represent. In a sense, these models could be thought of as a R = E conceptualization, but the details are unclear.

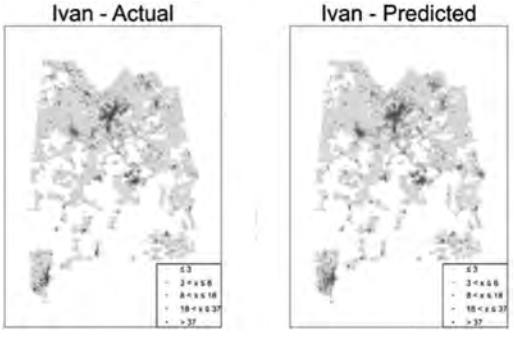

Figure 1. Example power outage forecasts from Nateghi et al. (2014a).

Even in these point-estimate models, some sources of uncertainty have been represented. For example, the models are usually in a forecasting mode, i.e., predicting outages based on a weather forecast, and arguably the largest source of uncertainty in the outage predictions is uncertainty in the weather forecast. The one paper I am aware of that explicitly included weather forecast uncertainty in outage forecasting is Quiring et al. (2014). In this approach, a deterministic model, the one underlying the results in Figure 1, was coupled with 1,000 replications of simulated hurricane forecasts. The deterministic outage forecasting model was run for each replication of the weather forecast, yielding an empirical probability density function for the outage forecast. An example, taken from Quiring et al. (2014) is shown in Figure 2.

In Figure 2, the red bar shows what the result would be if the deterministic model was run for the single best estimate weather forecast. The star represents the actual number of outages, and the green bar represents the mean of the ensemble. We see that there is a high degree of uncertainty in the outage forecasts due to the uncertainty in the weather forecast, uncertainty that is ignored in the deterministic forecasts shown in Figure 1. This approach can be conceptualized as a R = f(S,P,C) framework, though only a portion of the uncertainty is accounted for.

As a third approach, consider a model that is explicitly trained to estimate quantiles of the distribution for outages conditional on the input parameter values. This is the approach developed by both Guikema et al. (2017) and He et al. (2017). Both of these papers used a Quantile Regression Forest (QRF), a variant of the popular random forest algorithm that is designed to estimate specified quantiles of the distribution of the response variable. For concreteness, I will use the model developed by Guikema et al. (2017) as an example, though He et al. (2017) is similar.

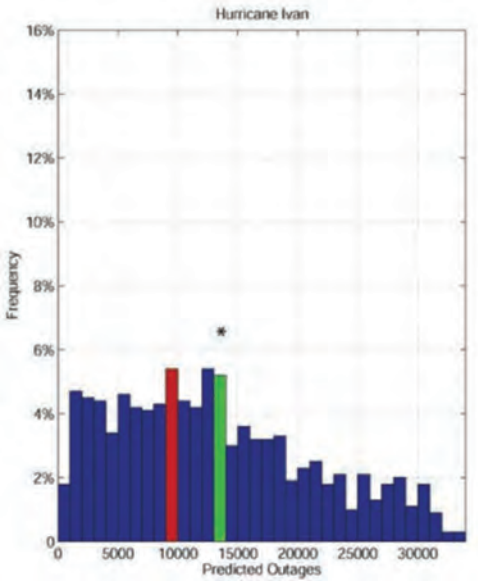

Figure 2. Example of including weather forecast uncertainty in an outage forecasting model. The figure if from Quiring et al. (2014).

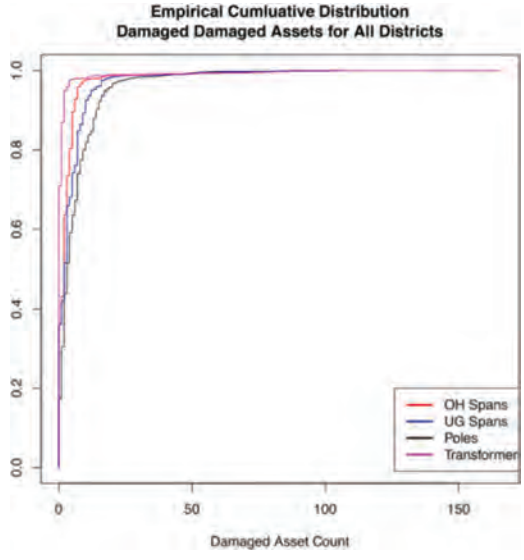

Figure 3. Example of the probabilistic predictions of asset damage from Guikema et al. (2017).

The Guikema et al. (2017) model was developed for estimating damage to power systems due to adverse weather events. Damage is estimated separately for four classes of assets—poles, transformers, overhead line spans, and underground cable runs—where the quantity of interest for each is the number of damaged items in each asset class. The model is a two-stage model. The first stage is a classification model the estimates the probability of their being damage in any one (or more) of the asset classes on a given day due to the weather. The second stage consists of four QRF models, one per asset class, that estimates quantiles (in 0.01 increments) of the distribution of the number of damaged assets in that asset class. There is a separate model that converts this into a probabilistic estimate of the person-hours needed for restoration, but I will focus on the damage model here.

To make a prediction for a given day with the Guikema et al. (2016) model, N (typically N = 10,000) replications are simulated from the two-step process, leading to an estimated probability distribution. Figure 3 shows an example of this type of prediction, presented as a cumulative density function. We see from this figure for that this particular day, there is a high probability of very little damage but that there is a long tail to the distribution. That is, there is a small chance of substantial damage on this particular day given the weather forecast. This approach directly captures the uncertainty in the forecast conditional on the weather forecast. It does not, however, explicitly model and propagate the weather forecast uncertainty through the predictive model as Quiring et al. (2014) does. This approach can be thought of as a R = f(S,P,C) approach, though it captures different aspects of the uncertainty differently than Quiring et al. (2014).

4 DISCUSSION AND RECOMMENDATIONS FOR A PATH FOREWARD

4.1 *Summary of the state of the literature in representing uncertainty in power outage forecasting*

From the discussion above, it is clear that power outage forecasting models have evolved over time in how they handle uncertainty and how they conceptualize risk. Early models were deterministic with at best an asymptotic approximation of the predictive distribution. One model that I am aware of has explicitly included weather forecast uncertainty, the largest source of uncertainty, in the forecasting. Two other models have used explicitly probabilistic prediction models to directly estimate probability distributions for outcomes, but they did not explicitly include weather forecast uncertainty. None of the models to date have moved beyond probabilistic representations of uncertainty to include descriptions of the strength of the knowledge underlying the predictions. This is potentially

quite important because there is substantially more knowledge and data about the performance of power systems under some storm conditions than others.

4.2 *Suggested path forward*

Much has been achieved in the past 12 years during which power outage forecasting has been an active area of research. Model accuracy has improved substantially, and an increasing number of explanatory factors are being included in outage forecasting models. Progress on incorporating uncertainty into the forecasts has been made as well, though this has been more limited as discussed above. Where should the field move next? What types of developments are needed? Here I discuss three key developments that are needed, focused on the treatment of uncertainty in outage forecasting models.

First, models should be developed that more completely characterize uncertainty probabilistically. I am aware of only one paper that has propagated weather forecast uncertainty through an outage forecasting model, and the model in this paper has not been used operationally due to computational limitations. The two probabilistic outage forecasting papers (i.e., Guikema et al. 2017 and He et al. 2017) only handle weather forecast uncertainty indirectly, to the extent that it is represented in the uncertainty in the conditional predictions given the outage forecast. Models are needed that combine these probabilistic conditional forecasts with an explicit modeling of weather forecast uncertainty. While this would be technically challenging it would give a much more complete picture of the uncertainty in a given forecast.

Second, approaches should be developed that move beyond probabilities to provide a clear description of the strength of the information underlying the prediction. Consider for example two situations. In the first, an outage model is to be run for weather event that is similar to a large number of past events that have impacted that utility system, and there is strong confidence in that weather forecast for that day. The model was presented with a large set of highly relevant data during the training process. In the second, the weather forecast is much more uncertain, and the forecast conditions have only been experienced by that power system a small number of times in the past. The model may give similar numerical estimates in these two cases, but many would argue that the utility should have much more confidence in the model in the first case. Qualitative descriptors of the strength of knowledge and the similarity of the forecast conditions to past events, if properly developed and described clearly in practice, could help utility decision makers better judge the degree of confidence they should have in the model in a given situation.

Third, better methods for communicating uncertainty in predictions to utility personnel need to be developed. This is related to the second suggestion, but the focus here is on how the probabilistic forecasts themselves are communicated to utility personnel. In my experience, utility personnel do not understand probability distributions as predictions or, in some cases, even discrete quantiles from the distribution particularly well. They are also making expensive decisions under intense time pressure after a major storm. If they are confused by model output, the model is not helpful to them. If probabilistic predictions are to be used in utilities in practice, new methods for communicating these predictions much be found.

5 CONCLUDING THOUGHTS

Much progress has been made in power outage forecasting for storms. Outage forecasting models are in increasingly wide use in practice, and the available models are increasing in both accuracy and sophistication. However, challenges remain in how these models conceptualize risk and uncertainty and how they model and present uncertainty in predictions to model users. This paper suggests some specific steps that should be taken as this field moves forward, steps that would help to improve how power outage forecasting models deal with the sometimes-substantial uncertainty in their predictions.

Probabilities in safety of machinery: Sample space of yearly accident data

Heinrich Mödden
German Machine Tool Builders' Association (VDW), Frankfurt am Main, Germany

ABSTRACT: The issues "risk assessment" and "tolerable risk" are causing conflicting reactions not only among Health and Safety experts. Experienced designers in the machinery sector are sometimes unsettled, too. The controversies are mainly about numerical probabilistic representations. These are new in the field of general machinery safety, and the key term "probability" turned out to be ambiguous. Recently introduced probabilistic methods encounter a well-proven practical state-of-the-art, which is merely based on qualitatively defined requirements.

If objective findings are to be taken as a basis, it is obvious that the sequence of the total annual figures for reportable accidents can be considered as random independent events in a population of comparable elements. Mathematical concepts seem to make sense if the annually recorded (machine-specific) accident data are interpreted as the overall result of a huge "random experiment" in a relevant observation framework (e. g. DGUV statistics in Germany).

1 PROBABILITIES IN SAFETY OF MACHINERY

The issues "risk assessment" and "tolerable risk" are causing conflicting reactions not only among Health and Safety experts. Experienced designers are sometimes unsettled, too. The controversies are mainly about numerical probabilistic representations. These were recently introduced in the field of general machinery safety, when the revised European Machinery Directive 2006/42/EG (2006) extended the "hazard analysis" of former versions to a "risk analysis" by introducing the term "probability" in the expression: "*estimate the risks, taking into account the severity of the possible injury or damage to health and the probability of its occurrence*". Since this alteration in a legal text, simplified probabilistic methods as in ISO 13849-1 (2008) are being developed. They encounter a well-proven practical state-of-the-art, which is merely based on qualitatively defined requirements. They were mainly focussing on hazards as such (and their countermeasures) rather than "risks, severities of injuries and their probability of occurrence". Nevertheless, on the background of customer demands for very high availabilities (which is equivalent to high inherent safety), it brought about a well-tried state-of-the-art following the three-step-reduction method of ISO12100 (2010).

It is hard to believe, but for the time being, the normative frame for machinery safety does not contain a numerical risk model, which summarizes the single factors plausibly to an overall risk, in order to e.g. compare theoretical results with empirical field data. As a consequence, fictitious hazards and actual risks are being mashed up again and again, so that in controversial discussions in the world of safety standardization, mostly the strongest gut feeling overtrumps logical considerations.

The state-of-the-art is defined on a non-quantitative descriptive background in harmonized safety standards in the Official Journal of the European Commission (2017) since more than 20 years. However, the advantage of the quantitative probabilistic theory is clearly visible: the entire risk reduction process can be detailed in single quantitative factors showing the proportions to enable a more effective engineering. Surprisingly, the transition from "qualitative" to "quantitative" requirements was not so easy, since the key term "probability" turned out to be ambiguous: subjective probabilities are disturbing the discussions, since many traditional experts claim that objective probabilities were missing or difficult to derive. Is this really so?

2 REFERENCE TO ACCIDENT RECORDS

The accident numbers of machine tools (for metal working) in Germany are decreasing since the introduction of a new statistical framework of the European Union in the year 2004, and also before. This pleasant trend of decreasing overall numbers

of reportable accidents is the result of a considerable effort among all stakeholders, on the manufacturer side and on the user side as well (BGHM).

For instance, German manufacturers of machine tools are closely working together in a specific working group of VDW (German Machine Tool Builders Association, Frankfurt) on safety issues in order to exchange their experiences. This is necessary, because the commenting phases of product safety standards, which are being repeated every 5 years, urge them to review existing standard provisions.

The predominant question is then, whether a state-of-the-art can be considered as "proven-in-use" to be safe, or if there are reports of accidents (or incidents) indicating the need for certain upgrades in the safety design.

Answering this question is only possible, if the relevant safety experts of BGHM (German Occupational Safety Organisation for metal-working machines) are involved, see Kesselkaul and Meyer (2016), Adler (2015), Platz (2016) and Preusse (2005).

2.1 *Record low for machine tools was in 2014 and it was missed in 2015*

Most recently, the journal "BGHM-Aktuell" reports in June 2016 a significant decrease of summarized accident data for the branches wood- and metal-working, see Platz (2016). For the separated numbers of metal-working machine tools (i.e. without wood-working), the situation of Figure 1 remains. The decreasing trend in the overall numbers of reportable accidents is also visible here. Noteworthy is that in 2015 "only" 17.235 reportable accidents are allocated to metal-working machine tools (out of the machine perspective). The delightful results in the overall numbers of wood and metal of are unfortunately different when focussing closer on the subsets of metal. For instance, in Fig. 2 the subset "new pention payments" is displayed for (metal-working) machine tools, and Fig. 3 "fatal accidents".

Obviously, since 2008 the numbers are oscillating up and down, e.g. 281 in 2014 and 350 in 2015; a stable decrease since 2008 is not visible. Thus, the above mentioned record low in 2015 does not exist

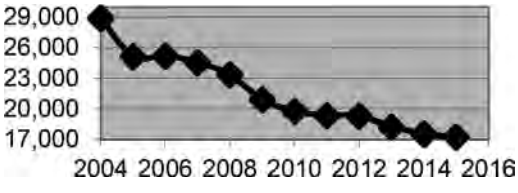

Figure 1. Reportable accidents of German machine tools from 2004 to 2015 (Source: DGUV, VDW (2015).

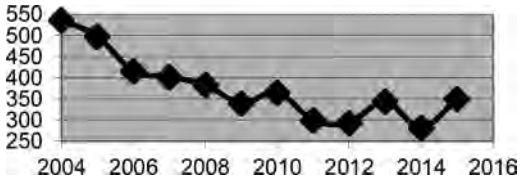

Figure 2. New pention payments for machine tools from 2004 to 2015 (Source: DGUV and VDW (2015)).

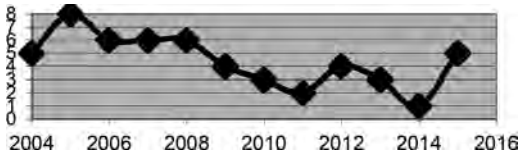

Figure 3. Fatal accidents for machine tools from 2004 to 2015 (Source: DGUV and VDW (2015)).

for machine tools, because it happened in the year before: so there is still a need for action.

Remark: the interpretation limits of statistical findings of DGUV are considered in an extended version of this paper.

3 CONNECTING THE ACCIDENT STATISTICS TO A PROBABILITY SPACE

Obviously, the sequence of yearly overall numbers for reportable accidents can be regarded as random independent events, since each year different random effects are causing the reportable accidents (different machines and operators are affected in different situations).

3.1 *Random experiments and accident modelling*

Mathematical concepts as in Barner et al (1983), Bauer (1990,1991), Bertsche et al (2004) and Feller (1967) seem to be useful for the reduction of real accident risks, if the yearly recorded accident data are interpreted as the overall outcome of a huge "random experiment" in a relevant observation frame (which e.g. is given by Occupational Safety (DGUV) Statistics in Germany):

a. the operation of an average number of α comparable machines during the actual record year;
b. an average number of β operators,
c. who are during an average number of γ hours busy in operating them.

Consequently, the annual accident statistics must be linked to a clearly defined "probability space" (also known as "sample space"). As a result, Health and Safety experts can monitor yearly accident

records on a probabilistic basis. This is recommendable, because the law in Europe Machinery Directive 2006/42/EC refers to the term "probability".

Regrettably, the probability theory does usually not belong to the education of engineers. Neither is the measure theory being lectured among mechanical engineers. Since the probability theory is based on the measure theory, some notations shall be explained graphically and vividly.

3.1.1 *Basic terms*

The term "probability" can be expressed in different ways, see Moedden (2015):

a. as a real number between 0 and 1, where 0 means impossible and 1 means a certain event; also
b. the expected frequency is used, which is the fraction of the number of relevant events over all possible events (e.g. expressing a statistical finding, empirical or theoretical); if this fraction is connected to a given period of time, it means the probability of an event per time;
c. where no statistical data exist, "probability" can express a degree of belief about facts (e.g. due to subjective "experience").

It is obvious that the latter might become a mere "gut feeling". This is the worst kind of a probability: maybe that is the reason, why Feller (1967) emphasizes in the preface: "it is the purpose of this book to treat probability theory as a self-contained mathematical subject rigorously avoiding nonmathematical concepts".

Also the expected frequency is often misunderstood. For instance, if there is a lack of experience, e.g. when empirical data or theoretical findings are not available, it amazingly often happens that the *probability* of an event is incorrectly mistaken for a *mere possibility* of occurrence. In doing so, the probability is not calculated with respect to the correct reference frame as a fraction of numerator/ denominator; this error is called "denominator neglect", see Blastland (2014), Spiegelhalter et al (2014). I.e. the reference frame for the calculation of probability is omitted or ignored.

As an important logical fundament for quantitative probabilities, Kolmogoroff's axioms are based on an event space of elementary singletons. The entire probability theory can be developed from them. Extract from Feller (1967) for the axiomatic probability definition (quote):

The "probability" is not defined as such. The modern theory rather uses the "probability" as a term, which has to fulfill certain axioms. The axioms established by Kolmogoroff are:

1. To every random event A a real number $P(A)$ can be assigned such that $0 \le P(A) \le 1$, which is called the probability of A. This leans on the properties of relative frequencies.
2. The probability of the sure event E is $P(E) = 1$ (scaling axiom).
3. If $\{A_i, i \ge 1\}$ are random events, which are pairwise disjunct, i.e. $A_i \cap A_j = 0$ for $i \ne j$, then follows with the limes $n \to \infty$ (countable additivity axiom):

$$\mathbf{P}\left(\bigcup_{i=1}^{n} \mathbf{A}_i\right) = \sum_{i=1}^{n} \mathbf{P}(\mathbf{A}_i) \tag{1}$$

3.1.2 *Four steps to build a probability space*

In order to take the bearings of an effective risk reduction, several steps are necessary to apply the probability theory to the "random experiment" of yearly accidents. To start with, the real accident records can be connected to some notations of the mathematical measure theory, see Bauer (1990).

Obviously, the number of accidents are "measures" in a sample space. Then, these measures need to be calibrated such that a probability space is built.

Step 1: Define the sample space Ω of this random experiment with all possible outcomes.

The entirety of all possible elementary outcomes ω_i, $(\omega_i \in \Omega)$ for every single machine and every single operator has a variety of numerous causes-to-effect relations. It spreads from technical failures over human errors to forces majeure risk (e.g. lightning stroke). So as regards the cause-to-effect relation, the elementary outcomes ω can be thought of as a countably infinite set of singletons $\omega_i = \{\omega_i, i \ge 1\}$. Nevertheless, the entirety of all possible elementary singletons, which are to be assigned to severities of injuries, can be divided in five subsets (i.e. resulting events in a record year, here sorted by their expected frequency of occurrence from high to low), as shown in Table 1.

In addition to this sample space Ω, there are some related events (e.g. further dimensions due to possible repetition): At the end of a record year in the above mentioned observation frame, every single operator in the basic population of β operators is going to be either in the fortunate subset A_1, or he/she was (once or more) lucky in subset A_2 or (once or more) unlucky in subsets A_3, A_4. Or it could even happen that he/she were in the mortal subset A_5. Accordingly for a record period, every single machine of the basic population of α comparable machines can be connected to subset A_1 or to one or more of the subsets A_2, A_3, A_4 or A_5. And finally, every single hour of the on average $\alpha \cdot \gamma$ hours can be allocated at least to event A_1, or to one of the other four subsets.

Table 1. Sample space Ω with all possible outcomes, examples given for singletons.

Subset of Ω	Meaning	Example of one singleton $\omega_i \in A_j \subset \Omega$
Event A_1	No hazardous event, i.e. undisturbed machine operation (or standing idle), no relevant hazards	Five days of automatic production from Monday to Friday without interrupts.
Event A_2	A hazardous event without causing an injury (i.e. a near accident occurred)	One Monday morning, a drilling tool broke. It was set free, but retained in the machine enclosure.
Event A_3	A hazardous event causing an accident with slight or severe reversible injury	During maintenance work, an operator crushed his finger. After months of medical treatment it healed.
Event A_4	A hazardous event causing an accident with a severe irreversible injury (pension payment)	After having defeated the safeguards of a turning machine, an operator's eye was hit by ejected swarf so heavily, that he was handicapped afterwards.
Event A_5	A hazardous event causing an accident with a fatal injury (pension payment to the relatives)	On a Friday afternoon, an operator was entangled by a CNC-lathe, when he was manually polishing the surface of the turning workpiece.

It has to be remarked that this sample space Ω is not absolutely "mathematically correct", because the fact is ignored that the basic populations of machines and operators presumably are slightly different from one year to the next. However, this "transition error" alters the findings below only gradually, but not substantially, because the conclusions remain the same.

As regards real design practice, Heisenberg (2013) illustrates an (implicitly described) sample space for a certain range of products and the according event records, which fits exactly to the explicit one in Table 1.

Step 2: A measure space is required, which contains the measurable sets (called events).

The measure theory illustrates that with a collection of measurable events $\mathcal{F} = \{A_i, i \geq 1\}$, we get the measurable space $(\Omega, \mathcal{F})$. A measure on $(\Omega, \mathcal{F})$ is a function $\mu : \mathcal{F} \to [0, \infty]$ such that:

i. $\mu(\varnothing) = 0$
ii. If $\{A_i,\ i \geq 1\}$ is a sequence of disjoint sets in $\mathcal{F}$, then the measure of the union (of countably infinite disjoint sets) is equal to the sum of measures of individual sets, i.e.

$$\mu\left(\bigcup_{i=1}^{\infty} A_i\right) = \sum_{i=1}^{\infty} \mu(A_i) \tag{2}$$

The second property stated above is known as the *countable additivity* property of measures. From the definition, it is clear that a measure can only be assigned to elements of $\mathcal{F}$. The triplet $(\Omega, \mathcal{F}, \mu)$ is called a *measure space*. μ is said to be a *finite measure* if $\mu(\Omega) < \infty$; otherwise, μ is said to be an *infinite measure*. In particular, if $\mu(\Omega) = 1$, μ is said to be a *probability measure*.

Since an event is a subset (of comparable singletons) of the sample space Ω, to which a probability will be assigned, for the measurable subsets of the accident sample space follows: The disjoint sets in $\mathcal{F}$ are here $\{A_i, i = 3,5\} = \{A_3, A_4, A_5\}$ with the property:

$$\mu\left(\bigcup_{i=3}^{5} A_i\right) = \sum_{i=3}^{5} \mu(A_i) = \mu \cdot (A_3 + A_4 + A_5) \tag{3}$$

Step 3: Assign measures to the events of $\mathcal{F}$.

The measure μ can be understood as the overall number of all accidents of the type reportable (R) in the relevant observation frame above, since the subsets of severe accidents with pension payments (PP) and mortal accidents (M) are contained therein.

$$\mu(A_3 + A_4 + A_5) = \mu R \tag{4}$$

However, a closer look to different severities requires a distinction of the numbers of the subsets so that they are disjoint:

M =: number of all mortal accidents (remains): this number corresponds to event A_5 above.

PP^* =: number of severe accidents with pension payments (PP) minus fatal accidents: $PP^* = PP - M$: this number corresponds to event A_4 above.

R^* =: number of all reportable accidents minus the number of severe accidents with pension payments (PP) and minus the number of all mortal accidents (M): $R^* = R - PP^* - M$: this corresponds to event A_3 above.

Now, the values R^*, PP^*, M can be derived from the yearly accident records. They can be assigned to the $\mathcal{F} = \{A_3, A_4, A_5\}$ following these principles:

$$\mu = R = R^* + PP^* + M \tag{5}$$

Remark: Since the measurable space $\mathcal{F}$ is simple with only three $\mathcal{F}-$ measurable sets $\{A_3, A_4, A_5\}$, it fulfills the conditions of a Algebra, a σ–Algebra and a Borel Algebra (see Feller (1967) and Jaganathan (2015)).

Step 4: Assign probabilities to the events of $\mathcal{F}$. The triplet $(\Omega, \mathcal{F}, \mathrm{P})$ is called a probability space, if the following three properties (sometimes referred to as the axioms of probability) are fulfilled: a probability measure is a function $\mathrm{P}: \mathcal{F} \to 0,1$ such that:

i. $\mathrm{P}(\varnothing) = 0$
ii. $\mathrm{P}(\Omega) = 1$.
iii. (Countable additivity:) If $\{A_i, i \geq 1\}$ is a sequence of disjoint sets in $\mathcal{F}$, then

$$\mathrm{P}\left(\bigcup_{i=1}^{\infty} A_i\right) = \sum_{i=1}^{\infty} \mathrm{P}(A_i) \tag{6}$$

Here, we have the single probability measures $\mathrm{P}(A_1)$, $\mathrm{P}(A_2)$, $\mathrm{P}(A_3)$, $\mathrm{P}(A_4)$, $\mathrm{P}(A_5)$, which are strictly positive. Because of the limitations of the above defined random experiment of yearly accident records, we know that for every combination of α, β, γ the following equation holds: $\mathrm{P}(A_1) + \mathrm{P}(A_2) + \mathrm{P}(A_3) + \mathrm{P}(A_4) + \mathrm{P}(A_5) = 1$. But, we don't know the actual numbers α, β, γ. Obviously, these probabilities are not easy to determine, because the frame parameters α, β, γ of the basic population are not known. Thus, the measures R^*, PP^*, F of the events A_3, A_4, A_5 are only rough reference numbers, which can be plotted of the years.

3.2 *Available data put into an observation frame*

So, for the sake of showing the proportions of $\mathrm{P}(A_1)$, $\mathrm{P}(A_2)$, $\mathrm{P}(A_3)$, $\mathrm{P}(A_4)$, $\mathrm{P}(A_5)$, some practical probability measures out of the record numbers R^*, PP^*, M, the values α, β, γ shall be estimated for above defined observation frame, to start with (see remark below):

$$\alpha \cong 500.000, \beta \cong 50.000, \gamma \cong 4 \tag{7}$$

The average hours per day $ah_d = \alpha \cdot \gamma$ are then: $ah = 500.000 \cdot 4 = 2{,}000.000$. And per year with on average about 220 working days: $ah_y = 2{,}000.000 \cdot 220 = 4{,}4 \cdot 10^8$.

The probability of an event A_5 can then be expressed as a relative frequency (rf):

$$\mathrm{P}(A_5) = \mathrm{rf}(A_5) = {}^{M}\!/_{ah_y} \tag{8}$$

Accordingly, the probabilities of the events A_3 and A_4 are:

$$\begin{aligned} \mathrm{P}(A_3) &= \mathrm{rf}(A_3) = {}^{R^*}\!/_{ah_y} \quad \text{and} \\ \mathrm{P}(A_4) &= \mathrm{rf}(A_4) = {}^{P^*}\!/_{ah_y} \end{aligned} \tag{9}$$

The residual probabilities $\mathrm{P}(A_1) + \mathrm{P}(A_2)$ are then:

$$\mathrm{P}(A_1) + \mathrm{P}(A_2) = 1 - \mathrm{P}(A_3) + \mathrm{P}(A_4) + \mathrm{P}(A_5) \tag{10}$$

The accident record for machine tools of 2014 shall serve as an example (see DGUV):

$M = 1$, $PP^* = 281 - 1 = 280$, $R^* = 17.563 - 280 - 1 = 17.282$.

$$\begin{aligned} \mathrm{P}(A_5) &= \mathrm{rf}(A_3) = {}^{1}\!/_{4{,}4 \cdot 10^8} = 2{,}3 \cdot 10^{-9} \\ \mathrm{P}(A_4) &= \mathrm{rf}(A_4) = {}^{280}\!/_{4{,}4 \cdot 10^8} = 6{,}4 \cdot 10^{-7} \\ \mathrm{P}(A_3) &= \mathrm{rf}(A_3) = {}^{17.282}\!/_{4{,}4 \cdot 10^8} = 3{,}9 \cdot 10^{-5} \\ &\to \mathrm{P}(A_1) + \mathrm{P}(A_2) \\ &= 1 - 3{,}9 \cdot 10^{-5} - 6{,}4 \cdot 10^{-7} - 2{,}3 \cdot 10^{-9} \\ &= 0.99996. \end{aligned}$$

In Figure 4 the proportions are illustrated according to the assumption of eq. (7). The light grey right column represents the probabilities of the subsets A_1 and A_2, where no injuries happen. The stepwise darker grey columns indicate the probabilities of the subsets A_3, A_4 and A_5, where accidents are rerted as slight or severe reversible injuries, severe irreversible injuries or even fatal injuries. Please take note of the fact that only the absolute values of eq. (10) should be questioned, since their relative proportions are largely independent of the presumptions made above in eq. (7). If absolute values were to be acquired, the assumptions in eq. (7) could be spreaded in terms of empirical worst case, average, best case as a histogram.

Because $\{A_i, i = 3,5\}$ is a sequence of three disjoint sets, eq. (6) is fulfilled:

$$\mathrm{P}\left(\bigcup_{i=3}^{5} A_i\right) = \sum_{i=3}^{5} \mathrm{P}(A_i) = P(A_3) + P(A_4) + P(A_5) \tag{11}$$

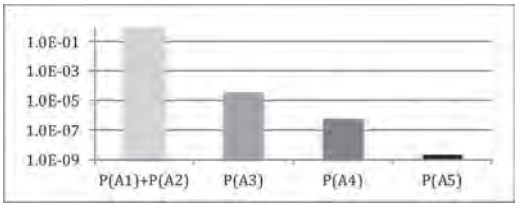

Figure 4. Relative proportions in event probabilities are largely independent of assumptions in eq. (7).

3.3 *Fascinating vision: no accidents ("zero risk")*

Now, as we have built a probability space based on a "σ–Algebra", we can have a closer look to the fascinating vision "zero risk". Based on the definitions 1. to 4. above, the zero-one-laws of the probability theory can be applied. They indicate that the probability of events of a certain type (here a set of the "limes superior") is either 0 or 1. That is to say: Those events happen either almost surely or they are almost impossible.

In particular the Borel-Cantelli Lemmas seem to be suitable to check the decreasing trend of accident numbers, whether possibly the fascination "zero risk" can be realized in the future (see Moedden (2017)). Thus, the sum of all single probabilities (of all subsequent events) is the crucial quantity: if the sum is increasing limitless, the repeated occurrence of events (here accidents) is virtually certain. As a consequence of this comprehension, safety experts cannot be content with current safety standards and their (implicitly/explicitly) defined tolerable risk.

Obviously, the tolerance level has to be continuously reduced for reaching a "zero risk". To start with the foundation of the Borel-Cantelli Lemmas in Moedden (2017), two for convergence and divergence relevant event types (or subsets) of a σ – algebra $\mathcal{F}$ shall be explained.

3.3.1 *"Limes inferior"*

The sequence of subsets $\{A_i, i = 1,n\}$ in a σ – algebra $\mathcal{F}$ shall be given, e.g. A_i could be a single record of reportable accidents of year "*i*" in an observation frame. Now, we form a specific subset of elements ω, which are contained in (only) almost all A_i, i.e. these elements are contained (at the utmost) in only a finite number of A_i:

The example in Figure 5 indicates that for a singleton ω, there are two subsets: i. $\{\omega \notin A_1, A_4, A_7\}$ and ii. $\{\omega \in A_2, A_3, A_5, A_6, A_8, A_9, \ldots\}$. The sequence of both subsets is called the "limes inferior", which is a kind of lower accumulation point of a sequence of random events. It is defined as of the union $(n = 1,\infty)$ of the intersections of all partial sequences $(i = n,\infty)$:

$$A_{\inf} = \lim\inf A_n = \bigcup_{n=1}^{\infty}\bigcap_{i=n}^{\infty} A_i \qquad (12)$$

The subset A_{inf} is the set of all elements $\omega \in \Omega$, which are contained in almost all (finitely many) of the subsets A_n. Let us have a closer look to a single element ω, which could e.g. mean that ω is the event "no fatal accide at grinding machines in an entire record year". As shown in Figure 5, the singleton ω is only contained in finitely many A_i. That is to say, there is a time point n^* such that for all $n \geq n^*$: $\omega \in A_i$. Then ω is in the inter-section: $\omega \in \bigcap_{i=n^*}^{\infty} A_i$, which means (in this example) no more fatal accidents would occur at grinding machines in the relevant observation frame beyond $n \geq n^*$ ("zero risk" accomplished). If all time points are considered, we get: $A_{inf} = lim\inf A_n = \bigcup_{n=1}^{\infty}\bigcap_{i=n}^{\infty} A_i$. The reverse argument needs to be proven. Let ω be one singleton with $\omega \in \bigcup_{n=1}^{\infty}\bigcap_{i=n}^{\infty} A_i$, then there is a number n^* with $\omega \in \bigcap_{i=n^*}^{\infty} A_i$. From this time point on, $\omega \in \bigcap_{i=n^*}^{\infty} A_i$ holds. For $1 \leq i < n^*$ (finitely many), we don't know how often ω is contained. Consequently, the element ω is contained in (only) almost all A_i.

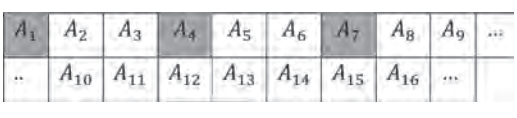

Figure 5. Example for the lower accumulation point "limes inferior".

3.3.2 *"Limes superior"*

The sequence of subsets $\{A_i, i = 1,n\}$ in a σ–algebra $\mathcal{F}$ shall be given. We form another subset of elements, which are contained in infinitely many A_i:

The example in Figure 6 indicates that for a singleton ω, there are two subsets:

i. $\{\omega \notin A_1, A_2, A_3, A_5, \ldots\}$ and
ii. $\{\omega \in A_4, A_6, A_8, A_9, \ldots\}$. So ω is contained in the non-prime number subsets, but not in the prime number subsets. This sequence of subsets is called the "limes superior", which is a kind of upper accumulation point of a sequence of random events. It is defined as the intersection $(n = 1,\infty)$ of the union of all partial sequences $(i = n,\infty)$:

$$A_{sup} = A_n \; i.o. = lim\sup A_n = \bigcup_{n=1}^{\infty}\bigcap_{i=n}^{\infty} A_i \qquad (13)$$

The subset A_{sup} is the set of all elements $\omega \in \Omega$, which are contained in infinitely many of the subsets A_n, and obviously $\omega \in A_n$ applies for infinitely many $n \in \mathbb{N}$, i.e. "A_n i.o." with "i.o. = infinitely often". A_{sup} is a nested intersection of unions. The union $\bigcup_{i=n}^{\infty} A_i$ can be thought of as a sequence $(B_n)_{n\in N}$ with $B_n \supset B_{n+1} \supset B_{n+2}$ … The (B_n) are

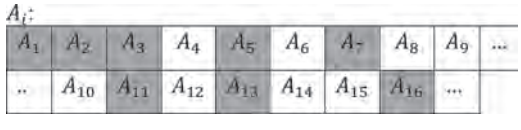

Figure 6. Example for the upper accumulation point "limes superior".

Figure 7. Matryoshka nested doll (Source: Elisabeth Mödden).

nested decreasing subsets. This resembles the Matryoshka nested doll in Fig. 7, where the smallest innermost doll is the "intersection" of all dolls.

Formally, let $(B_n)_{n\in N} = \bigcup_{i=n}^{\infty} A_i$, then $(A_n\ i.o.) = \bigcap_{i=1}^{\infty} B_n$. In doing so, B_n is the event that at least one event $A_n + A_{n+1} + \ldots + A_\infty$ occurs (that is a bigger set than at least one event $A_{n+1} + A_{n+2} + \ldots + A_\infty$ occurs). It is sometimes referred to as the "end-tail" event, which means that from n onwards at least one event $A_n + A_{n+1} + \ldots + A_\infty$. occurs. Then $(A_n\ i.o.)$ is the intersection of the "end-tail" events, it means that for n an event B_n occurs. That is to say, no matter how big n is, at least one of the A_i will occur.

$$P(A_n\ i.o.) = P\left(\bigcap_{n=1}^{\infty} B_n\right) = \lim_{n\to\infty} \mathrm{P}(B_n) = \lim_{n\to\infty} \mathrm{P}\left(\bigcup_{i=n}^{\infty} A_i\right) \tag{14}$$

It is obvious that $A_{inf} \subseteq A_{sup}$, because if one singleton ω is contained only in finitely many A_n, it is also contained in infinitely many A_n. Let one singleton ω be contained in infinitely many A_i. How can this be expressed without using the term "infinitely"? For every n there is one k \$ n: $\omega \in A_k$. For every n, $\omega \in \bigcup_{k=n}^{\infty} A_k$ holds, and therefore $\omega \in \bigcap_{n=1}^{\infty} \bigcup_{k=n}^{\infty} A_k$. The reversion is obvious.

As regards the application of the zero-one-laws on the accident records, it is fortunate that they consist of scalar values summarizing comparable singletons. So they resemble a sequence of values (a_n) which sum up a collection of $\omega_i \in \Omega$ that are assigned to a selected kind of events in the subset sequence A_n. For a sequence (a_n), the necessary and sufficient condition for convergence of sequences can be applied (see Barner (1983): (a_n) is convergent if and only if (a_n) is bounded and:

$$\lim_{n\to\infty} a_n = A_{inf} = A_{sup}$$
This is equivalent to: $A_{inf} = A_{sup}$ (15)

3.3.3 *Interpretation for available accident records*
The probability space from 3.1.2 is the platform for the interpretation: For the sake of simplicity, the accident records in Figure 1 can be interpreted as a finite sequence (i.e. as a partial sequence of an infinite sequence in the future), and the available records contain twenty-two random events $A_1, A_2, \ldots A_{22}$ until the year 2015 (i.e. the available "measures" of reportable accidents in the observation frame: injuries caused by machine tools in Germany). Since the sequence is monotonously decreasing (at least during the last ten years for the overall numbers), the "limes superior" of the only 22 (instead of ∞) events can be thought of as the minimum number of accidents, which happened in (almost) every of these twenty two years. Apparently, this is the number of accidents in the last recorded year A_{22} = 17.563. So, the "limes superior" for the partial sequence $A_1, A_2, \ldots A_{22}$ is the value of the lowest number of accident records (the "smallest doll" contained in all of the Matryoshka nested dolls from above, see Jaganathan (2015), which is here equal to the last record:

$$A_{sup} = A_n\ i.o. = lim\ sup\ A_n = \bigcap_{n=1}^{22} \bigcup_{i=n}^{22} A_i = A_{22} = 17.563 \tag{16}$$

It has to be remarked that this simplification is only "almost mathematically correct", because the intersection of the union of twenty-two different subsets ignores the fact that the basic populations of machines and operators presumably have been slightly different from one year to the next etc. However, this reservation does not alter the fact that the Borel-Cantelli lemmas can illustrate the vision "zero risk" mathematically.

4 SUMMARY AND OUTLOOK

Admittedly, theoretical risk assessment starts in the hypothetical "what if" domain, where theoretical risk can be estimated only logically in cause and effect (at the most), but not in an *absolute* scale. However, actual *relative* risk reduction effects between different yearly accident records can be calculated and compared quite exactly, because the real risk actually can be "measured" precisely as by the DGUV records, as well as in individual records of machine tool builders. Therefore, this paper tries to support plausible risk considerations connecting theory and reality. Hopefully, it also helps to improve a common understanding of the term "probability". Only then can the 1. Borel-Cantelli lemma be met, which leads the way to the fascinating vision "zero risk", at least approaching it yearly step by step.

Of course it is indispensable that the a.m. accident investigation of BGHM and DGUV is going to be continued meticulously. VDW is offering

support with this paper. This is a precondition such that a more complete Pareto diagram (than the one in Figure 12 of Moedden (2017)) can be brought about, showing potential safety gaps in current design and operational practices, which need to mended first. Subsequently, possible upgrades in the safety design against not significant hazards can be looked at: doing the first thing and not leaving the other option out. In addition, individual manufacturers of specific product ranges can monitor their own yearly records separately, such as convincingly demonstrated in Heisenberg (2013). Moreover, VDW is supporting the member companies accordingly in research projects (see Nowizki et al (2016)) in order to make German machine tools as safe as reasonably possible.

SYMBOLS AND OTHER DEFINITIONS

Symbol	Dim.	Meaning
α, β, γ	–	Parameters of the observation frame of acc. statistics
μ	–	Measure of a subset in a sample space Ω
$\sigma, \mathcal{F}$	–	Indicator for certain algebra
k_1, k_2	–	Adjustment parameter
Ω	–	Sample space
ω_i	–	Singleton of the sample space Ω
A_1 *to* A_5	–	Accident specific subsets of the sample space Ω
A_i, $P(A_i)$	–	General events in the sample space Ω and their probabilities P
$A_{inf} = \bigcup_{n=1}^{\infty} \bigcap_{i=n}^{\infty} A_i$	–	Limes inferior of a sequence A_i also indicated as: A_i *f.o.* = *lim inf* A_i
$A_{sup} = \bigcup_{n=1}^{\infty} \bigcap_{i=n}^{\infty} A_i$	–	Limes superior of a sequence A_i also indicated as: A_i *i.o.* = *lim sup* A_i
R, PP, M	–	Number of accidents: reportable, pension pay., mortal
$\in, \notin, \forall$	–	Element of, not an element of, holds for all

ACKNOWLEDGEMENT

Gratitude shall be expressed to Christoph Thomann (DGUV) for giving insight into the statistical framework of accident reports in Germany. Also to Ralf Kesselkaul, Christoph Meyer and Christian Adler (BGHM, 2015, 2016) for the very useful preliminary conclusions from their accident investigation reports, which presumably entailed a lot of depressing details of human misfortune.

Probabilities in safety of machinery—how fixed and movable guards bring about a significant risk reduction

Heinrich Mödden

ABSTRACT: If hazards arising from machine tools cannot be completely eliminated by design, protective devices must be provided. Separating guards prevent people from accessing or entering the danger area; in addition, they retain any parts that may have been released in the work area. An attempt shall be made here to supplement the currently purely intuitive (qualitative) consideration of the protection effects by a probabilistic scaling of the risk reduction effects. By scaling these effects, the Pareto principle can be applied: achieving the best possible benefit with minimal effort. This procedure is indispensable for machine tool manufacturers to master economic risks in global competition. Since there is no plausible risk model in current safety standards for machine safety with which risk reduction effects can be scaled, a simplified quantitative risk model is presented in this paper for this purpose (and two further papers are presented at ESREL 2018).

1 INTRODUCTION

In accordance with the guiding standard ISO 12100 (2010) risk is a function of possible damage severity and probability of occurrence, whereby the latter can be represented as the frequency of the damage. Because, over a large basic population of comparable situations, the mathematic-theoretical "probability" of an event becomes an empirical (countable) "relative frequency", which enables the verifiability of this event in the totality of all possible events, see Haigh (2012), Taschner (2013).

As a result, risk can be reduced by avoiding or reducing the extent of damage (effect related measure) and/or by reducing the probability of occurrence or frequency of the occurrence of damage or the associated hazard (cause-related measures). Separating protective devices (guards) plays an elementary role in both measures and also offer a high cost-benefit advantage. These have the effect of significant risk reduction both for protection against accidental access and for protection against flying parts, substances and, in particular, fire protection.

As for conventional machine tools with drive powers in the range of 100 kW and powerful hydraulic clamping devices, it cannot be denied that (very low) failure probabilities of technologically highly reliable machine functions or safety functions include also a basic possibility of serious damages/injuries. This is demonstrated, e. g. by the depressing fact that in Germany, machine tool operators suffer around 100 life-changing accidents and even fatal accidents in the single-digit range per year, see Kesselkaul & Meyer (2016). The typical distribution of severity is also known as the "accident pyramid" and can be displayed in a histogram, see Moedden (2017).

How can a designer live with this frustrating insight into the world of real probabilities, i. e. the annually recurring serious or even fatal accidents? One might even ask oneself the question: Can a machine tool be built safely at all?

The answer is "yes", because if the extent of injury cannot be reduced in itself, then the reduction of the relative frequency of injuries remains as a means of reduction, i. e. how often damage repeats itself in a given period of time. With reference to a basic population with comparable elements, this is equivalent to their probability.

The risk reduction of machine tools is therefore all about reducing the "probability of hazardous

situations", so that damage is avoided as far as practicable. The likelihood of hazards occurrence (see also ISO 12100 (2010), Section 5.5.2.3.2 "Occurrence of hazard events") can be reduced in several respects and is scalable as parameter O, e. g. with $0 \leq O \leq 1$ (see Fig. 2 in ISO 12100 "Risk reduction process from the viewpoint of the designer").

The starting point is always that technological machine functions (which can also become safety functions when the safety doors are open) already have very low failure probabilities. How the possible resulting hazards can be massively reduced even further with the help of separating protective devices shall be considered here and scaled plausibly. It is not the accuracy of the post-decimal value that matters, but rather the power of 10, as is usual in risk representations, see Baruch et al (2011).

2 SAFETY MEASURES IN PRODUCT STANDARDS

Separating guards for risk reduction on machine tools should be designed in such a way that they are sufficiently capable of holding back normally expected off-flying parts, see ISO 14120 (2002). The retention capability of a guard describes the resistance against the penetration of flying elements. Machine-specific design conventions are anchored in standards such as ISO 23125 (2010). In the case of impact energies that increase beyond the design conventions, e. g. due to the release of large workpieces or clamping jaws, the probability of failure increases, Meister (2017).

2.1 *Failure hypotheses*

Basic risk assessments have been carried out in product standards and corresponding safety measures have been defined for some typical machine configurations, such as machine tools, woodworking machines and balancing machines. There detailed dimensioning recommendations in the harmonized standards are available for separating protective devices in order to ensure the required retention capability. The starting point is a typical failure hypothesis for released elements that leads to defined masses, velocities and the energies derived from them, as in ISO 23125 (2010). Fragment energies that may exceed these hypotheses are therefore further reduced in terms of control technology, e. g. by limiting the number of r. p. m. of spindles or instructively by means of detailed instructions in the operating instructions, e. g. for the safe clamping of workpieces. This ought to reduce the risk of operator injury to a level that is "As Low As Reasonably Practicable" ("ALARP"), UK-HSE (1974).

The following constructional distinction is applied to protect against released elements in order to minimize the residual risk of injury:

i. Closed door (automatic operation): The safety guard must have sufficient impact resistance against ejected parts.
ii. Open door (setting mode, special or service mode): The rotational speeds of rotating parts are safely reduced, and unnecessary movements are safely stopped, so that the risk of ejected elements is reduced.

The application duration of operating modes according to ii.) should therefore be minimized as far as possible in order to minimize the risk. In the machining process, on the other hand, the observability of a process is sometimes indispensable.

2.2 *Guiding standard for safety guards ISO 14120*

For machine tools, the full enclosure as in Figure. 1 in particular is a very effective means for risk reduction (see below transition in probabilities from PFH_d to PHE; this is assigned to step two of the three-stage method in Figure. 2). For this purpose, important aspects are regulated in a Guiding Standard for separating protective devices, *e. g. access to hazardous areas (EN ISO 14120 (2002), Sec. 5.1.2), retention of ejected parts and other impacts (EN ISO 14120, Sec. 5.1.3), retention of hazardous substances (EN ISO 14120, Section 5.1.4), retention capacity (EN ISO 14120, Section 5.5) and corrosion resistance (EN ISO 14120, Section 5.6).*

In particular, the type of construction according to Section 3.5.2 is widespread in machine tools:

Figure 1. Automatic vertical turning centre acc. to ISO 23125 (2010) (Source: INDEX).

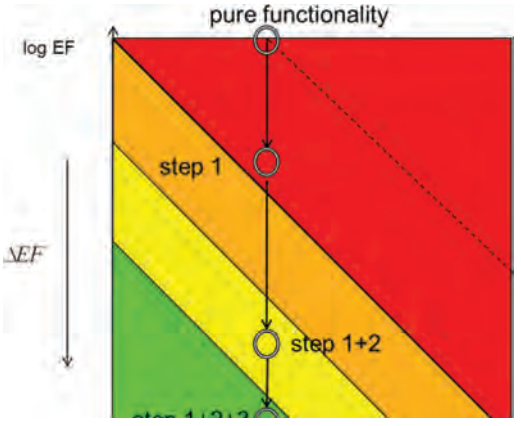

Figure 2. Risk reduction according to the three-step method in the Farmer Diagram, Baruch et al. (2011).

Interlocking guard with guard locking
Guard associated with an interlocking device and a guard locking device so that, together with the control system of the machine, the following functions are performed:

- *the hazardous machine functions "covered" by the guard cannot operate until the guard is closed and locked,*
- *the guard remains closed and locked until the risk due to the hazardous machine functions "covered" by the guard has disappeared and*
- *when the guard is closed and locked, the hazardous machine functions "covered" by the guard can operate (the closure and locking of the guard do not by themselves start the hazardous machine functions.)*

3 SEPARATING PROTECTIVE DEVICES (GUARDS) AND PROBABILISTIC SAFETY

The Machinery Directive 2006/42/EC requires the preparation of risk assessments for all life cycle phases of a machine as proof of compliance with safety and health requirements in accordance with Annex I. In point 1, it deals directly with the risk elements "severity of possible injuries" and "probability of their occurrence". Since 2012, ISO 13849 (2008) has been the new guiding standard for control safety in mechanical engineering. It determines the safety reliability of a control chain via the "Performance Level" (PL). A new feature is the quantitative treatment of safety: The PL is a theoretical characteristic value as "average probability of a dangerous failure per hour" and it is given as PFH_d-value. This concept is not yet fully compliant with the Machinery Directive 2006/42/EC and the Guiding Standard for Risk Assessment, as explained by Steiger (2014). This paper contributes to a better understanding.

3.1 *Intuition and better approaches*

It is hard to believe, but for the time being, the normative frame for machinery safety does not contain a numerical risk model, which summarizes the single factors plausibly to an overall risk, in order to e. g. compare theoretical results with empirical field data. As a consequence, fictitious hazards and actual risks are being mashed up again and again, so that in controversial discussions in the world of safety standardization, mostly the strongest gut feeling (subjective) overtrumps logical (objective) considerations.

The controversies are mainly about numerical probabilistic representations. These were recently introduced in the field of general machinery safety, when the revised European Machinery Directive 2006/42/EC extended the hazard analysis of former versions to a risk analysis by introducing the term "probability" in the expression: "*estimate the risks, taking into account the severity of the possible injury or damage to health and the probability of its occurrence*".

Intuitively, it is immediately obvious that a separating protective device (e. g. a full enclosure, as shown in Figure. 1) is an effective means of risk reduction—both with regard to the probability of occurrence and, in particular, with regard to the extent of damage. In addition, this applies to technical causes of failure on the one hand and to human error on the other. It is also clear that separating protective devices cause a considerable risk reduction because they significantly reduce the duration of the operator's exposure to hazards, for example, not only in the case of protection against unintentional access, but also for protection against ejected parts, substances and especially in the case of fire protection. This can significantly reduce both the expected severity of an injury and, in particular, its expected frequency.

An attempt shall be made at ESREL 2018 to supplement the intuitive consideration with an additional scaling of the risk reduction effects. Therefore, the key term "probability of hazardous situations" is explained in Moedden (2018). Therein, the scaling of risk reduction is explained by means of a detailed probabilistic risk model, see Moedden (2016).

For full enclosures, a high probability can be assumed that risks from the workspace are completely controlled in cases of failure that lie below the design convention (e. g. chips from machining).

For the range of energies up to the design concept (e. g. the chuck jaw hypothesis according to

ISO 23125 (2010), see also Mewes (1999), Ising (2001)), the standard-compliant safety guards contribute considerably every day to protect the operators. Beyond the design convention, however, the probability decreases significantly, see Meister et al (2017). As a separating protective device must be opened regularly, e. g. when changing workpieces manually, during troubleshooting or when setting up the machining process, the protective effect of the separating protective device is sometimes (partly) lost, too. The consequences of technical failure and human error can then be dramatic. This applies in particular if the automatic processing is carried out under "defeating" of the protective devices (manipulation), as explained in Kesselkaul & Meyer (2016), Preusse (2005) and Meyer (2017).

3.2 *Inherent safety and diagnostic functions*

As far as the reduction of technical failures is concerned, a reliable technological function is basically the starting point (step one in Figure 2), because the more reliable a function is, the less frequent are failures and even rarer failures critical to safety. This is because the latter have all failure events to the upper set; in any case, safety-relevant failures cannot be more frequent than all failure events as a whole. Obviously, non-safety-relevant and safety-relevant failures are in a complementary relationship to each other and form the entirety of all failures, see Bornemann et al (2015). Diagnostic functions can be used to anticipate some safety-relevant failure events, so that safety-related reactions can be carried out which lead to a (safe) standstill of the machine in the event of an imminent critical failure, see Moedden (2016). If this is done in time, a potentially safety-relevant failure becomes a non-safety-relevant failure with machine downtime as a result without any hazard from the motion control of the machine tool. This applies in particular if a full enclosure is closed when a safety-relevant failure is detected in order to prevent access to the working area (e. g. in case of fire extinguishing with CO_2 flooding after detection of a fire in the working area, ISO23125(2010)). After this step two in Figure 2, only the always possible stumbling, falling etc. remain as a hazard.

The entirety of all failures can be represented as a repetition rate in defined time periods, e. g. as "probability of failure per hour", PFH. In principle, the PFH value of a technological function does not increase due to an additional diagnosis, but rather if the diagnostic function is hypersensitive and fails to perform correctly (e. g. often in case of smoke detectors in living quarters).

A high reliability of a technological function (i. e. with low PFH-values) thus contributes to the inherent safety required by the Machinery Directive 2006/42/EC and ISO 12100 (2010) as a first step towards the three-step risk reduction method, see Figure 2 (Legend: EF: Expected frequency, S: Degree of severity). The diagnostic function itself is not an inherent safety element, but an additional safety measure according to step two of the three-step method. ISO 13849-1 (2008) uses the term "safety function" for this purpose.

3.3 *Target "zero risk" is missed*

With the measures described so far, an expected frequency of safety-relevant technical failures remains, because not all of them can be shut down safely with diagnostic functions. Therefore, if a "zero-risk" acc. to Platz (2016) cannot be achieved, a certain repetition rate of safety critical failures (which can cause hazards) must be expected, e. g. as "probability of dangerous failure per hour", defined as PFH_d in ISO 13849-1(2008).

A full enclosure primarily reduces exposure to hazards. However, this is not the only risk reduction achieved by safety guards. The controllability of a hazardous situation can also be increased by separating protective devices, e. g. for partial claddings around the primary flight circle of chips, so that the operator can either choose a safe location himself, or is compelled to take up a safe position by means of location binding of the control panel.

A further protective effect of a full enclosure results from the ratio of partial load operation to full load operation. In a paper at ESREL 2016, this important "secret of success in machine tool safety" is explained, the implicit error detection in the process on the basis of a full enclosure, Moedden (2016). The probability theory indicates that most of the failures are to be expected in automatic operation, i. e. when the safety doors are closed, i. e. then they occur (nearly) without hazard.

However, there is still a probability of occurrence of a hazard event with a full enclosure in automatic mode (index "1"): $PHE_1 > 0$ because a full enclosure cannot safely hold back all conceivable failures but only up to the respective design convention, as already mentioned, see Ising (2001).

With correct dimensioning, however, the far most common of the conceivable hazards are mastered, i. e. on this side of the dimensioning convention and partly beyond it. For example, the chuck jaw hypothesis of ISO 23125 (2010) partially covers the workpieces rotating around the main axis if a chuck loss leads to symmetrical release of the workpiece, Ising (2001).

In automatic mode, the numerical value for PHE_1 is close to $PHE_1 \approx 0$ because, according to accident records, damage caused by parts released from the working area actually occurs in the basic

population of all machines acc. to Kesselkaul & Meyer (2016), but it is extremely rare in standard-compliant machines, see Moedden (2017). Meister et al (2017) made a first attempt to describe the withstand probability and the probability of failure as a probability function depending on the translational energy of fragment impacts.

In the setting mode (index "2"), a numerical value $PHE_2 > 0$ must be assumed for the risk PHE_2, since, according to accident statistics, most of the damage occurs in the basic population of all machine tools when the safety doors are open. The same also applies to all other operating modes with open safety doors, in particular for "manipulation", Kesselkaul & Meyer (2016), Preusse (2005).

3.4 *The "accident pyramid" at the boundary of a "zero risk"*

According to Moedden (2018), the equation of a technical risk reduction for a. m. cases one and two is in the interval $t_a \le t \le t_b$, (eq. 1).

$$PHE''_{1,2} = \left(1 - C_{1,2}\right) \cdot t_{\text{exp},1,2} \cdot f_{\text{exp},1,2} \cdot O_{1,2} \times \int_{t_a}^{t_b} \sum PFH_{d,\,tech,1,2} \cdot dt$$

Eq. (1) contains all risk reduction principles from the three-stage method as illustrated in Figure 2.

Nevertheless, PHE > 0 remains as a finding, i.e. even with very reliable controls ($\sum$PFHd $\approx$ 0) and standard-compliant fully enclosed enclosures, residual hazards remain. But does a PHE > 0 really mean that there is an according percentage in the basic population of severe damages? The answer is "no", because the probability of a hazard must still be associated with the severity degree of an injury.

Furthermore, in the operational environment, there is a supplementing indirect, intuitive way of avoiding injuries. It is a kind of "statistical warning principle", based on the so-called "accident pyramid", see Manuele (2011). Considered as relative frequencies in probability theory on the background of a clear cause-to-effect relation, this means that—before a serious accident occurs—a lot of "near-accidents" occur first, then the less frequent accidents with real injuries, from slight reversible over severe to fatal. The severity of an injury needs to be connected to the equation of risk reduction eq. (1), it can be roughly estimated with the "accident pyramid".

As the "near-accidents" happen comparatively more often than real accidents, the critical situations in the operational area should be largely known. The warning effect takes place only on a averaged statistical background, because a "near-accident" takes place many times, before it comes to an injury, and even more times before it comes to a serious or fatal injury. This means that experienced operators can also protect themselves intuitively by being and remaining particularly vigilant in critical areas. Inexperienced operators should therefore pay close attention to the warnings of their experienced colleagues.

3.5 *Comparison of machine tool and robot*

In order to illustrate the probabilistic risk model in Eq. (1), a calculation example shall be used to compare an automatic machine tool with full enclosure, as shown in Fig. 1, with a collaborative robot without protective housing (instead using op-tical and/or tactile proximity sensors), as in Fig. 3.

In order to make the comparison easier to understand, the estimated average values in Table 1 are compiled on the basis of "risk snapshot parameters" of typical activities; these can, of course, be adjusted on a case-by-case basis, e. g. out of evaluated video records. For statistical purposes, they can be collected in a histogram, showing the bandwidth and share of the parameters.

A manual workpiece change on the machine tool, which should last 3 minutes and be repeated 11 times per hour, thus means 33 minutes of possible hazard exposure (per hour). The robot is a support device for collaborative manual activities as shown in Figure 3, which should last 1.8 minutes and repeat 25 times p.h, i. e. 45 min. hazard exposure (p.h.).

Using an 8-hour shift, the risk reduction of a machine tool (MT) is compared with that of a robot (ROB). The safety design of the latter depend almost entirely on reliable control technology, e. g. in the case of a safety function "safe operational stop"; three superimposed movements are assumed to be stopped safely. The safety concept of an automatic machine tool, on the other hand, depends heavily on a standard-compliant,

Figure 3. Coll. robot without protective enclosure, see Kentsch (2016).

Table 1. "Risk snapshots" of a) Machine tool with full enclosure, and b) collaborating robots without protective housing.

Object/ Action/ Safety function	$\Sigma PFH_{d,tech}$ [h^{-1}]	$t_b - t_a$ [h]	O [–]	$t_{exp,1}$ [h]	$f_{exp,1}$ [h]	C [–]	PHE [–]
a) MT/ manual workpiece change/ SCW	$6.5 \cdot 10^{-6}$	8	0.5	0.05	11	0.5	$7.5 \cdot 10^{-6}$
b) ROB/ manual support/ SOS	3-times $5 \cdot 10^{-7}$	8	1	0.03	25	0.1	$8.1 \cdot 10^{-6}$

fully enclosed work area and on the presumption that it is used as intended. For the sake of simplicity, one safety function is considered at a time. The above mentioned "Safe Operation Stop" (SOS) for the robot, whereby the associated hazard can constitute an impact to the operator's head, with potentially serious injuries and for the machine tool, a "Safe Clamping of the Workpiece" (SCW). The associated hazard during manual activities with open guards could be a loss of workpiece due to gravity, with a hazard of crushing the operator's hands in the work area and possibly serious injuries.

In the right-hand column of Table 1, the probability of occurrence of a corresponding hazard based on the input parameters acc. to Eq. (1) is estimated.

The simple example in Table 1 shows that:

a. A safety function (SF) with a PL = b (i. e. PFH_d in the range of $3 \cdot 10^{-6}$ $h^{-}1$ to $1 \cdot 10^{-5}$ $h^{-}1$, here averaged: $6.5 \cdot 10^{-6}$ $h^{-}1$). This is active as a technological work function within a full enclosure of a machine tool, but it becomes a safety function, when the safety doors are open. If the SF fails, the occurrence probability is assumed to be O = 0.5 and the avoidability to C = 0.5. Concerning the risk, it can be equivalent to:
b. A safety function with PL = d (i. e. PFH_d in the range of $1 \cdot 10^{-6}$ h^{-1} to $1 \cdot 10^{-7}$ h^{-1}, here averaged: $5 \cdot 10^{-7}$ h^{-1}, for three superimposed movements) of a robot without a full enclosure. Such safety functions are used without full enclosure for collaborating robots according to ISO 10218 [27]. If the SF fails, the occurrence probability is assumed to be O = 1 and the avoidability to C = 0.1.

Corresponding to the risk model in eq. (1), for the first case in Table 1 an occurrence probability of a hazard PHEMT can be derived to $7.15 \cdot 10^{-6}$ per 8-hour shift. And for the second case and occurrence probability of a hazard PHEROB is estimated to $8.1 \cdot 10^{-6}$.

For the robot, this means that the probability of a hazard occurrence can largely be compared with that of a fully enclosed machine tool, despite the higher reliability of the safety function (PL = d). The reason why the machine tool achieves (despite a comparatively low PL = b) a safety level comparable to a robot is that in the event of a control failure, the safety guard on the machine tool can still protect the operator here (but not for the robot). *This comparison demonstrates the significant risk reduction effect of a full enclosure!*

This protective effect of a full enclosure is not sufficiently taken into account in ISO 13849-1 (2008), especially the derivation of performance level recommended (PL_{rec}). This is the current reason why the technological clamping functions of machine tools, which can also be used as safety functions when safety guards are open, are underestimated (allegedly max. PL = b, c according to ISO 13849-1 (2008)). As illustrated by Steiger (2014), this standard is not correctly based on the three-step method of risk reduction in ISO 12100 (2010). The greatly simplified approaches of ISO 13849-1 (2008) may be suitable for the situation on robots, but not for the complex interactions involved in risk reduction of safety guards of machine tools.

3.6 *Best practice at the EMO safety day 2017*

The actual implementation of the three-step method described above depends on the type of machine. However, there are also cross-cutting issues, such as the operating modes of a machine, see Steger (2017), and the equipment for fire protection, see ISO 19353 (2016). Therefore, the machine-specific measures are summarized in product safety standards (here the type C standard EN ISO 23125 (2010)).

At EMO Safety Day 2017, field data evaluations of more than 93,000,000 operating hours of turning machines (Figure. 1) without accident were presented. These results and the subsequent discussion presented by Nowizki (2016) proved that the provisions in type C standards can be applied successfully, when a sufficiently dimensioned full enclosure is available.

The "secret of success" in reducing accidents lies, as explained above, to a large extent in the massive risk reduction effects of combining a) fixed and moveable guards for the full enclosure of stationary machines (comparable to a driver's cab in mobile work machines), and b) fault detection in the process, explicitly and implic-

itly, Moedden (2016). These two factors together result in a kind of "systematic safety integrity" at the machine level. In doing so, the very high availability of machine tools should never be ignored because this contributes to a high level of inherent safety,

The proven-in-use studies of the VDW and Nowizki (2016) thus confirm that the theoretically possible probabilities of hazards, as estimated in Table 1, can actually be significantly reduced by suitable measures, e. g. the protective effect of a properly designed full enclosure. The full enclosure as shown in Figure. 1 provides a practically proven state of the art which has been defined in product standards for more than ten years on a kind of "macroscopic" level (i. e. thicknesses of protective doors and windows are actually visible and measurable). The safety measures in it follow the three-step reduction method of ISO12100 (2010) and create a significant probabilistic distance between the failure probability (e. g. of a component) and the occurrence probability of according hazards.

On the other hand, the discussion about control failures takes place merely on a kind of "microscopic" level where the PFHd-values are invisible, not measurable. However, they must be brought to the "macroscopic" level, as suggested in eq. (1), in order to plausibly connect to the probability of occurring hazards.

4 LACK OF MAINTENANCE

Another important aspect for the operational safety is the maintenance in the plants. The ageing of sight protection windows has been known for more than ten years, see Würz et al (2002), Duchstein (2010), Mewes et al (1999), Wahrlich et al (1999), Mewes (2003) and Uhlmann et al (2012), and the countermeasures are anchored in standards such as ISO 23125 (2010), see also Adler (2013), Mewes (2001). Nevertheless, the criteria for replacing embrittled or damaged protection windows—the most important component here is polycarbonate—are still being ignored by some person in charge. This can pose a considerable risk to the machine tool operators who may not be protected sufficiently against fragments of material released from the work area.

This item also includes preventive maintenance which is intensively marketed for components that are relevant to machine availability and machining quality. In doing so, a great deal of effort to ensure that replacement / maintenance is carried out within the specified time intervals so that availability and quality do not suffer.

Unfortunately, in contrast to this, the component "safety window" which directly affects the safety of the operator is often seen as a "cost driver". Can availability and quality be more important than the safety of the operators who ultimately make availability and quality possible by exposing themselves to the above restrictions?

5 SUMMARY AND OUTLOOK

Since 1996, the Institute for Machine Tools and Factory Management (IWF) at the Technische Universität of Berlin in cooperation with VDW has used impact and ageing tests to define design recommendations for separating protective devices (i. e. fixed and moveable guards with vision panels) and to supplement existing knowledge. Both, this database and the experimental investigation possibilities in Berlin are used in many other industries for the dimensioning of guards in order to close gaps in the existing standardization. In addition, current research projects have considerably expanded the experimental equipment at the IWF in Berlin, see Prasol et al (2017), Meister et al (2014). And close scientific relations exist with comparable research institutes in Italy, see Landi et al (2017), and Japan, see Yui (2017). The longstanding cooperation of VDW and IWF has led to the fact that the German machine tool industry has a high level of safety ass proven by Nowizki et al (2016). This can be seen before all other factors due to the low number of accidents resulting from machine-related faults, see Kesselkaul & Meyer (2016), Moedden (2017).

Nevertheless, there is still a need for further research and knowledge transfer. On the one hand, this is aimed at the machine tools users, since these are the innovation drivers and define the requirements for the manufacturers. On the other hand, machine tool manufacturers should also be mentioned as a further target group, as they should also be made more aware of this issue. In particular, it is of interest to convey that safety does not in principle go hand in hand with an increase in costs. As an example, it is referred to the dimensioning of separating guards on grinding machines, see Adler et al (2017). In the area of marketing of safe machine tools, it would be possible to use safety as a "Unique Selling Proposition (USP)" similar to the "Blue Competence" label, in order to distinguish itself more strongly from competitors. This has been successfully practiced in the automobile industry for a long time with reference to the different consumer motivations and also of people who purchase industrial goods, see Duchstein (2011).

This composition is also an appeal to a professional use of the term "probability". An unprofessional application of the term leads to arbitrary interpretation which is not an option in effective safety engineering. The aim is always to reduce the number of accidents that are recorded annually by the strong effect of the "Pareto principle". These represent the sum of all probabilities of occurrence of hazards, with reference to a yearly period for the respective basic population. In Moedden (2017) the situation for machine tools in Germany is explained in detail; a transfer to other machine types and other countries is possible.

6 CONCLUSION

The current safety standards are difficult to understand and partly contradictory, especially when it comes to the use of the term "probability". Although, taken together, they contain a vast number of obligations, there is no common risk model in them. For effective risk reduction, however, a logically structured risk model is indispensable, which should also be probabilistically scalable. For this purpose, further proposals are presented here, in particular for a quantification of the significant risk reduction effect of full enclosures. Also, in order to put the following two previously not logically connected representations in relation to each other: a) a dimensionless probability (e. g. of the Machinery Directive and ISO 12100 (2010)), and b) a probability per time unit, in the context of control functions often indicated as PFH_d-value (e. g. in ISO 13849-1 (2008)).

Theoretically and empirically, it could be demonstrated that fixed and moveable guards make a significant contribution to reducing the probability of occurrence of hazard events. However, they cannot completely reduce the probability of hazard occurrence to zero for two reasons:

1. Fixed and moveable guards need to be opened for certain activities, see Moedden (2018).
2. In the closed state, they have only a defined retention capacity against released parts in the working area, see Meister (2017).

In order not to lose the protective effect of separating protective devices, two appeals to the operators remain important:

1. To keep the boundaries the intended use of the machines, such that manipulation of full enclosures does not happen.
2. Preventive maintenance of embrittled polycarbonate vision panels must be carried out carefully.

SYMBOLS AND OTHER DEFINITIONS

Symbol	Dim.	Meaning
PFH_{tech}, ($PFH_{d,tech}$)	h^{-1}	Acronym stands for "probability of (dangerous) technical failure per hour". It is shown in [11] that this is an average density function.
PHE	h^{-1}	Acronym stands for "probability of a hazardous event (technical and human sources)". In Eq. (1) the association with PFHd, tech value is shown.
Parameter O	-	Probability of occurrence of hazard events
t_{exp}	sec	Exposure time, expressed also as an intervall: $t_a \leq t \leq t_b$
f_{exp}	h^{-1}	Repetition rate of an exposure time
$F_{rel} = t_{exp} \cdot f_{exp}$	–	Relative share of exposure
A_v, C	–	Avoidability, controllability

Analysis of fatal fires in Norway over a decade, – a retrospective observational study

C. Sesseng, K. Storesund & A. Steen-Hansen
RISE Fire Research AS, Trondheim, Norway

ABSTRACT: Five-hundred-and-seventy-one fatalities were registered in the official fire statistics in Norway between 2005–2014. However, little is known about the victims. This study collected information from several sources to build a holistic database and gain more knowledge about the technical and social aspects of the incidents, forming a basis for more targeted measures. Human behaviour greatly affects the risk of fire, which supports why social aspects of incidents should be considered when identifying risk factors associated with the victims. The results showed a clear distinction between victims above and below the age of 67 with respect to risk factors. For the elderly, reduced mobility, impaired cognitive ability, mental disorders and smoking were observed risk factors. For the younger victims known substance abuse, mental illness, alcoholic influence and smoking were observed, mostly in combination. This shows that fire is a social problem, and should be prevented by initiating customised measures.

1 INTRODUCTION

In this study, information from fire statistics of the Norwegian Directorate of Civil Protection (DSB) and other sources has been analysed to gain more detailed knowledge than before about who dies in fires and why. This will help to implement more targeted measures in order to reduce the number of people perishing in fires. Results from previous studies in Norway and other countries have provided important data in designing the study, in the interpretation of results, and comparisons of the evolution of fatal fires over time. Demographic and cultural differences over time and between countries will amongst others impact on attitudes and risk behaviour as concern fires. Variations in the employment of various preventive measures will also be reflected in statistics on fatal fires. Factors that may impact on the proportion of registered victims in fatal fires are the methods of data collection, different definitions of fire fatalities and to what extent fires are investigated, plus the way in which fires are registered, and the thoroughness in which the consequences of a fire are followed up afterwards.

2 METHOD AND ANALYSES

2.1 *Data collection*

2.1.1 *Sample*

This study surveys persons having died in fires in Norway during the time period of 2005–2014. According to DSB's fire statistics 517 fatal fires with 571 fatalities occurred during this period.

2.1.2 *Sources*

Our data material consisted of DSB's fire statistics, police investigation reports, the fire victim's medical records, and the Norwegian Cause of Death Registry (NCoDR) from the Norwegian Institute for Public Health. Generally, the police investigation reports also include post-mortem reports.

In order to obtain access to these sources, authorisations were applied for and granted from several authorities.

DSB's statistics provided the basis for which police investigation reports we requested access to. Hence, cases not listed in these statistics are not included in the study.

By means of the police reports the fatalities were identified by name and national identity number. This formed the basis for which medical records we asked to access, and for which persons we requested data from NCoDR. The medical records are not accessible through a common register, but each medical record resides with the doctor who was general practitioner/family doctor at the time of death. This meant that the Norwegian Directorate of Health (NDE) needed to provide us with a key to connect each fatality to the GP/family doctor at the time of death.

2.1.3 *Data registration and categorization*

To register data from the various sources, a database was set up to handle the fire data and to

link data on fire victims. DSB's fire statistics were imported directly into the database, and were used as a basis for the requests to access investigation reports sent to the police districts. Additionally, variables to handle relevant data were added.

To ensure consistent extraction and storage of data from the various cases between project collaborators, an electronic form was prepared which was completed for each incident. Some of the input was pre-defined multi-choice categories, other was free text input. This made interpretations more objective, and it became easier to quantify qualitative data.

Extraction of data from NCoDR, which contained information regarding cause of death, was also made. Of all the identified persons there were 29 with an incomplete ID-number (lack of information in the police reports). Sixteen of these were found in NCoDR by searching their name. The remaining 13 persons were foreigners without a Norwegian ID-number or D-number (ID number for temporary residents in Norway) who had died in Norway. The extraction from NCoDR was also imported into our database and linked to each separate person. Of the NCoDR data we got access to, the categories *underlying cause of death* and *injury code* were of largest interest.

2.2 *Statistical analysis*

All data registered in the database was exported to the statistics program Statistica, version 12 (Dell Inc 2015).

Statistical tests were conducted to test and examine apparent differences between sub-groups in the population. In all essentials non-parametric tests were employed, such as Mann-Whitney U-test, Fisher exact-test, chi-square test and regression analysis. For all analyses a significance limit of $p \leq 0.05$ was employed. A p-value between $0.10 \geq p > 0.05$ is considered as a trend.

Multiple Correspondence Analysis was carried out in order to identify whether the various characteristics of the victims frequently occurred simultaneously. This includes e.g. examining whether victims with an established substance abuse also tend to be smokers. This method cannot quantify any similarities or dissimilarities, but it may provide a qualitative impression and give a basis for further analyses.

3 RESULTS

3.1 *Registration of fatalities*

DSB's fire statistics contain some data on the fire itself, as well as the number of injured persons and the gender and age of the fire causalities. Requests for access to police reports were made for all these fires, and we received 347 police reports (68% response) that were reviewed. Data from these reports were combined with data from DSB's statistics. The cases were geographically dispersed across the entire country, although we did not receive any police reports for three out of 19 counties in Norway.

From the received police reports 387 fatalities were registered. The vast majority of these were identified through their ID-number, and a request for access to the medical records was sent to the respective GP/family doctor at the time of death. A small number lacked ID-number data and were consequently excluded from the analysis of medical records. There were also a number of cases where only the name and date of birth were stated, which often sufficed to find the medical record of the person in question. We received 248 medical records, which represent 64% of the identified victims.

3.2 *The fatalities*

3.2.1 *Sample description*

Table 1 shows the distribution of various characteristics of the fatalities in fires during the 2005–2014 period.

As concerns the category «non-native speaker», it is meant to include persons who are assumed not to communicate adequately in a Nordic language or English, and with whom it will be difficult to communicate relevant information about fire safety. According to a rough estimate based on Norwegian statistics on immigration, there were 5–6% non-native speakers (to a varying extent) in Norway in 2014 (Sesseng et al., 2017).

3.2.2 *Age and gender*

The persons who perished were in all essentials well into their adulthood. Half of the fatalities had an age between 44–78 years, see Figure 1 showing the age distribution of the fatalities.

When taking the number of people in each age group into consideration, one sees there is almost an exponential connection between age and the number of fire fatalities, see Figure 2.

Table 1. Sample description.

Gender	Male	Female		n
	56.1%	43.9%		387
Age	Median	Interquartile range	Min–Max	n
[years]	59	44–78	1–97	386
Non-native speaker	No	Yes	Unknown	n
	88.6%	7.8%	3.6%	387

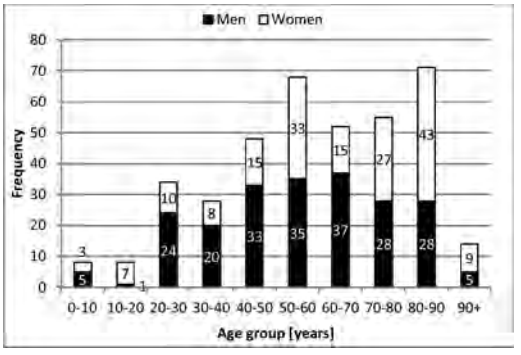

Figure 1. Age distributed on gender for fatalities, n = 386.

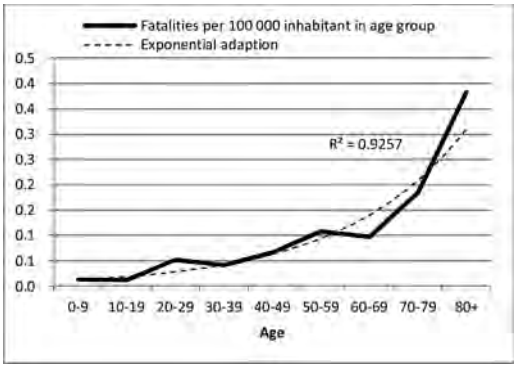

Figure 2. The graph shows the ratio between number of fatalities and number of inhabitants in each age group for fatal fires during the 2005–2014 period.

During the 2005–2014 period 56% of fatalities were men. Men are overrepresented in all age groups under 70 years, also taken into account the gender distribution in these age groups.

According to Statistics Norway, in 2007 there were about as many men as women around the age of 63 in Norway. After this age the proportion of women increased, and with age the surplus of women continued to rise. Among persons over the age of 80 around two thirds were women, and among those over 90 years three fourths were women (Falnes-Dalheim & Slaastad 2007).

After the age of 80, more women than men perish in fires (approx. 60% of the fatalities). However, taken the gender distribution in the age groups into consideration there is an equal risk for both genders (Statistics Norway 2017).

3.2.3 *Risk factors*

Table 2 shows the registered risk factors linked to the fire fatalities in our selection. The results show

Table 2. Registered risk factors related to the fatalities. The category «unknown» means that the medical records hold no data. Light grey cells mark a high proportion of observations of risk factor for persons above the age of 67, while dark grey cells mark the same for persons below the age of 67.

Vision	Normal	Visually impaired	Blind	n
All	86.8%	13.2%	0.0%	257

that the majority of the victims had normal vision as well as hearing. On the other hand, we see that half of the victims at pension age had reduced mobility. Further, one third of the same age group had impaired cognitive abilities, and an equally large share suffered from mental illness. For the younger age group we see that half of the victims had a reputation for substance abuse. Equally many suffered from mental illness, and an equal proportion was under the influence of alcohol during the fire.

When examining the fatalities confirmed being under the influence of alcohol compared to those not being under the influence at time of death, regardless of age, we find no difference as to the time of day they perished when dividing the day into four 6-hour periods (00–06, 06–12, 12–18 and 18–24) ($p = 0.147$). Even though there is no statistically significant difference between morning/day and night (06–18 and 18–06), there is a trend suggesting that more fatalities were intoxicated at night time ($p = 0.052$).

There is a significant difference between women and men when it comes to being under the influence of alcohol during the fire ($p = 0.000$). When disregarding the cases where it was not possible to neither prove nor disprove that there was alcohol in body fluids, one sees that around two thirds of all male fatalities were under alcoholic influence. The case is the opposite for women, where one third was under the influence of alcohol.

There is no significant difference in the distribution of the cause of fires in fires where the victim was under alcoholic influence compared with fires where the victims were not under alcoholic influence ($p = 0.433$, the rarest categories were excluded from the analysis).

To conduct a Multiple Correspondence Analysis the population was divided into two sub-groups; persons with age < 67 years, and age ≥ 67 years (Norwegian retirement age). Further, analyses were made of factors representing somatic ailments and factors relating to intoxication, psychiatry and lifestyle. The reason why psychiatry is placed in the same category as substance abuse, smoking and alcoholic influence during the fire, is because psychiatric cases may be triggered by drug abuse, and therefore drug abuse and psychiatry occur simultaneously in many cases.

For the group with age ≥ 67 years the material shows that persons with mental illness also frequently are smokers. Moreover, we have seen that being under the influence of alcohol during a fire does not appear systematically in combination with other factors (no pattern). As regards somatic ailments we do not see any evident patterns. This may signify that *combinations* of e.g. reduced mobility and vision impairment are not overrepresented in the fatal fire statistics for this group. Nevertheless, 61% of this group have *either* impaired vision, hearing, or mobility, which may have contributed to the death.

For the group of fatalities below the age of 67 our data material shows that factors «known substance abuse», «alcoholic influence during fire», «mental illness» and «smoking» often occur together. Only 13% of the fatalities in this age group had none of the mentioned factors, while the majority (66%) had various combinations of two or more factors.

As concerns somatic functional impairment no pattern is identified, except from the fact that factors normal mobility, normal vision, and non-reduced cognitive ability often occur together.

3.2.4 *Cause of death*

Figure 3 shows the distribution of cause of death for the fatalities in the sample. Asphyxiation is the chief cause (57%), followed by burns (15%). In addition to that, a combination of asphyxiation and burns was concluded in 10% of cases. In 13% of the cases the cause of death is unknown, which may be attributed to the fact that the victim was so heavily burnt that it was difficult to carry out an examination or draw some conclusions.

Information about the underlying incident and causes of death was collected from NCoDR. The underlying incident says something about the incident leading to the person's death (e.g. exposure to open flame), while the causes say something about the actual cause of death (e.g. burn).

The data showed that exposure to open flame stands for 88.4% of all incidents, and that 5.8%

Figure 3. Cause of death for fatalities in fires during the 2005–2014 period, N = 387.

of incidents involved intentional self-harm (suicide). Correspondingly, it was seen that one form of asphyxiation or other stands for 74.7% of the causes of death, while some form of burn stands for 21.6% of the causes of death. The asphyxiation rate in NCoDR (74.7%) is somewhat higher than what was registered from post-mortem reports in our selection (57%). By adding the fatalities where it was concluded that the cause of death was a combination of fire injury and asphyxiation, one gets a rate of (67%), which is still somewhat lower than in NCoDR. It therefore seems to be an inconsistency between the post-mortem reports and what is being reported to NCoDR.

4 DISCUSSION

4.1 *Cause of death*

The distribution of causes of death for fire fatalities in Norway are in stark contrast to the corresponding US numbers for 2012–2014 where e.g. asphyxiation alone stood for 37% of the causes of death (DHS 2016a). We are unaware of the reason for these differences, but an assumption is that the causes of death are defined and registered differently in the US compared to Norway. This emphasizes the uncertainty when making such comparisons between countries.

The content in fire smoke is complex, consisting of a number of components which have various effects on humans. Asphyxiation may occur at an early stage in the course of a fire, even before the fire has developed enough to have a visible flame. In order to prevent deaths caused by asphyxiation it is therefore important to focus on preventing fires from arising in the first place, and to ensure that outbreaks of fire are detected and extinguished as early as possible. Materials with a high combustibility should be avoided, and an adequate control of potential ignition sources should be in place.

4.2 *Number of persons involved and fire outcome*

From the police reports we retrieved data on the number of people present in the building or living unit when the fire started and the number of persons perished or injured. The results, presented in Table 3, show that in the majority of the fires only one person was present at start of fire, and that in over nine of ten there was only one fatality, and in an almost equal proportion there were no injuries in addition to the fatality.

4.3 *Risk factors*

For the purpose of the study the population is divided into different sub-populations, e.g. victims below the age of 67 and victims of 67 years or more. This makes it possible to identify the factors that often recur for these groups. These results should be used by home care services, the GP/family doctor and other agencies who are in contact with the inhabitants of the municipality, and who provide care or fire prevention measures, in order to implement the right actions for the individual. The subsequent sub-chapters deal with the various risk factors.

Table 3. Distribution of number of persons present at fire start, number of fatalities and injured.

Present at start	1 pers.	2 pers.	3 pers.	≥4 persons	n
Fatalities	71.1%	15.2%	5.0%	8.7%	342
	1	2	3	≥4.	n
	92.6%	5.7%	1.2%	0.5%	513
Number of injured	0 pers.	1 pers.	2 pers.	≥3 pers.	n
	86.1%	8.1%	3.5%	2.3%	347
Where victims were found	Point of origin	Neighbouring room of origin	Other room in living unit	Outside living unit	n
	40.1%	11,3%	42.7%	5.9%	354

4.3.1 *Age and health*

During the 2005–2014 period seven children aged 0–7 years died in a fire, which constitutes 2.2% of the fatalities. Six of the children died in fires occurring during the night while the family was asleep. In comparison 15.1% of all fatalities during the 1970–1979 period were children aged 0–7 years, and for the 1990 to 1992 period the rate was 4.5% (Storesund 2013). This means it can be confirmed that the number of children perishing in fires is comparatively low and that it has decreased since the 1970s. Childcare in Norway has undergone major changes since the 1970s. Children spend less time on their own and more time in buildings with high fire safety standards (schools and kindergartens), which altogether probably has contributed to improving fire safety, thereby reducing the risk of children perishing in a fire.

Studies establish that elderly people are more exposed to perishing in a fire than younger persons, and we have found the same in our study (DHS 2016a, 2016b, Xiong et al. 2015). Half of the fatalities are 59 years old or older. When taking into account the number of individuals within the various age groups, one finds an exponential increase in the number of fatalities with increasing

age. The increase is particularly noticeable for age groups 70–79 years and 80+. E.g., the latter group has a 9.3 times higher probability of perishing in a fire than persons between 30–39 years according to our material. DSB's study of fatal fires during the 1986–2009 period showed that elderly people over the age of 70 had a probability of perishing in a fire that was around 4 times higher than the population as a whole (DSB 2010). Figures from the US show that elderly people (age 85+) had a 4.1 times higher probability of perishing in a fire than the population at large. The corresponding figure from our study is 4.9 times, which must be said to be comparable.

With an anticipated population growth as well as a growth in the proportion of elderly people (67+), it will be important to target preventive measures toward this group in society, in particular in view of the fact that more of them will live longer in their own homes than before, and often also alone. Until date the number of places in Norwegian nursing homes and similar in recent years have remained rather stable (Kristiansen 2016). Nursing and care services have changed from being provided in nursing homes and similar to being provided to a larger degree at home, while places in nursing homes mainly are being offered to the most sickly of elderly people. There is reason to believe that this trend will continue (Steen-Hansen et al., 2010).

For those who have reached retirement age we principally see four recurring risk factors: reduced mobility (47%), impaired cognitive ability (the elderly people who fell into this category often had Alzheimer's disease or other forms of dementia) (33%), mental illness (34%) and smoking (33%). However, no recurring patterns of combinations of various risk factors were identified, except mental illness and smoking. The report entitled *Correct measures in the right place* (English translation) does not define age as a risk factor in itself, but argues that age may involve physical and cognitive challenges (Storesund et al. 2015, Gjøsund et al. 2016, Storesund et al. 2016). The thought behind such an approach is that one should not see elderly people as a homogeneous group facing the same challenges, but rather implement safety measures meeting individual challenges. The results of this study of fatal fires support this perspective. The fact that these analyses group persons having reached pensionable age in a separate group does not signify that one must or should introduce measures targeting all elderly people, but one should rather be particularly attentive to the risk factors that stand out for this age group.

For those below retirement age the most conspicuous risk factors are known substance abuse (54%), mental illness (52%), alcoholic influence (59%) and smoking (36%) It was also found that these risk factors often occur in combination with each other. This shows that some of those who perish in a fire in this age group carry several risk factors, which increases the risk of perishing in a fire. Actually, 87% of the fatalities in this group have one or more of the mentioned risk factors. Without having any basis for asserting it in this study, it cannot be excluded that these factors may affect their independent living skills, and consequently also the risk of a fire occurring in their living unit.

4.3.2 *Gender*

More men than women perish in fires. However, the gender distribution varies for the different age groups. In age groups 20–49 and 60–69 there are around twice as many men perishing than women, while there is an overweight of women in age group 80+ and between 10 and 19 years. The variations between women and men for some age groups may be explained by population distribution and risk behaviour.

The variations also show us that being male is not a risk factor. There is still a high proportion of women who perish in fires, and prevention measures must be directed toward this group on an equal footing with men.

Also for the 80+ age group the picture is more nuanced when taking the population into consideration. Sixty-two percent of the fatalities in age group 80+ are women. Figures from Statistics Norway show that the proportion of women in this age group is 62.3% (Statistics Norway 2017). However, these figures are from 2017, which is a few years after the focus period of this study. However, from what we know there is nothing to suggest that the gender composition has changed considerably during these years. Thus one may conclude that women in this age group probably do not carry a heightened risk of dying in a fire than men.

4.3.3 *Smoking*

Thirty-five percent of the fatalities were confirmed smokers (56% unknown), where 57% of the smokers were men and 43% women. Approximately 13% of fires were caused by smoking. In comparison, figures from Statistics Norway show that the rate of daily smokers in Norway has been reduced from around 25% to 13% during the period we studied (Kristiansen 2016). Since the share of smokers in fatal fires is a lot higher than in society in general, it appears that smoking is a risk factor.

4.3.4 *Influence of alcohol and intoxication*

The fact that known substance abuse and mental illness are relatively common occurring factors in fatal fires is not surprising, but coincides with previous studies made in Norway and abroad. Studies show that fatal fires more often than other fires are caused by the victim himself/herself; in our selection the fire was directly caused by the

victim in almost 40% of the fires. This points to the importance of being able to prevent and handle a fire, and it shows that the probability of fatal fire increases when these abilities are limited. Substance abuse and some mental illnesses may lead to impaired judgment, both as concerns the incidents leading up to fire start, and in connection with the fire itself.

In around 40% of the fatalities the post-mortem examination identified traces of alcohol in the body fluids, while no alcohol was found in an equally large proportion. As concerns the last 20% this is uncertain, as it was not reported in the post-mortem reports, or the post-mortem report was unavailable.

The figures also show that there are variations between women and men. When considering men only, one finds that the figures are not dissimilar to previously reported findings (Skaar 2013). There is, however, a larger discrepancy where women are concerned compared to the same study. It was reported that only 20% of women were under influence of alcohol during the fire, while our figures show a proportion almost twice as big (36%).

An explanation to this discrepancy may be differences in focus periods between the two studies, which were 1993–2008 and 2005–2014, respectively. If this is the explanation, it may point to a change in the drinking pattern of women (frequency and volume) over the period. However, we did not examine this aspect any further.

4.3.5 *Single persons*

In over 70% of the fires in our data basis there was only one person present at fire start. Forty percent of the victims were found in the room of origin, which suggests that the victims had few opportunities of handling the fire and escaping at an early stage of the fire.

These figures show that there is an inherent risk associated to *being alone*. The likelihood of the fire being detected in time to survive is reduced, and it is harder to escape if one is alone at the start of fire. Persons living alone are probably more often alone in the living unit than persons living with others. This means that there is probably an indirect, increased risk associated with living alone.

4.3.6 *Culture, attitudes and language*

Attitudes to fire safety impact on the likelihood of an occurrence of fire. Attitudes may be related to risk behaviour, the willingness to use preventive equipment, and tidiness and maintenance. In our study we registered whether the victim was a non-native speaker, which was not common. The background was amongst other to examine whether the ability to read and communicate in the Norwegian language had any large impact on the risk of perishing in fire. We did not register any detectable connection between being a non-native speaker and the risk of perishing in a fire.

Examination of socio-economic factors (income, education, ethnicity, profession, etc.) was not a part of this study.

4.4 *Social circumstances*

Social problems are described as challenges in the relationship between the individual and the society. The term embraces the individual's problems caused by societal circumstances and the individual's challenges in adapting to societal structures and norms. The causes of social problems are many and often interdependent, but factors such as poor working conditions, lack of employment and poor housing conditions are mentioned as examples. In medical context, it is said that social problems comprise a bodily, a mental and a social component, which all interact (Bruusgaard 2017).

The dominating risk factors in our material all fall in under social problems in the medical context, as they either affect the individual's bodily, mental or social functions, or a combination of these.

As discussed and exemplified by (Storesund et al. 2015), it is therefore of key importance to not only focus on the physical circumstances of the dwelling when initiating fire preventive measures, but also consider the individual's specific challenges and needs (bodily and mental) and the individual's social circumstances. E.g. a person with impaired hearing will have other challenges regarding preventing, perceiving and escaping a fire than a person with impaired vision. Further, a person with reduced cognitive abilities would have other challenges.

By conducting a thorough risk analysis, the individual's needs could be identified and suitable organisational and/or technical measures could be initiated.

4.5 *Critique of methodology*

The police reports vary when it comes to richness in detail, which may impact on our analyses. In some cases we see that investigation reports are highly inadequate, while in other cases they are exhaustive. This makes it difficult to draw categorical conclusions as regards some factors. We have taken care not to colour the information with our own interpretations, but have in cases where some factors are not mentioned labelled them «unknown» to underline the lack of data. In a few number of cases where the police concluded with an unknown cause of fire, but where we, based on a professional assessment, believe that one cause of fire is overwhelmingly likely, we have stated this as the cause. This was a conscious choice which we believe gives a more correct picture of the actual causes, even

though it may give an imprecise picture of the police's clearance rate as concerns fatal fires.

The medical records were also very thin in some cases. In these cases the majority of categories were therefore marked as unknown. Similarly, cases potentially relating to cognitive ability, substance abuse and mental illness were labelled as unknown, as these conditions most often are not evaluated in cases where the doctor does not have any suspicion. It is therefore reasonable to assume that a large percentage of cases where these conditions are labelled unknown that entails no existence of impaired cognitive ability, known substance abuse or mental illness. In cases where the victim rarely had been to see the doctor, the medical records tended to be old with scarce updated information. The relevance of data has therefore been evaluated from one case to the next.

To which extent one is affected by a certain blood-alcohol level depends on a variety of factors, e.g. weight and the person's alcohol tolerance. It can therefore not be stated with any certainty to which extent alcohol actually affected the victim and the outcome of the fire.

Based on information in the investigation reports and the post-mortem reports we therefore registered categorically whether or not the fire victims were under the influence of alcohol at the time of death.

5 CONCLUSIONS

Individuals who have died in fire cannot be divided into groups of common denominators, but there are some combinations of factors that we have seen repeatedly:

For those who have reached retirement age, we mainly see four risk factors: *reduced mobility, impaired cognitive ability, mental disorders* and *smoking*.

For those under retirement age, the risk factors are *known substance abuse*, *mental illness*, *alcoholic influence* and *smoking* that appear, either alone or in combination with each other.

There is an increasing risk of dying in a fire with increasing age. Generally speaking, men do not have a higher risk than women, but in some age groups, the risk of fatality is greater for men. Alcohol constitutes a greater risk factor for men than for women.

Fatal fires in Norway are a social problem, which calls for measures individually adapted to the persons with the identified risk factors.

The current study has generated extensive data which can serve as a baseline to track whether the fatality rate for different groups increases or decreases over time. This could also be valuable when evaluating the effect of future fire preventive measures.

Probabilities in safety of machinery—Markov model for the scaling of risk reduction effects due to limiting the hazard exposure

H. Mödden
German Machine Tool Builders' Association (VDW), Frankfurt am Main, Germany

ABSTRACT: The most recent product safety standards for machine tools such as ISO 16090 for the safety of milling machines follow the three-step-method of risk reduction, as it is explained in ISO 12100. Step 1 is always the design of inherent safety of the machine. Step 2 follows with the design of additional safety measures, and step 3 focusses on instruction for use (including warning signs at the machine) and training. A very effective risk reduction can be achieved, if the work area of the machine is fully enclosed (this belongs to step 2). In doing so, the automatic machining processes can take place without exposing the operator to the hazard. However, operator access to the work zone is sometimes necessary for manual intervention, such as setting actions inside the work area or workpiece change. Then careful instructions are necessary, which shall enable the operator to fully control the situation and protect himself by awareness of the respective hazards.

The many different kinds of operator activities, which vary with the selected machining process, can be allocated to specific modes of operation. In ISO 16090, a modes of operation concept comprises five selectable options: 0: manual mode/1: automatic machining/2: setting mode/3: special mode with limited manual intervention/and separately for selected operators only: service mode. The purpose of such a concept is to reduce the relative exposure of the operator to occurring hazards as far as for the intended use possible.

The combination of full enclosure and modes of operation concept brings about a significant risk reduction, however the effect is being discussed only qualitatively on an intuitive basis. Unfortunately, a scalable model is still missing, which could quantify the risk reduction effects, e.g. for the purpose of parameter optimization.

In order to improve the engineering abilities, a very first simplified Markov model is presented here, which is founded on a probabilistic concept for the description of the operator activities at a machine. As a result, the a.m. risk reduction effects can be scaled probabilistically. This is of advantage, if it comes to the quantitative reliability requirements of safety functions according to ISO 13849-1 such as e.g. a safe standstill of gravity loaded vertical axes. Because of the potentially severe hazards of those axes in setting mode or during manual intervention in the work area, the required reliability is high, e.g. performance level PL = d according to ISO 13849-1. This paper explains for typical manual interventions, how this requirement and supplementary safety provisions can be justified probabilistically.

1 PROBABILITIES IN SAFETY OF MACHINERY

Numerical probabilistic representations were recently introduced in the field of general machinery safety, when the revised European Machinery Directive 2006/42/EG extended the "hazard analysis" of former versions to a "risk analysis" by introducing the term "probability" in the expression: "*estimate the risks, taking into account the severity of the possible injury or damage to health and the probability of its occurrence*". Since this alteration in a legal text, simplified probabilistic methods as in ISO 13849-1 (2015) are being developed. They encounter a well-proven practical state-of-the-art, which is merely based on qualitatively defined requirements. They were mainly focussing on hazards as such (and their countermeasures) rather than "risks, severities of injuries and their probability of occurrence". Nevertheless, on the background of customer demands for very high availabilities (which is equivalent to high inherent safety), it brought about a well-tried state-of-the-art following the three-step-reduction method of ISO12100 (2010). The state-of-the-art is defined on a non-quantitative descriptive background in harmonized safety standards since more than 20 years.

2 CONDITIONS OF A MARKOV MODEL IN SHORT FORM

Markov chains are suitable for describing stochastic processes that change between finitely many states, as it is the case during machine operation. Markov's modelling is illustrated in Feller (1967), for example, by constant transition probabilities. Discrete system states are defined with according probabilities of a) either keeping a state, or b) the transition to another state. The representation with time-dependent transition probabilities on the basis of constant failure rates, as with an exponential distribution, is also possible. The relative frequencies of the system states (as an approximation of the according probabilities) could be derived, for example, from a video evaluation of typical activities. Because, probability values can be represented as relative frequencies, if a large basic population or a large number of repetitions of the observed random events are given. The latter is the case over the service life of a machine with regard to the system states defined under section 3 below. Accordingly, a Markov model shall be created here for the manual intervention in the workspace of a machine tool. In doing so, certain conditions need to be fulfilled.

Check the conditions:

Condition 1: The probability that the state Z_i, which occurs at an i-th time step, only depends on the state Z_{i-1}, which was present at the (i-1)-th time step, (Markov property).

Reflection: The probability of the state Z_i "Manual intervention" at the i-th time step depends only on the state Z_{i-1}, which was taken to the (i-1)-th state: namely, if the (i-1)-th state was "automatic processing", there is a certain (average) probability to change into the state "manual intervention".

The Markov property may not be fully attainable with very detailed state models, for example, if certain sequential patterns are passed through. In this case, the transition probability of the next state may not only depend on the last state, but also on the previous one. For a first simplified model with three states in Figure 1, however, the Markov property can be considered fulfilled.

Condition 2: In a homogeneous Markov process with a discrete range of parameters and finitely many states, the transition matrix B(i,i+1) must not depend on i. At discrete time intervals $t_i = \mathrm{i} \cdot t_{ref}$ this means that the transition matrix is independent of time, so it must be stationary.

Reflection: The use of a machine leads to changing operating modes. Their occurrence probabilities can be approximated as averaged constants at all transitions (i, i+1). The requirement for a transition matrix that is independent of "i" might not be fully satisfied in the short term, because, for example, certain sequences of machining steps that differ from the sequences averaged over long periods of time occur on a machine during a day shift. For long periods of time however, the requirement for a transition matrix that it is independent of "i" (i. e. indep. of time) is approximately met because of the average effect. But, only for the "inner states" of the model, because with the "absorbing states" a temporal increase relative to global time comes into play (see below). Unforeseeable failures during the repeated change of operating modes above, either of technical or of human cause, require "absorbing states".

Then, a homogeneous Markov model needs to be expanded to an inhomogeneous Markov process. The reason is that technical faults have a time-dependent probability of occurrence, e. g. exponentially distributed. Even an inhomogeneous Markov model still fulfils the Markov condition that the further course of the process is clearly defined at all times.

As a result, both conditions above are fulfilled and a Markov model can be created for manual intervention in the workspace of a machine tool.

3 SYSTEM STATES OF THE MODEL

In accordance with the normatively anchored operating modes, such as in ISO 16090-1 (2016), only 3 states of the machine are considered here at first:

System State 1: Production in automatic mode with closed prot. doors (with Z1 as state prob.)

System State 2: Setting mode to prepare automatic op. with opened prot. doors (with Z2 as state prob.)

System State 3: Manual intervention with opened protection doors, e. g. to carry out a workpiece change or to correct a fault; either from the previous state 1 or from state 2 (with Z3 as state prob.)

Figure 1 shows a possible sequence of changes of states: To prepare automatic operation from time 1 on, setting mode is started at time 0. In event

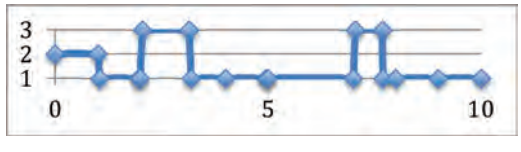

Figure 1. Example of state changes in automatic mode (x-axis: time in minutes, y-axis: indicator for state).

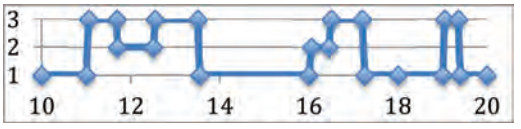

Figure 2. Example of state changes in setting mode (x-axis: time in minutes, y-axis: indicator for state).

2, a malfunction occurs (transition from state 1 to 3) that is rectified manually up to time 3.15. From then on, automatic operation continues undisturbed. At point 7, the workpiece is finished and is being replaced by an unmachined part, which lasts until point 7.7, after which the automatic machining continues. Fig. 2 shows another possible continuation of state changes. At time step 10, there is still automatic processing of Fig. 1.

The workpiece is finished at time point 11 and is being removed until point 11.7. Afterwards, a new setup operation takes place in which up to 12.6 manual operations are necessary. And from time point 13.5 on, a new workpiece is clamped.

Afterwards an automatic processing is carried out up to time point 16, where a malfunction occurs. This leads to a switch-over into setting mode, whereby manual intervention is necessary from point 16.5 to 17.3. From time point 17.3 the automatic processing can be continued. And with time point 19, another workpiece change takes place, which is finished at time point 19.4. The new workpiece is then to be processed aomatically.

The activities in Figs. 1 and 2 can thus be grouped into four types of human-machine interaction:

Activity A: Manual workpiece change in automatic mode (Z1è Z3)

Activity B: Manual troubleshooting in automatic mode (Z1è Z3)

Activity C: General setting mode (Z2) or manual workpiece change during setting (Z2è Z3)

Activity D: Manual troubleshooting in setting mode (Z2è Z3).

In the following section, another activity occurring in real practice shall also be introduced for the preparation of a follow-up paper:

Action E: Manual troubleshooting in setting mode (Z2è Z3), which could not be resolved.

4 PRESENTATION OF THE STATE AND TRANSITION PROBABILITIES

The real key question in this paper is: How likely or relatively frequent is it that the operator is exposed to hazards, which could possibly occur during manual work in the work area?

In order to answer the question quantitatively with scalable probabilities, a homogeneous

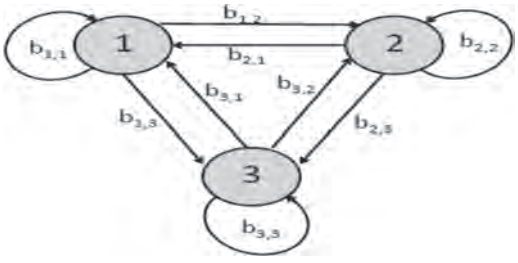

Figure 3. State and transition prob. of hom. Markov model.

Markov model is suitable as a quantitative reference frame. This should be adapted to the above three system states. Fig. 3 shows a graphical representation. The state probabilities at subsequent "i" time steps P(i) result from the so-called "B-matrix of state and transition probabilities" of a homogeneous Markov process, see Eq. (2).

The states 1,2 and 3 are called "inner states" because they can merge into each other.

For time step i = 0, an initial start vector P(0) from state probabilities is suitable as a representation:

$$\underline{P}(0) = \begin{pmatrix} Z1(0) \\ Z2(0) \\ Z3(0) \end{pmatrix} \tag{1}$$

$$\underline{B} = \begin{pmatrix} b_{1,1} & b_{1,2} & b_{1,3} \\ b_{2,1} & b_{2,2} & b_{2,3} \\ b_{3,1} & b_{3,1} & b_{3,3} \end{pmatrix} \tag{2}$$

The progressively developing connection probabilities are described in Feller (1967):

$$\begin{aligned} &\underline{P}(i+k) = \underline{P}(i) \cdot \underline{B}^k \\ &or\ \underline{P}(k) = \underline{P}(0) \cdot \underline{B}^k \end{aligned} \tag{3}$$

Thus, forecasts of repetitions of an assumed reference period can be deduced at time point $k \cdot t_{ref}$.

4.1 *Derivation of the transition probabilities*

As explained in section 2, probabilities over the lifetime of a machine and for a basic population of comparable machines can be presented as relative frequencies.

For the duration and repetition rates of the five a.m. activities, an averaging over several 8 hour shifts, shall be assumed. This serves as a frame of reference for the hypothetical estimation of the needed transition probabilities. In this paper, the values listed in Table 1 are assumed, e.g. a manual workpiece change on the machine tool takes

Table 1. Five typical activities on a machine tool.

Action	$t_{exp,1}$ [h]	$f_{exp,1}$ [h^{-1}]	F_{rel} [–]	*Fraction* [–]	*Coeff.* ($b_{1,j}$)	*Connecting Coeff.*
A	0.02	6	0.12	$(b_{1,3})_A = 0.12$	$b_{1,3} = (b_{1,3})_A + (b_{1,3})_B = 0.1325$	$b_{1,1} = 1 - b_{1,2} - b_{1,3} = 0.6675$ with: $b_{2,2} = 0$ and $b_{2,3} = 0.008$ follows:
B	0.05	0.25	0.0125	$(b_{1,3})_B = 0.0125$		
C	8	0.025	0.2	$(b_{1,2})_C = 0.2$	$b_{1,2} = 0.2$	
D	0.1	0.05	0.005	$(b_{2,3})_D = 0.005$	$b_{2,3} = (b_{2,3})_D + (b_{2,3})_E = 0.008$	$b_{2,1} = 1 - b_{2,3} = 0.992$ with: $b_{3,3} = (b_{2,3})_E$ and
E	0.5	0.006	0.003	$(b_{2,3})_E = 0.003$		$b_{3,2} = (b_{2,3})_D$ follows: $b_{3,1} = 1 - b_{3,2} - b_{3,3} = 0.992$

1.2 min. (= 0.02 hours) and repeats itself 6 times per hour, this means 7.2 min. of non-productive time p.h. The rel. exposure is 0.12.

From Table 1, the state and transition probabilities can be analytically derived from state 1 (with probability Z1) with $b_{1,i}$ (i = 1,3) to:

$$b_{1,1} = 0.6675;\ b_{1,2} = 0.2;\ b_{1,3} = 0 \tag{4}$$

Idition, it is clear that the setting mode (Z2) must always switch to automatic mode (Z1), either directly or via a troubleshooting of a fault (Z3) i.e.:

$$b_{2,2} = 0.0. \tag{5}$$

With the additional assumptions in Table 1, the remaining coefficients can be determined analytically as follows: 99.2% of the general setting mode (Z2) is transferred to automatic operation (Z1) without manual intervention (Z3). From the counterconclusion, a 0.8% usage share of the setting mode for troubleshooting can be deduced:

$$b_{2,1} = 0.992,\ b_{2,3} = 0.008 \tag{6}$$

In addition, it shall be assumed that in automatic mode (Z1), 100% of the faults are either eliminated or assigned to setting mode (Z2). For a follow-up paper, it could be further assumed that only 5/8 of all faults in the setting mode can be rectified and 3/8 cannot.

Assuming that the unrecoverable faults (E) occur in state (Z3) via setting mode (Z2), the result would be: $b_{3,3} = (b_{2,3})_E$. And because the remediable faults (D) are dealt with in setting mode, the result would be: $b_{3,2} = (b_{2,3})_D$. It follows:

$$b_{3,1} = 0.992;\ b_{3,2} = 0.005;\ b_{3,3} = 0.003. \tag{7}$$

Therefore, the state and transition probabilities required for the matrix representation of a Markov model are available as coefficients. The so-called "B-matrix of the state and transition probabilities" of a homogeneous Markov process results to:

$$\underline{B} = \begin{pmatrix} 0.6675 & 0.2 & 0.1325 \\ 0.992 & 0 & 0.008 \\ 0.992 & 0.005 & 0.003 \end{pmatrix} \tag{8}$$

Plausibility check: the row sum of $\underline{B}$. must be 1.

4.2 *State vector after repetitions*

For the i-th repetition of a state with a Markov model, the following vector of the state probabilities can be defined:

$$\underline{P}(i) = \begin{pmatrix} Z1(i) \\ Z2(i) \\ Z3(i) \end{pmatrix} \tag{9}$$

For example, to initialize the model with a completed setting operation to be followed by an automatic process, an initial condition (i = 0) can be:

$$\underline{P}(0) = \begin{pmatrix} 0 \\ 1 \\ 0 \end{pmatrix} \tag{10}$$

4.3 *State vector after one week/one year*

As assumed above, the reference frame t_{ref} for estimating the transition probabilities here is an 8-hour shift. The coefficients of the B-matrix are derived from Table 1 above in Eq. 3. In this way, the values of the time proportions of the states for a reference time period can be concluded (e.g., here a 40-hour week with 5 times 8-hour days):

Z1(i) Proportion of total usage time in state 1 (automatic operation),
Z2(i) Proportion of total usage time in state 2 (setting mode),
Z3(i) Prop. total usage time in condition 3 (fault).

As a representation in vector form:

$$\underline{P}(i)^T = \left(Z1(i), Z2(i), Z3(i)\right)^T$$

Table 2. Short oscillation of the Markov model.

Dur.	*Repet. i*	$\underline{P}(i)^T$
1 day	1	(0.6675, 0.20, 0.1325)
1 week	5	(0.748, 0.151, 0.101)
1 year	220	(0.789, 0.150, 0.100)

Table 2 shows the rapid transient oscillation of the Markov model, such that a quasi-stationary vector of the state probabilities already appears after 1 week. For the steady state after 1 week in table 2 a proportional undisturbed production of: Z1(i = 5) = 0.784 = 78.4% results.

The interruption of production results proportionately to: 1- 0.784 = 0.216 = 21.6%. And from this the system state 3 „manual intervention" has a share of Z3 = 0.1 = 10%, based othe assumptions above. This provides a comete a scalable framework for plausibly estimating the probability of a hazard or injury during manual iervention.

5 HAZARDS OF MANUAL ACTIVITIES

A whole range of hazards are conceivable during manual intervention in the work area: crushing of hands or arms, shearing of fingers, entanglement of clothing etc. are basically possible. Risk assessment is in the first step aimed at the completeness of all possible hazards. This was formerly known as a hazard analysis. However, in order to become a risk analysis, a continuation sp needs to follow: every "possibility of a hazard" is to be converted into a "probability of this hazard".

Here, state 3 is "Manual intervention" to carry out a workpiece change or to correct a malfunction; either from the previous state 1 or from state 2. The subsequent state after 3 could be a hazard with an injury. It shall be combined in a further state:

System State 4: Hazards can occur that could possibly cause injuries (with Z4 as the probability of their occurrence). Because these injuries could be severe, a standstill of the machine for accident investigation can be assumed such that (Z4 = 1) would apply. Thus, state 4 is an "absorbing state".

It is supplemented in Fig. 4. If an absorbing state is taken once, it will not change ($b_{4,4}$ = 1). Absorbing states represent critical states of a system. Therefore, one is interested in the probability with which such critical states occur during the process.

The extension of the model with state 4 turns the above *homogeneous* Markov model into an *inhomogeneous* Markov model. Because state 4 is not time-independent, i.e. the transition probability $b_{3,4}$ is not constant, but depends on the time: $b_{3,4} = f(t)$.

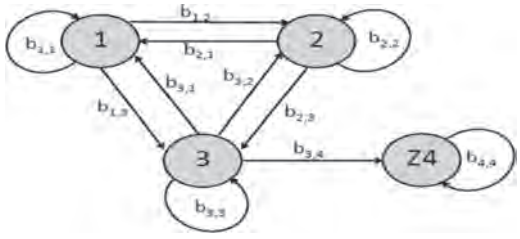

Figure 4. Extension to an inhomogeneous Markov model: state and transition probabilities and an absorbent state 4.

In simplified terms, the exponential distribution over the PFH_d-values assumed in ISO 13849-1 (2015) can be regarded as the trickle rate of an "hourglass" and thus a time proportionality can be applied, see Moedden (2014). The following hypothetically derived values for the above activities A, B, C, D and E are intended to provide the connection for an answer to the key question above.

It is a very first proposal of "risk snapshots". The purpose is merely to estimate the risk reduction of guards (e.g. full enclosure) in the context of an exemplary modes of operation concept.

A calculation example shall be used to compare the five activities A, B, C, D and E as "risk snapshots" in a scaled form, as assumed above, see Table 3. An 8-hour shift is used again. When manually intervening in the working area, the operator has to completely trust in reliable control technology, e. g. for the safety functions "Safe operation stop" and "Safe reduced speed".

The relevant failure probabilities can be assigned as $\sum PFH_{d,tech}$-values in a superimposed form. The typical hazards can be superimposed, too. The probability of occurrence of relevant hazards (risk element O according to equation 11) and their controllability (or avoidability, risk element C according to equation 15) are simply estimated on the safe side, just for illustration purposes.

Activity A: Manual workpiece change in automatic mode (Z1è Z3), with:

- Safety function "Safe operational stop (SOS):
- 2 rotary axes $\left(\sum PFH_{d,tech} = 2 \cdot \left(6.5 \cdot 10^{-6}\right) \frac{1}{h}\right)$, which can cause an entanglement hazard (EN),
- and 3 translational axes $\left(\Sigma PFH_{d,tech} = 3 \cdot (4.5 \cdot 10^{-6}) \frac{1}{h}\right)$, which can cause crushing (CR),

Activity B: Manual fault rectification in automatic operation (Z1 → Z3) with the same safety function and hazards as for activity A,

Activity C: General setting mode (Z2) or manual workpiece change (Z2 → Z3) with the same safety function as for activity A,

Activity D: Manual troubleshooting in setting mode (Z2 → Z3) with:

Table 3. "Risk snapshots" of fiveypical activities on a fully enclosed machine tool.

Activity/Safety function/Hazards	$\Sigma PFH_{d,tech}$ [η^{-1}]	*O* [–]	F_{rel} [–]	*C* [–]
A: /SOS/EN + CR	$2\cdot(6.5\cdot10^{-6})$ $+3\cdot(4.5\cdot10^{-6})$	1	0.12	0
B: /SOS/EN + CR	$2\cdot(6.5\cdot10^{-6})$ $+3\cdot(4.5\cdot10^{-6})$	1	0.0125	0
C: /SOS/EN + CR	$2\cdot(6.5\cdot10^{-6})$ $+3\cdot(4.5\cdot10^{-6})$	1	0.2	0
D: /RSP/EN + CR	$1\cdot(6.5\cdot10^{-6})$ $+1\cdot(4.5\cdot10^{-6})$	0.2	0.005	0.5
E: /RSP/EN+CR	$1\cdot(6.5\cdot10^{-6})$ $+1\cdot(4.5\cdot10^{-6})$	1	0.003	0

– Safety funct. "Safely reduced speed (RSP) with:
– 1 rotary axis $\left(\sum PFH_{d,tech} = 1\cdot(6.5\cdot10^{-6})\frac{1}{h}\right)$, which can cause an entanglement hazard (EN),
– and 1 translational axis ($\Sigma PFH_{d,tech}$ = 1 · (4.5 · $10^{-6})\frac{1}{h}$), which can cause crushing (CR),

Activity E (for a follow-up paper): Manual troubleshooting in setting mode whout success with the same safety function and hazards ain activity D; but without controllability: C = 0 and with very high probability of occurrence of a hazard: O = 1.

The likelihood of a hazard occurring after a control failure (e. g. causing an unexpected movement) has been assumed for activities A, B, C with O = 1. This means that a failure is very likely to lead to a hazard in the respective situation. For activity D, only O = 0.2 is assumed. For the first three activities a controllability is not possible: C = 0, and for the fourth activity it shall be estimated with C = 0.5.

The superimposed failure probabilities are compared in Figure 5 as $\sum PFH_{d,tech}$ – values.

These base values can be used to carry out a risk assessment for manual interventions A, B, C, D and E. For this purpose, the risk elements probability of occurrence of a hazard (after a control failure or after a human error), relative exposure and controllability ought to be reasonsmated for Eq. (14). In addition, the terms used should be clear in order to obtain a logical risk model.

5.1 *Key term "Probability of hazardous events"*

The likelihood of hazards can be caused by technical or human factors or force majeure. The designer cannot influence the latter, but he/she must concentrate on mastering the causes of technical failures (index "tech"), also on foreseeable human errors. For quantitative aspects, an objectively scalable probability plays a special role.

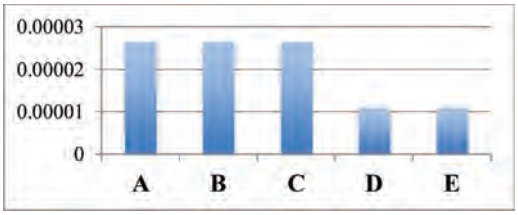

Figure 5. Bar chart of the $\sum PFH_{d,tech}$ – values of "Risk snapshots" (x-axis: indicator for activity, y-axis: values in h^{-1}.)

For this purpose, a correctly defined probability space is indispensable, see Moedden (2017). Two quantitative representations of the term "probability" are established: a) generally, in most cases the dimensionless probability such as illustrated in Feller (1967); and in the context of control chains for safety functions, often b) a probability per time unit (PFH_d-value, see ISO 13849-1 (2015)) is used. The first can be derived from the latter via a time integral, as explained by means of a "hourglass analogy" in Moedden (2014).

> In this context, the interpretation of the so-called "Murphy's Law" must be reasonably restricted, it reads: "Anything that can go wrong will go wrong". Murphy's law is an alleged wisdom of life, which makes a statement about human failure or sources of error in complex systems. In the short form with the emphasis on "…will go wrong" there is presumably an assumption contained, which must not go unmentioned here, since the key term "probability" has to be distinguished from the term "possibility". Presumably, the precondition of "Murpy's law" is: either an infinite number of repetitions, or an infinite basic population. But, "Murpy's law" doesn't work for finite repetitions and/or a finite basic population to the conclusion "…will go wrong".

5.2 *Scaling of risk reduction measures*

Practical machine design methods, as collected for a milling machine in ISO 16090-1 (2016), apply a whole range of measures that bring about a considerable distance in the probabilities of the following events:

Event I: a failure in a mechatronic control chain of a certain safety function, for instance due to the failure of a mechanical brake actuator in the safety function "SOS" (see abovtivity A) and

Event II: hazards occurring from this failure (here: crushing and entanglemen

The likelihood of event I. is being expressed as a PFH_d-value of the safety fction. The unit is a number per hour. The probability oevent II. in a certain time frame $t_a \le t \le t_b$, i.e. the occurrence

probability of according hazards, is given as a dimensionless number: it represents a probability and the parameter PHE is used here.

If the a.m. over-interpretation of "Murphy's Law" would be made, the conclusion were: $PHE = PFH_d \cdot (t_b - t_a)$

> The reality is different: there is a well-tried art of safety design such that PHE is generally significantly lower $PHE \ll PFH_d \cdot (t_b - t_a)$, because additional risk reduction measures "surround" the mechatronic control chains in a cascaded form. For instance, protective guards such as a full enclosure of the work area are very effective in reducing the probability of hazardous events, which might be caused by failures inside the work area. Thus, within in a cascaded safety design, not every failure of a safety function leads to a hazard. Only if an operator is exposed to potentially hazardous control chains, a hazard can occur. The PFH_d-values of control chains represent the "threatening" failure prob.'s. That is why a differentiation has to be made between an open or closed protective guard (see ste definitions above), if it comes to deriving PHE-values. Obviously, hazardous events can occur, when the protection grds are open. With closed guards however, an operator is n exposed to possible hazardous events inside the full enclosure.

The risk reduction effect by limiting the relative exposure is explained in section 6.1 below as a product of time duration and repetition rate.

A dimensionless probability wh a scaling factor "O" can be defined as follows for the time period $t_a \le t \le t_b$. It corresponds to the risk element "probability of occurrence of a hazard" (ISO 12100, section 5.5.2.3.2):

$$\begin{aligned} PHE &= O \cdot \int_{t_a}^{t_b} \sum PFH_d \cdot dt \\ &= O \cdot \sum PFH_d \cdot [t_b - t_a] \text{ with } 0 \le O \le 1 \end{aligned} \quad (11)$$

6 PROBABILISTIC RISK MODEL

In automatic operation (index 1 below), closed guards of fully enclosed work areas hold back any released tool and/or workpiece fragments up to the withstand capabilities of the respective dimensioning regulations as in ISO 16090-1 (2016). Even with open protection guards as in setting mode (index 2 below), a full enclosure can also considerably reduce the failure probability of a technological function (index "tech") during setting mode indirectly, as explained in the "implicit fault detection in the process", see Moedden (2016).

As regards released parts of tools or/and workpieces after a failure in a control chain, the withstand capability of the enclosure against causes a strongly reduced probability of occurrence of a technically caused hazardous event, i. e. with $O_{1a} << 1$. For other non-ejection hazards even $O_{1b} = 0$ holds (with $O_1 <= O_{1a} + O_{1b}$). Therefore, PHE_1 during automatic mode in the period $t_a \le t \le t_b$ is:

$$PHE_1 = O_1 \cdot \int_{t_a}^{t_b} \sum PFH_{d,tech,1} \cdot dt \quad (12)$$

In setting mode, a numerical value $PHE_2 >> 0$ ought to be assumed for hazardous events, because, according to accidents in the entire population of all machines, injuries occur more often, when the protection doors / guards are open than in closed condition, see Moedden (2017).

6.1 *Exposure reduction*

In the case of hazard exposure, reducing the duration of exposure time t_{exp} and reducing the repetition rate f_{exp} act as a product to reduce the relative exposure $F_{rel} = t_{exp} \cdot f_{exp}$. As there is a kind of double proportionality, this can lead to a considerable risk reduction. For example, if workpiece and tool changes are mainly carried out automatically (instead of manually) and the product $t_{exp} \cdot f_{exp} << 1$ reaches very small values. However, some recurring hazard exposure events in setting mode (e. g. to prepare for automatic operation) are always left over. This results for a.m. setting operation in the period $t_a \le t \le t_b$ to the following expression for a probability of a hazardous event:

$$PHE'_2 = t_{exp,2} \cdot f_{exp,2} \cdot O_2 \cdot \int_{t_b}^{t_b} \sum PFH_{d,tech,2} \cdot dt \quad (13)$$

6.2 *Increasing controllability/avoidability*

If the above risk reduction measures have been implemented as far as reasonably possible, a "zero risk" can practically almost be reached acc. to Moedden (2017). However, even then (theoretically hypothetically) a very small technical residual risk remains. For this purpose, step 3 of the three-step method of risk reduction is being applied, the so-called instructive safety: in risk models, mostly described as avoidability or controllability (parameter C) in ISO 12100 (2010). In the above case of setting mode (indicated as "2"), and considering the avoidability effect with $C_2 > 0$, the remaining event rate of hazards in the period is calculated as follows $t_a \le t \le t_b$ in (Eq. 14):

$$PHE''_2 = (1 - C_2) \cdot t_{exp,2} \cdot f_{exp,2} \cdot O_2 \cdot \int_{t_a}^{t_b} \sum PFH_{d,tech,2} \cdot dt \quad (14)$$

PHE''_2 can be equated with the probability of injury, i. e. it corresponds to injury risk during setting.

6.3 *Comparison of different activities*

In accordance with the risk model in Eq. (14), the probability of occurrence of a hazard event is shown in the right-hand column of Table 4; and a corresponding bar chart is shown in Figure 6. The proportions of activities A, B, C, D and E in system state 3 are taken from Table 3 with $F_{rel.}$. The simple comparison in Table 4 obviously proves that not only the PFH_d-values in the range of some $10^{-6}h^{-1}$ are decisive for the probability of occurrence of a hazard event PHE. The other risk elements O, F_{rel}, C also have a considerable influence. This can be seen, because the bar chart of PHE values in Fig. 6 differs from the bar chart in Fig. 5, which merely shows the distribution of the summed PFH_d-values. Fig. 6, however, is more important for the risk of injury than Fig. 5. And Fig. 6 shows that the highest probability of occurrence of hazardous events are in activities C and A of this parameter study. Activities B, D and E are far less hazardous.

The coefficient $b_{3,4}$ in Figure 4 and Eq. (8*) is time-dependent: $b_{3,4} = f(t) = f(i \cdot t_{ref})$. And $b_{3,4}$ results from the sum of the PHE-values in the right-hand column of Table 4 to $b_{3,4} = 0.00007$; it has to be multiplied by as much 8-hour-shifts, as shall be considered. And because state 4 is an absorbing state: $b_{4,4} = 1$. Based on an eight-hour shift, the B-matrix in Eq. (2) and Eq. (8) can be extended from 3*3 to 4*4. This means that the probability of a hazard event can also be estimated.

The new B-matrix would look like this, Eq. (8*):

$$\underline{B^*} = \begin{pmatrix} 0.6675 & 0.2 & 0.1325 & 0 \\ 0.992 & 0 & 0.008 & 0 \\ 0.992 & 0.005 & 0.003 & b_{3,4} \\ 0 & 0 & 0 & 1 \end{pmatrix}$$

Table 4. "Risk snapshots" and hazard probabilities.

Activity/ SF/HAZ.	$\Sigma PFH_{d,tech}$ [h^{-1}]	$t_b - t_a$ [h]	O [–]	F_{rel} [–]	C [–]	PHE [–]
A: /SOS/ EN + CR	$2\cdot(6.5\cdot10^{-6}) + 3\cdot(4.5\cdot10^{-6})$	8	1	0.12	0	2,5
B: /SOS/ EN + CR	$2\cdot(6.5\cdot10^{-6}) + 3\cdot(4.5\cdot10^{-6})$	8	1	0.0125	0	2,6
C: /SOS/ EN + CR	$2\cdot(6.5\cdot10^{-6}) + 3\cdot(4.5\cdot10^{-6})$	8	1	0.2	0	$4{,}2\cdot10^{-5}$
D: /RSP/ EN + CR	$1\cdot(6.5\cdot10^{-6}) + 1\cdot(4.5\cdot10^{-6})$	8	0.2	0.005	0.5	$4{,}4\cdot10^{-8}$
E: /RSP/ EN + CR	$1\cdot(6.5\cdot10^{-6}) + 1\cdot(4.5\cdot10^{-6})$	8	1	0.003	0	$2{,}6\cdot10^{-7}$

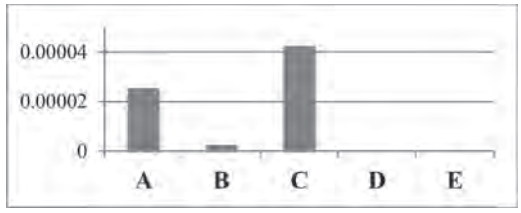

Figure 6. Bar chart of the PHE-values for the "Risk Snapshots" above (x-axis: indicator for activity, y-axis: values in [–]).

Table 5. Result for inhomogeneous Markov model.

Dur.	i	$\underline{P}(i)^T$
1 day	1	(0.6675,0.20, 0.1325, 0.00007)
1 week	5	(0.748, 0.151, 0.101, 0.00035)
1 year	220	(0.789, 0.150, 0.1000, 0.0154)

The state vector in vector form is:

$$\underline{P}(i)^T = \left(Z1(i), Z2(i), Z3(i), Z4(i)\right)^T$$

From Table 5, it can be seen that the values Z1, Z2 and Z3 are convergent, whereas Z4 is divergent, i.e. steadily increasing.

It can also be derived that the probability of the system state 4 in a basic population of n comparable machines is $Z4 \approx 1$ after 1 year, if $n = 1/0.01538 \approx 65$. This means that hazardous events, which can cause injuries, are very probable with above assumptions.

7 SUMMARY AND OUTLOOK

The system states of a simplified Markov model of man-machine interaction in operating machine tools have been defined. A diagram for the state and transition probabilities was developed for parameter studies.

The Markov model presented here has proven that reducing operator exposure is as important a means of reducing risk as the high reliability of control functions. Consequently, the model can also be used to compare safety measures with each other in a scaled form. In doing so, the designer has the opportunity to optimise effort and benefit. In addition, the model can also weigh different effects against each other in order to compensate, for example, i) an increased exposure due to extending the operating modes concept by ii) reducing the probability of failure of relevant control chains that can generate hazards, if they fail. This approach

has proven to be effective over more than a decade. Also a consideration of technical reliability versus human reliability can be performed in a scalable frame. For example, when clamping workpieces for machines equipped with the relatively new technology of vertical turning on milling machines, see Wittstock (2017).

Five typical activities have already been examined here in more detail to answer the key question above. Further operating modes are to be examined, i.e. mode 3: Special mode and Service mode.

NOMENCLATURE

Symbol	Dimension	Meaning
t_{ref}	h	Reference time step for the Markov model
t_{exp}	h	Time duration of a manual intervention
f_{exp}	$\frac{1}{h}$	Relative frequency of a manual intervention
O, F_{rel}, C	Probability	risk elements acc. to the parameters of ISO 12100
PFH_d	$\frac{1}{h}$	Average prob. of dangerous failure per hour. It is only for single i/o-channels equivalent to the failure rate (i.e. the frequency with which an engineered system fails, often denoted by λ)
$t_b - t_a$	h	Time period for integration
PHE	Probability	Prob. of hazardous event
$\underline{P}(n)^T$	Probability	State vector with prob.
$\underline{B}$	Probability	Transition matrix with prob. and coefficients $b_{i,j}$

Information flow and knowledge transfer of accident investigation results in the Norwegian construction industry

K. Wasilkiewicz
Department of Industrial Economics and Technology Management, Norwegian University of Science and Technology, Trondheim, Norway

ABSTRACT: This paper examines the information flow of accident investigation results in the construction industry, and how this affects learning processes. The aim is to document the state-of-the art in the industry on information flow that follow accident investigations, and to find how accident investigation results better can be learned from and used as input for proactive safety management. A literature review was undertaken on the relation between accidents and learning. An interview study was undertaken with different actors (clients, contractors and consulting engineers) in the construction industry on accident investigations and information flow of accident investigation results. The preliminary results from the interviews are presented. Mostly, results after accident investigations are shared within a company, and there is no systematic sharing of information between companies, other than occasional sharing. Further research needs on information sharing after accident investigations are discussed.

1 INTRODUCTION

The construction industry is a complex industry, with constantly changing processes and activities, several actors involved that depend on each other, and external factors, such as state of the market, that affect construction projects.

Just as the industry varies a lot in terms of company sizes, sizes of construction sites, resources available, and competence and experience of managers and workers, so are accident investigations and the results of them influenced by these characteristics and conditions.

The aim of this research is to look closer at safety in the construction industry, by studying the processes after accident investigations, which are meant to accommodate for learning processes and prevention of future accidents.

This paper presents preliminary results of research concerning the results of and the information flow after accident investigations, as it is a prerequisite for the learning processes.

2 BACKGROUND

2.1 *The complexity of the construction industry*

A construction project can be many things; a small cottage to be built, a highway, a tunnel or a skyscraper. "The construction of a building can be regarded as a complex, information dependent, prototype production process were conception, design and production phases are compressed, concurrent and highly interdepended in an environment where there exists a usually large number of internal and external uncertainties" (Pryke, 2012, p.64). This shows how the construction industry varies with regards to project size and durability, company size, contract models and so on. According to Lingard and Rowlinson (2005, p. 3) the project structure which companies in the construction industry operate in, is an important characteristic that challenges the safety work in the industry. Each project site is different, forming a new, temporary organisation. There are large circulations of personnel; some come in for as shorts as a day, others stay for the whole project period. Further, construction projects are operating in an ever-changing environment largely influenced by the state of the marked. All these variations are influencing how safety work is being implemented and executed in the daily life of construction projects.

The socio-technical system involved in risk management by Rasmussen (1997), illustrates the different levels that will influence the safety in the sharp end. The model includes environmental stressors that can influence the different levels that again can influence the overall safety.

Further early project phases can affect the next phases, i.e. decisions in early phases of projects can influence the safety during construction. Therefore, it is important to look at the whole range of actors involved in the project not only during the construction phase, but also in earlier phases.

2.2 *The construction industry in Norway*

The Norwegian construction industry was employing almost 235 000 people in 2016, and the industry comprised of more than 57 000 enterprises, of which approximately 90% had 0–9 employees, and around 1% had more than 50 employees (SSB, 2017a).

The industry is one of the industries with the highest number of work related fatalities and injuries on mainland Norway. Between 2010–2015, there was in total 69 fatalities related to construction work, i.e. close to 12 fatalities per year (NLIA, 2016). Most of the fatal accidents involve falls, followed by collisions, being hit by an object or being crushed or trapped.

In 2016, there were 9 fatalities and more than 2700 reported injuries in the construction industry (SSB, 2017b). More than half of these resulted in long term absence (more than three days' absence from work). The most frequent types of accidents resulting in serious injuries were: fall from roof/ floor/ platform, fall from scaffolding, contact with a falling object, contact with moving parts of machine, being hit by an object in a lifting operation, fall from ladder, and fall from height when unsecured (NLIA, 2017).

2.3 *Incident reporting and accident investigations*

Incident and accident reporting is an important tool for accident understanding, and thus learning and future accident prevention. Incidents and accidents should be reported and investigated internally to prevent them from reoccurring (Lingard & Rowlinson, 2005, p.163–164), and in some cases also investigated externally (e.g. incident with high or potentially high consequences).

According to the Working Environment Act §5–2 (2005) in Norway, employers are obligated to report accidents with fatal or serious outcome to the Norwegian Labour Inspection Authority (NLIA) or the Police. Nearly all fatalities are reported, however in the "serious injury" category there are still unrecorded numbers (NLIA, 2015a). NLIA conduct inspections after all fatal accidents (NLIA, 2015b), but less severe accidents are not examined as closely as accidents with severe outcome.

2.4 *Learning from accidents*

Learning from accidents is one of the goals with accident investigations, both to prevent similar accidents to reoccur, and to prevent other accidents.

Learning can refer to either a product or a process, respectively something learned and the activity of learning (Argyris and Schön, 1996, p. 3). In relation to construction safety, the product can be accident understanding, which is one of the products after an accident investigation. To improve the safety and avoid similar accidents from reoccurring, the knowledge obtained needs to be applied. However, taking actions might require major changes (e.g. cultural and behavioural) (Love et al., 2013), which in practice can be challenging and will require designated resources in a company. Correct actions taken after accidents, show the results of learning in practice, by applying the obtained knowledge. This takes learning one step further towards improvement.

Organisational learning can be divided in two types of learning. Single-loop learning refers to learning that results in changes of action so that the outcome is desired. It does not change the "theory of action" (Argyris and Schön, 1996, p.20), meaning that the focus is only on the symptoms of the problem, and not the underlying cause. Therefore, this is a lower level of learning. Double-loop learning on the other hand, focuses on changes "in values in theory in use" (Argyris and Schön, 1996, p.21), meaning that it goes deeper into the root causes of the problem.

Organisation size, complexity, and number of levels in the organisation are factors affecting what type of organisational learning (single or double-loop) learning results in (Argyris and Schön, 1996, p. 25–26).

3 METHODOLOGY

3.1 *Literature review*

A literature review was undertaken to get an overview of literature treating the relation between accidents and learning. The focus was on the construction industry, however papers discussing other industries were also looked at to find good examples and general knowledge about the topics of safety and learning.

Searches for literature were made in the following databases: Scopus, Googles Scholar and Oria. The search strings used were: accidents, learning, and construction. Searches were made both on two of the words at a time, and on all three at the same time.

In Scopus, the review was undertaken in a systematic way, which means it is a replicable, scientific and transparent process (Bryman, 2012, p.102). The search using "accidents" and "learning" as search string resulted in 4,983 results. From the 4,983 documents found from 1930–2017, the majority is published in the 2000s. After round of sorting out, first based on titles and years, then on abstracts, in total 34 articles were found as the most relevant concerning different fields, however not all were accessible.

The aim of the literature review was to get a background for the data collection.

3.2 *Interviews*

The first round of interviews was undertaken with actors in the Norwegian construction industry on information flow and knowledge transfer after accident investigations.

An interview guide was made with the following topics: general introduction, procedures for accident investigations, results of accident investigations, information flow, learning arenas, improvement potential and closing questions. The questions in the interview guide were adjusted to the three different actors (clients, contractors and consulting engineers).

In total 13 interviews with 19 persons responsible for Health, Safety and Environment (HSE) at clients, contractors and consulting engineers were undertaken. Table 1 presents an overview of the interviewees.

All the interviewed companies are large, professional companies that are well established in the Norwegian construction industry.

Interviewees were recruited through convenience selection, through contact persons in the industry. Further selection of interviewees will be done strategically to cover the construction industry widely.

The interviews were conducted between October 2017 and January 2018. Each interview took from 30–80 minutes. Most of the interviews took about an hour. Eight of the interviews were conducted in person, and five over phone. All the interviews except one, were recorded and transcribed. For the one that was not recorded, detailed notes were taken. The interviews were transcribed in NVivo, and coded according to the interview guide. Additionally, new codes were created while going through the data. A first, preliminary review of the data was done, resulting in main topics for discussion.

3.3 *Methodological considerations*

This research only comprises of a smaller sample of interviews and the preliminary results from these. To get a more general picture of the state-of-the art of the whole industry, more interviews will be undertaken, and preferably other methods should be used as well (e.g. questionnaire).

Table 1. Overview of interviewees.

Actors	Interviews	Documentation
Clients	2 interviews	1 company
Contractors	8 interviews^	3 companies
Consulting Eng.	3 interviews*	1 industry association

^one group interview with three interviewees.
*one group interview with representatives from five companies.

4 FINDINGS

4.1 *Accident investigations in practice*

The research shows that there are large variations when it comes to accident investigation practices between companies (within different actors) in the construction industry, and also between different projects within a company. The variations concern both resources available, investigation competence and investigations execution (i.e. methods used). Companies have their own criteria for when and how investigations should be performed, also these vary between the companies.

Mostly the accident investigations are undertaken separately by different actors, however interviews are conducted with persons in different companies during the investigations if it is relevant for the investigation. This results in separate investigations at clients, contractors and sub-contractor if more of the actors are deciding to undertake an investigation.

The consulting engineers reported that they are usually not involved in accident investigations, unless the unwanted event is directly caused by a calculation error performed by them.

Some companies use external parties to undertake investigations, others mainly perform internal investigations. It was also reported by one interviewee at a client, that they sometimes have to request contractors in order for the contractors to perform accident investigations.

Competence was seen as a success factor for performing good investigations However, the research shows that the knowledge and experience of HSE-managers about accident investigations varies. It was pointed out by the interviewees that methods and tools to be used for accident investigations should be pre-defined, and the methods and tools should be easy to use to ensure that the investigations can start quickly after the accident, and in order to conduct the investigations in a good way to obtain learning. Some of the HSE-mangers found this to be unclear in their company. One of the interviewees stated that it is important to go deeply into the causes to prevent future accidents:

> *"The most important thing is the learning one can get out of accident investigations. That must be the main goal. If you really manage to uncover the root causes, that is when you have the opportunity to prevent the same from happening again. That must be the foremost goal." (HSE-manager, contractor).*

Further, some of the HSE-managers reported that the roles and responsibilities in terms of who is responsible for the accident investigations and follow-up of it in the projects and in the companies, are sometimes unclear.

4.2 *Results of accident investigations*

The results of the accident investigations included investigation reports, learning sheets and changes of procedures. One of the companies had put together experiences from several accidents into a short film. Most companies finalise accident investigation with an investigation report. The reports vary between companies in size and content.

Learning sheets, which are short one page summaries of accidents, have started to become increasingly popular. The drawback that was pointed out with these by some of the interviewees, is that they do not go deeply into the causes and are more like event descriptions. Further, some remarked that the focus on these learning sheets as an answer to the challenge of learning and knowledge transfer is too large.

> *"Generally, I think that there is a large focus on learning sheets and sharing of learning sheets, as if they solve everything. I think perhaps it is somewhat too much focus on only this one solution" (HSE-manager, contractor).*

4.3 *Information flow of the accident investigation results*

The results of the investigations are mainly distributed within the company which undertakes the investigation. Some companies have systems for sharing results after accident investigations within the company, such as management systems, procedures, and best practice databases.

Information sharing across companies is even lesser systematised. There are no automatic mechanisms for sharing results between companies. In one contracting company, it was reported that if the unwanted event happened at a sub-contractor, and the main contractor or client investigated the event, the sub-contractor would have to request the report in order to get it. In the same way, the NLIA can request access to investigation reports from companies. It was also reported that the NLIA sometimes requests companies to make investigation reports. However, it was mentioned that this could affect what the companies put into the report, as they would not want to face additional consequences.

Further, "breakfast-meetings" that some companies hold after accidents, were perceived as very good knowledge sharing arenas across companies. At such breakfast-meetings, a company shares experiences from an accident they think the industry as a whole can learn from. These meetings are held rather seldom, and are suited only for certain types of incidents, e.g. general activities that resulted in an accident or near accident, and where good measures to prevent this type accidents are found.

Another arena for information sharing that was mentioned by several of the interviewees, were workshops held by the NLIA. These workshops were perceived as a good for knowledge sharing. Additionally, HSE-conferences (e.g. SHA-dagene, HMS-konferansen) were other examples of knowledge sharing arenas. These are large conferences that occur yearly, which mostly mangers with exceptions attend. However, not all the interviewees were aware of these arenas, and it was pointed out that the events are occasional.

How information is shared between companies, is in large degree steered by the systems within the companies, and the contracts between companies. It was also mentioned that a client or a main contractor can put requirements regarding incident and accident reporting into contracts to easier obtain safety information from projects.

4.4 *Utilisation of accident investigation results*

Experiences of the interviewees show that investigation competence in the investigation team is important for the outcome of accident investigation. Further, the team compositions regarding the members´ role in the event is also important, so the persons are not too closely related to events or persons affected in the event. The members of the team should not have a conflict of interest with the investigation.

Further, it was mentioned by the interviewees that certain events are better suited to learn and share knowledge from than others. The outcome or consequence of the event (e.g. fatality, serious injury etc.) in large degree influence how the results are used further. In cases where the events result in police investigations and legal proceedings, there can be resistance that will be of disadvantage for the results and for the learning process. Especially, near-misses and high potential incidents (HIPOs) which have not become police cases are good to learn from, as the question of guilt in larger degree is eliminated.

Several of the interviewees mentioned the question of guilt as a factor that impede knowledge sharing, as this concerns the reputation of the company, future projects as well as compensations for injuries.

Further, it was mentioned that it can be challenging to share information in cases of serious

injuries where police investigations are undertaken, as these often take long time. This leads to the company accident investigation report being held back and thus delayed, also delaying the learning processes.

5 DISCUSSION

5.1 *Deficits with accident investigations*

To be able to learn from something that has happened, information about what happened and why it happened is needed. Accident investigations are important to gain this information. Gibb et al. (2014) highlight the importance of going in depth into accidents and finding underlying causes of accidents for a good learning outcomes.

In the construction industry in Norway there are no standardised methods to investigate accidents. Accidents largely vary when it comes to type, size and severity, and different accidents may therefore require different types of investigations. One important issue to research in relation to accidents is how accidents are selected for investigation (Lindberg et al., 2010). The criteria for investigating accidents and the degree of investigations vary between companies, and even between projects within a company. This is a challenge when it comes to learning after accidents, as the investigations vary and thus give different foundations for further work with safety.

The quality of accident investigation results is in large degree dependent on the investigation team; their relation to the accident and to the company, knowledge about the industry, investigation knowledge and experience. The knowledge and the experience of the responsible persons in the companies varies as seen in the interviews undertaken, and this affects the outcomes of the investigations. Le Coze (2013) highlights the importance of expertise on accident models, to apply them in proper way. This was also states by some of the interviewees.

Further, as mentioned, the construction industry is characterised by having many actors, many phases, and constant progress and changes in the projects. The cooperation between levels of actors, between different phases of construction projects, between companies in the same phase performing different operations, and between operations within a company is important for good safety. From what is seen in the interviews, there is not much cooperation on accident investigation between companies that are involved in an unwanted event. Mostly, the investigations are performed separately between companies if more companies are undertaking investigations. The weakness with this is that important viewpoints and the causes behind the event can be overseen, due to lack of specialised knowledge (e.g. when consulting engineers are not involved), but also that other involved companies do not get access or ownership of the investigation results and measures suggested in the investigation report to prevent future similar accidents. Lundberg et al. (2009) write in their paper about WYLFIWYF (What You Look For Is What You Find), which shows the importance of using several perspectives in accident investigations, weather it is accident models, methodologies or specialists.

If the aim of the investigation is also to learn from what has happened, the learning perspective should also be integrated into the investigation, to provide for information that will lay the groundwork for learning.

5.2 *Knowledge transfer as a premise for learning*

Nonaka and Takeuchi (1995) describe knowledge as different from information as it is about beliefs, commitment and actions. Both have in common that they are about meaning. Simply said: *"Information is a flow of messages, while knowledge is created by that very flow of information, anchored in the beliefs and commitment of its holder"* (Nonaka and Takeuchi, 1995).

After accident investigations, the knowledge obtained needs to be shared if learning from previous accidents is the goal. The importance of how this knowledge is shared for learning is also highlighted by Lindberg et al. (2010). Drupsteen and Guldenmund (2014) point out that there often are limited processes to follow-up learning after accidents, and that such knowledge is often shared through one-way communication, which does not encourage interaction and thus learning processes. The findings of the current research are similar; uncertainties about who should follow-up the accidents were found, as well as examples of one way dissemination of accident investigation results (e.g. learning-sheets).

Further, the way information is shared is another challenge in the industry seen from the interviews. Internally, companies might have some systems or ways to share information, however they are not necessarily good enough to share information with all levels in the company. Within companies, results are often shared though learning sheets. These are meant as an information sharing arena for all levels in the company; from the top to the sharp end. However, different users require different degrees of details of the information. In example, for other HSE-managers, the information which is on the learning sheets might be too vague to be useful for safety work.

One further deficit as the research shows, is that this information and knowledge is not in large scale shared across companies. A good platform

for sharing information across the industry is missing, even though there are a few conferences and other smaller arenas where some experiences can be shared. A knowledge sharing platform can be one solution for sharing information and experiences across companies in the industry, e.g. a common database. An accident data base could be used to collect all severe accidents in the construction industry. Accidents with a potentially serious outcome also need to be registered. Having set criteria for systemising the accident types, causes and possible use would be useful for the user of such a database.

The knowledge from the investigations can serve several purposes such as input for risk assessments, decision making and to create awareness about important circumstances that can affect safety. To make use of such information companies and the industry need to have certain tools available. Information needs to be shared internally in the company, and externally for the whole industry to improve.

Lingard and Rowlinson (2005, p.366) write that learning from past accidents is important for safety management, and in an organisational context an incident information systems must be available to collect, analyse and create preventive measure. However, only having system is not enough according to them. It is also important to be aware of how the organisation is currently running, and having a vision for the desired safety work and performance, the management's safety focus and safety work being an integrated part of the operations is highlighted.

5.3 *Learning*

According to Nonaka and Takeuchi (1995) learning can be looked at as a dynamic spiral, between the two learning loops that Argyris and Schön (1978) describe. The spiral goes between tacit and explicit knowledge and from explicit to tacit through four phases. The spiral goes on as *"organisational knowledge creation is a continuous and dynamic interaction between tacit and explicit knowledge"* (Nonaka and Takeuchi, 1995, p. 70).

Lingard and Rowlinson (2005, p.365) highlight the need for collective learning in the construction industry and the current lack of this. They write that similar accidents reoccur in the industry across countries, and yet the industry does not manage to improve the occupational safety enough.

In relation to the construction industry and safe-ty, it is therefore important to acknowledge the individuals in the organisation when creating and implementing measures for accident prevention. In the same manner, during accident investigations, tacit knowledge should be a part of the information foundation in an investigation, as when it goes back as learning points.

Drupsteen and Guldenmund (2014) point out that it is hard to identify organisational factors and managerial weaknesses that are root causes of events, which limit the possibility of double-loop learning. Le Coze (2013) suggest more cross-disciplinary research on learning from accidents. This shows the need for more research on the topic, and combining different topics together.

5.4 *Input for safety management*

Which results that can be used from an accident investigations for proactive safety management, depend on the type of accident, the outcome of the investigation as well as the way the information it is shared. It is suggested to make specifications and criteria related to characteristics of accidents (e.g. types of accidents, causes, processes) in order to decide what learning purposes they can serve.

Results of accident investigations can in example be used as input for proactive safety management, e.g. in the Safety Management System (SMS) of a company, and as an input in building information models (BIM) which can include early phase actors (i.e. consulting engineers) in the learning loop. One of the challenges for consulting engineers when it comes to occupational safety during construction, is that they in small scale get feedback if their solutions could be executed safely in practice by construction workers. By using new solutions and tools (e.g. digital solutions), these actors could easier be involved in occupational safety work.

The results can also be adapted to serve safety purposes in different processes during a construction project. Procurement processes both in early phases of a project as well during construction put a foundation and boundaries for safety. It is important to transfer knowledge also to these processes from accident investigations, to reduce the safety risks during construction.

5.5 *Coping with the diversity of actors*

The industry is, as mentioned before, diverse and numerous actors are involved in construction projects. This diversity pose a challenge in relation to learning, as different actors have different needs and requirements. This means that adaptation is required when it comes to ways of sharing knowledge and learning. A flow of information is required both between the different levels, and at each of the levels.

To analyse this diversity of actors and activities Pryke (2012) suggests a graphical representation and a social network analysis of how the specific actors and activities are related. Such an analysis

could be linked to safety management. Mapping the relations and information flows after accident investigations might give a better understanding of deficits in communication and knowledge sharing. The different actors in the actor chain in the construction industry, introduce boundaries and conditions that affect safety. A social network analysis can also be used to map other factors such as frame conditions (e.g. contract conditions) and how they affect different actors (Pryke, 2012).

Different actors have different roles in safety management, and this apply also for learning. By mapping relations in the construction network, information flow, finding out who has which needs, and who should facilitate whom, can help in knowledge transfer and learning.

It is suggested to perform a similar analysis as the social network analysis on safety information flow after accident investigations.

6 CONCLUSIONS

Preliminary findings of the research show the importance of coordination and cooperation between actors of construction projects. Accident investigations are important to avoid that similar accident reoccur, however there are elements that hinder knowledge transfer and learning from earlier accidents. Accident investigations in large degree vary between projects, clients and contractors. Often each actor performs individual investigations with limited sharing of the results across companies. Consulting engineers are rarely involved in investigations, unless the problem has clearly been related to calculations.

Having a good knowledge foundation, based on facts including root causes, is crucial to ensure that correct measures are taken after accidents and to enable learning. For this it is important with competence and experience of the investigation team. It was found that experience and knowledge about accident investigations of the HSE responsible persons in companies varies a lot.

To obtain learning after accident investigations, information must be shared. Certain types of accidents are more suitable for sharing and learning purposes, e.g. near misses and high potential incidents. It is suggested to make specifications and criteria related to characteristics of accidents for specific learning purposes.

Information sharing after accident investigations mostly happen within companies. Between companies, knowledge sharing and learning is not systemised and occurs occasionally, and tools to share information between companies are lacking.

The large diversity of actors in the industry challenges practices, information sharing and learning processes. To enable learning in the industry both across organisations and within organisations, there is a need to understand the different relations between actors, processes and needs. A social network analysis of the information flow of the results after accident investigations in the construction industry might help to find the deficits as well as the centre points of communication and relations between actors, that might enable knowledge transfer and learning.

ABSTRACT: Organizations and industries must ensure safe operation of their facilities, employing rigorous risk management techniques for planning and executing their activities. The use of Personal Protective Equipment (PPE) represents the closest layer of protection to workers, and can considerably reduce the risk of exposure to hazards, being critical for safety in industrial environments. The hazards addressed by protective equipment include physical, acoustic, electrical, heat and chemicals. Despite the substantial efforts in increasing awareness about the benefits of PPE to strive towards zero accident philosophy, operators often neglect its use when not being supervised. However, organizations commonly have surveillance cameras installed which might provide useful visual information on correct usage of PPE. In this context, computer vision is an interdisciplinary field that seeks to automate tasks that the human visual system can do and includes domains of signal and image processing, pattern recognition and artificial intelligence. Moreover, object recognition is a prominent technology from computer vision for finding and identifying objects in an image or video sequence. Then, this work aims to create an automatic PPE detection from surveillance cameras and other video streams using computer vision and machine learning. Equipment such as helmets, safety glasses, earplugs and other garments are checked for whether they are being used by operators in a real-time monitoring, alerting supervisors to prevent accidents and ensure a safer environment.

1 INTRODUCTION

Even with the scientific and technological progress, statistics provided by the International Labour Organization (ILO) demonstrate that working conditions in many countries (e.g. European Union) have not changed to such a degree as to significantly reduce the problem of occupational injuries (Cavazza & Serpe, 2009). Therefore, every effort to decrease the number of accidents or, at least, maintain its rate at an acceptable range is highly important, and can be employed either by organizational actions, collective training or individual safeguard.

The traditional approach to avoid loss is the implementation of barriers, which plays a central role in the prevention of accidents. Sklet (2006) defines safety barriers as 'physical and/or non-physical means planned to prevent, control, or mitigate undesired events or accidents'.

Indeed, there are many opportunities to interrupt or change an accident sequence of events before it evolves into a loss. First, an answer is to change the preconditions for an accident to occur by eliminating the energy source or modifying the energy characteristics from the hazard. Second, barriers may interrupt, dilute, or redirect the energy flow during the latter part of the accident process (e.g. separating the victim from the energy flow). As last barrier, it is possible to improve the victim's ability to endure the energy flow (e.g. wearing some protective equipment), which is the ultimate protection to avoid damage (Kjellén and Albrechtsen, 2017).

In this context, Personal Protective Equipment (PPE) is usually adopted to protect the individual against health or safety risks at work. It includes items related with protection of head, face, eye, hand, arms, and legs (Health and Safety Executive, 2013). There are consolidated regulations for the usage of PPE in industries (Occupational Safety and Health Administration—OSHA 2004; U.S. Homeland Security 2002) that aim to decrease the frequency of misuse or absence of PPE. Also,

PPE's positive impacts are very significant (e.g. rate of eye injury and lost work time can be reduced by 50% or more when PPE is worn (Lipscomb, 2000).

Head, as a vital body part containing possibly the most important human organ, needs appropriate attention. Every year, approximately 1.7 million people are hospitalized or die as a result of a traumatic brain injury (TBI) only in the United States (McCrory et al., 2009). Protective headgear and helmets decrease the potential for severe TBI following a collision by reducing the acceleration of the head upon impact, thereby decreasing both the brain-skull collision, as well as the sudden deceleration induced axonal injury (Newman et al., 2005).

There are several types for head protection such as industrial safety helmets, bump caps and firefighters' helmets. The use of those equipment is necessary in activities like low-level fixed objects with risk of collision (e.g. pipework, machines, scaffolding) and transport activities involving the risk of falling material (e.g. hoists, lifting plant, conveyors) (Health and Safety Executive, 2015). The energy absorbing material of a helmet compresses itself to absorb force during the collision and slowly restores itself to its original shape. This compression and restoration has the effect of prolonging the duration of the collision, while reducing the total momentum transferred to the head (Pellman et al., 2006).

The problem relies on the fact that, even with understanding about the safety improvement that the usage of PPE leads, its usage is often neglected in industry. The report of the ILO estimates that 2.34 million people die every year in the world due to occupational accidents, some of these deaths caused by non-use of PPE (International Labour Office, 2011). A common approach is to impose fines and penalization to workers, who do not wear the required PPE when performing specific activities. However, supervision to guarantee its use is normally performed in person by a higher-level employee, which makes almost impossible to control all operators during the whole labor time.

Indeed, there is an extensive discussion concerning ethical issues in workplace surveillance, referring to management's ability to monitor, record and track employee performance, behaviors and personal characteristics in real time (Ball, 2010). Most of the discussion involves the so-called Electronic Performance Monitoring (EPM) about employee's control in social and technological forms (e.g. Internet and email monitoring, location tracking, biometrics) and the understanding of privacy boundaries surrounding employee information (Alder, 1998) (Allen et al., 2015). However, our discussion is to assure that proper safety protocol is followed, preventing injury to employees, as well as avoiding damage to the assets through a consistent and trustworthy model.

Therefore, an automatic method for monitoring PPE usage presumably is significant worthy for industrial safety, representing an impactful opportunity for the use of Computer Vision (CV). CV is an interdisciplinary field aiming to investigate and develop computers with high-level understanding from digital images or videos, describing the world that we see and to reconstruct its properties (Szeliski, 2010). From the perspective of engineering, it seeks to automate tasks that the human visual system can do (Sonka, Hlavac and Boyle, 2008). The development of high-powered computers, the availability of high quality and inexpensive video cameras, and the increasing need for automated video analysis has generated a great deal of interest in object tracking algorithms in CV field (Yilmaz, Javed and Shah, 2006). Therefore, this paper aims to develop a model for automatic PPE detection from industrial video streams using computer vision and machine learning, employing modern technologies to create tools capable of modifying and innovating methods currently used in industries.

The rest of this paper is organized as follows: Section II introduces some ideas and concepts on CV, while Section III presents some works of object/person detection, describing the methodology applied in PPE detection. Section IV demonstrates the developed model. Section V provides possible usages as decision supporter and Section VI concludes remarks.

2 COMPUTER VISION

Computer Vision (CV) studies the automated extraction of information from images and videos. Information can mean anything from 3D models, camera position, object detection and recognition to grouping and searching image content (Jan Erik Solem, 2012). CV gathers knowledge from many fields, such as image processing, pattern recognition, mathematics and artificial intelligence. One of its main goal is to enable computers to reproduce core functions of human vision, such as motion perception and scene understanding.

Hence, visual object tracking have been constantly studied and presents three key steps for detection in video analysis: detection of movement of objects, tracking of such objects from frame to frame, and analysis of object tracks to recognize their behavior (Yilmaz et al., 2006). Essentially, the basis of visual object tracking is to robustly estimate the motion state (i.e., location, orientation, size, etc.) of a target object in each frame of an input image sequence (Li et al., 2013).

Specifically, intelligent visual surveillance systems deal with the real-time monitoring of persistent and transient objects within a specific environment (Valera & Velastin, 2005). The goal of these systems is not only to put cameras in the place of human eyes, but create an entire surveillance system as automatically as possible (Hu et al., 2004).

There exist some well-known visual surveillance systems such as W4 (Haritaoglu et al., 2000); Haar-wavelet Adaboost (Enzweiler & Gavrila, 2009) and ViBe (Barnich & Van Droogenbroeck, 2011), mainly developed to detect different vehicles types, groups of people, pedestrians, people access control. Every system is developed seeking to compensate the capability limitation of human operators in monitoring enormous number of cameras at the same time. Thus, exploring similar tools and challenges to detect usage of PPE in order to avoid accidents in industries represents an interesting case.

3 REAL TIME OBJECT DETECTION

Techniques from statistical pattern recognition have, since the revival of neural networks, obtained a widespread use in digital image processing (Egmont-Petersen et al., 2002). Due to the outstanding work of Krizhevsky et al. (2012) for image classification, Deep Neural Networks (DNN) have been successfully studied in different fields of application such as speech recognition (Hinton et al., 2012), vibration analysis (Guo et al., 2016), electronic nose data (Längkvist et al., 2013) and physiological data (Mirowski et al., 2008). However, surely, the most promising results are found in the field of computer vision, bringing impressive developing in tasks like automatic object and face recognition.

One promising, open and free project that uses DNN for object detection is You only look once (YOLO). YOLO is a system for detecting objects and was first created on the Pascal VOC 2012 dataset, detecting the 20 Pascal object classes, such as person, birds, dogs, car, bicycle, bottle, table and chair, as could be seen in Fig. 1 (Redmon et al., 2015).

The developers adopt a different approach than the standard object detection models that uses classifier based-systems applied at multiple locations and scales in an image, which typically considered as detections high scored regions of the image. In YOLO, a single DNN is executed to the full image. This network divides the image into regions and predicts bounding boxes and probabilities for each region, with these bounding boxes being weighted by the predicted probabilities. It has considerable

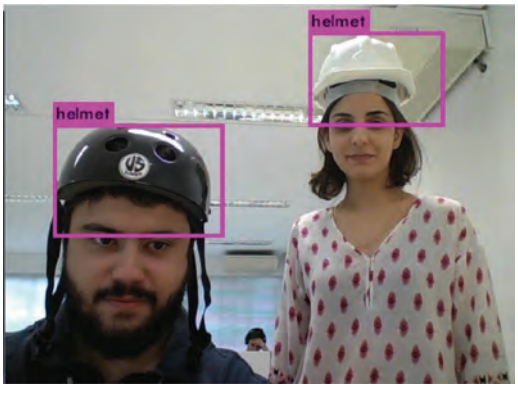

Figure 1. Example of object detection using YOLO. Adapted from Redmon et al. (2015).

advantages to other object detection models, once it looks at the whole image, and then its predictions are informed by global context in the image (Redmon et al., 2015). It also makes predictions with a single network evaluation, making YOLO extremely fast, allowing usage even for computers without a Graphics Processing Unit (GPU).

Still, an improved model, YOLOv2, has already been developed. More robust, detecting more than 9000 objects without losing real-time performance, YOLOv2 is a state-of-art object detection system with results comparable or with even better than many other systems (Redmon & Farhadi, 2017). Moreover, the YOLO project is open, well described, easily explained and user-friendly to anyone, who has some basis in computer programming. It even demonstrates how to include objects that were not on its detection basis, how to process and train a new model, allowing adaptation for different purposes.

Hence, using YOLOv2 as a key tool, we trained a new model to automatically detect PPE usage. Specifically, we were interested in identifying whether workers were wearing or not a safety helmet when performing some activities in which the protection was required.

4 HELMET DETECTION USING YOLO

YOLO project easily provides a pre-trained model, which could be used as a basis for detecting new types of objects. As any machine learning algorithm, YOLO requires a training dataset that will 'teach' the machine how an unknow object looks like. For our specific goal, 731 images containing helmets were used to give sufficient information about its appearance. All images were obtained from ImageNet (Jia Deng et al., 2009), and loca-

tion of helmets in images were annotated manually. ImageNet is an image database organized according to the WordNet (Fellbaum, 1998) hierarchy, in which each node of the hierarchy is depicted by hundreds and thousands of images. It presents useful resource for researchers that needs image data, containing innumerous classes of items.

The network was trained for about 8 hours, running in a Nvidia GeForce GTX 960 m GPU, with 4GB of video random access memory (VRAM). Once the algorithm finished its training, our helmet detection model could be applied to a specific image or to a video stream, such as a camera feed, processing every frame. Our model runs in real-time, maintaining the frame rate of the camera (30 frames per second—FPS). Fig. 2 depicts the model applied to a standard web camera video streaming.

Then, a script was created to alert surveillance operators whether an abnormal situation appears (i.e. helmets were not detected). Due to simplifications proposed, the model aims to be applied in a room containing specific number of employees that should be using helmets. For each frame, our algorithm detects the use of helmet and counts how many are present in the scene. If the number of detected helmets is different from number of previously defined people in the room for more than a brief period (e.g. 10 seconds, or 30 seconds), then an alert was emitted. Fig. 3 shows a computer screen when an alert was presented (i.e. one person is not using helmet in the image).

Moreover, if the number of detected helmets does not return to its normal value, alerts may continue to be emitted, but the period between alerts may be defined as desired (e. g. 30 seconds, or two minutes). Properly adjusting this period avoids unnecessary alerts that will continually distract the surveillance operator even after recognition of first anomaly situation, while still reminding that an abnormal situation is ongoing.

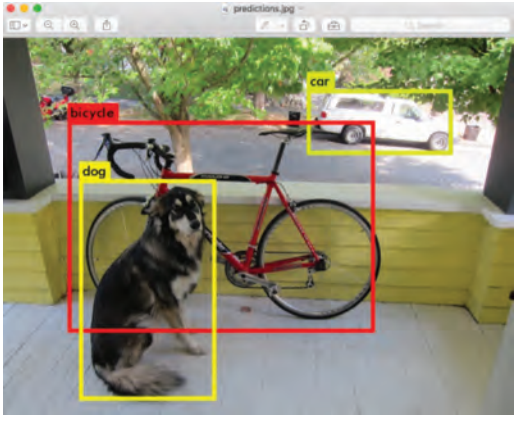

Figure 2. Helmet detection model applied for video streaming.

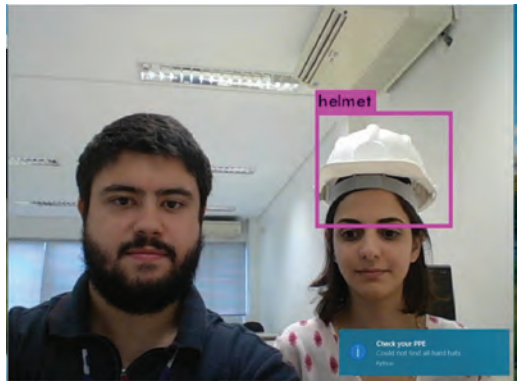

Figure 3. Alert emitted when model detect anomaly situation.

5 SUPPORTING DECISIONS

In practice, the presented model could be explored as a tool in different contexts, supporting decisions for the safety manager. The idea was to develop the model to be highly adaptable and manageable for various situations, providing specific information accordingly.

For example, as aforementioned, the alert period is easily adjustable to avoid unnecessary warnings. Still, other types of warnings (e.g. depending on how long operators remains without PPE; how many operators are not wearing the PPE) could be easily implemented and customable, providing information for the decision-maker to determine whether or not someone must be notified. Moreover, it is also possible to use information and statistics provided by the model (e.g. how many times alerts were displayed per day; who long operators had remained without PPE) as a safety indicator.

Still, implementation of a real time alert for the operators (e.g. a particular warning light is lit somewhere in the room) connected with the model would emphasize (or create) the sense of autoregulation among them, reducing (or sharing) the surveilling workload expected for the supervisor.

With further and wider adaptations, this surveillance technology could be also implemented to monitor other barriers than PPE. Related with the initial barriers where, usually, reliable sensors are already available, CV could act as a redundancy, rather than substituting existing technologies, aiming to improve detection effectiveness of hazards (e.g. fire, toxic gases) in order to interrupt the energy flow in case of accidents. For inner barriers, it is possible

to create alerts and warnings for whether an operator approaches a danger zone based on images of the area. In both previously mentioned barriers, CV would help to eliminate or reduce the consequences of unwanted energy flow, rather than dealing with the last safety impediment represented by the PPE.

6 CONCLUSIONS

This paper presented an approach for automatically detecting PPE usage in a controlled environment, using object detection with YOLO. By using YOLO, this method achieves a reasonable balance between speed and confidence, running in real-time, which results in relative low computational resource usage. Moreover, it is possible to adjust the model to different scenarios according to specific requirements. This could lead to beneficial results to safety engineering since the detection is performed automatically and does not require constant human attention.

As a matter of our current research, we aim at extending this model for application in a wider range of situations. For instance, YOLO can be trained to identify other types of PPEs, so that it could be used for simultaneously monitoring usage of different PPEs. Also, the script used for alerts could be improved, allowing this method to cover a wider range of scenarios. A further step is to use real surveillance videos as input, detecting the usage of PPE in realistic environment, preventing accidents and providing an improvement on the safety monitoring system of industries.

Norwegian police training in the use of force: A preparation for facing the realities of street challenges?

S. Vee Henriksen & A. Snortheimsmoen
Norwegian Police University College, Oslo, Norway

B.I. Kruke
Centre for Risk Management and Societal Safety, University of Stavanger, Stavanger, Norway

ABSTRACT: The Norwegian police have a tradition for reticent use of force. Norway is one of the very few countries in the world with unarmed police on daily duty. The aim of this paper is to study the degree to which the Norwegian Police University College (NPUC), and the police districts, training in the use of force reflects the need for reliable handling of the various weapons at the disposal of the police officers and how experiences on the use of force gained by police officers in their daily duty is made available for police training. However, there is no national strategy on collection, dissemination, interpretation and integration of experiences from the streets of Norway. Even though experienced police officers lecture and supervise students and fellow police officers, the lack of systematic collection of experiences hampers the quality of the training, especially at the NPUC, but also in the police districts.

1 INTRODUCTION

The Norwegian police have a tradition for reticent use of force, a tradition rooted in the Norwegian society (NOU 1981:35; Norwegian Parliamentary White Paper No. 42 (2004–2005)). However, from 2007–2016 the Norwegian police has experienced a sharp increase in armed assignments from 1507 in 2007 to 5816 by November 2016 (POD 2017a). It is mostly ordinary emergency response police personnel who handle the acute phases of armed assignments (Norwegian Parliamentary White Paper No. 21 (2012–2013)). Heightened terrorist threats and organised crime may expose the police to extreme situations characterized by rapid assessments and decisions, based on ambiguous information and the possibility of fatal consequences. Changes in street realities may challenge both operational training and practice in the use of force in the Norwegian police.

This paper aims to study the degree to which the Norwegian Police University College (NPUC), and the police districts, training in the use of force reflects the need for reliable handling of the various weapons at the disposal of the police officers facing street challenges, and how experiences on the use of force gained by police officers in their daily duty is collected, disseminated, interpretation and integrated in police training. The paper draws on observations made through many years of experience from operational service in the police. One of the authors is former head of the police counter terrorist unit (Delta), and another is a former lecturer and head of studies at NPUC. The paper starts with a historical introduction to the police use of force, followed by a presentation of the frameworks on crisis, situational awareness, decision-making, training, exercising and learning. We then present the results on operational use of force based on literature studies of the results of the Firearms Commission (NOU 2017:9) and of reports on the use of force. We also include findings based on participant observation in training sessions at the NPUC and in the police districts. These findings are then discussed together with the theoretical frameworks before we make some concluding remarks on police training on the use of force in relation to the operational needs on the street.

2 THE NORWEGIAN POLICE

A Norwegian national police force organized and employed by the state has existed since 1936. The Norwegian police is organized under the Ministry of Justice and Public Security, and managed by the Police Directorate (POD). All police services in the

12 police districts, and the five national specialized agencies[1] (POD 2017b), follow the same law, instructions and guidelines.

2.1 *The Norwegian Police and the Norwegian Police University College (NPUC)*

The NPUC is one of the national specialized agencies, and is responsible for all under graduate and post graduate education, including all police training in the use of force. The joint national basic education program secures the same basic training in the use of force and coercive means, including firearms. The police are divided into five competence levels for emergency response personnel (IP), according to the level of annual operational training (PBS 1:38):

IP 1: The police counter-terrorist personnel (Delta)
IP 2: The dignitary protection personnel
IP 3: The police special response unit personnel
IP 4: The police emergency response personnel (ordinary police personnel)
IP 5: The police emergency response personnel with limited operational training (not licensed to carry firearms).

To be authorized to carry firearms, emergency response personnel have to carry out at least 48 hours of operational training and pass a standardized annual firearms test to reach competence level 4 (IP 4). It is NPUC, along with POD, which determines the annual joint national operational training. The yearly training normally consists of firearms training, arrest techniques, first aid, tactics and situational training. In recent years training on how to handle an active shooter has been emphasized for all police emergency response personnel (Norwegian Parliamentary White Paper No. 10 2016–2017).

2.2 *Directives and instructions on the use of force*

There are no written directives on how the police should perform their operational training. NPUC develops the professional content on the basis of inputs from instructors, collaboration with POD and PJS (Police Joint Services), dialogue meetings with police districts, participation in national exercises and regular meetings with the National Reference Group for Police Operative Disciplines. The professional content of the training is detailed in relevant academic literature, in instructor manuals and in subject booklets, which ensures an equal approach in all police districts. Thus, at a strategic level, NPUC has a central role in developing and coordinating national training.

The specific instructions for use of force are provided in the Police Act, Police Instructions and Firearms Instructions (Lovdata.no 20.11.17). The use of physical force is authorized through law in the Police Act, is defined in the Police instructions and is essentially exercised on the basis of professional judgment and discretion. Use of coercive measures, such as pepper spray, baton and firearms, are strictly regulated in the Firearms instructions.

2.3 *Models for the force continuum*

The Norwegian police use a model, "Force pyramid" (see Figure 1), for visualizing coercive measures in a force continuum. The model shows how the use of force is increased the higher up in the pyramid one comes, based on the amount of physical and mental injury which may be expected from the respective coercive measure. The pyramid is not a complete and generally valid description of the use of force, but a ranking of different coercive measures (Lie & Lagestad 2011:10). However, the model is used in all training in the use of force at NPUC:

In this paper we limit the further discussion to *physical* force, shown as the steps above the dotted horizontal line in Figure 1. The first steps are use

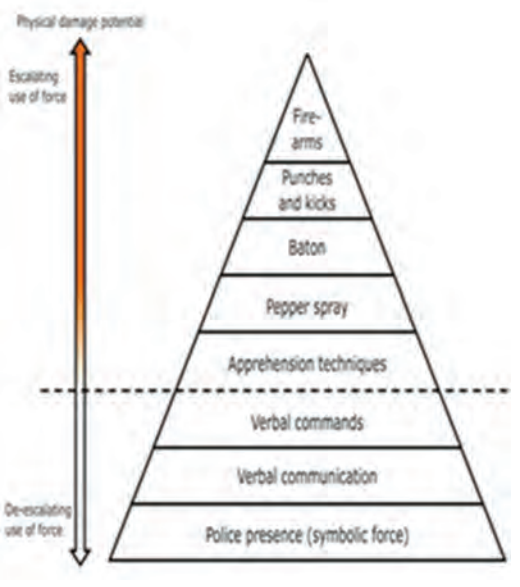

Figure 1. Force pyramid.

[1]Norwegian Police University College (NPUC), Central Mobile Police Service (CMPS), National Criminal Investigation Service (NCIS), Police Joint Services (PJS) and Norwegian National Authority for Investigation and Prosecution of Economic and Environmental Crime (NNAIPEE).

Figure 2. Police use of force model.

of arrest techniques in more controlled situations, the use of pepper spray, and the use of baton. The next step is the use of punches and kicks as self-defence in more uncontrolled situations. As a last resort, the police can use firearms. The police use of force may also be displayed in another model (see Figure 2).

This model, unlike the force pyramid model (Figure 1), also includes Electronic control devices (ECD, for example TASER) and the use of dogs, in addition to situational assessment. ECD is under review for possible acquisition. The police use of force model (Figure 2) is based on the New Zealand Police "Tactical options framework" model. This modified version was first presented at the annual research conference at NPUC in 2016 (Vee Henriksen 2016). The inner circle of the model describes the level of resistance faced by the police. The outer circle describes the coercive measures in relation to the level of resistance. Proportionate use of force is decided based on situational assessment, conducted by the police emergency response personnel.

It must be emphasized in both models that the police do not have to try every step before stronger force is used; this depends on the development of the situation in question. In daily service the Norwegian police will carry pepper spray and baton in the belt, but their firearms will be stored in locked boxes in the patrol cars.

3 CONCEPTUAL FRAMEWORKS

To be able to understand and discuss police use of force, we need to clarify our understanding of incidents, crisis, situational awareness and decision making. We then need to look at collection, dissemination, interpretation and integration of experience and finally learning about police use of force.

3.1 *Incident and crisis*

A crisis may be defined as "a serious threat to the basic structures or the fundamental values and norms of a system, which under time pressure and highly uncertain circumstances necessitates making critical decisions" (Rosenthal et al. 1989: 10). This definition points to critical decision-making in the midst of the uncertainty and time pressure of a dynamic incident or crisis. For the sake of this paper we will not distinguish between the terms incident and crisis. There is some research on differences between events such as incident, crisis and catastrophe (Engen et al. 2016), for instance due to their response needs. We will not go into this discussion in this paper, but use the terms incident and crisis independent of the size of the event in question.

Some crisis characteristics may be of particular importance in incident or crisis management. 't Hart and Boin (2001) distinguish crises based on their development and termination patterns. A fast burning crisis develops and terminates fast. A slow burning crisis has slow development and termination patterns. Gundel distinguishes crises based on their predictability and the degree to which they can be influenced (Gundel 2005). Unexpected crises are in his terminology difficult to predict, but fairly easy to influence. Intractable crises are easy to predict but difficult to influence. It is fair to assume that an unexpected crisis (Gundel 2005) with a fast developing pattern ('t Hart and Boin 2001) may be particularly challenging to manage for police officers.

3.2 *Situational awareness and decision-making*

Situational Awareness (SA) is crucial for decision-makers in dynamic incident management. Situational awareness is defined by Endsley as "the perception of the elements in the environment within a volume of time and space, the comprehension of their meaning and the projection of their status in the near future" (Endsley 1997:97). SA makes it possible to operate quickly and efficiently even during demanding operations (Lee and Kirlik 2013) necessitating swift decision-making, also on the use of force (including firearms). The quality of decision-making on modus operandi, and the ability to switch from one practice to another (Schakel et al. 2016), to manage the situation at hand, including the use of force, may have a crucial impact on the police officers and the public. Decisions may be based on analytic and/or intuitive reasoning

(Eid and Johnsen 2006, Helsloot and Ruitenberg 2004). The important issue initially is to reduce uncertainty, to find out what is going on. Boin and colleagues describe this initial phase as the sense-making phase, or the "what the hell is going on" phase (2005). In unexpected and fast developing situations, characterized by a high degree of uncertainty, it is fair to assume that intuitive decisions will be of particular relevance. Intuitive decisions are based on previous experience from similar situations (Eid and Johnsen 2006) and on improvisation (Weick 1993). Recognition of familiar patterns, déjà vu (Weick 1993), is a comforting thought for decision-makers in these situations, for recognition-primed decision-making (Klein 1989, 2011). Weick describes decision-making in this connection as «an act of interpretation rather than an act of choice» (1995:185). Furthermore, Weick (1995) points out that a good decision-maker is as good as his memory and the type of information that is stored there, and that good decisions are just as much based on a correct understanding of what has happened as on a correct understanding of what is going on. The level of expertise, based on experience, training and education, is therefore important for situational awareness and decision making.

3.3 *Training, exercises and learning*

Paoline and Terrill (2007) focus on experience as being the most important factor for learning within the police. Experiential learning is a form of learning that builds on practical situations and practical exercises that provide personal experience as well as learning (Kolb 1984), as learning by doing (Dewey 1938). Dreyfus and Dreyfus (1988) present five levels of proficiency; novice, advanced beginner, competent, proficient and expert. They focus on the development of occupational knowledge in an educational perspective: «If, and only if, experience is gained in this a theoretical manner, and intuitive behaviour replaces considered reactions, can mastery be regarded as developed» (Dreyfus and Dreyfus 1986:56). The transferring of experience and development of competence at the moment of learning however requires occupational experience to be passed on as knowledge-based learning. Thus, police officers experiential learning (Kolb 1984) need to by shared, disseminated, and collectively integrated and interpreted (Dixon 1999) in the police force and thereby made available for instructors and training sessions in the NPUC and the police districts.

4 EMPIRICAL FINDINGS

The empirical findings stem from participant observation in training sessions and operational use of force, and statistics from the Norwegian Police Directorate (POD), and the Firearms Commissions report (NOU 2017). Reference will also be made to earlier surveys relating to the subject.

4.1 *Use of force*

Even though risk assessments must not only take into account experiences but also cater for surprises and uncertainty (NOU 2012:14), proper data gathering is a vital foundation for these assessments. The Norwegian police do not collect data on the use of force in a structured way. Based on the lack of reporting systems in Norway, there is limited knowledge about to which extent and in which contexts the police exercise force. The only use of force that is being reported is in the form of statistics for armed assignments, when the police have threatened to use firearms and where they have actually used them. However, there is no national standard for reporting on the use of firearms. Thus, routines may vary amongst the police districts.

Figure 3 shows the development of armed assignments from 2007–2016. It is noted that the sharp decline in the period 2014–2015 is due to the temporary arming of the Norwegian police due to the increased threat of terrorism (NOU 2017:9). The temporary arming meant that all uniformed emergency response personnel approved to carry firearms, were required to carry a pistol during regular service. In most police districts, assignments that required armed response were no longer registered, as the police already had a general order for arming (therefore the decline in Figure 3 in this period). Some police districts, however, continued the normal practice of registration, despite the fact that the police already were armed (NOU 2017:9).

How many shots are fired by police officers each year? Figure 4 shows the numbers of shots fired at a person in the period 2005–2014.

Figure 4 shows an average of 2,5 shots fired at a person per year. In 2014, with just above 4000

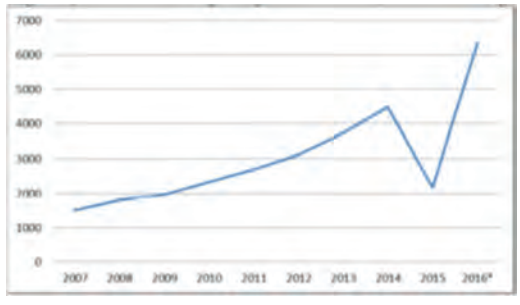

Figure 3. Annually reported armed assignments (POD 2017a:8).

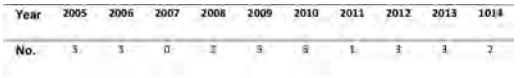

Figure 4. Annually reported shots fired at a person (POD 2015:3).

armed assignments (see Figure 3), 2 shots were fired at a person (Figure 4).

In situations where police officers have fired shots at a person, an investigation must be carried out according to the Norwegian Prosecution Instructions (Lovdata 22.08.16). The investigation will check the police officer's action only based on a *legal perspective*, and the incidents will not be evaluated for gathering knowledge in a *learning perspective*. All cases of police use of firearms in the period specified in Figure 4 have been filed without any form of legal consequences against the police. The number of shots fired at persons each year is low, and no substantial change was recorded in the number of situations where the police threatened to use firearms or actually fired shots during the period of temporary arming (NOU 2017:9:153).

Except for various standards of reporting related to the use of firearms, it is no national reporting system on the police use of force. Any documentation will only appear in the police local orderly book and/or administrative documents in the individual criminal cases. The lack of an overall police system for collection, dissemination, interpretation and integration of experience in the use of force has been pointed out in official reports (NOU 2009:12; NOU 2013:9). A comprehensive police analysis in 2013 pointed out that: «Despite the fact that expertise is a crucial input factor, the police today lack a comprehensive strategy and approach to the development and management of competence in the police. Competence and personnel development work in the police is to a lesser degree systematic» (NOU 2013:9, p. 209). In this context, it is reasonable to ask questions about the basis for Norwegian police training in the use of force. Is the training based on proven experience-based knowledge or based on assumed needs of the police? Very few surveys related to police use of force have been conducted in Norway. Lagestad (2008) conducted a study which included examining how often the police train and use arrest techniques. In this study the participating police officers assumed that they were using physical force approximately once a month. Lie (2010) prepared a report on mapping and testing of police knowledge and skills in arrest and control techniques. 90% responded using physical force to put someone on the ground once or twice the last two years, 16% had used pepper spray in the last year and 4.5 percent had used telescopic baton. According to Holmberg's (2013) report on the use of pepper spray in the Scandinavian countries, in Oslo Police District the use of pepper spray was reported approximately twenty-seven times a year on average in the period 2005–2011. It must be underlined that the Firearms Commission suggested that the Norwegian police should report on all use of force (NOU 2017:9). It is not known if and when this will be implemented.

4.2 *Temporary arming in 2014–2016*

Due to a heightened terrorist threat ordinary police officers were armed on daily duty in the period 25th November 2014 to 3rd February 2016. The Norwegian police officers were armed while on daily duty for the first time, with no time for preparations. In the Norwegian Official Report (NOU 2017:9) it is pointed out that the Police Directorate particularly noticed two main issues regarding the arming; (1) the risk for accidental discharges (AD), and (2) the possibility of the police being deprived of their own firearms. According to the Norwegian Official Report (NOU 2017: 9, 151) "it cannot be said that a central and systematic risk assessment of accidental discharges was made in advance of the arming."

4.3 *Accidental Discharges (AD)*

Prior to the period of temporary arming, there was no systematic registration of accidental discharges (AD) in the Norwegian Police Force, nor was there any clear specification of what should be considered as AD (NOU 2017:9). Guidelines for preventing ADs when the arming occurred were not in place. It was also not established a system for collection, dissemination, interpretation and integration of experiential learning from such incidents. However, AD became a very relevant issue during the temporary arming. In a letter of 10th August 2015 the Ministry of Justice and Public Security requested the registration of ADs during the temporary arming, and instructed POD to retrospectively map ADs in the period 2011–2015. Twenty-eight ADs were registered during the period of temporary arming, a sharp increase from earlier years, but earlier numbers are uncertain as they have been retrieved retrospectively (NOU 2017:9:147), and not based on a continuous systematic reporting. Figure 5 shows accidental discharges registered in the period 2011 – January 2016.

It must be underlined that the registered numbers of ADs do not include ADs during firearms training or when weapons have been emptied and checked in projectile collectors, unless resulting in injuries.

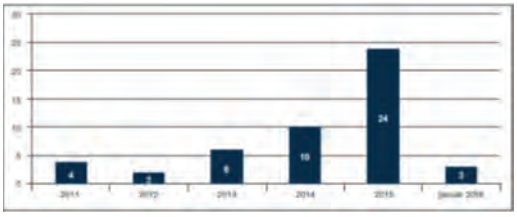

Figure 5. Shows AD registered in the period 2011-January 2016 (NOU 2017:9:148).

4.4 *Attempts to deprive the police of firearms*

During the period of temporary arming the Police Directorate received twenty-two reports of attempts to deprive the police of firearms. The numbers might be incorrect because the reporting was not mandatory until august 2015, nine months after the Police Directorate gave the order to arm all police emergency response personnel (NOU 2017:9). The attempts to deprive the police officers of their firearms occurred in different contexts. There were reports of several attempts to deprive the police of their firearms assisting medical care, include transportation of mentally ill persons. Similar incidents occurred when the police performed arrests. At least two such incidents resulted in injuries on police officers while defending their firearms.

4.5 *Police basic education on the use of force*

The Norwegian police basic education lasts for three years (a bachelor degree). The program consists of one year of theory at one of the NPUC`s three departments, a year of practice where each student is guided by an experienced police officer/tutor, and a final year of theory back at the NPUC. The operational education, in terms of training in the use of force, is primarily distributed throughout the second and third year. The operational training reflects that the Norwegian police officers still are unarmed in their daily duty. In the first year of studies there is no regular tactics or weapons training. However, the students receive basic training in arrest techniques, and training and approval to use OC pepper spray and the telescopic baton. In the second year the students undergo a two week course in basic tactics, situational training and basic training on Heckler & Koch MP5 (sub-machine gun). Tactical and situational training takes place without students carrying firearms during this course. The students also attend a basic course in the use of the Heckler & Koch P30 L pistol. Students will to varying degrees also participate in the operational training held in the police district in which they are assigned. This applies to both tactics training and weapons training. In addition, they continue to receive basic training in arrest techniques. During the third year the students have a number of exercises in situational training. In addition, they receive training in a simulator with exercises in situational awareness and decision-making connected to the use of force, including focus on the use of firearms. The simulator training focuses on the model for force continuum (see Figure 1) and the legal framework for police use of force. During this final year the students also continue training in arrest techniques, and have their final exam. During the last semester, students participate in a three-week course, which places special emphasis on firearms training and armed assignments. During this course, students also undergo the standardized annual firearms test for both firearms (pistol and sub-machine gun). When completed, they will be approved as police emergency response personnel (IP4), authorized to carry firearms in service.

4.6 *Use of experiential learning*

There is no position or function on a national level explicitly responsible for the collection of experiences from operational service, and making these experiences available for education and training in the police. Use of experiential learning is sporadic and dependent on individual initiatives. Experience is not collected in a systematic manner. We have also seen variations both between departments and police districts on collection, dissemination, interpretation and integration of experience-based learning. At the same time there are some good examples where experience-based operational training has been developed. The police counter terrorist unit (Delta) participated in the development of a concept for arresting a person with a knife based on experiences from such arrests. This concept is now mandatory training for all students at the NPUC.

The project manager for the development of the NPUC simulator training in the use of force, including firearms, used all available Decisions of Prosecution from the Norwegian Bureau for the Investigation of Police Affairs as a basis for the professional content of the simulations. All relevant legal assessments were reviewed and implemented in the training, and many of the scenarios that were recorded are based on real events. This training is also mandatory for all the students at the NPUC.

5 DISCUSSION

Is the police training in the use of force based on experiences from incident management on the streets, preparing students and police officers for facing the realities of street challenges? First of all we have to go back to our understanding of

incidents and incident management, and try to find out what characterizes assignments where coercive force may be used. As previously stated, there is a lack of reporting in connection with experiences gained by police officers in the use of physical force, except in the case of firearms. Reporting in the use of firearms is also fragmented and not based on a standardised format implemented by all police districts. There has been a sharp increase in the number of armed assignments in Norway. At the same time the number of fired shots from the police emergency response personnel stays at a very low level (se Figures 3 and 4). Armed assignments may suddenly arise, leaving limited time for preparation and decision making. Some assignments terminate without any kind of contact with a suspect, some result in arrests without use of force and a few results in confrontation with a suspect where various forcible measures are used. Armed assignments may escalate to a crisis as they represent a serious threat to the security of the people involved and the surroundings. Nevertheless, time pressure and highly uncertain circumstances may necessitate the need for critical decision-making (Rosenthal, Charles et al., 1989). Based on the numbers of armed assignments (see Figure 3) it is fair to assume that new incidents will arise, but it will be difficult both to depict the time and place of occurrence and therefore the ability to influence the development of the event in question. Unexpected crisis (Gundel 2005) with a fast developing pattern ('t Hart and Boin 2001) may therefore be difficult for police emergency response personnel to plan for and manage. The NPUC, and the rest of the police force, need to consider both expected and unexpected scenarios when planning and developing the proper competence level for police students and officers. It is difficult to predict the future challenges the police may face, fully implement measures related to preventing and preparing for worst case scenarios, and plan police preparedness in case of unlikely events. Risk assessments must not only take into account experiences but also cater for surprises and uncertainty (NOU 2012:14). Thus, a reliable modus operandi to manage the situation at hand may not only be based on "following the book". Reliable decision-making in a crisis situation may be the result of an ability to switch from one practice to another (Schakel et al. 2016), on intuitive decisions based on previous experience from similar situations (Eid and Johnsen 2006), on a feeling of déjà vu (Weick 1993), on improvisation (Weick 1993), and, finally, on recognition of familiar patterns (Klein 1989). These are capacities normally associated with highly experienced response personnel. However, mostly ordinary police emergency response personnel (IP: 4) manage the initial phase of an acute incident or crisis. They need to be trained and equipped to face such situations. How do the police use experience to manage these types of events in training and education? Besides the statistics on armed assignments and the use of firearms there is no national systematic collection of experience on the use of forcible measures for use in training and education, either at the NPUC or the police districts.

In armed assignments adequate situational awareness (SA) is crucial for decision-making undertaken by police officers, and thus the outcome of the situation. These assignments are often characterized by rapid development, uncertainty and lack of or ambiguous information. SA makes it possible to operate quickly and efficiently even during such demanding assignments (Lee and Kirlik 2013). We are well aware that SA is one of the most central elements in training on the use of force, both at NPUC and in the police districts. During simulator training at NPUC SA is constantly referred to in connection with the choice of coercive measures based on the force continuum models (Lie and Lagestad 2011, Vee Henriksen 2016). As a result of their SA the police emergency response personnel decide whether or not to use force, and the appropriate kind of force and forcible means to be used. In situations where the police are armed, decision making will be particularly important since the use of firearms may have fatal consequences. To make the right decisions Eid and Johnsen (2006) point out that intuitive decision making will be of particular relevance as it is based on experience from similar situations. Weick (1995) also underlines that a good decision maker is as good as his memory and the available information that is stored there. However, training in the use of force is primarily done in orderly terms with less influence of interfering factors that will be applicable to real situations. Paoline and Terril (2007) underlines that experience is the most important factor for learning within the police, and Kolb (1984) refers to experiential learning based on practical situations that provide experience and learning. As we have pointed out, there is a severe lack of structured approach to collection, dissemination, interpretation and integration of experience on the police use of force in Norway. There is no documentation for the extent of use of force, what kind of force is being used and the outcome in these situations. How can we then maintain that the training is experience-based? And how can we be sure that this training prepares police students and officers for street challenges? Our experience shows that training largely depends on the individual instructor's experience, and random work based on individual initiatives as for example the development of the simulator training at NPUC. This means that there will be varying quality in the professional experiences conveyed during training.

Norwegian official reports have several times pointed out a lack of systematic use of experiential

learning in the police (NOU 2009:12, NOU 2012:14, NOU 2013:9, NOU 2017:9). It is a fundamental principle in learning theory that training and education should be based on experience. You train as you fight. The Firearms Commission has suggested a systematic registration of police use of force and evaluation of incidents where the police have used firearms (NOU 2017:9). This would be an important contribution to the systematic use of experiences in the future, and support competence development within the police preparedness. The police response is not likely to be more efficient than the actual police preparedness when an incident occur (Norwegian Parliamentary White Paper 2012–2013). Thus, as also reflected in the report of the 22nd July commission (NOU 2012:14), the police emergency response personnel must have relevant competence and training in the use of force. The number of accidental discharges in the police (see Figure 4), lack of systematic reporting on the use of force, and the less degree of systematic competence and personnel development work in the police (NOU 2013:9, p. 209), indicate that experience is an underused asset in police training.

6 CONCLUSIONS

The aim of this paper has been to study the degree to which the NPUC and the police districts training in the use of force reflects the need for reliable handling of the various weapons at the disposal of the police officers facing street challenges, and how experiences on the use of force gained by police officers in their daily duty is collected, disseminated, interpretation and integrated in police training.

Even though experienced police officers lecture at the NPUC, and supervise police students during the three-year study program, it is no national overall strategy on collection, dissemination, interpretation and integration of experiences from the street in the Norwegian police force. It is fair to say that this is hampering the quality of the professional content of the training, especially at the NPUC, but also in the police districts. As long as there is no documented experience that can be conveyed in the form of experience-based knowledge, the quality of the professional content of the training and lecturing will depend on the individual instructor`s experience and competence, also related to the street challenges faced by police officers.

The role of employers, safety engineers and safety reps in the improvement of safety level at enterprises

G. Hrenov, K. Reinhold, M. Tint & P. Tint
Tallinn University of Technology, Estonia

ABSTRACT: Fifteen Estonian enterprises were investigated to determine the safety level, using Method for Industrial Safety and Health Activity Assessment (MISHA) method. Some of the firms have implemented OHSAS 18001 or belong to the foreign companies. One of the ideas to improve the safety level at the enterprise is learning through the interviews. The interview was based on MISHA method. The safety performance elements were divided into three parts: formal, real and combined ones. The statistics was carried out using factor analysis with Barlett's test, ANOVA and T-square test with Wilks' Lambda row. The main possibilities to influence on safety level in the firm to employ the Working Environment Specialists (WES), as they are more educated and supported by the law in the work safety area. In small- and medium-size enterprises, there are only few resources to hire the WES. If the OHSAS 18001 was implemented, then the assignment of tasks and responsibilities in Occupational Health and Safety (OHS) was committed to the top management ($p = 0.000$), the employer was revising the safety policy ($p = 0.000$), the personnel's responsibilities and authorities in OHS were clearly defined ($p = 0.013$). The role of the working environment representative was not particularly significant in the investigated enterprises ($p = 0.350$). At the same time, the firm's type was significant on the supervisor/employee communication ($p = 0.001$) and on general communication procedures ($p = 0.006$).

1 INTRODUCTION

The work environment is a multifunctional term and it occupies not only the physical work settings, but also the psychological and psychosocial features that are subject to the people personalities and approaches (Hrenov et al. 2017a). Treatment of risks at work is a key apprehension in today's working environment (Lafuente & Abad 2018). Researchers and general practitioners have perceived a remarkable modification in the role of safety supervision, which has developed from a slim view associated to an overpriced managerial problem do an functioning primacy with significant economic and social impression (Abad et al. 2013; Das et al. 2009). According to the European Agency for Safety and Health at Work (EU-OSHA 2013), the economic costs and functioning damages of work accidents to workers, productions, and public supervision signify 3% of the EU's gross domestic product.

The OHSAS 18001 certification is becoming the leading international safety system approved by the administrations to involve in processes to encourage constant developments of work safety conditions (Fernandez-Muniz et al. 2012; Lo et al. 2014). OHSAS 18001standard is the basis for the new ISO 45001 standard that would likely to be accessible in the nearby time.

There are many different safety management systems (Li & Guldemund 2018). A safety management system in industry (SMS) (Robson & Bigelow 2010) can be defined as a planned, documented safety program that incorporates certain basic management concepts and activating elements into a well-organized safety system. The safety activity areas and supporting elements that comprise this system act and interact on one another to help achieve the desired safety or risk level. A total safety management system (SMS) consists of the following objects: parametres such as input, process, output, and feedback control; attributes: properties of parameters such as the external manifestation of the way in which an object is known, observed, or introduced in a process; relationships: bonds that link objects and attributes in the system process.

SMS can be categorized as a set of institutionalized interconnected and interacting strategic elements designed to establish and attain occupational health and safety goals and objectives (Yurio et al. 2015; Kim et al. 2016).

There are different key persons in the enterprise who have to take care of occupational health and safety (OHS): the employer (EMP), the working environment specialist (in some countries safety engineer, WES) and working environment representatives (or reps, WER) (Hrenov et al. 2017a). The roles of these key-persons in dissimilar nation

states are different (Paas 2015a, b, c, d; Hrenov et al. 2016).

The previous studies for improvement of safety and health at workplace (Paas 2015a; Hrenov et al. 2016, 2017a, 2017b), the roles of the employer, working environment specialist and working environment representatives are given specifically.

The current study gives the comparison of the results of the interviews of these three parties (EMP, WES, and WER).

The aim of the study is to improve the safety level at small- and medium-sized enterprises in Estonia through the cooperation and close communication of the employer, working environment specialist and the working environment representative.

2 THEORETICAL PART

Safety is an intellectual conception. This state of freedom from something that could have undesirable consequences, such as damage to humans or nature, financial loss, or any other form of damage or defeat. For example, in a hospital, the safety of patients means holding patients in a steady state by avoiding the risk of adversarial occasions (Shojania et al., 2001). The current paper is concerned with industrial safety, the unexpected events and risks arise within the context of manufacturing activities. However, a zero-risk condition, does not occur. Although some companies achieve a zero accident record for a convinced period of time, it does not indicate they are risk-free. "Risk is a degree of the likelihood and consequence of undefined upcoming occasions; it is the casual of an undesirable endings" (Yoe, 2011), while safety is, according to IEC 61508, "freedom from unacceptable risk". We can consequently settle that the safety of an industry is judged by its acceptable risk.

Safety management (SM) means "a systematic control of worker performance, machine performance, and the physical environment" (Heinrich et al. 1980).

Over the latest past, the incidence of major accidents and crises have made it clear that organizations must still progress their competencies to discourse safety through the application of a systematic and proactive attitude. Safety management systems (SMS) are changing from a prescriptive style to a more "self-regulatory" and "performance oriented" model (Frick & Wren, 2000; Bluff 2003) that is more proactive, participative and better integrated with commerce activities.

Goetsch (1998) introduces the concept of total safety management (TSM) as a performance-oriented approach that gives organizations a supportable advantage in the market-place by creating a safe work environment that is conductive to ultimate performance and persistent improvement. In a total safety approach, business processes are combined with safety engineering methods within a nonstop upgrading culture that affects all levels in the organization. A work process is a complex network of interdependencies between physical items, information, communication and knowledge passages and decision-making activities (Zou & Sunindijo 2015; Kontogiannis et al. 2017).

2.1 *Participative risk assessment*

In furthermost cases, a risk assessment is performed on how jobs should be accomplished rather than on how they are actually performed in practice. As a result, critical alterations or destructions of events are missed in this analysis. To avoid this oversight, a participative risk assessment is required that would involve people at all organizational levels in certain stages of the analysis. This has the benefit of catching risks associated with how the work is done and also involves staff in SM. Finally, it would be easier to design safety measures and barriers that are compatible to the competencies and preferences of workers when they are part of that process, hence enabling a more efficient human-system interface (Kontogiannis et al. 2017).

2.2 *Processes for appreciative hazards and risks*

Risk assessment (RA) is significant because it helps create awareness of hazards and risks related to serious work activities. A participative method to safety analysis will allow workers and supervisors to update the risk analysis with everyday information about critical risks in the workplace and technical processes. Hence, a process of "safety preview and screening" would be required at the start of risk analysis. Some tests related to overwhelming weaknesses of RA (like residual risks) should be addressed through new changes in RA methods (Kontogiannis et al. 2017). Digital RA methods are very looked-for in the current area.

The research question in the current study is the following: which are the possibilities of the employer, working environment specialist (safety engineer) and working environment representative (rep) to improve the safety level at small and medium-sized enterprises (Figure 1).

In the previous study (Paas 2015a,b,c), the key-elements of safety management system have been divided into formal (like safety documents, content of the policy, correlation between the safety activities and the implementation or non-implementation of OHSAS 18001, revising the safety policy, written safety policy existence, assignment of tasks and responsibilities etc.), real (like top management commitment to the safety policy,

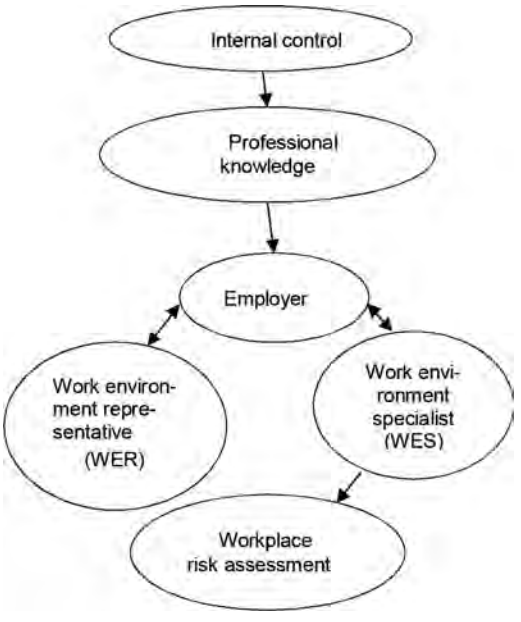

Figure 1. The arrangement of OHS command at workplace.

communication, participation in workplace design etc.) and combined (like participation in the preparation of the safety policy, workplace hazard analysis, the assessment of the work environment etc.) safety elements.

Three hypothesis were formulated and the area in which they are proved concerning employer's activities were as follows:

H1. Standard OHSAS 18001 has an impact on Formal safety performance in companies,
H2. Standard OHSAS 18001 has an impact on Real safety performance,
H3. Standard OHSAS 18001 has an impact on Combined safety performance at enterprises.

2.3 *Learning from experience*

Learning involves a monitoring process of near-misses, changes and success/failures of modifications as well as a reviewing process of strengths/weaknesses of risk analysis, unreliability risk assumptions and problematic risk acceptance criteria (Kontogiannis et al. 2017). This TSM mainstay also includes communication and training intended to provide safety information and skills to the employees to manage risks. Communication includes spread of information throughout the organizational hierarchy and feedback from the workforce. Safety training is very important. Safety training can take several forms such as classroom seminars, apprentice training, simulator training and computer-generated reality training. Although many small and medium-sized enterprises (SMEs) have understood the importance of the safety monitoring, they rarely know what data to collect, what safety parameters are important, how often to collect the data and what safety parameters are important, how to assure data reliability and confidentiality. For example, many workers may hold significant risk information but they do not know when and how to report it. Other cases contain the reporting of near misses in standard forms without the identification of causal factors (Kontogiannis et al. 2017).

One of the ideas to improve the safety level at the enterprise is learning through the interviews in the course of the questioning the employers, WES and WER (workers) using modified MISHA method (Paas 2015d). For example, the interview with the employer individually lasts 2–3 hours and is focused only of OHS matters. During this time, the person (employer or worker) learns as much as he will learn during the compulsory safety training course (24 hours) carried out in groups of people from different areas and interests and sometimes the lecturers on these safety training course (outside the house) are not giving not-interesting and old-fashioned information. This modified MISHA questionnaire is an educational tool for the WES: this is the mode of learning through interviews (Paas 2016d).

3 MATERIAL AND METHODS

Fifteen Estonian manufacturing enterprises (Table 1) were examined with modified MISHA method (Kuusisto 2000; Paas 2016d) to explain the role of EMP, WES and WER in OHS matters as well as for studying the perspectives to improve the safety level of the enterprise through their co-operation.

There are four areas in MISHA method: A) organization and administration; B) participation, communication, and training; C) work environment, D) follow-up (altogether 200 questions).

The MISHA questionnaire was modified taking into account some of the workplace hazards that were not included into the original MISHA questionnaire (Kuusisto 2000). For example, the influence of vibration and electromagnetic fields on the workers was asked in the course of the interview (Guldemund 2007).

The interviews with the learning aims consist of the questionnaire that includes "whether" and "how" questions. In the original questionnaires compiled for the assessment of safety, activities at

*Mean difference in reviewers (4) assessment score.

enterprises can be used as a tool for learning and obtaining more information on safety in companies. Learning is likely to be more effective when participants are actively involved in dialogue in which they are co-constructors of the meaning (Kines et al. 2011).

In locally owned companies, where the safety level is rather low, the managers did not recommend to have interviews with WER as by their (employers') view, the knowledge of WER in OHS tends to be negligible.

In those companies where OHSAS 18001 was implemented, the work instructions, instructions for safety training and safety organization's activity programs existed. This may not be the case in companies where OHSAS 18001 was not implemented.

The statistics used in the paper involved IBM SPSS Statistics 22.0 and R.2.15.2. The following statistical methods were used: correlation, MANOVA, factor analysis, principal component method, independent T-test (Field, 2013).

4 RESULTS

The interviews with the enterprises' representatives (column 3, Table 2) were carried out and recorded; afterwards listened and analysed by the three authors of the paper and one expert independently. The total average score (column 4) is derived with MISHA method.

4.1 *The employers role in safety level formation*

From the MISHA questionnaire, the questions concerning the activities of the employer were selected. The comparison of the interviewer assessments' on OHSAS-implemented companies compared with non-implemented companies was assessed with the statistics (Tabel 3).

In these safety areas (Table 3), the implementation of OHSAS 18001 has been successful.

Table 3. SM areas where the employer's influence on the safety level is significant.

Safety key element	Sum of Squares (KMO and Barlett's test	p-value
Formal safety elements		
A1.4. Assignment of tasks and responsibilities to the top management	13.375	0.000
A1.8. Revising the safety policy: has the employer defined how often the policy is revised?	25.688	0.000
C2.3- Does the personnel's responsibilities and authorities are clearly defined?	4.576	0.013
Real safety elements		
A1.9. Dissemination of the policy: has the employer defined how the policy is made available to the personnel?	21.007	0.000
A2.8. Resources: does the company has the resources for OHS improvement?	22.688	0.000
B2.1. Does the manager arrange the information meetings to the employers on OHS?	2.896	0.006
D2.1. Does the company has the system for redesigning the work or workplaces of a person with disabilities?	0.047	0.013
Combined safety elements		
A1.6. Dissemination of the policy: has the employer defined how the policy is made available to the personnel?	13.375	0.001
A1.10. Informing external bodies about the company's safety policy	17.241	0.001
B3.1. Does the employer affords the safety training for the personnel in a regular basis?	2.854	0.004
D1.2. The reduction of accidents: has the plan elaborated and presented to the top manager?	4.125	0.007
D3.1. Does the company have a system for measuring social climate?	19.125	0.000

4.2 *The working environment specialist role in safety level formation*

Similarly to the chapter 4.1, the questions concerning the WES activities, where selected (Table 4).

Table 4. SM areas where WES has the strongest influence on the company's safety level.

Safety key element	Sum of Squares (KMO and Barlett's test	p-value
Formal safety elements		
A1.1. Does the company has the written policy?	22.250	0.000
A1.3, Comments of the policy: a description of the safety tasks?	19.285	0.000
A1.4. Are the tasks assigned to the safety and health personnel?	13.375	0.000
A1.8. Revising the safety policy, who are responsible?	25.688	0.000
C2.3. Definition of the personnel's responsibilities: are the persons responsible for health and safety trained for their responsibilities?	4.576	0.0013
D1.1. Does the company make statistics on accident rates and summaries on accident causes?	21.000	0.000
Real safety elements		
A1.9. DEssemination of the policy: is safety involved?	21.007	0.000
A2.8. Does the company seek advice in resources to health and safety from safety personnel?	22.688	0.000
B1. Does the safety manager instruct the personnel?	5.672	0.001
B2.1. Has the safety manager arranged the hazards management system in the workplace?	2.896	0.006
B2.4. Does the safety manager arrange the safety campaigns?	9.797	0.001
B3.4. Has the safety manager defined which work permits are necessary (e.g., permit do fire hazardous work?)	6.750	0.004
C1.8. Has safety manager involved in the cleaning of plant area?	4.500	0.002
Combined safety element		
A1.5. Participation in preparation of the safety policy	21.500	0.000
A1.6. Initial status review	13.375	0..001
B3.1. Safety training needs, are they determined to the personnel?	2.854	0.004
C3.1 Workplace hazard analysis: has safety manager carried out?	9.491	0.000
D1.2. Accident investigation: are the near accidents investigated?	4.125	0.007

The main possibilities to influence on the safety level in the company is to employ the working environment specialists, as they are more educated and supported by the law in the work safety and health (OHS) area. Nevertheless, in OHSAS 18001 implemented companies, the results are better than in non-implemented ones.

4.3 *The working environment representatives' role in safety level formation (all combined area)*

The questions were selected from the interviews, where WER activities could possibly improve the safety level at enterprises (Table 5). All these questions happened to be only in the combined safety elements' area.

4.4 *Results of the hypothesis*

Three hypothesis were formulated and the area in which they are proved concerning employer's activities were as follows:

H1. Standard *OHSAS 18001* has an impact on *Formal* safety performance in companies (*p value* < 0.013) – if OHSAS 18001 has been implemented, then the assignment of tasks and responsibilities in OHS is committed to the top management, the employer is revising the safety policy, and the personnel's responsibilities in OHS are clearly defined.

H2. Standard *OHSAS 18001* has an impact on *Rea*l safety performance. ($p < 0.013$) – if OHSAS 18001 is implemented, then the top manager promotes dissemination of safety policy: the policy is made available to all of the personnel; resources for improvement are arranged by the top management; the top manager arranges meetings in OHS; there is a system for redesigning the workplaces for the persons who have difficulties in coping with the work.

H3. Standard *OHSAS 18001* has an impact on *Combined* safety performance ($p < 0.007$) – if OHSAS 18001 implemented, then: the top management is participating in the preparation of safety policy, top manager is reviewing the safety policy and is informing the external bodies about the company's safety policy's effectiveness; the top manager arranges safety training for all of the personnel; there is a plan for reduction of accidents; it has been elaborated by the top manager; the company has a system for measuring the social climate in the company.

Table 5. SM areas where WER can influence on the safety level at enterprises.

Combined safety elements	Sum of Squares (KMO and Barlett's test	p-value
A1.5. Participation in the preparation of the policy	21.250	0.000
A1.6. Initial status review	13.375	0.001
A1.10. Informing external bodies about the policy	17.241	0.001
A3.3. Selection of the line management	3.063	0.017
B3.1. Safety training needs	8.491	0.000
D1.2. Acident investigation	4.125	0.007
D3.1. Assessment of the social environment	19.125	0.000

5 DISCUSSION

Our study revealed that management plays an essential role in OHS improvement in the company. By O'Toole (2002), it is also postulated that the leadership's position is influencing the employee's perceptions of the safety management systems. Those perceptions appear to influence on the employee's decisions that relate to at-risk behaviours and decisions on the job. Organizational commitment did affect the perceived safety at work, but not on work accidents.

In the current study, it was declared that the plan for reduction of accidents if it is worked out by the employer, has very strong influence on the combined safety at enterprises. If the safety standards (OHSAS 18001 etc.) are implemented then the organizational climate will also be in higher level (Neal et al. 2000).

Taking into account the results of the previous studies (Hrenov et al. 2016; Arghami et al. 2014), where the safety and health level on the enterprise measured with MISHA method was carried out from the viewpoint of the working environment representative (WER) (Hrenov et al. 2016) and the employers (Arghami et al 2014), it can be concluded that the safety engineers have the best overview and knowledge of the safety system.

The other key persons (WER, employer) are hesitant in some questions, concerning for example, the safety policy expanding to the workers in the firm. The working environment specialist often views the current situation realistically while WER and employer may overestimate the situation as their daily work is not connected with safety matters.

MISHA method is not the only method for assessment and showing the improvement's points in safety and health at enterprises (Kines et al 2011;

Guldemund 2007). By Arghami et al. (2014), the safety climate questionnaire is built up on another principle than in MISHA method. It contains seven (7) different factors: management commitment to safety and personnel collaboration (the influence of total safety level R = 0.954), safety communication (R = 0.830), supportive environment (R = 0.793), work environment (R = 0.803), formal training (R = 0.774), priority of safety (R = 0.740), personal priorities and need for safety (R = 0.547). These results are comparable with the results in the current paper: the safety policy might be worked out properly and on the high level, but the safety policy usually does not reach the personnel, from up to down. One of the lowest scores (R = 0.431) is given to the question: "my line manager/supervisor does not always inform me of current concern and issues".

Our study examined three different types of companies: OHSAS certified companies, corporated companies and small and medium-sized locally owned companies. It turned out that "small enterprises" may be diverse: the definition covers many types of work activities, which naturally lead to large differences in the work environment. Small enterprises are more susceptible to influence from various "external" sources e.g., though the ownership structure. It might be important whether the small enterprise is part of a larger organization and whether it is publicly or privately owned (Sorensen et al., 2007). This problem remains for the future research.

Compared to Estonian OHS system in companies, Nordic OHS regime contains three different collaborating structures within the company: 1) a work environment or safety committee with balanced representation from the parties; 2) safety representatives elected by the employees; 3) in-house or external health and safety experts employed by and representing the management (Lindoe et al., 2001). According to the OHS Act (1999), based on EU Framework Directive 89/91, the employer and employees have to co-operate and opportunities for both parties to consult on the relevant OHS matters should be available. The need to ensure worker participation is stated in mandatory forms of industrial health and safety national legislation and in the EU Framework Directive 89/391. In Estonia, WER has to be trained following the 24-h training programme provided in the regulation. In Norway, the social partners agree that a 40-h course covers the basic training necessary to function as a WER (Hovden et al., 2008).

From our interviews, we concluded that WERs assessed the time for dealing with OHS matters unsatisfactory. The results in Nordic countries (Hovden et al., 2008) show similar pattern – often WERs complained about lack of time. The examples of the best experiences of the Nordic countries should be used in order to increase workers' participation and representation in health and safety matters.

6 CONCLUSIONS

1. OHSAS 18001 implementation helps to improve the following *formal* safety elements where safety manager is involved: to write the safety policy, the description of tasks of the personnel in safety area, the responsibilities of the safety personnel are clearly determined.
2. OHSAS 18001 implementation helps to improve the following *real* safety elements: dissemination of the safety policy, the safety personnel is advising the top management in safety and health questions, the safety manager instructs thoroughly the personnel in safety matters, the safety personnel is advising the top management how to allocate the resources.
3. OHSAS 18001 implementation in the firm helps to improve the following *combined* safety elements: safety manager compiles the initial safety review, the safety training needs of the personnel are determined, workplace hazard analysis are carried out.
4. The position of safety representative has often a low status in the company. WERs do not have enough time to fulfil their safety functions to keep employees safe.
   There is a limited understanding among employers about the role of WER. The study showed that in small enterprises, the WER has a formal position, although required by the law. In that case, employers do not understand the need of the WER and while electing them only formally, there is no practical value and often, employees are unaware of the position. The interviews also revealed that it is complicated to find the candidates to the WER position even in larger companies, especially in locally owned companies as managers do not know how to motivate workers on taking an additional responsibility. Safety management system plays a role in effective work of WERs. If the management does not give enough priorities to OHS, the employees will follow the example of the employer. WER should be elected among the peers rather than using WERs from other departments.
5. The WER of the organization is not well known or acknowledged by all the employers and subcontractors. The subcontracting work may cause several accident and near-accident situations. The importance of the person (WER), who knows how to deal with the problems in OHS, becomes evident only after the accident

has occurred or some of the workers are already seriously ill with occupational disease, such as musculoskeletal disease (MSD). The MSD is, at the present time, the number one occupational illness in almost every European country (Kaergaard & Andersen, 2000).

6. To be successful in WER commitments may be complicated due to conflicting expectations from employer and colleagues. The interviews revealed that nobody in the enterprise wants to be the resolver of a risky situation or even accident. Therefore, it is particularly important to prevent these situations by increasing the knowledge on OHS. For this occasion, WER and his/her knowledge and activities are a very good solution. It is important to mention that he/she needs enough time to gather the information on OHS and his/her activity has to be acknowledged by the employer.

ABSTRACT: The publication in 2018 of ISO 45001 is the first international ISO standard in the field of occupational health and safety management systems. ISO 45001 is the result of an international consensus on the subject and describes the best international preventive practices and incorporates the requirements of a management system aligned with the so-called High-Level Structure of the ISO standards of management systems. Simultaneously, ISO/IEC 31010:2009 provides for the selection and application of systematic techniques for risk assessment. However, this standard does not address safety in a specific way. It is a generic standard for risk management and any reference to safety is simply informative. Thus, the main objective of the present work is to identify and classify the main techniques included in the ISO/IEC 31010:2009 standard applicable in the field of occupational safety and in line with the requirements for the ISO Standard 45001. As a secondary objective, it is sought in the same context to identify the main non-standard techniques of new or emerging nature. This process of identification and classification has been carried out by means of a systematic review of the scientific literature specialized in the matter. The results have been classified according to bibliometric indicators in the following groups: (a) Main standard techniques for application to occupational safety; (b) Main techniques developed through specific standards (such as: IEC 61882:2016 – Hazard and operability studies [HAZOP studies] – Application guide; IEC 61025:2006 – Fault Tree Analysis [FTA]); (c) Main non-standard techniques of a new or emerging nature for application to occupational safety. Finally, the results obtained by the classification mentioned above have been analyzed in order to determine the degree of coverage and standardization of the main risk assessment techniques applied to occupational safety.

1 INTRODUCTION

The European Agency for Safety and Health at Work together with the International Labour Organization has estimated of the cost of poor occupational safety and health. Such estimation reveals (EU-OSHA, 2017): Worldwide work related injury and illness result in the loss of 3.9% of GDP, at an annual cost of roughly € 2680 billion; Work-related illnesses account for 86% of all deaths related to work worldwide, and 98% of those in the EU; 123.3 million DALY (disability-adjusted life years) are lost globally (7.1 million in the EU) as a result of work-related injury and illness. Of these, 67.8 million (3.4 million in the EU) are accounted for by fatalities and 55.5 million (3.7 million in the EU) by disability; and in most European countries, work-related cancer accounts for the majority of costs (€ 119.5 billion or 0.81% of the EU's GDP), with musculoskeletal disorders being the second largest contributor.

In order to combat the problem, ISO has developed a new standard, ISO 45001, Occupational health and safety management systems—Requirements, that will help organizations reduce this

burden by providing a framework to improve employee safety, reduce workplace risks and create better, safer working conditions, all over the world. This standard follows other generic management system approaches such as ISO 14001 and ISO 9001 (ISO, 2017).

The current version ISO/DIS 45001.2:2017, contemplates in its section 6.1.2.2 that the organization must establish, implement and maintain one or several processes to assess the risks for safety and health at work from the identified hazards, taking into account legal requirements and other requirements and the effectiveness of existing controls (the concept of organization, include among others, a company, firm, enterprise, etc.). Nevertheless, this standard does not specify the techniques or methodologies to assess the occupational safety and health risks.

Simultaneously, the standard ISO/IEC 31010:2009 provides for the selection and application of systematic techniques for risk assessment.

However, this standard does not address safety in a specific way. It is a generic standard for risk management and any reference to safety is simply informative.

Thus, the main objective of the present work is to identify and classify the main techniques included in the ISO/IEC 31010:2009 standard applicable in the field of occupational safety in a way in line with the requirements for the risk assessment included in the ISO Standard 45001 (Currently, ISO/IEC 31010 is under review. For the moment, ISO/IEC/DIS 31010: 2017 is published under development)

As a secondary objective, it is sought in the same context to identify the main non-standard techniques of new or emerging nature.

2 METHOD

We conducted a systematic search in the occupational safety literature. A systematic review of the literature is typically based on a detailed and comprehensive plan and search strategy derived a priori in order to reduce bias (Uman, 2011). We aim to present an overview of techniques addressed in both quantitative and qualitative research on occupational safety, and their general direction (e.g. Cornelissen et al., 2017). Below, we will elaborate on our systematic selection process and analysis.

2.1 *Literature search*

As indicated by Goerlandt et al. (2017), in traditional indexing systems such as Scopus and Web of Science, risk analysis is not considered as a separate category in the scientific research areas. Instead, contributions related to risk are typically listed under "mathematics", "social sciences" or "engineering". Hence, general searches in those systems on terms such as "risk analysis", "validation" and "QRA" results in many hits, with low relevance to the above stated aims.

Therefore, another review method has been applied (November, 2017). To do this, we chose a literature search using broad search terms as a starting point. To this end, we selected as search criteria the use of the keywords "risk" and "review" in the journal title. In addition, we delimited the search in "engineering" and "chemical engineering" fields using ScienceDirect databases. The results were the following: Engineering field: 90 records published all years (1995–2018); Chemical engineering field: 48 records published all years (1988–2017).

With these criteria, the journal principals identified in the work of Reniers and Anthone (2012) have been included, except Journal Risk Analysis. These authors found that the most well-respected journal by expert opinion was the Journal of Loss Prevention in the Process Industries. However, taking into consideration both the respondents' results and the citation-based results into consideration, the Journal of Hazardous Materials is the most influential journal, followed by Reliability Engineering and System Safety, Risk Analysis, Accident Analysis and Prevention and Safety Science.

2.2 *Article selection*

The further selection of articles was performed in steps, as depicted in Figure 1.

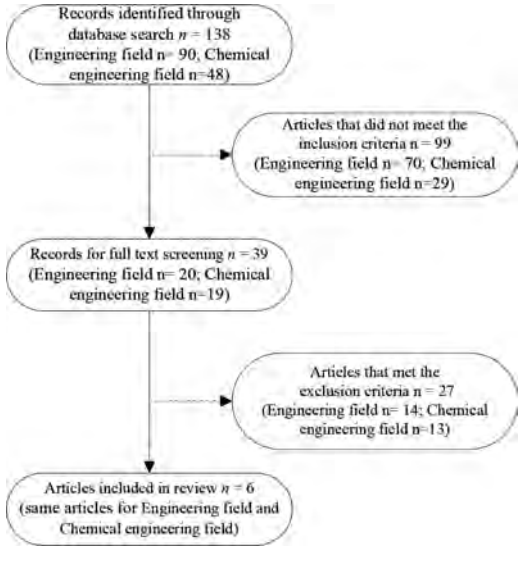

Figure 1. Flow diagram of study selection.

First, the titles were evaluated and articles that did not meet the following inclusion criteria were marked: (a) describe safety in an occupational setting; (b) focus on the application, study or analysis of techniques of identification, analysis or risk assessment applied to occupational safety; (c) conducted in the construction, manufacturing, offshore, or petrochemical sector; (d) published in a peer-reviewed journal; and (e) be written in English.

Second, the full text of the articles obtained after the application of the previous step, were analyzed. In this regard, the following exclusion criteria were applied: (a) only one specific technique is applied; (b) collect several techniques only by way of example; (c) conducted on driving or transportation; (c) conducted on risks in natural disasters.

Third and finally, the articles obtained were included in the review process. In this regard, both the Engineering field and the Chemical engineering field obtained the same 6 results (Table 1).

2.3 *Analysis*

The analysis of the articles was developed as follows.

a. Articles that contain a classification or set of techniques related to standard ISO/IEC 31010: 2009. First, each article has been analyzed with the aim of identifying those techniques that coincide with the list of techniques included in Annex A of ISO/IEC 31010: 2009. Second, those techniques that are developed through specific standards have been identified. To do this, the reference documents of the standard have been analyzed (ISO/IEC 31010: 2009 and ISO/IEC/DIS 31010:2017). In addition, each technique has been checked if it has been developed through any standard published by any of the following standardization bodies: International Organization for Standardization (ISO), European Committee for Standardization (CEN) and International Electrotechnical Commission (IEC).
b. Articles containing other techniques not collected to ISO/IEC 31010. The main techniques have been identified.

Table 1. Articles included in review (n = 6).

Nr	Paper citation	Field of application	Journal
1	Kjellén and Sklet (1995)	Offshore industry	SS
2	Tixer et al. (2002)	Risk analysis on an industrial plant	JLPPI
3	Marhavilas et al. (2011)	Work sites	JLPPI
4	Dallat et al. (2017)	Safety management, (risks that may lead to accidents)	SS
5	Villa et al. (2016)	Chemical and process Industries	SS
6	Yang et al. (2017a)	Petroleum activities	SS

SS: Safety Science; JLPPI: Journal of Loss Prevention in the Process Industries.

3 RESULTS

The results presented in this section follow the scheme accordingly for the analysis of the articles included in the review.

3.1 *Main standard techniques for application to occupational safety*

Table 2 lists the existing relations between the techniques identified in the reviewed articles (1–4) and the techniques included in Annex A of ISO/IEC 31010: 2009.

The following results can be observed in the Table 2: 18 techniques are collected in a single reference (Nr Paper citation); 7 techniques are collected in two references; 3 techniques are collected three references; and 3 techniques in four references.

3.2 *Main techniques developed through specific standards*

Those techniques that are developed through specific standards have been identified in the Table 3.

Thus, 10 techniques of the 31 collected by ISO/IEC 31010: 2009 are identified. Comparing these 10 techniques with the results of Table 2, it can be observed: 4 techniques are collected in a single reference (techniques Nr 11, 12, 24 and 25); 1 technique is collected in two references (13); 3 techniques are collected in three references (6, 20 and 22); and 2 techniques (14 and 15), in four references.

Of the 10 techniques listed in Table 3, all of them except Reliability centered maintenance (RCM), have also their correspondence with European Standards (ENs) published by the European Committee for Standardization (CEN, 2017).

3.3 *Main non-standard techniques of a new or emerging nature for application to occupational safety*

Tables 4 and 5 list the existing relations between the techniques identified in the reviewed articles (5–6).

Table 2. Relations between techniques identified in reviewed articles and Annex A of ISO/IEC 31010: 2009.

(NOT): The technique (Nr) is not collected by Paper (Nr).

Theoretical and practical limitations affecting results of hazard identification suggest the need for an improvement of current techniques (Paltrinieri et al., 2016). Yang et al. (2017a) indicated that several aspects of operational decision making creates a need for different risk analyses compared to the traditional Quantitative Risk Analysis (QRA) with principles and guidelines described in standard ISO 31000:2009, which are developed more for design purposes.

Yang et al. (2017a) reviewed 11 risk influence-frameworks that integrate organizational and human factors in a structured way (Table 4). The intention was to evaluate how these frameworks

and identified Risk Influencing Factors (RIFs) can be used for activity related risk analysis.

Real-time data and periodical risk evaluation may be considered as a key improvement to allow for effective decision-making support (Bucelli et al., 2017). However, being static QRA precludes any possible update and integration of the overall risk figures, due to the actual real world ever-changing environment or later improvements based on new risk notions. To overcome this limit, during the last decade several efforts have been devoted to the development of novel approaches to risk assessment and management, which can be considered the dynamic evolution of conditions, both internal and external to the system, affecting risk assessment (Paltrinieri and Scarponi, 2014). The main purpose of dynamic risk assessment is the development of an appropriate technique that allows for the effective aggregation of heterogeneous information and provides risk estimation over time reflecting the current condition of the system (Yang et al., 2017b).

Villa et al. (2016) reported a brief description of the most relevant methodologies and applications of dynamic approaches to risk analysis in the chemical process industry.

Table 5 shows a list of these dynamic methodologies. These methodologies (or techniques) have evolved over time according to Villa et al. (2016) describe in detail. In this way, the list of techniques collected in Table 5 are linked to the most recent citations according to Villa et al. (2016).

4 ANALYSIS AND DISCUSSION

The results obtained can be grouped into two groups of techniques for application in the field of occupational safety: standardized and non-standard techniques of a new or emerging nature.

In relation to the standardized techniques, of the 31 techniques included in Annex A of ISO / IEC 31010, the following techniques are among the most used: HAZOP, SWIFT, HRA, FTA, ETA and RCM. In turn, these techniques are developed through specific standards (IEC-EN), except the SWIFT technique.

Regarding non-standard techniques of a new or emerging nature, new risk influence frameworks as well as new dynamic techniques are observed.

Among the first techniques, the following ones can be cited according to its closeness in time (last decade): HCL (2009), RISK_OMT (2012), SoTeRia (2009) and Phoenix (2016). In relation to dynamic techniques, stand out the following: DRA, DyPASI, DRA-DyPASI and Risk barometer.

However, the set of the foregoing results should be considered as an approximation in the framework of occupational safety. This approximation is due to the characteristics of the method followed, which are linked to three important limitations. The first limitation is due to the use of a single database; the second to the inclusion and exclusion criteria used; and the third limitation is due to the lack of differentiating and applicative criteria between the techniques used in the field of safety occupational and safety linked to major accidents.

In relation to the first limitation, it has allowed analyzing the main journals that emerge from the work of Reniers and Anthone (2012). However, these authors analyzed a total of 35 representative safety journals, of which with the present work a total of 11 journals have been analyzed.

Regarding the inclusion and exclusion criteria used, they prevent analyzing the evolution of standardized risk assessment techniques in a broader and deeper way through the scientific literature.

As for the third limitation, with this work the dividing line that exists between occupational safety and safety linked to major accidents has not been analyzed directly (for example, this important aspect can be observed in the Table 5). It is evident that both branches of the safety are interconnected and that therefore share risk assessment techniques with the aim of avoiding accidents in processes and industries.

However, such dividing line between these safety branches is diffuse, so it would be advisable to deepen the analysis of differentiating and

applicative criteria. The differentiating criteria could allow a structured and interconnected risk and loss analysis. These criteria could be aligned with the results of the EU-OSHA (2017). With the application criteria, the scope, use, complexity, strengths and limitations of each technique in the field of occupational safety could be defined.

5 CONCLUSIONS

With this work the main objective consisting in identifying and classifying the main techniques included in the ISO/IEC 31010:2009 standard applicable in the field of occupational safety, was achieved. These techniques could be compatible with the current version ISO/DIS 45001.2:2017 (section 6.1.2.2).

In addition, a secondary objective has also been achieved, that is, to identify the main non-standard techniques of new or emerging nature (especially dynamic characteristics).

However, three important limitations have been identified that can point the direction of future research. Such research could focus on two objectives. The first objective concerns pursuing analyzing in greater depth the impact and degree of development of standardized techniques and non-standard techniques of a new or emerging nature. To do this, the method used must be modified to obtain results with greater representativeness. This modification should include an update of the results obtained by Reniers and Anthone (2012). The second objective concerns the focus on the analysis of differentiating and applicative criteria between the techniques used in the field of safety occupational and safety linked to major accidents.

In any case, the final publications of ISO 45001 as well as ISO/IEC 31010 should be considered, both publications being foreseen for 2018.

ACKNOWLEDGEMENTS

This work was funded by the Ministry of Economy and Competitiveness of Spain, title: "Analysis and Assessment of technological requirements for the design of a New Emerging Risks standardized management SYStem (A2 NERSYS)" with reference DPI2016-79824-R.

Indicator on the performance of barriers against fatal accidents in construction

U. Kjellén
NTNU, Trondheim, Norway

ABSTRACT: The paper presents work to develop a safety performance indicator suitable for real-time management of major accident hazards in construction. Data on 60 fatal accidents in the period 2011–2016, resulting in 63 fatalities, have been analysed. About 70% of the accidents belonged to three main categories: fall from height, driver or person outside the cabin killed by moving construction machine/vehicle, and person killed by load or equipment during material handling. The three main categories have been further divided into subcategories (seven in all) and analysed to identify barriers to prevent adverse consequences. This analysis has resulted in checklists, one for each subcategory. They list observable conditions at a construction site that, if found substandard, will indicate that one or more of the important barriers are seriously deteriorated. The paper highlights the results of the accident concentration and barrier analyses. It also reviews remaining work to develop and test the performance indicator.

1 INTRODUCTION

Construction activities are characterized by the management of large amounts of energy such as in transportation, excavation, assembly, work at height etc. Loss of control of the energy flow may have major consequences. Natural hazards (rock fall, land slide etc.) represent significant additional risks. The statistics on severe accidents in construction reflect these conditions. According to ILO estimates, the fatal accident risk in construction is five times the average among workers worldwide (Murie 2007). Statistics from Norway for 2009–2014 show a fatal accident frequency rate of three times the general average for workers (Norwegian Labour Inspection Authority 2015).

Construction work is organised in projects with a limited duration. A project goes through different phases from site establishment and excavation to installation and completion, and the conditions at site and the activities change accordingly. Traditional safety management using performance measurements (such as the TRI rate) and feedback control is inadequate, due to lagging characteristics of most current safety performance indicators (Kjellén 2009, Lingard et al. 2017). There is a need for indicators that provide real-time data on safety performance to ensure timely feedback for control of safety performance (Kjellén 2018).

Behavioural sampling was developed in the 1950s to meet this requirement (Rockwell 1959). The method uses observations on deviations from safe work practices and conditions as data input. The "TR safety monitoring method" represents an application of behavioural sampling to the construction industry (Laitinen et al. 1999, Laitinen & Päivärinta 2010). Experiences show that the method produces reliable and valid results related to the prevention of ordinary occupational accidents.

There is a general lack of 'real-time' performance indicators suitable for the control of hazards in construction with fatal accident potential. The principles behind the "barrier performance indicators" developed by the process and oil and gas industries for the prevention of fires and explosions offer such as opportunity (Health and Safety Executive 2006, OGP 2011). The indicators measure the compliance of safety barriers to a standard.

Accident statistics indicate that this approach may be valid for the construction industry, despite the high variety of activities in the industry. A relatively small number of types of central events according to the bow-tie accident model, each representing the loss-of-control of significant amounts of energy, account for a substantial share of the fatal accidents in construction (Visser 1998, Swuste et al. 2012). By identifying barriers to prevent these central events and/or reduce their consequences, input may be provided to performance indicators on the risk of fatal accidents in construction projects.

Experiences from two case studies support the validity of this approach. An Indian hydropower project reported eight fatalities due to road departures and falling rocks in tunnels during 2,5 years

after start-up (Kjellén 2012). The project implemented improved safety routines directed at barriers to prevent these types of accidents. It was completed three years later with one additional fatality not related to these types of events.

A large international construction contractor identified six dominating concentrations of fatal accidents in their operations world-wide (A. Berglund, personal communication, Nov. 17, 2017). These included falls from height, conflict between human and machine, structural failure, lifting operations (falling objects), fire/explosions, and electric arcs. The contractor implemented lifesaving rules directed at barriers to prevent these types of accidents. They experienced a reduction in the frequency of the affected types of fatal accidents by 60% in a five-year period after the intervention, compared to the previous five-year period. The number of construction workers was about the same in the two periods.

1.1 *This paper*

The paper presents research that is part of an ongoing project for the construction industry. Its aim is to develop safety performance indicators that are better suited for the management of safety by client and contractor companies than the lagging safety performance indicators in use today.

The research presented here focuses on developing a performance indicator of the availability of barriers against hazards with fatal accident potential. The intention is to provide data in 'real time' and thereby allow the involved companies to accomplish effective feedback control of the fatal accident risk at construction sites.

The paper highlights the first part of the research, aiming at identifying dominating fatal accident concentrations in the Norwegian construction industry and critical barriers that will prevent the relevant types of accidents from occurring. In the subsequent steps, these results will be used as input to the development of indicators for barrier availability for use by safety practitioners in the industry. These indicators will be tested and evaluated in intervention studies in construction projects.

2 MATERIAL AND METHOD

2.1 *Sources of data*

The analysis consists of two parts, an accident concentration analysis and a barrier analysis. A set of 60 fatal accidents resulting in 63 fatalities in the Norwegian construction industry between 2011 and 2016 represents the source data for the accident concentration analysis. The Norwegian Labour Inspection Authority (NLIA) provided the data from their general register of fatal occupational accidents in Norway.

The accident data was documented in a spreadsheet with the following information on each accident: date of the accident, registration number, type of construction business (classification), type of activity (classification), number of people killed, type of injury (classification), accident type (classification), free text resumé of the sequence of events.

In the subsequent barrier analysis, data from NLIA was supplemented with data from other sources:

- Observations at three construction sites and interviews with senior construction managers
- The author's library of in-depth investigations into fatal accidents and high potential incidents that fall within any of the accident concentrations selected for further analysis
- Lifesaving rules developed by major construction contractors
- Relevant regulatory requirements in Norway

The results were reviewed in workshops by high-level safety experts from construction client companies, contractors and an organisation of regional safety representatives.

2.2 *Methods*

2.2.1 *Accident concentration analysis*

An accident concentration analysis aims at identifying clusters of 'accident repeaters' with common characteristics (Kjellén & Albrechtsen 2017). By directing preventive measures at a selection of dominating accident concentrations, a significant risk reduction is expected.

The analysis is carried out stepwise in several dimensions to identify accidents with common characteristics. A natural starting point for the analysis of fatal accidents was to group the accidents according to the main type of energy involved.

In the current study, the dataset was first analysed by accident type according to NLIA's classification. For each accident type, the free-text descriptions of the accidents were reviewed to identify common patterns. A new, composite classification of the accidents was developed, where each 'accident concentration' was made-up of at least three fatal accidents with common characteristics.

2.2.2 *Barrier analysis*

The barrier analysis is rooted in the principles of defence in depth and the energy model of loss causation (Rasmussen 1993, Haddon 1980).

A model of the accident sequence encompassing three successive phases is shown in Figure 1

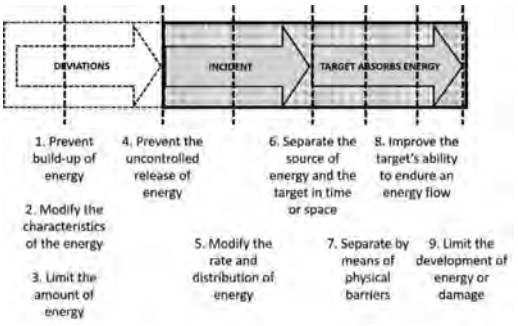

Figure 1. Barrier intervention in the accident sequence to eliminate or reduce loss (Kjellén & Albrechtsen 2017).

(Kjellén & Larsson 1981). Nine of Haddon's ten accident prevention strategies are introduced in the model as barrier functions. Each of these may, dependent on the type of accident, have the capacity to change the sequence of events and thereby eliminate or reduce loss.

The function of a barrier is realised through a barrier system. Whereas passive barriers consist of a physical element, active barriers are more complex with several elements including a control system. One or more human operators may be part of the control loop.

Input data to the barrier analysis consisted of the results of an analysis of accident concentrations among fatal accidents in construction in Norway between 2011 and 2016. For each accident concentration, barriers that are critical in preventing accidents in the accident concentration in question were identified. Next, the required performance of the elements that make up the barrier were identified for each identified barrier.

3 RESULTS

3.1 *Accident concentration analysis*

The distribution of the 60 fatal accidents in NLIA's database by accident type is shown in Table 1. This analysis represents the starting point for the identification of accident concentrations.

Falls represents the most common accident type in NLIA's database, followed by squeezed/caught and hit by object.

The analysis revealed some inconsistencies in the accident type classification by NLIA. A2 and A3 include accidents involving vehicles, but similar vehicle related accidents were classified as category A4.

The accident concentration analysis identified 12 categories of 'accident concentrations', covering 93% of the fatal accidents in the material,

Table 1. Distribution of accidents in NLIA's database on fatal accidents in construction in the period 2011–2016 (N = 60). The table also shows a summary description of accidents with common characteristics for each accident type.

Accident type (NLIA)	# of events	Coarse description of accidents
A1 Hit by object	9	Hit by load or machinery part during material handling, structural collapse, falling rock, flying object (bolt from pistol)
A2 Collision, hit by vehicle	11	Road/work area departure by vehicle (incl. mobile machine), collision, hit by vehicle
A3 Roll-over	3	Roll-over of vehicle
A4 Squeezed or caught	13	Hit by vehicle, road/work area departure by vehicle, roll-over of mobile machine, squeezed by lifting/transportation equipment during operation, rock fall, collapsing trench, structural collapse
A5 Fall	19*	Electric current through body (resulting in fall), fall from height (roof, deck, scaffold, ladder, machinery/equipment)
A7 Electric voltage	2	Electric current through the body from electric installation or hand tool
A10 Explosion, fire	3**	Accidental blast, explosion

* Two persons killed in one fall accident, ** Three persons killed in one blast accident.

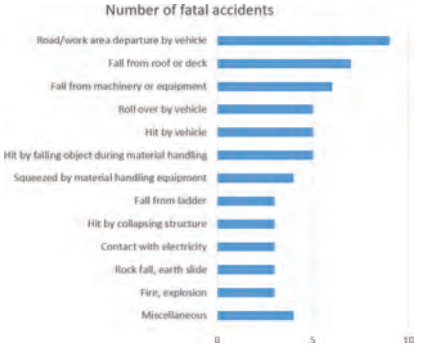

Figure 2. Distribution of fatal accidents by 'accident concentration' (N = 60).

Figure 2. The category 'miscellaneous' made up the remaining 7%.

28% of the accidents were related to fall from height. Similarly, 23% involved vehicles (including

mobile construction machinery). If we add material handling by crane, conveyor belt, truck etc., we cover in all two thirds of the fatal accidents.

Accident concentrations with four or more fatalities were selected for further analysis. These included:

- Road or work area departure by vehicle: The driver was killed due to loss-of-control of the vehicle followed by departure from a road or construction area.
- Fall from or through roof or deck: The person being killed fell either outside the edge of a roof or deck or through and opening or weak point of the roof/deck.
- Fall from machinery or equipment: The person being killed fell when moving or working on machinery or equipment. Falls from ladder was introduced as a special case.
- Roll over of vehicle (or machine during transfer): The driver/operator has been killed due to roll-over during unloading, during transfer (when a machine behaved as a vehicle), or when a parked vehicle has accidently started to move.
- Hit by vehicle: The person being killed was present in the danger zone of a vehicle in motion and the driver was either not aware of the person or lost control of the vehicle.
- Hit by falling object during material handling: The fatalities occurred during crane handling or unloading of truck or trailer. The accidents involved loss of control of load or sudden, uncontrolled movements of equipment.
- Squeezed by movements of personnel lifts or material handling equipment: The person being killed was either squeezed by uncontrolled machinery movements, missing machine guarding or because the operator was not aware of the person being in the danger zone.

3.2 *Barrier analysis*

A basic assumption in this research project is the considerations of barriers as an additional measure implemented in a production system to achieve a tolerable level of risk. It means that the basic design of the work system, where the fatal accidents occurred, has not been questioned. Surface transportation, for example, was not considered as a barrier function to avoid being hit by falling objects during material handling. In Table 2, barrier types 1 and 2 have been excluded for this reason.

The barrier analysis has been based on some additional assumptions:

3. Limit the amount of energy: Has been included in barrier function no. 8 for falls from height (use of fall arrest system).

Table 2. Results of the barrier analysis. A barrier type marked "X has a function that is considered essential to prevent fatalities in the accident concentration in question.

	Type of barrier (see Figure 1):						
Accident concentration	3	4	5	6	7	8	9
Road/work area departure by vehicle		X	X		X	X	X
Fall from or through roof or deck	X	X	X		X		
Fall from machinery or equipment	X	X	X		X		
Fall from ladder	X	X	X				
Roll over of vehicle (or machine during transfer)		X	X		X		
Hit by vehicle		X		X			
Hit by falling object during material handling		X		X			
Squeezed by movements of lifting and material handling equipment		X		X	X		

4. Prevent uncontrolled release of energy: This barrier function is relevant to all analysed main types of accident concentrations. The barrier function is not relevant to subsets of accidents, where a machine operator has not been aware of personnel being present in the danger zone.
5. Modify the rate and distribution of energy: This applies to the use of safety belt in case of road/work area departure or roll-over and use of fall arrest system.
6. Separate the source of energy and the target in time or space: This barrier function is relevant to vehicle and material handling related accidents. A possible exception is sudden machinery movements due to mechanical failure, which could not reasonably have been foreseen.
7. Separate by means of physical barriers: This barrier function is relevant to all types of accident concentrations. In practice, the implementing this type of barrier is restrained by feasibility considerations.
8. Improve the target's ability to endure an energy flow: This barrier function is implemented through personal protective equipment. It is especially relevant to falls, when collective measures (physical barriers) are not applied. Use of helmet has limited effect in case of falling objects with high energy.
9. Limit the development of energy or damage: The general organisation of emergency response at site falls outside the scope of this analysis. Preparedness directed at specific types of hazards has been included such as use of mobile machine close to water way. In this case, the barrier relates to preparedness to safe the driver from drowning in case of departure from road or work area.

Table 3. Requirements related to barrier elements for each of three barriers essential to prevent fall from ladder.

Limit the amount of energy	Prevent uncontrolled release of energy	Modify the rate and distribution of the energy transfer
• Ladder used as an exception in lack of feasible alternative?	• Ladder checked and found in adequate condition?	• Use of safety harness and life line hooked to a solid attachment point
• Ladder used for a height difference to solid ground <6 m?	• Ladder positioned on solid ground and secured from tilting? • Ladder raises > 1 m above roof or landing?	

Table 4. Requirements related to barrier elements for each of two barriers essential to prevent personnel being hit by vehicle.

Prevent uncontrolled release of energy	Separate the source of energy and the target in time or space
• Vehicle is certified and regularly checked and maintained?	• Areas for transportation and loading/unloading separated from work areas and pedestrian traffic?
• Driver instructions regarding controlled operation of the vehicle available?	• Driver has full overview from the cabin of the operating zone?
• Adequate training and certification of driver?	• Driver instructions to have control of the operating zone for other personnel? Adequate operator training and certification?
• Foundation of the operating area of the vehicle adequately stable, inclination and friction satisfactory to ensure full operator control?	• Site instructions and training regulating avoidance of the operating zone of mobile machines? Adequately supervised and respected? • Use of highly visible uniforms by all personnel at the site? • Adequately illuminated work areas and roads?

The next step in the analysis has aimed at identifying performance requirements of barrier elements necessary for the applicable barrier function to be effective. These requirements provide the basis for the barrier performance indicator, which will measure average percent compliance with the requirements. The results of this analysis are illustrated by two examples in Table 3 and Table 4.

4 FURTHER WORK

Work is under way to develop and operationalise the identified performance requirements in cooperation with Client and Contractor personnel of a large infrastructure construction site. The requirements for successful performance of the different barrier elements will be scrutinized by site personnel in cooperation with the researchers and further developed to meet certain quality criteria (Kjellén & Albrechtsen 2017, Laitinen et al. 1999):

– Flexible for use at different types of construction sites,
– Transparent and easily understood by site personnel,
– Address site conditions that are observable and quantifiable,
– Sensitive to changes in the safety standard at construction sites,
– Produce reliable results when applied by different observers,
– Robust against manipulation.

The task of the observers will be to identify work at the construction site involving any of the seven identified major accident hazards. Next, the observers will use the relevant checklist to review the status of the different barrier elements and classify them as either correct or incorrect or not relevant. Incorrect barrier elements will be qualified through a short description. The results will be summarized, showing% of the checked barrier elements that are correct. This can be shown in total and for each type of major accident hazard.

To produce reliable results, characteristics of the various barrier elements that separate correct from incorrect must be defined in the checklists to the extent needed when used by experienced personnel. In addition to physical observations of the work, the observers will have to consult available documentation and make interviews to check items such as operator training and qualifications and maintenance standard of vehicle. This makes the use of the method to resemble a system audit more than an inspection, but not fulfilling the requirement to independence.

The next step of the research project will include testing and evaluation of the barrier performance

indicator and underlying requirements to barrier elements in routine safety practice. A systematic approach will be applied in assessing the operational experience of the intervention itself, and various stages of outcome, including degree of implementation and immediate, intermediate and end results (Shannon et al. 1999). It will not be possible to monitor any effects on the fatal accident rate by this trial.

5 CONCLUSIONS

The work presented in this paper represents the first phase in developing a real-time performance indicator aiming at managing the risk of fatal accidents.

An important prerequisite has been the existence of dominating fatal accident concentrations in construction that may be prevented through a few well-defined barriers. This will allow the development of an indicator based on requirements for barrier availability that is adequately comprehensive still practicable. Results of the accident concentration analysis shows that this prerequisite generally is satisfied. There exists variation between individual accidents in the concentrations that are more complex. It is necessary in the further development and operationalisation of the requirements to check for these variations to ensure that the prerequisite is satisfied.

Another critical issue is the representativeness of the data used in this analysis for the fatal accident risk in construction in Norway. The period and number of events covered by the analysis, and the consistence of the results with findings in international research and safety practice referred to in this paper, call for a positive answer to this question.

The ultimate test of the viability of the proposed performance indicator will take place through integration is safety practice at selected construction sites. Here it will be possible to evaluate the indicator against predefined criteria. Only extensive and long-term use will validate the performance indicator as an efficient tool in preventing fatal accidents.

ABSTRACT: The present study compares professional seafarers and private leisure boat users in Norway and Greece. The aims of the present study are to examine the safety behaviours related to personal injuries and accidents among these groups and to study the factors influencing these behaviours. This will serve as a backdrop to a general discussion of why the level of fatalities is higher among private boat users than among professional seafarers and what the former may learn from the latter. The study is based on surveys to crew members on Norwegian and Greek cargo and passenger vessels and leisure boat users in Norway and Greece. Our study indicates that while unsafe behaviours related to work pressure and risk taking are important among professional seafarers (i.e. risk acceptance and violations), unsafe behaviours related to the leisure/holiday situation was important for the leisure boat users (i.e. alcohol use while driving a boat). Additionally, we discuss how the situation of private leisure boat users is less regulated than that of professional seafarers. Our study indicates that both in the professional and the private setting, norms for interaction and conduct seem to be influenced by norms and expectations rooted in different socio-cultural groups, e.g. the national culture, the specific sector in question, the organisations and in peer groups.

1 INTRODUCTION

1.1 *Background*

Maritime transport is a substantial part of world trade, as approximately 90% of the goods traded worldwide are transported by sea. Although safety improvements have led to a significant decrease in the mortality rates of seafarers in recent decades, seafaring is still termed one of the most hazardous occupations (Oldenburg & Jensen 2012). In a questionnaire study including 6461 participants in 11 countries, Jensen et al. (2004) found that during the latest tour of duty, 9% of all seafarers were injured and 4% had an injury with at least 1 day of incapacity. According to Nævestad et al. (2015) there were on average 15 killed and 424 injured annually on Norwegian ships, i.e. Norwegian Ordinary Ship Register (NOR) and Norwegian International Ship Register (NIS) in the period 2004–2013. At EU level, in the period 2011–2016, there were on average 100 fatalities and 935 injuries annually reported in the European Marine Casualty Information Platform (EMCIP) (EMSA, 2017).

In Norway, as in many other countries, the number of persons killed using different transport modes has decreased since 1970. This is especially true for road transport, but it also applies to professional seafarers (Nævestad et al 2015). Leisure

boating on the other hand, have not had the same positive development, and in Norway the number of deaths using leisure boats have more or less stayed the same since 1995 (with some annual variations).

In 2006–2015, on average 33 people died each year in recreational boating accidents in Norway, which is about 0.65 persons per 100 000 inhabitants. Approximately 4,4 persons have died per 100 000 vessels (registered and not). More than 90% of these persons are men, and a majority of the victims were not wearing personal floating devices (PFD). Most of the accidents happen during the summer months, when the boats are in more use. Only 20–30% of the people found dead was wearing a lifejacket.

1.2 *Aims*

The present study compares professional seafarers and private leisure boat users in Norway and Greece.

The aims of the study are to examine the safety behaviours related to personal injuries and accidents among these groups and to study the factors influencing these behaviours. This will serve as a backdrop to a general discussion of why the level of fatalities is higher among private boat users than among professional seafarers and what the former may learn from the latter.

The data in this study have been collected as part of the SafeCulture project, which is funded by the Norwegian Research Council, and undertaken by the Institute of Transport Economics—TØI (Norway) and the National Technical University of Athens—NTUA (Greece).

The research on safety culture suggests that if we are to fully understand its effects on safety in transport, we should study not only safety culture particular to organisations, but that particular to peer-groups, sectors, regions and nations. We define transport safety culture (TSC) as shared norms prescribing certain transport safety behaviours, shared expectations regarding the behaviours of others and shared values signifying what's important (e.g. safety, mobility, respect, politeness) (Nævestad & Bjørnskau, 2012). An important aspect of our approach is that overall TSC is a composite of overlapping safety cultures associated with different types of sociocultural unit. Thus, we apply the safety culture concept to the national level, to organisations and to peer groups in the present study.

1.3 *Previous research*

There seem to be few studies examining the relationship between safety behaviours and work accidents in the maritime sector, although there are some exceptions (cf. Håvold and Nesset, 2009). The existing studies within this area do, however, indicate that demographic factors (age, nationality, position, line of work) influence work accident risk, and we should assume that this relationship is mediated by some kind of unsafe behaviour (e.g. risk taking, violations), resulting in injuries. Younger seafarers have a higher risk (Hansen et al 2002; Jensen et al 2004). Foreigners have a considerably lower accident risk than local (in the specific study, Danish) citizens (Hansen et al 2002). Previous research also indicates that alcohol consumption may be an important risk factor in the maritime sector (Akhtar & Bouwer Utne 2014, Hetherington et al 2014), and that alcohol and drug abuse are greater for seafarers compared to workers ashore (Nitka 1990; Kariris 2012 in Zhang & Zhao 2017), partly because of their working situation (e.g. social isolation). However, given the relatively unregulated character of private boat use, we may perhaps assume that alcohol consumption "boating while under the influence", is an even more important risk factor in this sector. Likewise, me may perhaps also assume that the other risky behaviours related to boating accidents (e.g. over speeding close to shore) are more prevalent among the less regulated private boat users.

Based on a review of previous foreign studies of recreational boating accidents in Norway, Amundsen (2016) asserts that questions about alcohol use and lifejacket use are common in almost all of the international surveys. We may infer from this that alcohol use and life jacket use are key safety behaviours influencing the risk of accidents among private leisure boat users. Amundsen (2016) reports that the questions used in the different countries are adapted to the specific use of leisure boat in that country, and the accident situation. Based on a review of studies relevant to Norway, Amundsen and Bjørnskau (2017) point to the following safety behaviours as likely to influence the safety of private boat users: Drive faster than the permitted speed close to shore, Carry more passengers than the boat is licensed for, Drink a beer or a glass of wine before going boating, Drive in the dark without using the lantern/lights, Wearing a life jacket, Carrying enough lifejackets for everybody onboard the boat. The questions are partly based on the findings from a review of the safety situation for the recreational boaters performed by the Norwegian Maritime Authority in 2012.

Moreover, it is also important to ask whether the difference between the two groups are due to differences in private and professional maritime safety culture in Norway and Greece. The professional maritime safety culture is closely related to the safety regulation (e.g. the ISM-code) in

professional maritime transport. The International Safety Management (ISM) code of the International Maritime Organisation requires shipping companies to implement Safety Managemen Systems (SMS) on board their vessels, including describing safety roles, goals, procedures, monitoring, reporting, follow up etc. (Thomas 2012). Studies indicate that the SMS requirements of the ISM code foster a positive safety culture on board vessels (Lappalainen et al 2014). Additionally, shipping companies also often work to implement a positive organizational safety culture, including policies for seafarer behavior. Based on previous research, we may hypothesize first that organizational safety culture influences safety behaviours among professional seafarers (cf. Håvold & Nesset 2009, Lu & Tsai 2010).

Also, professional seafarers have undergone an IMO approved training in their respective home countries. Thus, this training, the SMS and safety culture are elements which are likely to influence the professional maritime safety culture. Additionally, it is important to remember that professional seafarer culture also is likely to be influenced by the working conditions of professional seafaring, which may include a high work pressure, demanding working conditions, fatigue etc. (cf. Nævestad 2017). Størkersen et al (2011) found that a third of the respondents in the Norwegian coastal cargo sector reported that they put themselves in danger to get the job done, while about 40% violate procedures to get the job done, especially because of efficiency demands (Størkersen et al 2011).

Moreover, research has also highlighted the importance of national safety culture for the safety behaviours of professional seafarers (Håvold 2005). We compare two countries (Norway and Greece), and we therefore, also compare the influence of national safety culture. The theoretical link between safety culture and safety behaviours is often omitted in research (Ward et al 2010). In the present study, we conceptualise this relationship as both direct social pressures and more subtle social mechanisms, producing important normative influences on behaviour (Cialidini et al., 1990). Individuals' perceptions of peers' opinions about a given behaviour are often defined as injunctive norms, while individuals' perceptions of what peers actually do often are defined as descriptive norms (Ajzen 1991; Rivis & Sheeran 2003; Ward et al 2010). Since injunctive norms are normative they can be expected to directly influence peoples' behaviour (Cialidini et al. 1990). In the present study national culture is measured as descriptive norms. Descriptive norms may influence behaviour by providing information about what is normal, but they can also influence behaviour through the false consensus bias, in which individuals overestimate the prevalence of risky behaviour among their peers in order to justify their own behaviour. The focus on normative influences on behaviour is important in the theory of planned behaviour (TPB) (Ajzen, 1991, 2006), and in the critique of it (Rivis & Sheeran 2003). In short, TPB predicts that our behaviour is the result of our intention to carry out the behaviour, and that our intention to carry out a particular behaviour is influenced by our attitudes towards the behaviour, injunctive norms and our perceived control over our behaviour (Ajzen 1991, 2006).

Additionally, research on maritime safety has found that the framework conditions and safety level varies considerably between (sub)sectors (Størkersen 2017; Hansen et al 2002; Jensen et al 2004). The influence of sector and sector safety culture is examined for professional seafarers. Studies of private transport operators have found that other sociocultural groups, e.g. peer groups (Nævestad et al 2014) and region (e.g. urban vs. rural) (Rakauskas et al 2009) are important when it comes to influencing safety behaviours Thus, we also seek to examine the influence of peer-groups and regional maritime safety culture. Boat type and background variables are examined for leisure boat users.

2 METHOD

2.1 *Recruitment of respondents*

The Norwegian professional seafarers were recruited through the Norwegian researchers' contact with Norwegian shipping companies, i.e. shipping companies that are located in Norway, with mainly Norwegian crew members. Web links to the questionnaires were distributed by the shipping companies to all employees working on board vessels, along with an introductory text explaining the purpose of the survey, and stressing that the surveys were confidential. The Norwegian private boat users were recruited through a) the Norwegian researchers' contact with a boating association distributing survey links to members, and b) distribution on a member website for leisure boat owners, which in many years has been Scandinavia's largest boat forum (e.g. with 1.6 million posts submitted by members). The Greek professional seafarers were recruited through a marketing research company in Greece, which was under the scientific supervision of researchers from the NTUA. Seafarers working for Greek shipping companies, i.e. shipping companies that are located in Greece, with mainly Greek crew members, were approached. Private boat users in Greece were also recruited by the same marketing research company.

2.2 *Survey measures: Professional seafarers*

The present paper analysis of professional seafarers builds on and takes further the knowledge gained from two previous conference papers. The first (Nævestad et al 2017) compares organizational safety culture, working conditions and occupational injuries in Norwegian cargo and passenger transport. The second (Nævestad et al 2018), compares cultural influences on maritime cargo transport in Norway and Greece. The present paper takes the knowledge from these two papers further, as it compares professional seafarers with private leisure boat users.

1. **Background variables** (15 questions): e.g. gender, nationality, age group, seafarer experience, position/area of work, employment status, vessel type, vessel size, manning on board, ship register,
2. **Safety performance** (5 questions): respondents' occupational injuries on board, ship accidents, type of ship accidents, safety compromising fatigue and assessment of work place safety level (1–10).
3. **Safety behaviours** (7 questions): questions on safety behaviours. Respondents were asked: How often do you think the following events tend to occur for every 100 working days/nights on board?: 1) I accept small risks because the "situation demands it" (e.g. because of time pressure, bad weather), 2) I violate procedures to get the job done, 3) I work, even though I am so tired that safety may be compromised, 4) I refrain from using the required protection equipment in my work, 5) I work while being under the influence of alcohol (e.g. one beer or more), or while being hungover, (Answer alternatives: 1) Never, 2) 1–2 times, 3) 3–5 times, 4) 6–10 times, 5) 11–15 times, 6) 16–20 times 7) More than 20 times, 8) Do not know/not relevant)
4. **Working conditions** (3 questions): How often do you think the following events tend to occur for every 100 working days/nights on board: 1) Your shift change is delayed because of work operations, for instance port calls?, 2) You work more than 16 hours in the course of a 24-hour period?, 3) You are interrupted when you are off duty". (Answer alternatives: 1) Never, 2) 1–2 times, 3) 3–5 times, 4) 6–10 times, 5) 11–15 times, 6) 16–20 times 7) More than 20 times, 8) Do not know/not relevant).

We removed the eight answer alternative and made a "Demanding working conditions index" of these three questions (Cronbach's Alpha:.728). The survey also included a question on work pressure: "Sometimes I feel pressured to continue working, even if it is not perfectly safe"

5. **Organisational safety culture** (7 questions): We made an organisational culture index, consisting of questions from the GAIN-scale on organisational safety culture. We have used this scale in previous research from different transport sectors (Bjørnskau & Longva, 2009; Nævestad & Bjørnskau, 2014). The GAIN-scale is presented in the "Operator's Safety Handbook" (GAIN 2001). The GAIN-scale originally consists of 25 questions measuring five themes, but we have reduced the scale to 7 questions, e.g. 1) Ship management regards safety to be a very important part of all work activities, 2) The shipping company regards safety to be a very important part of all work activities, 3) Ship management detects crew members who work unsafely, 4) Ship management often praises crew members who work safely etc.
6. **National safety culture** (7 questions): In the present study we measure national safety culture as descriptive norms (Cialdini 1990) at the national level meaning "what respondents expect that other seafarers from their own country do" expressed through question"When working on vessels, I expect the following behaviours from other seafarers from my country:" 1) That they sometimes violate procedures to get the job done, 2) That they sometimes refrain from using the required protection equipment in their work, 3) That they sometimes work, even when they are so tired that safety may be compromised, 4) That they sometimes work being under the influence of alcohol (e.g. one beer or more), or while hungover, 5) That they sometimes take small risks if the "situation demands it" (e.g. because of time pressure, bad weather), 6) That they sometimes avoid telling colleagues taking risks to work safely, 7) That they sometimes refrain from reporting safety problems and unsafe situations that they experience in their work to the ship management. An exploratory factor analysis (EFA) was conducted to examine the underlying factor structure of the 7 national safety culture (descriptive norms) items.
7. **Sector safety focus** (2 questions): We measure sector safety focus by means of two questions that were selected after a "scale if items deleted" analysis (including five items): 1) Safety is more important than deadlines to our customers, 2) Safety is more important than price to our customers (CA = .875).

2.3 *Survey measures: Private boat users*

1. **Background variables** (12 questions): gender, nationality, age group, experience as a boat driver, participation in organized boat training/ educational programme, boat type, use of navigation equipment, boat length, engine capac-

ity, maximum boat speed, purpose of boat use, municipality of residence, education level.

2. **Safety performance** (4 questions): respondents' accidents/incidents, injuries in accidents, safety self-assessment as a boat driver (1–10), boat use duration.
3. **Safety behaviours:** (12 questions): Respondents were asked:
   A. For every ten times you are driving your boat, approximately how often do you do the following things, before you go out: 1) Tell someone where I will be going and when I will be back, 2) Check the weather forecast, 3) Check the fuel level, 4) Drink two units of alcohol (e.g. two beers, two gl. of wine)
   B. For every ten times you are driving your boat, approximately how often do you do the following things: 1) Personally wear a life jacket the entire trip, 2) Drink two units of alcohol (e.g. two beers, two glasses of wine), 3) Drive faster than the permitted speed close to shore, 4) Drive so fast or offensively that passengers or others (e.g. other boat drivers) express concern or react in other ways, 5) Look down at navigational equipment/GPS for so long that I have been surprised to see other boats, islands, skerries etc. when I look up, 6) Become angered by a certain type of boat driver and indicate your hostility by whatever means you can.
   C. For every ten times you are driving your boat with passengers, approximately how often do you do the following things: 1) Ensure that adult passengers on your boat wear a lifejacket, 2) Ensure that child passengers on your boat wear a lifejacket. (Answer alternatives for A, B and C: 1) Never, 2) 1–2 times, 3) 3–4 times, 4) 5–6 times, 5) 7–8 times, 6) more than 8 times but not always, 7) Always
4. **National safety culture** (3 questions): National safety culture is again measured as descriptive norms at the national level meaning "what respondents expect that other boat drivers from their own country do" expressed through question "Based on your experience, how many boat drivers in your country do you think do the following:" 1) Drink two units of alcohol (e.g. two beers, two glasses of wine) while driving the boat, 2) Drive faster than the permitted speed close to shore, 3) Drive so fast or offensively that passengers or others (e.g. other boat drivers) express concern or react in other ways. The questions were combined into an index. The survey included six additional questions about this that are not listed here.
5. **Peer group safety culture** (3 questions): The same principle and questions as for national safety culture are applied.
6. Safety culture at municipality level (3 questions):

The same principle and questions as for national safety culture are applied.

3 RESULTS

3.1 *Professional seafarers*

3.1.1 *Which behaviours influences personal injuries?*

A logistic regression analysis was conducted with personal injuries as dependent variable, to find the variables predicting personal injury among our respondents (Table 1). In this analysis, the injury variable, which originally had four answer alternatives, was dichotomized, 0 = no personal injury, 1 = personal injury. B values are presented and they indicate whether the risk of personal injuries is reduced (negative B values) or increased (positive B values), when the independent variables increase by one value.

Table 1 provides three main results. The first is that nationality influences respondents' work injuries in the last two years on board. This is the variable with the strongest contribution. The Norwegian seafarers reported to have been more involved in injuries than the Greek seafarers. The variable with the second strongest contribution is the Risk acceptance/violations index; indicating that the more violations and risk accepting behaviour you are involved in, the more likely it is that you are injured on board. The variable with the third strongest contribution is age group, indicating that controlled for the other variables, the youngest seafarers have a higher risk of being injured on board. In Table 1, the Nagelkerke R^2 is 0.188 which indicates that the independent variables explain 19% of the variance in the dependent variable.

3.1.2 *Which factors influence safety behaviours?*

In Table 2 we show results from a hierarchical, linear regression analysis, where independent variables are included in successive steps to examine the variables predicting respondents' scores on the Risk acceptance/violations index.

Table 2 provides five main results: first, the more demanding working conditions that the respondents experience, the more likely they are to be involved in Risk acceptance/violations. Second, we see that the national safety culture—descriptive norms index contributes positively, indicating that the more unsafe behaviours the respondents say that they expect from seafarers from their own country, the more likely they are to be involved in unsafe behaviours themselves. Third, the higher organizational safety culture scores the respondents report, the less unsafe are their behaviours.

Table 1. Logistic regression. Dependent variable: Personal injuries on board in the last two years (dichotomized: 0: no personal injury, 1 = personal injury). B values.

Variables	B value
Age group (26 years = 0, Other = 1)	0.373**
Nationality (Greek = 0, Norwegian = 1)	2.226**
Vessel type (Live fish carrier = 0, Other = 1)	0.888
Position/line of work (Deck crew = 0, Other = 1)	0.657
Risk acceptance/violations index	1.164***
Working under the influence of alcohol/ hungover	0.304
Non-reporting/non-intervention index	0.940
Sometimes I feel pressured to continue working even if it is not perfectly safe	1.224
Organisational safety culture index	1.025
Nagelkerke R^2	0.188

*P < 0.1, **p < 0.05, ***p < 0.01.

Table 2. Linear regression. Dependent variable: "Risk acceptance/violations Index". Standardized beta coefficients.

Variables	Beta coeff.
Age group (26 = 2)	0.003
Nationality (Greek = 2)	–0.030
Position (Apprentice = 2)	0.052
Vessel type (Tank = 2)	–0.031
Sometimes I feel pressured to continue working, even if it is not perfectly safe	0.167**
Demanding working conditions index	0.281**
Organisational safety culture index	–0.195**
Sector focus on safety	–0.144**
National safety culture: descriptive norms	0.206**
Adjusted R^2	0.453

*P < 0.1, **p < 0.05, ***p < 0.01.

Thus, a positive organisational safety culture may reduce the negative contribution of demanding working conditions and safety compromising work pressure. The same applies to the index "sector focus on safety". In Table 2, Adjusted R^2 is 0.453 which indicates that the independent variables explain about 45% of the variance in the dependent variable.

3.2 *Private boat users*

3.2.1 *Which behaviours influences personal injuries?*

A logistic regression analysis was conducted with boating incidents (grounding, collision, intake of water) as dependent variable, to find the variables predicting personal injury among our respondents (Table 3). Seven percent of the respondents had experienced this. The incident variable, was dichotomized, 1 = no personal injury, 0 = personal injury. B values are presented and they indicate whether the incident risk is reduced (negative B values) or increased (positive B values), when the independent variables increase by one value.

Table 3 provides two main results. The first is that nationality influences respondents' experiences with boating incidents in the last two years. This is the variable with the strongest contribution. The effect is negative, meaning that Greek boat users are involved in fewer incidents, controlled for the other relevant variables.

The second result is that alcohol use during trips as a boat driver contributes significantly and negatively, meaning that increased alcohol use increases the likelihood of boating incidents. In Table 3 the Nagelkerke R^2 is 0.222 which indicates that the independent variables explain 22% of the variance in the dependent variable.

3.2.2 *Which factors influence safety behaviours?*

In Table 4 we show results from a hierarchical, linear regression analysis, where independent variables are included in successive steps to examine the variables predicting respondents' scores on the variable "Alcohol use during boat trip as driver".

Table 4 provides four main results: first, national safety culture, specified as descriptive norms (boat users from your own country's alcohol use, over speeding close to shore and offensive driving) provides the strongest contribution to respondents' alcohol use while driving a boat. Respondents who report of unsafe behaviours among boat users in their country are more likely to drink alcohol while boating themselves. We made similar indexes for the peer group and the municipality level. The peer group level refers to "friends who own a boat".

Table 3. Logistic regression. Dependent variable: boating incidents in the last two years (dichotomized: 0: incident, 1 = no incident). B values.

Variables	B value
Age group (46–55 years = 0, Other = 1)	0.711
Exposure	0.002
Boat type (motor boat w/sleeping facilities = 0, other = 1)	0.328
Alcohol use during trip as boat driver	–0.359**
Nationality (Greek = 0, Norwegian = 1)	–1.683***
Education/training in boat use (No = 1)	–0.179
Navigational equipment on board	0.826
Nagelkerke R^2	0.222

*P < 0.1, **p < 0.05, ***p < 0.01.

Table 4. Linear regression. Dependent variable: "Alcohol use during boat trip as driver". Standardized beta coefficients.

Variables	Beta coeff.
Age group (Under 56 years = 1, over = 2)	–0.147**
Nationality (Norwegian = 1, Greek = 2)	–0.160**
Boat type (Other = 1, motor boat w/ sleep = 2)	0.171***
Purpose of trip (Other = 1, Leisure = 2)	0.119*
Perceived enforcement: police/coast guard	0.028
Peer group safety culture	0.151*
Municipal safety culture	–0.157*
National safety culture	0.218***
Adjusted R^2	0.167

*P < 0.1, **p < 0.05, ***p < 0.01.

We see that that peer group safety culture and municipality safety culture only contributes significantly at the 10% level. The contribution of peer group safety culture is positive, as the national culture variable, but the municipality contribution is negative. This is unexpected, and we return to it in the discussion section.

Second, we see that boat type (motor boat with sleeping facilities) contributes positively, indicating that using this boat type involves a higher incident risk in our sample. Third and fourth, we see that age (>56 years) and nationality (Greek) gives a lower risk of having experienced incidents.

Finally, we also see that purpose (i.e. leisure and holiday) contributes positively to incidents, but only at the 10% level. Thus, we see, not unexpectedly, that compared with other purposes (e.g. fishing, transport), boat drivers on leisure/trips are more likely to drink alcohol while driving. In Table 4, Adjusted R^2 is 0.167 which indicates that the independent variables explain about 17% of the variance in the dependent variable.

4 CONCLUDING DISCUSSION

The aims of the study were to examine the safety behaviours related to personal injuries and accidents among professional seafarers and private leisure boat users in Norway and Greece, and to study the factors influencing these behaviours.

4.1 *Factors predicting injuries/accidents*

Looking at the factors predicting injuries/accidents in the two groups, we saw that nationality (Norwegian), risk acceptance/violations and age group (<26 years) predicted professional seafarers' work injuries in the last two years on board. The contribution of age and nationality is in accordance with previous research on professional seafarers (Hansen et al 2002; Jensen et al 2004).

Looking at the private boat users, we also saw that nationality influenced respondents' risk of boating incidents in the last two years. Second, we found that alcohol use during trip as a boat driver increased the likelihood of boating incidents. Working under the influence did not contribute significantly to professional seafarers' risk of work accident.

This contrasting result is in line with the hypothesis we mentioned in the introduction; that private boat use seems to be a relatively unregulated behaviour compared with professional seafaring. Previous research indicates that alcohol consumption may be an important risk factor in the maritime sector (Akhtar & Bouwer Utne 2014, Hetherington et al 2014), and that alcohol and drug abuse are greater for seafarers compared to workers ashore (Nitka 1990; Kariris 2012 in Zhang & Zhao 2017), partly because of their working situation (e.g. social isolation). However, as private boat use is less regulated than professional boat use, we hypothesized that alcohol consumption "boating while under the influence", would be an even more important risk factor among private boat users. Results indicate that this is the case, at least based on our sample.

As noted, Amundsen (2016) also asserts that questions about alcohol use and lifejacket use are common in almost all of the international surveys, indicating the importance of these factors for boating safety. Moreover, Norwegian boating accident statistics report a number of death involving alcohol, and where the drowned person did not were a life jacket (Amundsen & Bjørnskau 2017).

4.2 *Factors predicting safety behaviours*

Analysing the factors influencing professional seafarers' risk acceptance and violations, we found that demanding working conditions and work pressure were important factors. This is in line with previous research (Størkersen et al 2011, Nævestad 2017). The former was the most important factor. We also found that a positive organisational safety culture may reduce the negative contribution of demanding working conditions and safety compromising work pressure. This has also been pointed out in a previous study (Nævestad 2017). We also found that "sector focus on safety" may reduce the negative influence of demanding working conditions on professional seafarers' safety behaviours.

Additionally, we, found that the national safety culture—descriptive norms index contributed

positively, indicating that the more unsafe behaviours the respondents say that they expect from seafarers from their own country, the more likely they are to be involved in unsafe behaviours themselves. We found the same in the analysis of the private boat users; in fact, this analysis showed that, national safety culture, specified as descriptive norms (boat users from your own country's alcohol use, over speeding close to shore and offensive driving) provided the strongest contribution to respondents' alcohol use while driving a boat. To our knowledge, there are few other studies that have examined the influence of national culture (specified as descriptive norms) on both professional seafarers and private boat users.

Examining the cultural influences on private boat users' safety behaviours, we also found that peer group and municipality safety culture contributed significantly at the 10% level. The contribution of peer group safety culture is positive, as the national culture variable, but the municipality contribution is negative. This is likely to be a result of a collinearity effect, indicating that these two variables are strongly related and measure "the same effect". In practice (and based on observing the means and the standard deviations on these two variables) it seems that respondents do not separate clearly between boat users in their own municipality and their peer group. This is understandable, given the memory, knowledge and analytical separation required to do this. Thus, we should exclude the municipality level from the analysis, as it is likely that this is the level (compare to peer group) that respondents know less about.

Analysing, the influences on private boat user behavior, we also found that boat type (motor boat with sleeping facilities) involves a higher incident risk in our sample. We also found that age (>56 years) and nationality (Greek) gives a lower risk of having experienced incidents. We also found that purpose (i.e. leisure and holiday) contributed positively to incidents, but only at the 10% level. This brings us to the important differences between the two groups that we study. Finally, previous research on private boat users has also found such background variables to be important for safety behaviours, e.g. type of boat used, gender, age, experience, what kind of activity they usually use the boat for (e.g. fishing, competition, holiday, recreation), type of location where they usually use the boat (cf., Amundsen 2016; Amundsen & Bjørnskau 2017).

4.3 *Why are the number of fatalities higher for leisure boat users than professional seafarers?*

An overarching purpose of our study was to discuss possible reasons to the higher number of fatalities for leisure boat users than professional seafarers. We wanted for instance to examine the kind of behaviours that are related to injuries/accidents in the two groups, and subsequently to examine the factors influencing these behaviours. We may of course only speculate based on our study, indicating hypotheses that should be examined further in future research, but our study indicates that the settings and purposes are important to understand this difference.

While unsafe behaviours related to work pressure and risk taking are important among professional seafarers (i.e. risk acceptance and violations), unsafe behaviours related to the leisure/holiday situation was important for the leisure boat users (i.e. alcohol use while driving a boat).

Additionally, it seems that the situation of private leisure boat users is less regulated than that of professional seafarers. The International Safety Management (ISM) code of the International Maritime Organisation requires shipping companies to implement Safety Management Systems (SMS) on board their vessels, including describing safety roles, goals, procedures, monitoring, reporting, follow up etc. (Thomas 2012). Additionally, shipping companies also often work to implement a positive organizational safety culture, including policies for seafarer behavior. Also, professional seafarers have undergone an IMO approved training in their respective home countries. Thus, this training, the SMS and safety culture are elements which are likely to influence the professional maritime safety culture.

Private boat users, on the other hand are not part of such a system of international and national regulation, involving education, inspections from port states, flag states, classification societies, transport buyers etc. Compared to the number of people who go boating in different countries, the risk of accidental death is quite high compared to that of other private transport modes. Despite of this, recreational boating is to a small extent being regulated and the level of enforcement is low (Amundsen & Bjørnskau 2017). Some countries seem to take safety for leisure boat users more seriously than others. In a few countries it is, for instance, now mandatory to report all incident you experience while boating, even if no persons were injured in the incident/accident. Finally, it is important to remember that the above mentioned view points merely are hypothesis that must be examined in future research.

4.4 *Cultural influences on maritime safety behaviours*

The theoretical link between safety culture and safety behaviours is often omitted in research

(Ward et al 2010). In the present study, we conceptualise this relationship as descriptive norms, that may influence behaviour by providing information about what is normal. In the professional (organisational) setting, managers are an important source of social pressure, as well as colleagues, and the interaction between people within the organisation is important for the creation and maintenance of a safety culture influencing behavior, as indicated by the effect of organizational safety culture on professional seafarers' safety behaviors in Table 2.

In the private setting, there will not be a similar strong link from managers to transport safety culture. Some peers are, however, likely to assert stronger social influence than others, and may be as important as managers in organizations in exerting social pressures that shape safety culture and influence behaviour. In our study (Table 4), we saw that peers are central as advocates of social norms related to safety (i.e. drinking alcohol while boating), but we also saw that the reference to other people in the boat users' country were even more important. In Table 2 we also saw the importance of sector for professional seafarer behavior.

To conclude, our study indicates that both in the professional and the private setting, norms for interaction and conduct seem to be influenced by norms and expectations rooted in different socio-cultural groups, e.g. the national culture, the specific sector in question, the organisations and in peer groups.

Accident and disease prevention in working life: Common grounds and areas for mutual learning

E. Albrechtsen, R.B. Jørgensen, T.Ø. Kongsvik & K.V.H. Svendsen
Norwegian University of Science and Technology, Trondheim, Norway

ABSTRACT: Globally, there are more than six times more fatalities caused by a poor working environment than due to occupational accidents. In this paper we compare the basic strategies involved in accident and disease prevention. We find that the basic thinking is the same. The preventive strategies involve control of hazards in a hierarchy from elimination to application of personal protective equipment. Also, the Norwegian regulation on internal control of HSE is applicable for both accident and disease prevention, involving the idea of continuous improvement. Still, the nature of the hazards differ, as well as the possible consequences. In the area of occupational safety, the hazards are usually visible and the consequences of accidents are immediate. In the area of occupational health, the hazards are often invisible and the consequences of exposure delayed. There is a potential for better integration of the two areas in practical management, and a potential for mutual learning from concepts and models in the two fields.

1 INTRODUCTION

Protection from harm in relation to work is a responsibility for politicians, authorities and employers. Still, work related diseases, accidents, injuries and fatalities continues to be a significant challenge.

According to ILO, globally 2.3 million deaths take place due to occupational injuries and diseases each year (Takala et al., 2014). Of these, over 2 millions of deaths are due to occupational diseases, among them 23% due to work related cancers.

In Norway, we have from 47 to 25 deaths each year from injuries in the period 2013–2016 (The Norwegian Labour Inspection Authority 2017), and 1% of the working population reported work related lung complaints in 2013 (NOA, 2017). In addition, it has been estimated that approximately 3000 new cases of work related Chronic Obstructive Pulmonary Disease (COPD) each year in Norway, and that 200 persons will die from this disease due to working conditions (Leira, 2011). Although these figures are high, there seems to be a positive trend both in work related accidents and diseases. The number of fatalities was more than 100 annually in the early 1970s, but has steadily declined. In 2016 the number of fatalities was 25 (The Norwegian Labour Inspection Authority 2017). The number of self-reported exposures for chemicals are declining, as well as reports of other work-related diseases (NOA, 2011, 2017)

Accidents in the construction industry still get high attention. However, some highlights the fact that the workers in this sector have increased risk for lung diseases (Bergdahl et al., 2004; Robinson, Petersen, Sieber, Palu, & Halperin, 1996; Vermeulen, Heederik, Kromhout, & Smit, 2002). Also in Norway the statistics from NOA shows that workers in the construction industry have more respiratory complaints, and more declared work related respiratory complaints than the national mean (Aagestad, 2015). Recent studies have also detected an association between exposure and an increased risk of COPD in the construction industry (Fell, Aasen, & Kongerud, 2014). In addition 59% of construction workers state that that they inhale smoke, dust or exhaust in their work situation (NOA, 2017).

The purpose of this paper is to compare the main strategies for the prevention of occupational diseases and occupational accidents.

2 PREVENTION OF OCCUPATIONAL DISEASES

2.1 *Exposure assessment*

The traditional approach for chemical risk assessment is to compare the exposure level of the chemical agent to their Occupational Exposure Limits (OELs). These OELs were established from late 19 century (Jayjock MA, 2000). Still this approach is regarded to be the best practice for risk assessment for chemical agents and noise. These limit values are given for occupational exposures during 8 hours shift, and there is guidelines on how

to assess risk of exposure to noxious agents (NS-ISO689) and sound (NS-4815–1).

The sampling and analyses of airborne contaminants and comparing results with the national OELs have been challenging for different reasons. Due to variability in exposure both within workers and between workers, several samples have to be taken for each group of workers regarded as homogenously exposed (Chen, Chuang, Wu, & Chan, 2009; Rappaport, Lyles, & Kupper, 1995). The cost for each analysis and the resources needed to perform the measurements have resulted in a limited number of measurements from the different parts of the Norwegian industry. Reported measurement results from the construction sector are rather sparse, except some from tunnel construction, cement work and Bricklayeres (Bakke, Ulvestad, Thomassen, Woldbæk, & Ellingsen, 2014; Beaudry et al., 2013).

A new approach to risk analyses on health effects have been widely used since the introduction of REACH (Money, 2003; Office, 2017; UK, 2017). This new approach take into consideration the health classification of chemicals or particles are use this together with an exposure assessment (Money, 2003). The classification of health effects are performed on the basis of the agent's inherent toxic property, often by use of the CLP classification (CLP-ref) but the risk assessment are also dependent on the exposure. This exposure assessment may be founded on subjective assessment and exposure toolkits (Office, 2017; UK, 2017). The subjective assessment method uses a structured approach, based on descriptive information about work activities and the work environment, and have been validated against exposure measurements (Cherrie & Schneider, 1999). This new approach makes it possible to do risk assessment of chemicals and particles which do not have an OEL and without measurements. However, when the risk analyses shows that there may be an unwanted risk; measures have to be taken to comply to the model, or measurements have to be performed in the old fashion way to document that there is an acceptable risk.

2.2 *Hierarchy of exposure controls*

Within occupational hygiene, control of exposure is a fundamental method for protection of workers. Traditionally ahierarchy of controls has been used as a mean of determining how to implement feasible and effective control solutions. The hierarchy is often illustrated as in Figure 1, where elimination is the most effective measure, and include physically removal of the hazard. Substitution is replacement of the hazard, engineering controls isolate people from the hazard, administrative

Figure 1. Control of exposure.

controls change the way people work and Personal Protective Equipment (PPE) is the weakest measure protecting the worker against the hazard.

The principle behind this hierarchy is that the control methods at the top of graphic are potentially more effective and protective than those at the bottom.

In practical use, however, it is often more difficult. Using a smelting plant as example, the production of metal or metal alloy like aluminium, silicon, silicon carbide or ferromanganese is the basic idea behind a production plant. The top two measures, elimination and substitution of the raw material is impossible; and the occupational hygienist only have the three lowest ranked measures available. The smelting industry is very energy-intensive and access to cheap energy often determines where the factories are located. The processes are often old and physically relatively simple, but produce large amounts of pollutants. In the silicon carbide industry the cancer risk have been documented since 2000 (Romundstad, Andersen, & Haldorsen, 2001), and the dust exposure is documented to contain both fibers (Bye, Eduard, Gjonnes, & Sorbroden, 1985) crystalline silica, silicon carbide (SiC) and sulphur dioxide (S. Føreland, Bye, Bakke, & Eduard, 2008). The workers in this industry is heavily loaded by personal protective equipment using dust mask, CO alarm, eye protection, hearing protection, safety helmet, gloves and safety clothes. The Silicon carbide industry is not the only industry using this as main principle, even that isolation of the process; local exhaust ventilation or general ventilation would have been more effective types of measures.

This was pointed out by Føreland (Solveig Føreland, Bakke, Vermeulen, Bye, & Eduard, 2013) as late as 2012stating that "recommendations for exposure reduction based on this study are (i) to separate the sorting area from the furnace hall,

(ii) minimize manual work on furnaces and in the sorting process, (iii) use remote controlled sanders/grinders with ventilated cabins, (iv) use closed systems for filling pallet boxes, and (v) improve cleaning procedures by using methods that minimize dust generation".

Following the hierarchy normally leads to the implementation of inherently safer systems, where the risk of illness or injury has been substantially reduced, but as the example shows, it is not always possible to use the most favorable measure.

The same kind of example could be used for the construction sector, as the work itself produces pollutants that is impossible to avoid as concrete, wood dust, stone dust and exhaust from vehicles. The only one that may be substituted is the exhaust when new vehicle technology is developed. This makes it necessary to use the last favorable protective measure; the personal protection devices.

3 PREVENTION OF OCCUPATIONAL ACCIDENTS

The barrier concept is a basic foundation in strategies for occupational accident prevention. An accident can be understood as caused by energy out of control (Gibson, 1961), where a hazard (source of energy) releases energy. This energy is then absorbed by a victim which leads to loss (health, life). Following this energy model, accidents can be prevented by barriers that stops or prevents a sequence of events that lead to loss of control of hazards (Kjellén and Albrechtsen, 2017). As shown in Figure 2. the barrier philosophy follows the same logic as control of exposure (Figure 1)

Seen in a functional perspective, safety barriers perform tasks, such as preventing falling objects from hitting people working below. Such functions or tasks are performed by different barrier elements that constitute a barrier system (Rosness et al. 2010). Physical devices, human actions and administrative procedures serve as barrier elements meant to protect vulnerable targets from harm (Sklet, 2006).

A 'defence in depth' strategy is commonly applied in the prevention of accidents. According to Reason (1997:12), major accidents occur as a result of failures in multiple layers of the defences separating potential hazards from people and assets. Accident trajectories pass through 'holes' in these defences, created by active failures—errors and violations—and/or latent conditions, such as lack of competence, design flaws and unrealistic procedures.

For example for a lifting operation, two barrier functions must be in place: 1) prevent sudden release of the gravity energy that the lift represent and 2) separate the gravity energy that the lift represent and workers (establish a safety zone). The first barrier function (prevent sudden release of energy) is realized by a set of barrier elements: sling mechanism, crane driver competence, slinger competence, signal man, control rope etc.

Haddon's (1980) defined ten generic principles for the prevention of harm (injury) from transfer of energy. These ten strategies are generic barrier functions to either control the hazard; separate the hazard and a victim; or make the offer more robust to harm. See Figure 3.

Haddon's (1980) strategies and the energy accident model (Gibson, 1961) have had significant influence on European legislation and standardisation work such as that related to hazardous chemicals (European Council 1998) and machinery safety (European Council 2006). The strategies are central components in accident investigation methods such as in the OARU, Management Oversight and Risk Tree MORT, Safety Management and Organisation Review Technique (SMORT) (Kjellén and Albrechtsen, 2017).

Figure 2. Control of hazards.

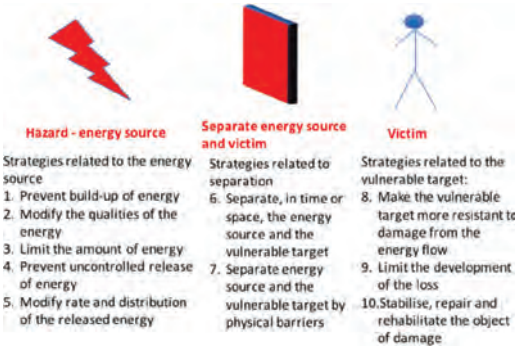

Figure 3. Haddon's principles for accident prevention.

Risk mitigation in the European Council (2006) Directives on Machinery is based on Haddon's strategies. ISO 12100:2010shows a strategy for selection of safety measures of machinery, see Figure 4. The strategy reflects that hazards should be prevented or limited at the design stage, i.e. designed out. If this is not possible, protective measures and safety controls should be established to separate victims and the hazards of the machinery. Residual risk after these measures can be accepted, but requires that the producer inform the user about these. The user of the machinery is responsible for training, and safe operation at work, including providing necessary personal protective equipment.

To implement the correct barrier system (functions and elements) risk assessments are essential. The results of risk assessment serve as decision-making support to implement adequate safety measures. ISO31000 Risk Management gives descriptions of the principles and steps in risk assessment and risk handling. Briefly, the steps are: identify hazards and incident scenarios; analyze causes; analyze frequency and consequences; analyze risk; evaluate risk according to risk acceptance criteria; and mitigate risk. The analysis of risk is made by systematically collect available knowledge about the analysis object and use this knowledge to express what can go wrong in the future; what the likelihood of it happening; and the consequences if it happens (Rausand, 2011). This risk picture is then evaluated to risk acceptance criteria to detriment whether the risk is acceptable or not.

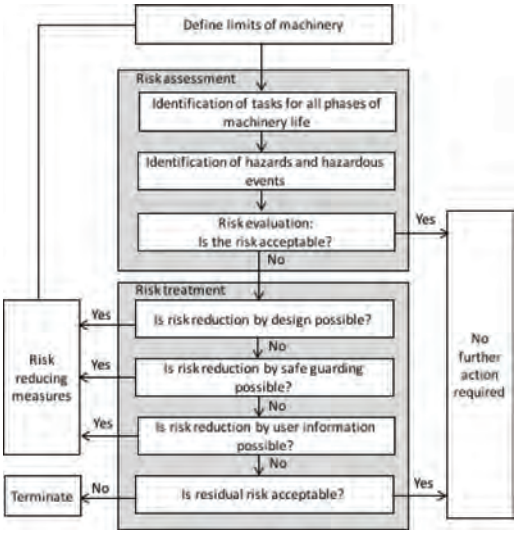

Figure 4. Risk treatment and risk assessment of machinery (based on ISO12100).

The Directives of Machinery shows how risk assessment is the input to risk mitigation, see Figure 3. ISO 12100:2010show the steps for risk assessment of machinery. It follow the same steps for risk assessment as described in ISO31000, but starts with an identification of the machinery and intended/unintended use of the machinery for all life phases of the machinery.

3.1 *Tunnel construction as example*

An analysis of fatal accident from hydropower instruction projects in Kjellén and Albrechtsen (2017) show that there are two types of fatal accidents in tunnel excavation: falling rock/rock burst and workers squeezed or driven over by vehicle. Barriers to prevent such fatal accidents would mainly be to separate in time/space the hazard and the victim. For blasting work workers are moved away from the blasting area.

During construction work other than blowing work, accident risks are in particular conflicts between workers and heavy machinery, falling objects (rock fall/rock burst) and getting squeezed during rigging.

One of the work activities in tunnel excavation are assembly of different materials and infrastructures in the roof. The accident risk for such operations are falling objects and squeezing. In Norway, there has been fatal accidents at scissor lifts, where the victim has been squeezed between the lift and the roof. Risk mitigation for this scenario is to design in pressure-released stop of the lifting mechanisms.

Work at height will also involve significant occupational hygiene risk. From an occupational hygiene perspective it is well known that tunnel workers are exposure to both particulate and gaseous air pollution and that tunnel workers are known to be at increased risk of long-term and short–term lung function decline and CORP (Ulvestad et al.). Different activities causes different exposures to these workers. Exposure to gases and particles from diesel emissions has been considered to be among the dominating burdens during tunnel construction due to weel-going diesel machines; also during drilling and blasting operations, workers are exposed to dust, with α-quartz as the most important agent. α-quartz in the dust from tunnels varies between <1% and more than 50% (Norwegian Tunnelling Society,Publication No.13) and α-quartz exposure may lead to COPD. Exposure to oil mist and oil vapour is another type of exposure that may also occur during drilling. Exposure to oil mist may cause occupational asthma and also pulmonary fibrosis (Robertson et al., 1988) Risk assessment hence have to be performed with focus on all these possible exposures.

If we look into Figure 1 in order to identify preventive measures it seems logic that elimination and substitution is difficult. None of these activities could be eliminated if the tunnel should be constructed. Substitution might be possible if we look into the type of explosive used for blasting. Ammonium nitrate fuel oil is used as explosive, and if this agent is substituted with size-sensitised emulsion, the worker exposure lower (Ulvestad). Apart from this example engineering controls often is the first possible preventive measure, where ventilation of the tunnel, pollution-abatement equipment for diesel vehicles is some of the measures often used. High frequency maintenance routines are an example of administrative controls, while personal protection equipment only should be the last solution, but in real life often is used on a daily basis.

Figure 5. Deming's circle.

4 DISCUSSION

4.1 *Common grounds*

The law/regulation on internal control makes it clear that all enterprises in Norway should have a system for safeguarding health, safety and environment. This system includes information on health and safety regarding issues in the working environment, requirements for establishing goals for the HSE-work, performing risk analyses for any hazard and establish routines for unveiling, correcting and preventing violations of the law and regulations.

The internal control regulation that is the source for management systems for HSE control is the same for both safety and workers health, and builds on quality principles. Theories on quality gained much attention in industry from the 1980s, and was first related to improvements in the production processes. Total quality management became an influential movement, spurred by the works of Deming (1986) and Juran. Later, the principles were used as a foundation for internal control for HSE in Norway (Saksvik & Nytrø, 1996).

The idea of continuous improvement is evident in both the prevention of occupational diseases and in the prevention of occupational accidents, illustrated in Deming's circle (Figure 5):

In the prevention of occupational diseases related to the exposure to chemical, quality principles are at work when exposure levels are compared to OELs, and when measures are taken to mitigate or eliminate the exposure, illustrated in the hierarchy of controls (Figure 1).

In the prevention of occupational accidents, the idea of continuous improvement is the foundation for safety information systems, and the experience feedback such systems entail. By means of safety indicators, safety audits, and accident investigations, information is applied to implement measures for accident prevention.

The barrier philosophy of both areas is the same. Both aim at first prioritizing efforts directed at the source of danger by elimination, modification and limitation. Second, both areas emphasize to avoid interface between risks and victims by substition and separation. Third, both areas emphasize engineering control by built-in solutions in design. Finally, the last measure in both areas is to approach the victim by information, training, procedures and lastly personal protective equipment.

Many of the occupational hygiene risk factors can contribute to higher accident risk by influencing human performance. The human operator is an essential barrier element to realize barrier functions. Stress (fatigue, time load and task load); situation/environment (physical and chemical work environment); and human-machine interactions are among performance shaping factors (Groth and Mosleh, 2012) that affect the quality of the human barrier element in accident prevention.

4.2 *Differences in the nature of hazards and consequences*

One obvious difference between the health and safety field, is the nature of the hazards that should be handled. Hazards in the field of safety are a form of energy that is not properly controlled. Further, hazards may cause immediate harm if safety barriers are not in place, or if they are not functioning as intended.

In the area of occupational health, hazards are not limited to energy sources, although vibration, radiation and noise is clearly within the energy perspective. But also toxic fumes, cancer inducing and poisonous agents represent hazards, not directly related to energy and more or less invisible in nature.

Further, hazards within the occupational health domain do in many instances not cause immediate harm, but the harm may be delayed. In some instances it may take several decades from exposure to the loss is evident. Although there are nuances in this, this can be summed up in a general manner as in Table 1:

Even if more than six times more occupational deaths are caused by diseases than accidents, there is a tendency that accidents get more attention. Accidents are concrete, often dramatic events, and with immediate consequences. This will naturally generate attention from employers, authorities and the general public, often followed by demands for measures that ensures that similar events will not take place in the future.

Occupational diseases are less dramatic, and as the consequences are often delayed, there will also be an issue of employer responsibility for the harm. The employee might have changed employer several times before the disease is evident. Diffused responsibility, coupled with the more invisible nature of the hazards, and the latency period from exposure to disease, might result in less attention from outside actors.

In the end it might also lead to less resources to the prevention of occupational diseases, relative to the needs. The regulatory authorities should be aware of such mechanisms, and implement requirements to ensure that the prevention of occupational diseases get proper attention and the resources.

4.3 *Cross-disciplinary learning?*

Although some of the preventative strategies related to accidents and diseases seems to be the same, the professional concepts that are applied differ. For example, control of exposure vs. control of hazards refers to the same line of thinking. The professional concepts in the two fields have developed over a long period, and are institutionalized and applied in research and theory building. The distinct repertoires of concepts ensures precision and are a foundation for theory development within the two fields. Thus, the development of a common professional language seems unrealistic and also undesirable.

Table 1. Differences in the nature of hazards and consequence in occupational safety and occupational health.

	Hazards	Consequences
Occupational safety	Visible	Immediate
Occupational health	Invisible	Delayed

Still, mutual awareness of the concepts, models and theories that have been developed in the respective fields can represent a fruitful cross-pollination, and instigate new ideas for prevention. For example, within the safety field, there exists many accidents models; domino models (Heinrich, 1931), information models (Turner & Pidgeon, 1997), and the swiss cheese model (Reason, 1997) to name a few. There are also perspectives related to what kind of organizational characteristics that may prevent accidents, including the theory of high-reliability organizations (Weick, Sutcliffe, & Obstfeld, 1999) and Resilience Engineering (Hollnagel, 2014). Researchers with occupational health might find such models to be inspiring and of relevance.

A basic concept related to the prevention of occupational diseases is OELs. Actual exposure levels of chemical agents are compared to OELs to determine whether the exposure might induce harm. Much research lies behind the definitions of OELs. This might be an interesting area for occupational safety. Although the hazards are of a different nature, setting clear thresholds for exposure might be an issue for further exploration, even if there exist similar lines of thinking (e.g. the notion of acceptance criteria, and the ALARP principle, As Low as Reasonably Practicable).

In many instances, HSE practitioners working within companies (e.g. HSE engineers, managers etc.) will have responsibilities related to both health and safety. From their professional background, they will have insight into the different research fields, and be in a position to integrate them, and treat HSE as a holistic concept. Academics tend to be more specialized within one of the fields of research. Thus, for researchers interested in cross-disciplinary learning, HSE practitioners might be a resource for practical knowledge integration. It is also a responsibility for academics and educators to prepare prospective HSE workers for the cross-diciplinary challenges they will meet in working life. Real working life problems do not necessarily follow professional boundaries, but require a cross-disciplinary approach. Thus, cross-disciplinary learning in the areas of occupational health and safety should be an important issue in university education.

5 CONCLUSIONS

The paper demonstrates that there are similarities between management of occupational health and

safety, but also that there are potential improvements for better integration of the two areas in practical management.

As indicated in the introduction of the paper there are far more death and personnel harm due to poor working environment than there are deaths and injuries due to occupational accident. However, accidents and accident prevention seems to get more attention by HSE practitioners and mass media. Possible explanation for this picture could be the different nature of the hazards and the lagging consequences of occupational exposure compared to the sudden consequences of an accident.

Common for both prevention of both occupational disease and occupational injury is that adequate planning would prevent many events by establishing adequate barriers

Topics for further research of the interaction between occupational health and safety can include:

How is HSE implemented in practice in the building and construction industry? Is safety more focused than work environment? And if any difference could be identified, what is the explanation behind this. Some hypotheses could be investigated: A) Simple measurable parameters within security, such as accidents per 1000 hours of work or absence per 1000 hours make safety easier to control. B) Control of exposure is not defined as a project-specific activity and hence an activity belonging to the internal control system of the sub contractors, which in practice means greater variation in how much focus it gets in practical work. C) Differences between safety culture and work environment culture exist.

Customs—a vital contributor to safe societies? A study of the Norwegian customs service

L.K. Stene & R. Folgerø
University of Stavanger, Norway

ABSTRACT: Prior to the 2011 Norway terrorist attacks, widely referred to as '22 July', the Norwegian Customs Service (Customs) had alerted the Norwegian Security Police Service to the importation of weapon-related products by a known terrorist. The purchases made by this terrorist initially led officials to place him on the watch list of the Norwegian Security Police Service, but no action was taken based on the information given. In the federal Report of the 22 July Commission, the poor coordination of the Norwegian Security Police with Customs was criticized. In this paper, we address whether Customs, as an important player in preventive safety and security, is actually being regarded as such. From a societal safety and risk-based regulatory perspective, we discuss the challenges of the state in recognizing and supporting the effectiveness of Customs as a vital contributor to a safe society.

1 INTRODUCTION

In today's struggle to ensure safe, secure and resilient societies, we strive to avoid industrial and technological accidents and hazards, man-made disasters and health-threatening hazards and pandemics. We take steps to prepare for natural disasters and climate change as well as to ensure the safety of critical infrastructures and supply chains. In this effort to ensure safe societies, federal customs services are increasingly important players, especially with respect to ensuring border security and fighting international crime and terrorism, as well as addressing the relatively recent European migration challenge.

A safe society must find a way to regulate and control the above-mentioned hazards and threats, which might initially seem to be an impossible task. Safety and security policy frameworks cover many societal levels and sectors. The implementation of such policy frameworks presupposes the interaction and close coordination between politicians, bureaucratic organizations, interest groups and other relevant players, as well as citizens in general. This again depends on the effective exchange of information and communication between the relevant players. This information may include, for example, policy documents, project or research results and field or operational experiences, all of which requires horizontal and vertical coordination. Security and risk management in the areas of border control and criminal networks is also influenced by international policies covering various sectors and operations. As such, many individuals at different levels in a range of organizations must be aware of each other. Are they? In this article, we discuss the extent to which the resources held by the Norwegian Customs Service (Customs) are recognized and utilized in Norway's effort to ensure a safe society. In our study, one of the authors investigated a total of 36 official strategic documents both from Customs and other significant organizations that had been generated over a 17-year period (2000 to 2017).

2 WHAT IS A SAFE SOCIETY?

What do we consider to be a safe society? The term safe society is related to the threats and dangers faced by that society. We can define a safe society as follows: *The ability of a society to uphold important social functions and safeguard its citizens' lives, health, and basic needs under different forms of strain* (Engen et.al. 2016:30).

According to Beck (1992), our perception of risk and the development of modern societies are closely connected. Beck argues that globalization and societal development brings new risks and threats that require new ways of thinking to effectively protect ourselves. The author divides modern development into three phases—pre-modern society, modern society and risk society. These phases or stages are essentially connected to the periodization of social change, namely pre-modernity, simple modernity and reflexive modernity.

In Beck's (1992) perspective, modern society is associated with how old and new risks are organized

and how a society develops its social systems, governance, and politics with respect to risk handling. The risk society developed as an outcome of the industrial society. The hallmarks of industrial and modern societies are technological and economic progress and the development of national democratic institutions. In this phase, the state is governed by regulations that guarantee economic growth and the distribution of wealth, risk, safety and security.

However, Beck (1992) also argued that modern societies' continuous production of more goods to an increasingly wealthy population has drawbacks. These include the side effects of chemical, biological, and/or environmental pollution, as well as complex technological developments that increasingly intervene into the social life of individuals, and which lead to new risks and insecurities. The risks associated with technological development and globalization are complex, are not always obvious or easy to detect and can strike arbitrarily. Individuals cannot protect themselves against these risks, in contrast to the risks associated with the industrial society, which are more often aligned with social class. The risk society is more individualized, but is also still an industrial society, due to its involvement in the creation of the technologies leading to the new risks.

Beck (1992) argues further that the transition from a modern society to a risk society can be described as a transition from the distribution of goods to the distribution of risk, which implies that new risks can strike at random and individually, and they can be global and impossible for national institutions to manage. This random aspect can be debated as, for example, climate change is likely to impact third-world countries harder than westernized countries.

An interesting point in Beck's (1992) description of a risk society is the question of how societies can meet the challenges of living in a world with so many uncontrolled risks. Can we fully depend on existing risk analyses and political strategies to effectively address these new risks?

The hallmark of a safe society is its population's trust in the state governance (Engen et. al. 2016). One way states gain this trust is to develop their abilities, to the extent possible, to appropriately regulate risks (Baldwin et. al. 2012).

1.1 *Societal safety and security*

According to Beck (1992), Kaldor (2007) and Giddens (1999), among others, we have moved from a threat perspective, in which state security was the main focus, to a perception in which the threats to the society have become our essential focus. Today, our vulnerability is more dependent on global events and processes, so customs services have become even more relevant as societal protectors.

Engen et al. (2016) argue that the terms risk, security and safety have politically explosive force. Questions concerning national security, sustainable development, accident prevention and human security are examples of this force and give us some clue to the most important aspects characterizing a safe society.

Also central to the concept of a safe society is the term insecurity. Risk, simply defined, is a product of probabilities and consequences that tell something about the future. Insecurity is a more interesting dimension of risk. Insecurity can sometimes be offset by broadened knowledge, but always involves the absence of future insight, which must be compensated for by political assumptions and estimations when making decisions (Engen et. al. 2016).

Threats and vulnerability have different time perspectives; some occur suddenly, some develop slowly, and all require good and flexible planning, regulation and handling (Rosenthal et.al.2001).

What is most important to protect? Some areas have already been mentioned, and critical infrastructure is certainly an important component. In this paper, however, we focus on the public institutions that safeguard the important functions that ensure the proper functioning and safety of societies. These formal organizations, for example, customs services, are fundamental and essential societal arrangements.

Our 'modern threats' challenge these institutions in that they often do not recognize national borders. Examples include international criminal networks, climate change, large migration populations, epidemics and economic/ financial systems, which all increase the vulnerability of our society.

In the struggle to ensure a safe society, Norway has highlighted the need for key resource organisations to identify and cooperate with each other in appropriate ways by implementing contingency preparedness principles that are applicable to public institutions. These principles, including responsibility, proximity, similarity and coordination (also known as risk management principles), underpin the support and regulation of governance in the crisis management practices adopted in ministries, departments and directorates. These kinds of regulations, regulations in general and especially risk regulation are needed to ensure a safe society. Risk regulation is a challenging task in modern societies, termed "risk societies" by Beck (1992), due to the pace of globalization and change.

2 RISK REGULATION IN A CHANGING SOCIETY

To build a safe society, the state establishes risk management practices through regulations, stand-

ardizations and requirements that stipulate the responsibilities of different actors in the marketplace (Lindøe et al. 2015). Risk management is mainly the balance between the ability to realise what is wanted and avoiding what is unwanted. According to Lindøe et al. (2015), the general economic liberalization characterizing the globalized marketplace has led to a focus on effective production and division of labour, as well as the removal of trade barriers and the development of harmonized regulations.

Risk management governance has been on the OECD agenda for some years. Regulation policy has evolved from a focus on negative effects and costs to a positive regulatory approach as an important premise for added value and democratic governance. Many policy documents, guidelines, reform programmes and procedures have been issued to ensure the use of regulation as a positive policy instrument (OECD 2010, OECD 2011). Risk analysis and risk considerations have also become more integrated in matters of common governance and inspections (Lindøe et. al. 2015).

What *is* risk regulation, why do we regulate and what is "good" regulation? These are vital questions for political debate and discussion regarding regulation to better understand the need for risk regulation in a changing society. Selznick (1985) defined regulation as "*a sustained and focused control exercised by a public agency over activities that are valued by a community.*"

Baldwin et al. (2012) described regulation as a specific set of commands involving a social group, such as Health, Safety and Environment (HSE) rules, a deliberate state influence (like revenue) and all forms of social and economic influence, whether they are state-based or have other sources such as the self-regulating marketplace. The latter is addressed by the theory of 'smart regulation,' which states that regulation may be carried out by a host of bodies other than the state. These might include corporations, self-regulators, voluntary organizations or professional or trade bodies.

Regulation represents a multidisciplinary approach whereby political, financial, juridical and social matters are taken into consideration. Regulation discussions are wide-ranging and can be based on assessments or official and political debates related to, e.g., social protection, future planning, the challenge to ensure human rights and the principle of division of powers, or to counter monopolization and ensure the fair allocation of scarce resources (Baldwin et.al. 2012).

A conglomeration of laws, regulations, standards, guidelines, rules and procedures are taken into consideration in discussions of how to regulate areas of interest. "Red-light" and "green-light" concepts are then used, which are based on different regulatory perceptions. The red-light concept is based on the idea of regulation as restricting behaviour and preventing the occurrence of undesirable activities. The green-light concept, in contrast, is based on a broader view of regulation as more enabling or facilitating of desired behaviours or activities.

With respect to risk regulation, there are particular areas of interest related to a safe society. These interests might be, for example, ensuring the provision of product information to citizens, establishing social solidarity (to support a welfare state), maintaining important basic state services, discouraging unwanted or criminal behaviour, and protecting vulnerable interests and citizens from harm or hazards in their work environment and in general.

Engen et al. (2016) argues that regulation is both a controlling mechanism and a judicial body that regulates a special area or field. For example, how should resources, safety and security be addressed in the oil and gas industry? Generally, there will be public interest in good governance and risk control regarding the threats and hazards associated with this industry. Risks that threat public infrastructure, public interests, human or technical security or the environment—both with respect to material and intangible values—as well as crime and terrorist attacks are often subject to risk assessment and regulation, which are in the public interest.

Nevertheless, legislation, regulation, governance and jurisdiction often lead to dilemmas, such as that referred to by Foucault (1999) in his term 'governmentality,' which pertains to how power (the state) establishes itself and constructs 'truth,' which becomes the basis for measures to facilitate regulation and control mechanisms.

According to Baldwin et al. (2012), a number of pitfalls must be avoided to ensure that affected citizens, interests or social groups will accept the given regulation. First, there must be a balance between efficiency and control—the regulator must be sensitive to democratic rights. This again presupposes regulatory legitimacy, which is a premise for success. The premise of legitimacy is that a regulator has the necessary competence and a relationship of trust with the affected group. Experience shows that, to succeed, the processes of implementation must be transparent and fair, as well as efficient and easy to implement.

Baldwin et al. (2010, 2012) argues that there are some well-recognized reasons for regulation, including social protection to ensure social solidarity, human rights to protect weaker citizens, rationing to ensure the allocation of scarce commodities or goods based on the public interest, and the avoidance of moral hazards in sharing costs and benefits.

However, many sectors and industry regulation efforts are based on a combination of rationales and have corresponding strengths and weaknesses related to their design and implementation, including the societal safety and preparedness principles operating in Norway, which we discuss in the following.

3 CUSTOMS' CONTRIBUTION TO A SAFE SOCIETY

Is Customs regarded as an important contributor to ensuring safe societies? Customs in Norway is organized under the Ministry of Finance, is divided into six regions and a directorate, and employs roughly 1,600 people.

Societal safety efforts to ensure public security and civil protection in Norway is based on four principles: responsibility, similarity, proximity and cooperation, as found in the abovementioned contingency preparedness principles applicable to public institutions. The first three principles were established in 2000 by the Norwegian Official Report NOU 2000:24 A vulnerable society. The principle of responsibility implies that an organization normally responsible for a task is also responsible for the necessary emergency preparedness and crisis management in that area. The principle of similarity means that the organization operating during a crisis should be as similar as possible to the regular organization. The principle of proximity states that a crisis should be handled at the lowest possible level.

The principle of cooperation was introduced after the terrorist attacks in 2011, which are referred to as 22 July. It requires authorities and agencies to have independent responsibility to ensure good cooperation with relevant parties in prevention-related issues and crisis management (White Paper: Meld. St. 10 (2016–2017) Risk in a Safe and Secure Society).

As a contributor to societal safety, Norwegian Customs seemed to have been given scope for a greater role following the establishment of the principle of cooperation. Customs' presence along the borders of Sweden, Finland and Russia, and at international airports and along the coast, points to its great potential for becoming a vital contributor to the protection of society.

The goal of this study is to determine the extent to which Customs is actually regarded as a contributor to Norway's societal safety, and if it is so regarded, whether or not this attitude has changed over the past 17 years.

The reason for the rather limited time span is that the term societal safety had not yet been established in Norway prior to this time. The term was officially defined in 2002 (White Paper (St.meld. nr. 17 (2001–2002)), although it had been in unofficial and limited use for a couple of years prior.

Nine of the documents we investigated in this study were strategic official documents from Norwegian Customs, 15 were from the Ministry of Finance, and 12 were strategic official documents related to societal safety published between the years 2000 and 2017. The latter were mainly Official Norwegian Reports, White Papers and draught resolutions to Parliament (Stortinget).

In this study, we examined strategic Norwegian Customs documents published in the past 17 years, since in 2001, Customs began to explicitly claim its role as an important protector of society. Customs has been increasingly conscious of this role in recent years, and its intention seems to have intensified after the Norwegian Tax Administration took over the responsibility of collecting taxes and duties in 2016. In the last document studied (2017), high ambitions are expressed in Custom's statement that it protects society through risk-based, customized and effective control measures.

The strategic documents produced by the Ministry of Finance that we investigated in this study do not explicitly acknowledge the role of Customs as a protector of society until 2016, but then do so emphatically.

The first Norwegian Official Report included in this study is the "NOU 2000:24 "A vulnerable society." Its main focus was to assess societal vulnerability to strengthen Norway's levels of security and preparedness. The role of the Ministry of Finance with respect to societal protection is limited to banking and financial issues, and Customs is not mentioned at all as a relevant contributor.

Only two of the 12 documents related to societal safety clearly recognize Customs as a protector of society. After the terror attack of 22 July 2011, a government-appointed commission authored a Norwegian Official Report (NOU 2012:14 22. juli-kommisjonens rapport) evaluating the incident and proposing answers as to how such a terrorist attack could happen. In that report, Customs is mentioned almost 150 times, and it is evident that prior to the terrorist attacks, Customs had alerted the Norwegian Security Police Service regarding the terrorist's importation of weapon-related products. The terrorist's purchases initially resulted in his being placed on the watch list of the Norwegian Security Police Service, but no further action was taken in response to the information given. The commission states in its report that Customs is an important contributor to societal protection, and it criticized the Norwegian Security Police's poor coordination with Customs.

The second document that acknowledges Customs as a protector of society is the Office of the

Auditor General of Norway, who audited the Customs' border control in 2014 (Document 3:7 (2013–2014).

The most recent document included in this study is the white paper titled: Risk in a Safe and Secure Society (Meld.St.10 (2016–2017). It defines and discusses eight core areas considered to be highly significant for public security, three of which are contagious diseases, hazardous substances and civil–military cooperation. With respect to contagious diseases and dangerous substances, the white paper refers to the national strategy for Chemical, Biological, Radiological, Nuclear, and Explosive (CBRNE) preparedness. It also addresses various kinds of heavy crime, including the financing of terrorism. In all these fields, Customs plays a natural role through its administration and control of the flow of goods over the border.

The white paper clearly states the legal authorities considered to be relevant contributors to a safe and secure society, and Customs is not among them. Despite the fact that Customs obviously protects society from, e.g., CBRNE-goods and the transportation of dangerous goods over the border, the agency is only marginally referenced and is not mentioned at all in relation to societal protection.

The term societal safety has also changed during the years included in this study. After the 22 July terrorist attacks, the concept was broadened, and today it also includes a preventive dimension, i.e., the protection of society. This change affects Customs as it now is aligned with its core responsibility. Through the administration and control of the flow of goods, Customs can contribute to the protection of society. Specifically, it does so by preventing the smuggling of dangerous goods and illegal imports/ exports that can destabilize the economy and/or may be directly hazardous to the population. One could perhaps expect this definition change to naturally move Customs closer to its role as societal protector. However, the results of this study reveal that there has been no change in the way Customs is officially regarded in the documents presented to Parliament in 2000 versus those in 2017.

4 DISCUSSION

Is Customs regarded as a vital contributor to societal safety?

Beck (1992) emphasized that political and public institutions lack the political expertise to handle risks and threats. With this in mind, we might ask why the administrative system in Norway did not follow up on the proposals concerning risk management coordination and cooperation introduced in the "NOU 2000:24 "A vulnerable society", and later in the 2006:6 white paper, and most recently in the 2012 22 of July report. By implementing the societal safety and preparedness principles of responsibility, similarity, proximity and cooperation, Norwegian authorities have made efforts to regulate and meet the requirements of societal protection. Societal protection, as Baldwin et al. (2012) argue, is a well-recognized justification for risk regulation. However, in reality, its implementation, especially with respect to organisational cooperation, has not been an easy task.

The Ministry of Justice is in charge of the overall horizontal governance between ministries and departments for the enforcement of the societal safety and preparedness principles. The review of the public documents in this research project spanning the past 17 years reveals that cooperation between governmental departments is fragmented. This situation might be related to the principle of responsibility, which is strong in Norwegian governance, thereby leading to ministries to leave this responsibility to the Ministry of Justice, and to forsake their own capacities to implement cooperative measures.

With the focus on enabling and facilitating desired behaviour and activity—the intention of the societal safety and preparedness principles—regulating public institutions according to "green-light" concepts is a challenging task. Public institutions are to some extent self-governing and represent complex organizations with many levels and factions.

The National Audit Office (Riksrevisjonen) has noted the difficulties of the Ministry of Justice in accomplishing organisational cooperation (Document 3:8, 2016–2017). This report found the mechanisms for cooperation to be weak or not functioning at all, as presupposed. When rules and regulations are to be enforced by various authorities under different departments, the inevitable result is weaker cooperation mechanisms.

Additionally, the fact that Customs is organized under the Ministry of Finance, whereas the Ministry of Justice has the responsibility for providing risk or societal safety regulations, highlights the fragmentation of the hierarchy in maintaining and enforcing laws and regulations. Vital societal safety actors, such as the Ministry of Justice, seem to lack sufficient knowledge about how Customs enforces numerous regulations related to various authorities. This knowledge gap regarding the opportunity set of Customs might be the main reason for the Ministry's failure to involve Customs in cooperation and coordination efforts to prepare for and manage the risks related to societal safety.

The result of this situation has been fragmentation, and the dilemma regarding the adoption of

centralized or decentralized management has led to something in between, or a vacillation between both. According to Fimreite et.al. (2011), an overall body is missing, one whose main tasks include the effective cooperation, harmonization, and integration of societal safety public authorities in Norway.

The specialization and resources of Customs and their broad control authority do not yet seem to have been taken into consideration with respect to ensuring societal safety. The question is whether the Customs' vague or less visible role as a vital societal safety actor can be regarded as an informal deregulation, which can only lead to increased risk in the form of undesired incidents or accidents that threaten societal safety.

4.1 *Risk management in public institutions*

When vertical cooperation in public institutions does not function optimally, neither do the communication and information processes that are vitally important in effective risk management. Some public institutions have developed a hierarchical steering model incorporating a hierarchical command and control system. In these systems, the horizontal dimension of cooperation and coordination can be challenging.

Risk regulation presupposes that governing units hold a combination of specializations, both vertically and horizontally, which is one reason why the task of ensuring overall cooperation, as led by the Ministry of Justice, is so important. Critics from the National Audit Office (Riksrevisjonen) (Document 3:8, 2016–2017) point especially to the need to strengthen cooperation between actors across sections or sectors during planned exercises and to then follow up. Customs' role in societal safety issues would benefit from better horizontal cooperation and coordination,

Despite the stated ambitions of both the Ministry of Finance and Customs itself regarding the important role played by Customs in societal protection, there remains a dilemma. This dilemma is between the sectorial decentralized responsibilities and follow up regarding societal safety issues on one side and the centralized decision-making authorities and resources on the other. This leads to weak governance and cooperation and, accordingly, the inevitable invisibility of the role of Customs to central decision-making authorities.

This contrasts with Baldwin's (2012) concept emphasizing that, to be efficient and easy, processes of implementation must be transparent and fair. How else to ensure legitimacy, which presupposes that the regulator has the necessary competence and trust of the populace?

4.2 *An appropriate regulation regime?*

If we consider Norway's public institutions such as Customs and other important cooperating authorities, can we conclude that Norway has an effective risk regulation regime?

The societal safety and preparedness principles of responsibility, proximity and similarity are based on an understanding that various specializations are needed in public institutions. The concept behind the cooperation principle is to ensure that the other principles are not developed using a sectorial approach that erects barriers between actors.

In white paper No. 17 (2001–2002), the cooperation responsibility of the Ministry of Justice concerning the preparedness and civil protection of society was underlined.

As Customs is subordinate to the Ministry of Finance and the Ministry of Justice has responsibility for societal safety, it is difficult to readily achieve the necessary horizontal cross-section overview and cooperation necessary for good societal safety governance.

Governance consists of planned and objective-oriented activities coordinated between relevant actors, which presupposes mutual dependence (Engen et. al. 2016). If the vertical coordination (between departments and directorates) is weak and controlling authorities lack knowledge about Customs' enforcement of regulations related to various authorities, the opportunity set for Customs to contribute to safe societies is reduced.

This highlights the importance of the participation of relevant actors in the decision-making process. If the Ministry of Finance does not participate in relevant assemblies in which societal safety issues are discussed and decided upon, there is no avenue for obtaining the support from those in charge of societal safety. The successful outcome of political decision-making processes depends on who participates and the responsibilities or mandates of the actors.

When these actors do not view Customs as an equal participant, the decision-making processes and negotiations concerning the role of Customs as a societal protector cannot be effective. In addition, Customs must be allowed to participate in these processes to demonstrate their societal protection resources and goals.

Since societal safety policy is organized piecemeal across sectors, it has become fragmented due to the spread of responsibilities among many actors. Fimreite et al. (2011) stated that with improved horizontal cooperation between the departments involved, the development of different policies that undermine each other can be avoided. Instead, Norway can make the most of

scarce resources by bringing together various policy interests to initiate combined action and synergy in the field of societal safety.

The Ministry of Finance may not be reaching the necessary political circles to share the goals and resources of Customs, since there is such a clear discrepancy between the Ministries of Finance and Justice regarding the role of Customs in matters of societal safety.

5 CONCLUSIONS

Is Customs recognized as an important contributor to ensuring a safe society in Norway? In this article, we discussed the extent to which the resources held by Customs are known and utilized in this effort to ensure such a safe society.

There will always be dualism in the Customs portfolio, i.e., despite its ambitions to do so, it can never fully control the flow of goods over its borders. Societal safety must be balanced against democratic values and the national obligation to maintain free movement of legal goods, as aligned with what Baldwin et al. (2012) refers to as regulator sensitivity to democratic rights. However, the documents we analysed reveal that, although Customs and the Ministry of Finance are eager to perceive Customs as having a vital role in protecting society, Customs is not sufficiently visible in the national preparedness overview. Our analysis indicates that the intensified focus of Customs itself as well as the Ministry of Finance with respect to its societal safety role has not been recognized by the Ministry of Justice, which is responsible for societal safety and preparedness in Norway. Based on the societal safety and preparedness principles of responsibility, proximity, similarity and cooperative governance, Customs has knowledge of, presence and wide statutory authority along Norway's borders, and can thereby make a vital contributions to ensuring a safe society. However, it seems that Customs has yet to be regarded by the state as an important contributor to safe societies; at least Customs is not *described* as such in the documents analysed. Furthermore, there has been no change in this perspective over the 17-year study period. This represents a paradox in light of Beck's (1992) description of a risk society and the increasing globalization in recent decades.

The results of this study shed light on the potential for better governance with respect to the cooperation principle related to risk management efforts. By focussing more on cooperative governance, Customs' importance as a societal protector in the nation's preparedness regime might become more visible, effective, and valued.

As yet, however, the complexity of the policy frameworks, lack of cooperation between vital actors and the resulting fragmentation of information can only lead to a continued lack of awareness and poor capacity building and training initiatives that are so vital for ensuring Customs' ability to be fully operationalised in ensuring a safe society.

Management of airport security screening system effectiveness

J. Skorupski
Faculty of Transport, Warsaw University of Technology, Warsaw, Poland

P. Uchroński
Upper Silesian Aviation Group, Poland

ABSTRACT: Airports are potential targets for terrorist attacks. High level of risk inclines airport managers to take preventive measures. The decision-making process is difficult, as there have been no methods for the quantitative assessment of changes in security levels as a result of the actions taken. The aim of this study is to develop a method that quantitatively evaluates the effectiveness of security screening, based on various operating parameters of the system, which may become decision variables in the safety management process. The method uses the theory of fuzzy inference for overall assessment of the effectiveness of three key ways to secure air transport: screening of passengers, hand and checked baggage. The method based on multi-criteria group decision making was adopted for validation of the method and the developed calculation tool FASAS. The simulation experiments that were carried out allowed a practical presentation of a method for increasing security levels in medium and long time horizon. The method gives also an answer to the question about the quantitative effects of the decisions made. Application of the fuzzy inference theory enables an effective calculation tool to be developed which is usable in managerial practice.

1 INTRODUCTION

Every air travel is preceded by passenger and baggage screening. Terrorist threats forces the airport management to take measures to ensure security to the passengers and personnel. These involve considerable expenses and pose a serious organizational challenge. Therefore, the security control becomes a significant part of airport budget and affects the functioning of the entire company. At the same time, process management is difficult due to the lack of proper supporting methods. This applies particularly to evaluating the effects of the measures taken in relation to the achievable security levels.

In this study a quantitative method for evaluating the effectiveness of the airport passenger and baggage security screening system is proposed. It is difficult to accurately describe this ill-defined problem, so it often comes down to an intuitive or a 'trial and error' approach. Our approach allows us to formalize the expert knowledge and achieve more objective results, and certainly makes it possible to carry out a comparative analysis.

The method is based on fuzzy logic, more precisely on the fuzzy inference systems. The computer-aided tool FASAS (Fuzzy Airport Security Assessment System) enables practical support of airport management in terms of security control.

1.1 *Managing the system of an airport passenger and baggage security screening*

The security checks of passengers and baggage in airports is regulated by extensive regulatory system (European Commission 2015). However, compliance with the regulatory requirements does not exclude the option of making individual managerial decisions that can significantly affect security, capacity or comfort of passengers. The legislation in force does not give an indication on how to practically organize the airport control system, which includes not only the physical activities visible to the passengers, but also a series of infrastructural, personal and procedural actions, requiring expenses relevant to the scale of passenger traffic.

There are usually several key issues found in the passenger and baggage security screening management.

1. Choosing the number of Security Control Areas (SCA).
2. Having a proper number of staff to perform their duties.
3. Selection of SCA equipment.
4. SCA organization.
5. Dynamic modification of system operating parameters.
6. Operational management of the system.

The airports mostly function as economic agents and attempt to achieve a positive financial result, which in turn is a determinant of the investments planned for airports. However, the managers responsible for planning investments (in security equipment or training, for example) would like to know the measurable effects of such actions. This also applies to the comparison of several alternative investment decisions. The lack of quantitative methods makes it impossible to evaluate their actual effects.

In the literature on airport security management an important issue is the scope of control operations and their effect on an airport capacity (Hainen et al. 2013, Butler & Poole 2002, Leone & Liu 2005, Van Boekhold et al. 2014, Kierzkowski & Kisiel 2015) and the passenger comfort and satisfaction (Alards-Tomalin et al. 2014, Benda 2015, Gkritza et al. 2006, Sakano et al. 2016). Increasing the scope of control operations requires obviously increased expenditures which are not always reasonable (Stewart 2010, Stewart & Mueller 2014 2015, Gerstenfeld & Berger 2011, Gillen & Morrison 2015, Prentice 2015).

1.2 *Concept of the study*

This study assumes the perspective of airport management and, more precisely, the person in charge of passenger and baggage screening, undertaking medium—and long-term upgrade actions. The method developed will meet the proactivity criterion, which means that it will allow planning of actions before security risks are present. We will seek an action strategy that will increase the effectiveness of control without compromising the capacity, assuming that funds to pay for the actions are available.

This study is a finalization of the previous works, in which we proposed methods for evaluation of hand baggage (Skorupski & Uchroński 2015a), checked baggage (Skorupski & Uchroński 2015b) and passenger (Skorupski & Uchroński 2016a) screening systems. All those methods are based on fuzzy inference systems. The objective of this paper is to integrate in hierarchical structure and demonstrate that the calculation tool FASAS created can be used for operational management of an airport security screening system.

The remaining part of the paper is organized as follows. Section 2 gives a brief overview of theoretical grounds and presents an integrated fuzzy inference system which is the result of the study. Section 3 provides an analysis of the passenger and baggage security screening system at Katowice International Airport (ICAO code: EPKT, IATA code: KTW). Section 3.2 analyses several scenarios and determines quantitatively the effectiveness of the control relative to the upgrade actions taken in the medium-time horizon. Section 4 contains the summary and conclusions.

2 FUZZY SETS IN ASSESSING THE EFFECTIVENESS OF SECURITY SCREENING IN AIR TRANSPORT

2.1 *Uncertainty and subjectivity in making decisions in aviation security screening systems*

In technical activities, including transport processes, the information available often tends to be inaccurate and incomplete. If this is the case, decisions are made in uncertainty conditions. There are many types of uncertainty and various mathematical methods and ways to reduce its adverse effects on the decisions being made.

In airport passenger and baggage screening systems, the knowledge of the effectiveness of screening cannot be obtained from measurements. It is necessary to acquire the knowledge from experts in the field. They usually use informal language and their knowledge is expressed inaccurately and in approximation. This is therefore a typical example of acting in linguistic uncertainty conditions. For that reason, fuzzy inference systems based on fuzzy logic were used in this study (Siler & Buckley 2005).

2.2 *General information on fuzzy inference systems*

As a fuzzy set we understand a set in a form

$$A = \left\{ \left(x, \mu_A(x) \right) : x \in X, \mu_A(x) \in [0,1] \right\}$$

where μ_A is a membership function of this set. Every object can belong to a certain degree to a fuzzy set. The element degree of membership in a fuzzy set is determined by the membership function. They can have various shapes as the case may be.

A linguistic variable refers to a variable whose values are words or sentences in a natural or artificial language. Such words or sentences are called the linguistic values of a linguistic variable. In formal terms, a linguistic variable can be defined as the five-tuple (Czogała & Pedrycz 1980):

$$L, T, X, G, M \tag{1}$$

where:
L – linguistic variable name,
T – a set of syntactically correct linguistic variable values L,
X – consideration space of a linguistic variable L,
G – syntactics of a linguistic variable,

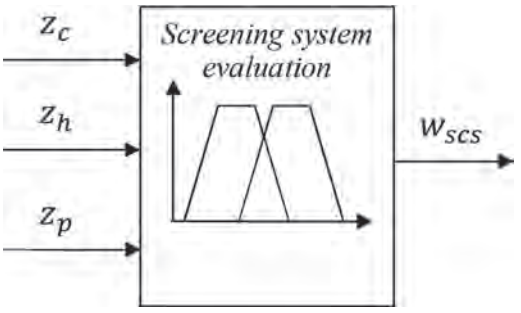

Figure 1. General scheme of the fuzzy model of an airport passenger and baggage screening system.

M – semantics of a linguistic variable, determined by a set of algorithms allowing the assignment of linguistic variable value of certain fuzzy set A.

2.3 *General structure of a fuzzy model Screening system evaluation*

The general structure of the fuzzy model for evaluating the effectiveness of the passenger and baggage screening system is shown in Fig. 1. The input variables of the *Screening system evaluation* model are:

Z_h – effectiveness of hand baggage screening (linguistic variable *Hand baggage*),
Z_c – effectiveness of checked baggage screening (linguistic variable *Checked baggage*),
Z_p – effectiveness of passenger screening (linguistic variable *Passenger screening*). All the input variables are the outputs of other local models. They are presented in detail in the following sections.

2.4 *Input variable hand baggage*

Hand baggage screening has two aspects. The first one of them is scanning luggage with X-rays. The second one is manual inspection carried out by the security screening operator (SSO). Three input variables correspond to those two aspects (Skorupski & Uchroński 2015a). Two of them—*Device evaluation* (y_d) and *Type A Errors* (x_{eA}) – are related to the X-ray scanning of cabin baggage.

The *Device evaluation* linguistic variable makes it possible to express the impact of the technical factor on the possibility of effectively detecting a prohibited article in baggage (Skorupski & Uchroński 2016b). That parameters taken into account are: detectability of different materials, presence and efficiency of Threat Image Projection (TIP), the number of detection lines used, and the age of the device.

The other linguistic variable—*Type A Errors*—describes the actual skills of SSO to use the X-ray device smoothly and efficiently. Type A error consists in failure to indicate the virtual prohibited item interposed on the image of the scanned baggage by the TIP system.

The third variable used in the model is *Manual Inspection* (y_m). It is used to describe the efficiency of manual inspection carried out for some cabin baggage. We assumed that the quality of inspection depends on linguistic variable *Employee Evaluation* (y_p). It is, in turn, dependent on the experience of SSO, the amount of time since the last comprehensive or current training they have undergone, and their overall attitude to work they perform (Skorupski & Uchroński 2015c). On the other hand, the quantity of baggage subjected to manual inspection also has an impact on the efficiency of such screening. We have broken down the concept of manual inspection into two linguistic variables *Number of type B manual inspections* (x_B) and *Number of type C manual inspections* (x_C).

2.5 *Input variable checked baggage*

Evaluation of the effectiveness of checked baggage screening depends on two factors: efficiency of X-ray equipment and efficiency of the checks performed at SCA, particularly with participation of SSOs (Skorupski & Uchroński 2015b). So the local model *Checked baggage* has two input variables—*Device's assessment* (y_d) explained in Section 2.4 and *SCO control* (y_o). The latter depends on the employee evaluation, type A errors (variables *Employee Evaluation* and *Type A Errors*—Section 2.4) and an important variable *Control organisation option* (x_o). This variable describes the checked baggage screening organisation.

2.6 *Input variable passenger screening*

The *Passenger screening* variable (z_p) depends on three input variables: *WTMD's evaluation* $\left(y_{WTMD}\right)$, *Frequency of manual control* $\left(x_{mp}\right)$ and *Manual Control* $\left(y_m\right)$. This fuzzy inference system creates a hierarchical structure as the *WTMD's evaluation* and *Manual control* are outputs of local fuzzy models (Skorupski & Uchroński 2016a).

An evaluation of the effectiveness of Walk-Through Metal Detector (WTMD) in the passenger security control depends on: number of detection areas, ability to set sensitivity in different detection areas, visualisation of the detection areas and the system for the support of manual control.

The input variable *Frequency of manual control* is functionally dependant on two decision variables: *WTMD's sensitivity* $\left(x_s\right)$ and *Frequency of additional controls* $\left(x_{am}\right)$. The former may be set

directly at the WTMD, while the latter is arbitrary based on the applicable, current regulations and the current threat level for the given airport.

The *Manual control* variable is in fact an output of the local fuzzy inference model. The inputs of the model are the linguistic variables: *Employee number* (x_w) and *Employee evaluation* (y_p), which is the output of local inference model with the appropriate inference system (Section 2.4).

2.7 *Output variable screening system evaluation*

A general evaluation of the effectiveness of a security screening system at an airport is described by the linguistic variable *Screening system evaluation*. Its membership function which is the same as the one presented in Fig. 2, is the output value.

A group of experts were asked to define the fuzzy inference rules. They are practitioners with extensive experience in airport security management. The following problem has been brought before them. If we assume that the purpose of the whole security system at the airport is a safe flight (in which there is no explosion, hijacking or an assault on another passenger), which of these three types of screening is the most important to achieve this objective? The knowledge base consists of 125 fuzzy rules. Some of them are presented in Table 1.

2.8 *Validation of the model Screening system evaluation*

To validate the rules of the model and also to remove any inconsistencies the method described in (Skorupski, 2015) was used. It consists in using expert opinions expressed in terms of multiple criteria in the form of both numerical and linguistic assessments. Experts define the conclusions of rules as so-called half-marks in order to increase the method's flexibility. Automatically generated rules are compared to the rules that were provided by experts in order to detect inconsistencies. As a result of using a new concept of half-marks, it is possible to perform not only the verification, but also automatic selection of the final form of a conclusion.

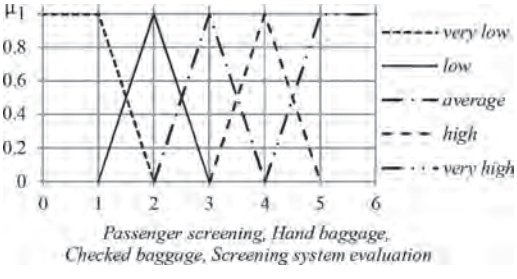

Figure 2. Membership functions of the linguistic variables: Passenger screening, Hand baggage, Checked baggage, Screening system evaluation.

Table 1. Fuzzy inference rules for the model *Screening system*.

Rule	Passenger screening	Hand baggage	Checked baggage	Screening system evaluation
6	Low	Low	Very low	Very low
17	Average	High	Very low	Low
54	Very high	Very low	Average	Average
93	High	High	High	High
120	Very high	High	Very high	Very high

3 EVALUATION OF THE EFFECTIVENESS OF AN AIRPORT PASSENGER AND BAGGAGE SECURITY SCREENING SYSTEM

This section describes the experiments with the use of the method. At first, the reference variant will be examined, and then the variants presenting the benefits of various actions: extending the scope of training, equipment change and organisational activities.

3.1 *Example of a security screening system effectiveness assessment in KTW airport*

This section will present the reference variant that corresponds approximately to the situation in KTW in 2014. The starting point in various airports may differ, however the solutions proposed constitute a kind of a standard that can be assumed as a typical situation. The basic scenario S_0 parameters required are compiled in Table 2.

Simulation analysis carried out for typical values of parameters listed in Table 2, using the FASAS tool, provided the results as given in Table 3.

The final, defuzzified rating value of the entire system is 2.95, which corresponds to the value *medium*. This is in line with the expectations and typical for most airports. Meeting the regulatory requirements and acting in typical threat levels causes the system to be configured so as to achieve the average effectiveness in detection of prohibited items.

3.2 *Analysing the possibilities of influencing the effectiveness of airport security screening*

This section analyses the effects of implementing some measures to improve the security screening effectiveness: shortening training intervals, partial or complete replacement of equipment, greater emphasis on the system condition monitoring.

Table 2. Input parameters of scenario S_0.

Parameter	Passenger screening	Hand baggage screening	Checked baggage screening
Security screening operators			
Experience [mth]	36	36	36
Comprehensive training [mth]	18	18	18
Ongoing training [mth]	2	2	2
Attitude	2 (average)	2 (average)	2 (average)
Type A errors	–	15%	20%
X-ray equipment			
Age [yrs]	–	9	5
Number of TIPs	–	6000	0
TIP frequency	–	2.8%	0
Number of lines	–	1	2
Detectability	–	6	6
Walk-Through Metal Detectors			
Visualisation	20	–	–
Detection areas	20	–	–
Sensitivity [g]	165	–	–
Support	1 (yes)	–	–
Other parameters			
Organisation variant	–	–	4
Number of employees	4	–	–
Additional checks	13%	–	–
Checks B	–	9%	–
Checks C	–	0%	–

Table 3. Evaluation of the passenger and baggage screening system in the scenario S_0.

System	Defuzzified rating	Linguistic rating
Passenger screening	3.16	> *medium*
Hand baggage screening	2.30	*low*/*medium*
Checked baggage screening	2.72	*low*/*medium*
Total	2.95	*medium*

3.2.1 *Greater emphasis on training and staff awareness*

As a standard, comprehensive training is given every 3 years which results in the average time from the last comprehensive training is 18 months. In the simulation experiment described below (scenario S_1) it was assumed that the training intervals were reduced to 6 months, which means that the mean time, and therefore the value of the *Comprehensive training* variable (for all three systems) is 3 months.

Shortening the training intervals has also positive effects on the number of type A errors made by the SSOs. Measurements using the software available in TIP system showed that a comprehensive training results in a decreased number of type A errors on average by 3 percentage points for hand baggage screening operators, and on average 8 percentage points for those screening the checked baggage.

The results of evaluation of the passenger and baggage screening system in the scenario S_1 are given in Table 4.

As can be seen, reducing training cycles do not give satisfactory improvement of an airport security screening system—the grade is 2.98 vs. 2.95 for a standard training system. It is basically understandable, as already for the initial parameters the ratings of staff in all subsystems are at the level *very high* and there is not much room for improvement.

3.2.2 *Equipment change*

Given in Table 2, the specifications of the equipment used at Katowice Airport indicate that it is not very advanced. The evaluation made with the use of FASAS system shows that they vary between *low* and *medium*.

The effects of the decision to replace the X-ray equipment with more advanced devices will be analysed. Let Scenario S_{2a} denote replacing half of the equipment and Scenario S_{2b} denote replacing all equipment.

A part of input data that has been changed in relation to the reference variant is shown in Table 5.

The simulation experiments carried out indicate a noticeable improvement in the assessments of those systems which had been provided with new equipment, and also the overall rating of the entire screening system. The results are listed in Table 6.

As it can be noted, the effect of an upgrade activity is considerable. This is particularly true for the replacement of all equipment. However,

Table 4. Evaluation of the passenger and baggage screening system in the scenario S_1.

System	Defuzzified rating	Linguistic rating
Passenger screening	3.24	>*medium*
Hand baggage screening	2.51	*low*/*medium*
Checked baggage screening	2.72	*low*/*medium*
Total	2.98	*medium*

Table 5. Input data for the equipment upgrade decision (Scenarios S_{2a} and S_{2b}).

Parameter	Passenger screening	Hand baggage screening	Checked baggage screening
Age [yrs]	–	0	0
Number of TIPs	–	6000	1000
TIP frequency	–	2.8%	2.8%
Number of lines	–	4	2
Detectability	–	10	10

Table 6. Evaluation of the passenger and baggage screening system in the scenarios S_{2a} i S_{2b}.

System	Scenario S_{2a}		Scenario S_{2b}	
	Defuzzified rating	Linguistic rating	Defuzzified rating	Linguistic rating
Passenger screening	3.16	>*medium*	3.16	>*medium*
Hand baggage screening	2.9	<*medium*	3.67	*medium*/*high*
Checked baggage screening	3.68	*medium*/*high*	4.0	*high*
Total	3.25	>*medium*	3.75	*medium*/*high*

attention should be drawn to quite a considerable cost of such project.

3.2.3 *Combined activity—equipment replacement and changing the training system*

The results of the experiment discussed in Section 3.2.1 indicate that shortening training intervals for employees working on low standard equipment does not give the desired outcome. Let us discuss Scenario S_3 involving this solution to be implemented as the second stage of the upgrade, after upgrading the equipment. Table 7 presents the experiment results.

In this case, further improvement of grades to *high* is noticeable. It is worth mentioning here that this does not prevent the possibility to improve the effects of security screening system management, as the changes in equipment did not affect the passenger screening system at all. There is further potential for growth in it.

3.2.4 *Emphasis on the diagnostics of personnel status*

While the role of the ongoing diagnostics of a facility condition is very important, when analysing

Table 7. Evaluation of the passenger and baggage screening system in the scenario S_3.

System	Defuzzified rating	Linguistic rating
Passenger screening	3.24	> *medium*
Hand baggage screening	4.0	*high*
Checked baggage screening	4.0	*high*
Total	4.0	*high*

Table 8. Evaluation of the passenger and baggage screening system in the scenario S_4.

System	Defuzzified rating	Linguistic rating
Passenger screening	3.24	> *medium*
Hand baggage screening	3.5	*medium*/*high*
Checked baggage screening	3.5	*medium*/*high*
Total	3.66	*medium*/*high*

reliability of socio-technical systems, it seems that it is slightly underestimated in diagnosing the personnel status.

The task of diagnosing personnel status in a security screening system is performed in many ways. One of them include the use of TIP system. The effects of resignation from using that system were analysed (Scenario S_4). This is practically reasonable in little used passages. Table 8 presents the results of Scenario S_4.

As can be seen, resignation from using TIP system results in lowering the grades to somewhere between *medium* and *high*. The extent of the reduction can be even greater since an SSO who is aware of not being evaluated may work carelessly, and take a very light-hearted approach by investigating minor doubtful issue less carefully or not at all. The above issues will be subject of further studies.

In contrast to the resignation from the TIP system, let us consider the effectiveness of the screening system change if more stringent standards are established, for example that an SSO is to make no more than 10% of type A errors (Scenario S_5).

The simulation experiment proves that imposing so high requirements does not result in further improvement in the effectiveness of the screening system. Reducing the type A error rates to 12% proves to be sufficient to achieve the best assessment of a worker. It is impossible to completely eliminate the errors in recognising images

of prohibited items, and moreover, the parameter discussed is not the only, but still very important, factor describing the quality of screening.

The last scenario (S_6) to be considered is the influence on the alertness (suspicion) of the SSOs in relation to the persons and baggage being checked. In the study (Skorupski & Uchroński 2015a) it is referred to as the B type checks.

Simulation experiment for Scenario S_6 was performed by modifying the input data for the Scenario S_3 in such a manner that we increased the number of B type checks from 9% (as observed and measured in real work conditions at KTW) to 15%.

The results of the experiment for the Scenario S_6 show that this results in an overall effectiveness grade of 4.41, which corresponds to somewhere between the *high* and *very high* rating. The result is so much interesting that it means a relatively high increase achieved by 'soft' actions involving influencing the SSO psychology.

4 SUMMARY AND CONCLUSIONS

In many areas the priority of security is declared as the governing rule. These areas include transport, particularly the air transport. Surprisingly, however, introducing innovations intended to increase security levels is often delayed in those areas and forced mainly by effective legislative procedures and enforcement methods. In our opinion, one of the major causes of that is the lack of tools providing an objective and quantitative assessment of the effects implementation of a given solution.

The method developed, together with the FASAS computer tool enables quantitative assessments of the effects of various managerial decisions on the effectiveness of an airport security screening system. It was discovered that, for the personnel training to bring a positive effect, the equipment needed an upgrade first. Of course, the equipment replacement alone contributes to the improved system effectiveness. A reverse approach proves to be less effective.

An important observation is the importance of personnel diagnostics. While monitoring of technical equipment condition is quite common, the ongoing diagnostics of the human factor is rare. Perhaps, it is because there are no proper methods and tools to do so. An example of such a tool in an airport security screening is the TIP system. It is not always possible to use similar solution in other areas, however, such attempts should be made and the role of diagnostics in management process should be increased.

Further works, including multi-criteria analyses, are required taking into account the overall security and capacity maximisation. In general, activities in average risk situation should focus on increasing security levels without compromising the capacity. Regrettably, for most of the solutions possible, this involves great cost and is time-consuming.

To conclude, simulation experiments indicate the importance of quantitative methods for evaluating the effectiveness of airport security control systems. The lack of such methods makes it difficult to provide reasoning for their implementation. A commonly observed attitude is that if ones activity complies with the standard and regulatory requirements, and possible innovation is expensive, there is not much sense in introducing it. A hypothetical quality improvement in the security level is difficult to prove. However, the quantitative methods, similar to that presented herein, make it possible to compare the results from various possible innovative activities what is critical for sound management.

Information power supporting the rail systems safety

T. Kertis & D. Procházková
Czech Technical University in Prague, Praha, Czech Republic

ABSTRACT: Railway systems are complex systems interconnected with other concurrent or superordinate systems by physical, information, territorial and logical linkages, i.e. they are so-called system of systems. Introduced linkages are the causes of system of systems vulnerabilities, which directly limit the rate of safety of such system. The railway systems are also complex cyber-physical systems, because they use an information system (cyber space) that manages the physical system and they are also influenced by the physical system. The cyber (information) domain is very important because it ensures the semiautomatic and automatic control of system technology during the normal, abnormal and even critical conditions. Therefore, it is very important the care on the information power. The information power is defined as the rate of information effectiveness of systems. The information effectiveness is the key aspect for coping with risks connected with the interconnections in management of complex system, and it is main assumption for protection or ensuring the cyber security of such systems at build up their safety. The present work is focused on the information power, its definition and issues, how to manage and improve the system property. It also provides two examples of selected railway accidents, on which the information power issues are demonstrated. By multicriterial approach application the main criteria for information power size are proposed.

1 INTRODUCTION

Today's society is dependent on the technical and cybernetic systems that help to satisfy its basic needs. The systems, for their proper function, need correct and timely information from a real physical environment. For this purpose, information and communication systems and their technologies are used to create links between systems of different kinds and are able to process information according to the given rules faster than a person.

The stronger the human effort in improvement and streamline of processes towards their higher economic benefit is, the stronger dependency of human society on information technologies is, and therefore, the incessant need for their development arises. By improving and streamlining the processes in the direction to growth of economic benefits, we are introducing the new links, i.e. dependences, and by this we make up more complex systems, which are more vulnerable. This vulnerability leads to their failures in critical conditions, which have in many cases an impact on human security, provision of basic human needs and main functions of states. Therefore, also in the field of information technologies we are talking about critical information infrastructure, which, however, is rightfully interconnected with other technologies. The critical cyber-physical system arises by linking these elements.

To ensure the human security, we need to ensure the secured and, in many cases, the safe cyber-physical system. For formation of appropriate principles for ensuring the secure and safe cyber-physical systems, it is necessary to use the theory of information, and especially to determine parameters, which affect information power. Information power is just the quantity, which size determines the quality of decision; the higher information power is, the higher probability of quality decision is, and vice versa.

Transportation infrastructure and rail systems are not different; they are complex systems of systems and cyber-physical systems are dependent on information technologies, in which it is number of vulnerabilities that can lead to severe traffic accidents. Therefore, the work gives a selected part of theory of information related to the information power. It analyzes two examples of railway accidents and demonstrates the role of information performance on them. The result of work is the proposal of criteria determining the size of information power for different places of railway cyber-physical system.

2 THE INFORMATION TECHNOLOGIES INFLUENCE ON TRAIL SYSTEMS SAFETY

We are influencing the level of railway safety by improving the qualitative parameters, which are transport speed, capacity and the amount of goods and people transported, RAM parameters (Reliability, Availability, Maintainability), Life Cycle Costs, interoperability. In some cases, the qualitative parameters improve the safety, especially when safety is dependent on reliability and availability of performed function. In other cases, the qualitative parameters impair the safety, e.g., the increase of speed and coincident shortening the intervals between trains with a larger number of passengers, lead to higher danger for people.

Railway safety has a long-standing tradition in terms of technology, but there is still site for improvement in terms of human security. The level of safety is always limited by the operating conditions in which the system operates; if the conditions are very different from those for which the system is designed and when certain limits are exceeded, the system gets into a dangerous state, i.e. in state, in which it endangers itself and its surroundings, i.e. the surrounding systems, technology, the environment, economic links, the lives and health of people, and others (Kertis & Prochazkova 2017a, b, c).

Safety of the railway system means to ensure that the rail system is able to work perfectly in wide range of conditions. If range limits are exceeded, the system needs to recognize the change of conditions and to pass to another mode of safety management system, e.g. to apply measures and activities according to security plans, continuity plans, etc. At present, great emphasis is given on the development of well-secured rail systems (ARTEMIS 2014, CEN-CENELEC 2017, EU 2020a,) and therefore, they are focused mainly on safe technological platform, which is very important in terms of safety, but it does not solve complex issues, i.e. human security. Integral safety focusing on human security is still mostly ignored in practice. The size of investment in safety and security is also given by economic aspects (Prochazkova 2013, Kertis 2015, 2016, Kertis & Prochazkova 2016).

Information systems based on information technologies are implemented in all above mentioned areas, i.e. ensuring the quality of railway transportation, security and safety of railway systems. Information technologies interpret, help to manage or, in the case of automated operations, control all of these qualitative and safety parameters. Information systems and technologies are integral part of rail systems. Table 1 shows examples, how information systems are used in different areas of railway transportation. Correctly chosen information system parameters ensure the size of their information power, i.e. quality of information enabling the system to effectively react on possible unacceptable conditions. By this way they improve railway safety, not only at normal conditions, but also at abnormal and especially critical conditions.

Table 1. Examples of information systems used in railway domains.

Management and planning:
– evaluation of data from operation, timetabling,
– breakdown of staff services,
– decision-making, economic, accounting,
– communication with rescue forces and the police.
Management and control of operation:
– central supervision and management, dispatching,
– station and track technologies,
– data collection and processing on the train route,
– communication between stationary and train systems,
– protection devices.
Train operation:
– train control, vehicle control units,
– data transmission among train devices,
– tracking and control of train equipment (door, air conditioning, train radio, power equipment),
– human-machines interfaces (HMI, driver-technologies).
Passenger:
– information light boards,
– passenger check-in systems,
– entertainment systems, Wi-Fi,
– navigation systems—direction signs, for the disabled.

3 INFORMATION SYSTEMS AND TECHNOLOGIES, INFORMATION ORIGINATION PROCESS, INFORMATION POWER AND SECURITY

The theory introduced below is based on knowledge in domains of information systems, cyber-physical systems, complex systems and critical infrastructure (Moos & Malinovsky 2008, Prochazkova 2012, 2015, Novobilsky at. al. 2016, Kertis & Prochazkova 2017b, c).

Information, information systems and technologies include very wide domain that makes up the couplings among the systems. Information is today beside the material, energetic and financial resources ranked to main factors that determine the progress, not only in technology, but also in other domains of human activities. Information flows in systems make up the important linkages

and couplings the elements and whole systems in complex technological facilities. Without certain level of information, it is not possible to make up and to manage the processes of any nature, including the human society. The origin of information is conditioned by monitoring the certain properties of observed object or the common properties of group of objects. Each information system follows the entity properties using the particular language, which serves to creation of information on observed object. Following types of information systems are distinguished according to how the information is interpreted: syntactical information systems, which create the set of information images of state quantities of the object being observed; and process information systems, which represent the set of processes. Then an action information system affects the observed object by feedback, or it creates a model or a real object. In area of railway operation management, the action process information systems are mainly applied, and therefore, our work is focused on them. The process of origin of information, information system, new object or modify object, consists of sub-processes, or sets of links and their relationships, which are described in Table 2.

The qualitative characteristics of information systems and technologies can be influenced by appropriate settings of their parameters, such as: quality of process of producing information images (based on Frege's concept); information amount (equation 1); parameters of transmission matrix (equation 4). These parameters influence the size of information power (equations 5 and 6), and thus also the ability to deliver quick and correct decision of information system (7). Fregge functional concept of information image origination is composed from the sets: O_i is set of rated quantities on the object; P_i is set of states (observers); Φ_i is set of syntactic strings (data flow); I_i is set of information images of state quantities. Relations of the mentioned sets, which determine the quality of the

Table 2. Process of information origin.

No.	Process/set	Affected abstract nodes	Used information technologies	Process inputs	Process outputs
	Object identification	Object, observer	Physical receptors (sensors)	Observed condition (physical) quantities of object	Signals
2	Observation statement	Observer, language (syntax)	Sampling, quantization, coding/encoding	Signals	Data
3	Communication between the source and receiver of message	Language (of observer resp. System of data acquisition), message receiver	Telecommunication, transmission and communication systems	Data	Data
4	Interpretation set, information origination	Language (of observer or system of data acquisition, or receiver), information set (see no. 6)	Ontology, language	Data	Information
5	Relations hips of functions and structural arrangement of object, integrity verification	Information (see no. 6), the object	Actuator of system, action information system	Object, information	Information correctness, change of object
6	Information set in set of information systems	Information systems	Information systems	Information	Information
7	Interpretation process	Information (see no. 6), the new object	Signalizing and representation technology, artificial intelligence	Information	Image of object, new object

information image origination process according to are described by following parameters:

- a_{OP} identification,
- a_{PO} invasity (danger of breaking the integrity of state variables on the object being observed),
- $a_{P\Phi}$ projection in a set of symbols and syntactical strings,
- $a_{\Phi P}$ uncertainty correction and identification,
- $a_{\Phi I}$ interpretation, information origin,
- $a_{I\Phi}$ language constricts reflection,
- a_{IO} relation of functions and structural regularity,
- a_{OI} integrity verification.

The information measure is mostly characterized by Hartley tolerance rate, the information amount for the binary symbols' system (i.e. for the most present cyber-physical systems) it is expressed by equation:

$$I = \frac{1}{\ln(2)} \cdot \ln(N) \tag{1}$$

in which N is the number of possible reports (data):

$$N = S^n \tag{2}$$

where "S" means the number of characters in the alphabet A(A1, A2,…AS) and "n" is the number of elements in the character set.

The process information systems are characterized by graphs assigned to relationships:

$$I_i \approx F\left[P(t), \Phi(t)\right] \tag{3}$$

This assignment enables to perform the structural interpretations of complex information systems, evaluation of feedbacks, and the quality of transmission and information processing in partial information systems, and its information segment goes out from the matrix representation in following form equation:

$$\underbrace{\begin{pmatrix} I_2 \\ \Phi_2 \end{pmatrix} \approx \begin{pmatrix} t_a & t_b \\ t_c & t_d \end{pmatrix} \cdot \begin{pmatrix} I_1 \\ \Phi_1 \end{pmatrix}}_{[T_i]} \tag{4}$$

where T_i is the transmission matrix of i-th information segment (information systems segment). In real system from equation (3) it follows that information or set of information I_i is in relationship with set of system conditions and information flows in time. We can assign the information segment from equation (4) to data acquisition system, where I_1 are input (initial) information, Φ_1 is an input information flow and on output side I_2 are output information and Φ_2 is a transmitted information flow. Parameters $t_{a,b,c,d}$ can be obtained using both, the quantitative and the qualitative ways and in terms of case from they express:

- t_a – interpretation capability (for $t_a < 1$ the system has very small knowledge and interpretation capability, for $t_a = 1$ it has capability of interpretation of object properties in information system, for $t_a > 1$ it goes on the expert system with capability to create own information about the object on the basis of obtained data),
- t_b – filtration capability (for $t_b < 1$ the system on its output interprets lower amount of information than it obtained at its input information flow, for $t_b > 1$ vice versa),
- t_c – communicativeness (capability to provide output information flow on the basis of input information),
- t_d – system information throughput (i.e. the capability to transfer the input information flow to output information flow, in case of redundancy t_d is much higher than 1).

Qualitative parameters of systems of systems (including rail systems), which directly affect human security, such as safety, integrity, reliability, quality, availability, continuity, accuracy are directly dependent on the effectiveness of information systems. Information systems provide the required accuracy and timeliness of information and, in the case of action information systems, also the speed of the right decision. The efficiency level of the information system is expressed by quantity of the information power quantity:

$$P_i(t) = I_i(t) \cdot \Phi_i(t) \tag{5}$$

where Pi(t) is immediate information power (performance). The information power is also equal to the value of eliminated uncertainty quantity E per time unit t:

$$P = I \cdot \Phi = \frac{E}{t} \tag{6}$$

To ensure the safety of railway control systems, it is important to operate information systems, which provide quickly correct decision, which is closely related to information power. The probability of correct solution choice from set of alternatives and the probability of proper decision of control operation system, i.e. PCD (Probability of Proper Decision), are given by function that is dependent on level of knowledge of function "k" and information flow in time "Φ (t)":

$$PCD = F\left[\Phi(t), k\right] \tag{7}$$

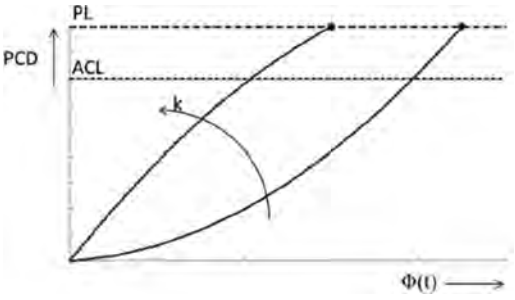

Figure 1. Probability of proper decision in systems control operation (Moos & Malinovsky 2008).

The relationship is depicted in Figure 1, where PL is the PCD maximum, and ACL is acceptable PCD level.

From these facts it follows that control systems, which rely on higher level of knowledge, are able to make quickly correct decision at lower load, i.e. they decide faster.

Each system works correctly only under certain conditions. Therefore, cyber-physical systems need to have: determined certain limits and conditions, which determine their qualitative parameters; and mechanisms, which react to surrounding system conditions. For very different conditions, they need to have plans for transition to other activities, i.e. operation rules for abnormal and critical conditions, which can happen at disaster origin. These issues of information systems are done by processes ensuring the information security, which are based on the protection of important cyber assets in a way that provides the required degree of confidentiality, integrity and availability for important information (CIA).

4 CASE STUDIES, ACCIDENTS COMMON CYBER CAUSES

For illustration of causes of traffic accidents caused by cyber network failures, we give two real cases; the first from the Czech Republic and the other from Spain.

4.1 *Moravany 2008*

On May 19, 2008, the serious railway accident at the rail station was in Moravany at 4h 48m; crash of freight train with passenger train followed by derailment. The accident caused one death, 4 slight injuries and direct financial damage were 12 643 092.- CZK (CR MD 2017).

The accident investigation report states the following direct causes: track circuit contact loss between train No. 5011 and track circuit 1K; reaction of interlocking system ESA 11 on unexpected change of station track No. 1 status of occupation. Next underlying causes: incompatibility of railway vehicles and track circuits as far as sanding (improving the friction between wheel and track) is concerned; internal logic of interlocking system, as far as processing of information about station track occupation received after track circuit reactivation is concerned. In terms of safety management system, the report emphasizes: operation of railway vehicles incompatible with track circuits without adequate safety measures.

This event is not unique; source (CR MD 2017) also states: "On August 29, 2008 at the Hulín railway station the event with the same background took place on an event as the event on May 19, 2008 at the Moravany railway station. After the same defect of same sending device of same railway vehicle of same series, the same procedure of the stationary protection device of the same type occurred at 17 h46 m55 s to change the status indication of the 3rd station track to "free", although it was still occupied by the stationary personal train Os 4256. This event took place without consequences only because of favourable circumstances and immediate proper response of the participating employees.

This event, in terms of common cyber causes (Kertis & Prochazkova 2017a), is combination of two types of causes, namely the false SW and/or inadequate HW: the failure of the sanding device that was still active after switched off by engine driver—insufficient maintenance (HW); use of sand with larger grain size—organizational error (HW); the sanding indication for the driver does not signify the actual state, only the intention—whether an electronic signal is given for sanding—insufficient design (SW/HW); signalling the unoccupied track circuit at the occupied track—insufficient design (HW/SW); automatic route setting to occupied track circuit—insufficient design (SW); absence of a remote train stop system—insufficient design (HW/SW); and insufficiency of communication equipment (freight train driver did not react to the stop call) - insufficient design, organizational error (HW).

The main cause of the accident is the fact that information was distorted due to both, the sanding and the bad response of rail protection system in the station, i.e. it is an error that occurred at interface of cybernetic and physical (cyber-physical) system.

4.2 *Santiago de compostela 2013*

The rail accident in 2013, which was a few kilometres from Santiago de Compostela in Spain, was

the worst rail accident in Spain in the last forty years. On July, 2013 at 20 h41 m, the derailment of high-speed passenger train at 179 km/h velocity originated on the Angrois curve (where the speed limit is 80 km/h). After the derailment, the most of coaches hit the concrete wall along the curve and the rear generator car caught fire. The result was 80 fatalities and 152 injured (almost all the passengers) (EU 2015).

Cause of the accident was the speed of train and the state working professional commission of inquiry ultimately arraigned the engine driver from failure and non-observance of rail regulations. These commission conclusions are not open for public, and they were questioned by the European Rail Agency (ERA). This agency described the root accident causes in its document for EU, i.e. it also revealed the weaknesses in the overall rail control system.

We briefly outline the ERA report conclusions (EU 2015) and we append the comments from our experiences from similar accident investigation (Prochazkova 2017):

1. The accident of the Alvia Class 730 passenger high-speed train 150/151, modification of Class 130; both train ends are equipped by generator car including the diesel tank. *Note:* just spilled diesel has being the main cause of huge fire in railway accidents.
2. Train 150/151 assembles from 13 vehicles: two power cars appended by two generator cars at both ends; eight passenger coaches; and restaurant car. The train weight was 382 tons. *Note:* just the train's parameters have a direct influence on impacts and severity of the accident.
3. The train was equipped by two security systems, the ASFA Digital and the ERTMS/ETCS. Due to problems in reliability and availability of ERTMS configuration in this railroad, the operator (Renfe Operadora) applied to operate under a trackside signal block (BSL) with the protection of ASFA Digital. Note: just incompatibility of multiple systems from different levels of automation cause disruption of safety integrity, and contribute to serious accidents.
4. The followed rail line is equipped with the BSL device, ERTMS/ETCS level 1, with exception of its beginning and end, and with the back-up ASFA Digital. *Note:* just the transition between various control systems leads often to confusion of staff and to human errors.
5. The low speed curve (max. 80 km/h) with design radius of 402 m is located in the end of rail line solely equipped with ASFA Digital. *Note:* at that time this system did not consider the speed limit and allowed to train to pass at with unacceptable speed, which contributes to the derailment.
6. Along the curve, the massive, concrete wall is. Maximal permitted speed is 80 km/h, which is given on table at railway. *Note*: such tables are not clearly visible in the speed and driver's occupancy, which contributed to the accident.
7. The signals and path for the train was set in position that indicated "track clear". ***Note:*** just the gaps in the automatic control system, which allow incorrect indication of freedom or limitations on the track, caused the accidents.
8. The speed change marker before the curve at kilometre point (PK) 84 + 273 did not warning. *Note:* this seemingly malignant fact has been often the cause of traffic accidents.
9. In the engine driver cabin there were several communications systems (e.g. the radiotelephones between trains; the mobile phones (GSM-R)) for corporate communication in train control system; they were in order. *Note:* service calls and communication with dispatching, along with other train control tasks, especially at changes of control systems, lead to heavy workload of engine drivers and contribute to mistakes.
10. The timetable book for driver showed the speed change: i.e. limitation of speed to 80 km/h at PK 84 + 230 (the Angrois curve). *Note:* this is possible driver's mistake due to oversight.
11. According to regulations, in this site the driver needs to start the slow down (form 200 km/h to 80 km/h), namely without technical supports of control. *Note:* this is a possible driver's mistake.
12. In a given case, the train was delayed, ca 2 up 3 minutes. *Note:* such delay often increases the engine driver stress because he/she needs to adhere the timetable.
13. The records showed that the engine driver reacted to service call of train manager ca 6000 meter before curve beginning and the call lasted 100 seconds. *Note:* this is possible cause, why driver did not react to sign dictating the speed reduction.
14. The technical analysis showed that the train brakes were not sufficiently activated for ensuring the required speed reduction. *Note:* it goes on late reaction of engine driver.

The ERA conclusion stated that the formal investigation of the Commission for investigating railway accidents in Spain (CIAF—Comisión de Investigación de Accidentes Ferroviarios) did not consider all facts at accident root causes determination, because it leaned on narrow view on matter, i.e. the driver always needs to respond well, and he / she cannot rely on notice from security systems, i.e. he / she promptly needs to adjust the train speed to required 80 km/h by braking (EU 2015).

The assessment of traffic accident made on the basis of the ERA conclusions and our notes to 14 domains, shows that the combination of number of mistakes have been occurred in this case, especially the rail traffic safety management system complexity contributed to accident.

From the viewpoint of cybernetic causes given in (Kertis & Prochazkova 2017a), it goes on: distortion of monitoring data—according to driver's testimony, it came to his confusion on current position due this fact; and inadequate HW—in dangerous part the security level was reduced owing to the ETCS, level 1 switching off, which leaded to loss remote control of permitted line speed in that section.

4.3 *Common cyber causes*

From the analysis of above-mentioned railway accidents, their common cybernetic causes are clear. They are mainly connected with problems on systems' interfaces, which are designed, implemented and operated by various subjects on the different level of their responsibilities. In goes on: problems at human-machine interfaces; problems at cyber-physical systems interfaces; problems at socio-technical systems interfaces; problems at determination of responsibilities, namely not only between subjects but also between system processes (mutual compatibility); problems at interfaces among systems with different criticalities (levels of automation, levels of security, safety integrity levels).

These problems correspond to the findings of the analysis of common causes of railway accidents in the Czech Republic (Kertis & Prochazkova 2017a), which are in terms of cybernetics: distortion of monitoring data; false software that does not consider all possible variants of operating conditions; insufficiently robust hardware that causes incorrect or slow processing and evaluation of data. In some cases, there were noticed also hackers' attacks on control centre of dispatcher's workplace. The underlying root cause of accidents is insufficient system decision-making validity, i.e. the low information power and low knowledge of information systems, i.e. their low information amount.

5 METHOD OF CONSTRUCTION OF MEASURES IMPROVING RAIL SAFETY

To reach the highest level of safety of rail control system, i.e. also the information power, all stakeholders need to introduce the TQM approaches (Zairi 1991) with taking into consideration of integral risks. The approaches need to be adapted to specific features of rail systems. Therefore, for work with risks, multi-criteria approaches need to be used. Because some criteria for reaching the safety integrity are conflicting, the optimal solution needs to be determined for certain sufficiently wide extent of conditions can be used to respect the limits (Prochazkova 2013, 2015, Kertis 2015).

6 MEASURES IMPROVING RAIL SAFETY

In the present case, we have adjusted the above-described approach for the rail information systems, which are characterized above. According to (Kertis & Prochazkova 2017b), Figures 2 to 4, with a certain degree of abstraction, show a gradual change of system during the implementation

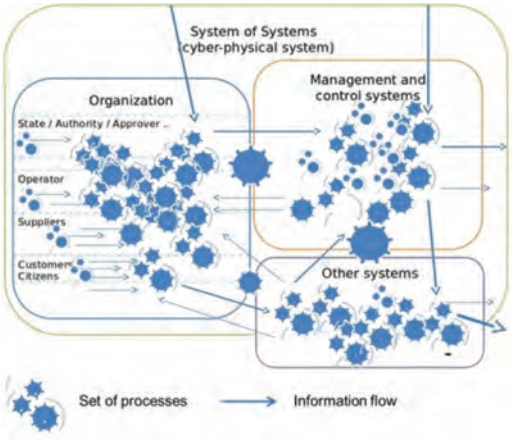

Figure 2. Level of CPS security (Common system of systems).

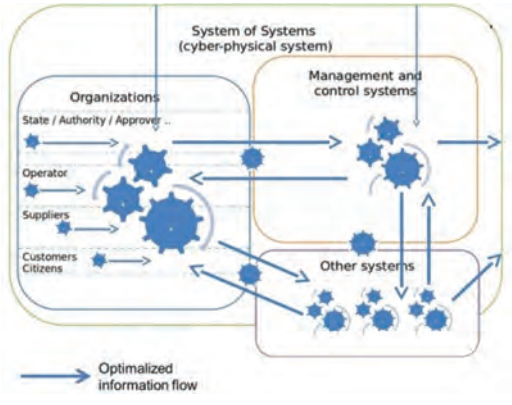

Figure 3. Level of CPS security (an optimized system with higher information power).

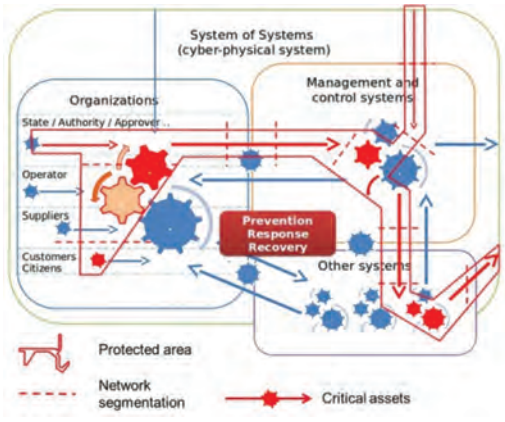

Figure 4. Level of CPS security (the secured system with higher information power).

of various techniques for increase of information power and system security.

Figure 2 shows the open system of systems, in which processes and linkages are implemented to perform defined functions. With consideration of large number of system linkages and interactions of large number of entities involved in the system, under normal conditions, the system performs the required functions, but it is prone to errors, especially in the case of higher operational deviations and imbalances in external system environment.

Figure 3 shows the system of systems with optimized information power that increases the system's durability and maintainability, and by this security. By optimization, i.e. streamlining the flows and improving the information power parameters, it reaches that the system is less prone to internal mistakes in the case of various known deviations in operation and in the surroundings.

For increase of information power and minimizing the resources, which are necessary for these systems formation, a number of methods can be used in practice, e.g.: COBIT for auditing the information systems from the top management point of view (Vitous 2000); ITIL for management of information systems and services, the parts of which are standardized (ISO 2011); refactoring, i.e. changes in software system, which do not influence the external behaviour of information system, but they improve its internal structure (Moos & Malinovsky 2008).

Introducing the management systems (ISO 2015, 2017) with the support of information systems designed using the methods listed above, greatly contributes to improving the information power and transmission matrix parameters according to the formula (4), but only in case if the context of management systems focuses on the rail system as a whole, with a uniform terminology and focus on interfaces of the systems across all stakeholders, i.e. concerned subjects.

Figure 4 shows a well-secure system with optimized information power that we get from the case, shown in Figure 3 by protecting it against significant external and internal influences, i.e. we introduce the preventive and mitigating measures, and prepare reactive measures for case of incidents, as well as also measures for rapid recovery by help verified continuity plans.

In management and governance of railway system and related organizations, the systems and methods according to (ISA 2007, ISO 2009, 20013) are gradually introduced. However, they need to be implemented by all stakeholders and, mainly, the problems associated with system interfaces need to be get over; i.e., it needs to consider the whole information origin process, used information technologies and the quality of their parameters according to Chapter 3.

From this it follows that for safe operation it is very important to deal not only with security of information and technological assets, but also to provide the required information power of the system across all levels and concerned subjects. Parameters of information power are influenced in all sub-processes of information origin process, i.e. the optimization needs to take into consideration each such sub-process and the appropriate information technology listed in Table 2.

Security of such system is then focused on identification and management of important assets. Since, everything cannot be ensured, we need to select critical assets, i.e. critical processes, information flows or other supporting information and physical assets. On the basis of their criticalities, we assess the primary risks and introduce appropriate preventive measures. In case of disaster occurrence (including the cyber-attack), we perform response and recovery according to established policy (Kertis & Prochazkova 2017b, c).

According to the systems of system safety principles, the whole rail system needs to be built according to the Defence-in-Depth approach (Prochazkova 2015) and to introduce different types of safety management to reflect the expected operating conditions of system, and eventually, for severe disasters, to have also way of management that protects also other assets than the assets of system under consideration, in which we monitor physical, organizational and cyber assets.

7 CONCLUSION

Examples of rail accidents presented in the paper point several common cybernetic causes, which

consist in combinations of several errors, mainly in design of safety management system and in its information systems, which should be increased not only the operation economic benefit, but also level of system safety regarding the public assets of European space. With regard to the fact that today's processes of railway management, i.e. the considered safety management and other parts of the railway system (control systems, infrastructure, vehicles and devices) cannot do without information systems, it is very important to find faults also in cyber domain.

Analysis of common cybernetic causes performed on basis of two case studies points to issues connected with systems' interfaces, which are in administration of different subjects, or have different physical nature. On the basis of above mentioned outcomes and knowledge, it is needed to use multi criterial approaches and propose measures for coping with found vulnerabilities, i.e. improving the parameters that heighten the information power and ensuring the information security at critical processes of railway management systems, namely in whole information origin process and at information processing. In the case of application of proposed principles, the work contributes to increasing the railway safety.

Empirical studies of methods for safety and security co-analysis of autonomous boat

Erik Nilsen Torkildson, Jingyue Li & Stig Ole Johnsen
Norwegian University of Science and Technology, Norway

Jon Arne Glomsrud
DNVGL, Norway

ABSTRACT: Many autonomous systems are safety-critical, e.g., autonomous cars, boats, or aerial vehicles. Autonomous systems rely on software and communications. Security vulnerabilities of software and communication will give adversaries possibilities to attack and compromise security and safety. Therefore, when analysing safety, security should be co-analysed. In this study, we explored three safety and security co-analysis methods: Systems-Theoretic Process Analysis (STPA) plus STPA-Security Analysis (STPA-Sec), Failure Mode, Vulnerabilities and Effect Analysis (FMVEA), and Combined Harm Assessment of Safety and Security for Information Systems (CHASSIS). The purpose is to compare applicability, efficiency, and hazards identified by the different methods. An autonomous boat is used as the case study. Results of the study show that STPA plus STPA-Sec and CHASSIS can be more time consuming to use than FMVEA. However, STPA plus STPA-Sec and CHASSIS can help analysers identify more hazards of autonomous systems than FMVEA. Results of the study reveals weaknesses of each method to analyse autonomous systems with different levels of autonomy. We therefore propose possible improvements and combinations of the methods.

1 INTRODUCTION

Autonomous systems like drones, driverless cars, and autonomous boats are being developed. The key mechanism in an autonomous system is its ability to be independent of a human operator. The system manages to sustain situation awareness and decision-making capability, when an expected or unexpected event occurs. By shifting degrees of situation awareness and decision-making responsibilities from humans to the system, we can design autonomous systems with different levels of autonomy. As an example, the Society of Automotive Engineers have described 6 levels of autonomous driving (SAE, 2016) from no automation, driver assistance, partial automation, conditional automation, high automation, to full automation.

Without systematic safety/security analysis and design of autonomous systems, mishaps can happen and harm users and the environment. For example, on 24th July.2015, Fiat Chrysler Automobiles ordered recall of 1.4 million vehicles that was vulnerable to a threat of remote control and hijacking (Guzman, 2015). In 2013, Samy Kamkar demonstrated with the Parrot AR that it was possible to hijack other drones, with what he called SkyJack (Kamkar, 2013). Google self-driving cars had few accidents but was sometimes involved in a rear-end collision with human-driven cars, due to that human drivers did not anticipate actions from the autonomous system (Teoh and Kidd, 2017).

Traditionally, system safety analysis focuses on accidental component failures or software bugs. As industrial and autonomous control systems are increasingly interconnected through networks, system safety can also be compromised by security breaches. "*Although of great importance, it is not sufficient to address accidental threats (hazards) of such systems—also threats of intentional origin need to be covered* (Aven, 2007)." "*Security functions are not meant to cope with physical hazards and failures; likewise, safety functions might not detect and respond to attacks that target the digital components of the system. We infer that safety and security are complementary and should be treated jointly to improve risk management* (Kriaa et al., 2015)."

Several methods have been proposed to combine safety and security analysis of industrial control systems. Some studies have empirically compared different security and safety co-analysis methods using specific systems. For example, FMVEA (Failure Mode, Vulnerabilities and Effect Analysis) and CHASSIS (Combined Harm Assessment of Safety and Security for Information Systems) were compared using an automotive cyber-physical system (Schmittner et al., 2015). The comparison focused

on level of abstraction, comparability of repeated analysis, reusability of analysis artefacts, scope of analysis, suitability for risk rating, and adaptability to changing context. However, we believe that more empirical comparisons of different security and safety co-analysis methods are needed, because many methods are proposed but are not thoroughly evaluated. In addition, few studies have used autonomous systems as cases for evaluation. We have been interested in several methods including the STAMP method (STPA—System-Theoretic Process Analysis) since it has a modern system approach, looking at key control issues.

In this paper, we present an empirical study that compares three security and safety co-analysis methods using an autonomous boat that is under development as the case. The autonomous boat Revolt (www.dnvgl.com/technology-innovation/revolt/index.html) with the present design and sensor fitting is not pure autonomous yet, but a remotely operated dynamically positioned boat. This boat still misses sensors and functions for tracking other objects to be more autonomous. This study is just the first step of analysing safety and security of the autonomous boat. We will follow the development of Revolt and perform re-analysis when new functions are added. Such follow-up analyses will give us insights into different safety and security issues of autonomous systems with different levels of autonomy. Our key focus of our study was to compare *applicability, efficiency, and hazards identified by different methods.* The methods piloted and the sequence of the pilot are 1) FMVEA, 2) STPA plus STPA-Sec, and 3) CHASSIS.

Results of the study show that STPA plus STPA-Sec and CHASSIS are potentially more time consuming than FMVEA. Results also illustrate that different methods have different strengths and weaknesses for identifying different hazards. Based on results of this study, we propose to improve and combine the methods to meet the requirements of security and safety analysis of different autonomous systems.

The rest of this paper is organized as follows. Section 2 defines relevant terminologies. Section 3 introduces the state of the art of security and safety co-analysis, focusing on the three methods we evaluate. Section 4 presents our study design and results. Section 5 discusses evaluation results, and Section 6 concludes.

2 DEFINITIONS

There are many definitions of security and safety. Usually, safety is being used to describe accidental harm, while security is used to describe intentional harm. In (Firesmith, 2003), safety is defined as "*the degree to which accidental harm is prevented, reduced and properly reacted to*", and security is defined as "*the degree to which malicious harm is prevented, reduced and properly reacted to.*" In SEMA reference framework (Pietre-Cambacédès and Chaudet, 2010), safety and security are graphically mapped on a conceptual grid, which has two dimensions. The first dimension distinguishes between accidental and malicious threats. The second dimension differentiates safety and security based on origin and consequences. In the SEMA reference framework, the origin and consequence of safety is system and environment respectively. For security, the origin and consequence could be environment to system, system to environment, and system to system. In (Schmittner et al., 2016), the authors clarified the terminologies to be used for STPA plus STPA-sec analysis as follows. We follow the safety and security related definitions in (Schmittner et al., 2016) in our study.

- *Accident*: Event which causes undesired losses of life, asset damage, data, availability etc.
- *Hazard*: Dangerous system states which can lead to accidents.
- *Threat*: Potential cause of an unwanted incident, which may result in harm to a system and/or environment.
- *Vulnerability*: Weakness of an asset or control that can be exploited by one or more threats.
- *Attack*: Attempt to gain unauthorized access to or make unauthorized use of an asset.

3 STATE OF THE ART

3.1 *Security and safety co-analysis*

Many studies listed in (Kriaa et al., 2015) propose that it is necessary to consolidate the security and safety co-analysis, because security breaches can bring risks to system safety. However, the study (Eames and Moffett, 1999) identifies possible disadvantages of security and safety co-analysis "*We believe that consolidation of safety and security could reduce developers' understanding of the system being analysed, and prevent a thorough analysis of either property*." In addition, the study (Eames & Moffett, 1999) says that "*An additional danger is that a unified approach might actually hide the requirements conflicts that it aims to resolve.*" To address the possible disadvantages, it is critical to closely examine the various kinds of interdependencies between safety and security. Safety–security interactions can be classified into four categories (Pietre-Cambacédès, 2010).

- Conditional dependency: Satisfaction of safety requirements conditions security or vice-versa.

- Mutual reinforcement: Satisfaction of safety requirements or safety measures contributes to security, or vice-versa, thereby enabling resource optimization and cost reduction.
- Antagonism: When considered jointly, safety and security requirements or measures lead to conflicting situations.
- Independency: No interaction.

The security and safety co-analysis methods can generally be classified into three categories (Kriaa et al., 2015). One category is generic approach, such as FMVEA (Schmittner et al., 2014a) and Fault Tree Analysis (Kornecki and Liu, 2013). Another category is model-based graphical methods, such as CHASSIS (Raspotnig et al., 2012) and method using Bayesian Belief Networks (Kornecki et al., 2013). The third category is model-based non-graphic methods, such as STPA (Young and Leveson, 2013) and unified framework (Asare et al., 2013). Autonomous systems are often cyber-physical systems that integrate computation, networking, and physical processes. In addition, autonomous systems need to have proper situation awareness using various sensors, and need to make correct decisions based on the sensor information. Thus, we decided to evaluate one method that is relevant to cyber-physical system in each category mentioned in (Kriaa et al., 2015). We chose FMVEA, CHASSIS, and STPA plus STPA-Sec, because FMVEA and CHASSIS are shown to be applicable to automotive cyber-physical systems (Schmittner et al., 2015), and STPA plus STPA-Sec focuses strongly on software dependent systems.

3.2 *FMVEA*

FMVEA (Schmittner et al., 2014a, Schmittner et al., 2014b) is a FMEA (Failure Mode and Effect Analysis) analysis technique extended with security analysis. FMVEA is based on a three-level Data Flow Diagram (DFD). The first step of the method is to model the system and then to identify failure and threat modes of each component of the system. The failure mode covers the safety aspect, by describing the way the component could potentially fail. The threat mode covers the security aspect, describing the way the component could be potentially misused. The threat modes are based on the STRIDE model, developed by Microsoft (Microsoft, 2002). The STRIDE classification (spoofing/authentication, tampering/integrity, repudiation/non-repudiation, information disclosure/confidentiality, denial of service/availability, elevation of privilege/authorization) enables possible attacks on such components to be found. What is dependent on creating failure and threat modes is knowledge about the system. The potential risks and the effect they could have, are each related to a component (context level).

In addition to identifying vulnerability, threat modes, threat effects, and system effects, FMVEA also tries to quantify the attack probability by estimating system susceptibility and threat properties.

3.3 *CHASSIS*

CHASSIS (Raspotnig et al., 2012) defines a unified process for safety and security assessments. The process includes the use of Misuse Case (MUC) (Sindre and Opdahl, 2005) and Misuse Sequence Diagram (MUSD) (Katta et al., 2010) for visual modelling for security analysis. MUC is also used for safety assessment, but it is combined with Failure Sequence Diagram (FSD) instead of MUSD for detailed failure analysis (Raspotnig and Opdahl, 2012). As shown in Figure 1, there are three stages and 8 steps in CHASSIS. The first stage (steps 1–3) is to draw Use Case and Sequence Diagrams based on some operational and environmental descriptions of the system. In the second stage (steps 4–6), MUC diagrams are created by using a set of hazard and operability study (HAZOP) guidewords (Kletz, 1997) applied for the use cases. The MUC diagrams are then described in textual MUC templates (step 5). FSDs and MUSDs are used to refine the harm scenarios defined in the templates (step 6). When the textual Misuse cases are finished, HAZOP tables are prepared (step 7) and corresponding safety or security requirements are defined (step 8).

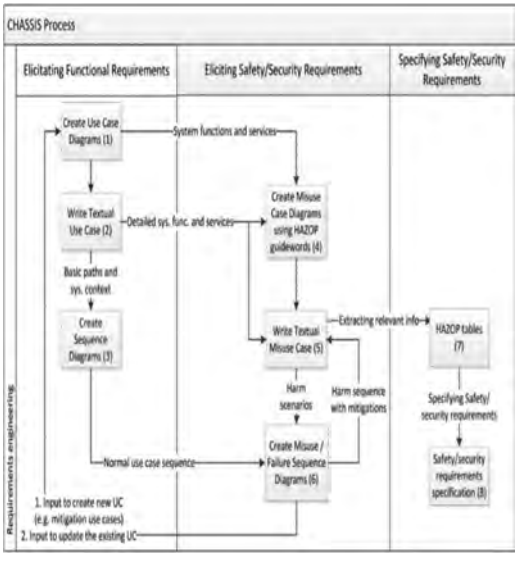

Figure 1. CHASSIS' unified process.

3.4 *STPA and STPA-Sec*

STPA-Sec (Young and Leveson, 2013, Young and Leveson, 2014) extends STPA, which is a safety analysis method (System-Theoretic Process Analysis) (John P., 2013, Leveson, 2012). The extension is to includes security analysis. STPA-Sec "*Shifts the focus of the security analysis away from threats as the proximate cause of losses and focuses instead on the broader system structure that allowed the system to enter a vulnerable system state that the threat exploits to produce the disruption leading to the loss (Young and Leveson, 2013)*."

The main steps of STPA plus STPA-Sec are:

- Identifying what essential services and functions must be protected or what represents an unacceptable loss.
- Identifying system hazards and constraints.
- Drawing the system control structure, physical hardware and network structure, and identifying unsafe control actions.
- Determining the potential causes of the unsafe control actions. The potential causes could be security vulnerability and threats. To facilitate the security analysis, some guide words like tampered feedback, injection of manipulated control algorithm, and intentional congestion of feedback path, are added (Schmittner et al., 2016).

Compared to other security analysis methods, STPA-Sec does not focus on countermeasures that should be taken. STPA-Sec focuses mainly on identifying those scenarios that could lead to losses.

4 STUDY DESIGN AND RESULTS

4.1 *Scope: Autonomous boat*

The autonomous boat Revolt shown in Figure 2 was made by Stadt Towing Tank (STT), on a mission from DNVGL in 2014. The model is a 1:20 scale model of the concept ship. The model ship has a length of 3 meters and weighs 257 kg.

Although Revolt is still under development and is not a fully autonomous boat, we still want to use it as a case since it gives us the opportunity to explore hazard and threats of two main issues i.e. 1) Safety and security of autonomous steering of the ship (i.e. losing control; ship damaged/ destroyed) and 2) security of data-communication between onshore and offshore (sensitive data compromised).

4.2 *Security and safety co-analysis using FMVEA*

The FMVEA analysis focuses on the embedded computer. The attack surface is the highest for

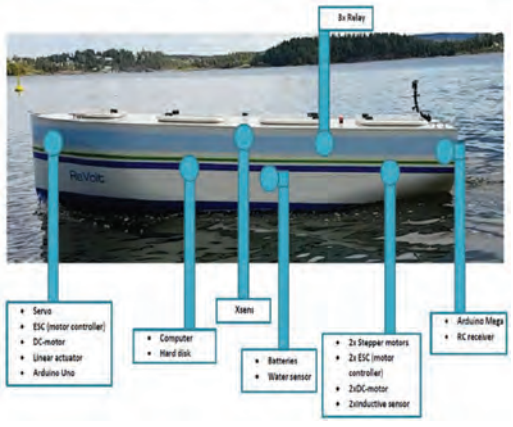

Figure 2. Overview of Revolt and its components.

the embedded computer in the Revolt, since other components in some way are connected to it. Microcontrollers are connected to (and controlled by) the embedded computer via USB. Analogue components (water sensor etc.) are connected to the microcontrollers.

To perform the FMVEA analysis, we fill in the table as proposed in (Schmittner et al., 2014a). The table includes columns for qualitative safety and security analysis, such as component, failure mode, threat mode, failure effect, threat effect, system status, system effect. The table also includes columns, such as severity, system susceptibility, treat properties, attack/failure probabilities, and risks, for quantitative analysis and for ranking the hazards.

4.3 *Security and safety co-analysis using STPA plus STPA-Sec*

When performing STPA plus STPA-Sec analysis, we start with the following unacceptable losses/ accidents and safety constraints.

- Collision with vessels, objects, humans/mammals, structures, grounding
- Fire or explosion
- Foundering (sinking, failing or plunging)
- Loss of cargo
- Loss of mission objectives
- Loss of information

Then, we read the network structure and the control structure documents of the boat to identify unsafe control actions. We follow the systematic method proposed in (John P., 2013) and enumerate full combinations of possible values of process variables and evaluate where control actions can be unsafe if the control action is given, is not given, is given too early or too late, too large or too

small value. The control actions (CAs) we analyse include:

- CA1: Control the position of the vessel
- CA2: Control the speed of the vessel
- CA3: Control the course of the vessel
- CA4: Control the access to the vessels system

After identifying the Unsafe Control Actions (UCA), the last step of the analysis is to identify possible causal factors of the UCA, including possible security breaches that can lead to the UCA. In this last step, STPA-Sec analysis is applied by using the guide words proposed in (Schmittner et al., 2016).

4.4 *Security and safety co-analysis using CHASSIS*

To perform CHASSIS analysis, we first identify use cases and draw use case diagrams. The use case we focus on is "operating and monitoring Revolt remotely through the Revolt Intelligent System (RIS)". Then we make security and safety misuse case through using the HAZOP keywords proposed in (Schmittner et al., 2015). Examples of the safety and security misuse cases are shown in Figure 3.

4.5 *Comparisons of effort spent on co-analysis*

The inputs to the methods are very different. FMVEA analysis focuses on components. STPA plus STPA-Sec analysis focuses on control actions. CHASSIS analysis focuses on use cases. Thus, it is difficult to have direct comparisons of the effort spent on applying the methods. However, by analysing the hours spent on each activity shown Table 1, we can still observe that STPA plus STPA-Sec and CHASSIS can be more time-consuming than FMVEA, because more activities are included and each activity requires more effort.

4.6 *Comparisons of safety hazards identified*

Like comparisons of effort, it is difficult to perform direct comparisons of safety issues identified by using different methods, because the methods have different inputs. However, through comparing safety issues identify by each method, we can observe strengths and weaknesses of each method. FMVEA helps us identify mostly the hazards that are related to single component failure, e.g., communication connection is lost or updates fails. The input of FMVEA does not require as many inputs as the two other methods. It requires only a list of components of the system and how they are connected. This is an advantage. However, it may also be a restriction for early analysis, because early system development might not have a system design.

Compared to FMVEA, STPA plus STPA-Sec method helps us identify more hazards that are related to interactions between different components or actors. STPA is a top down approach that

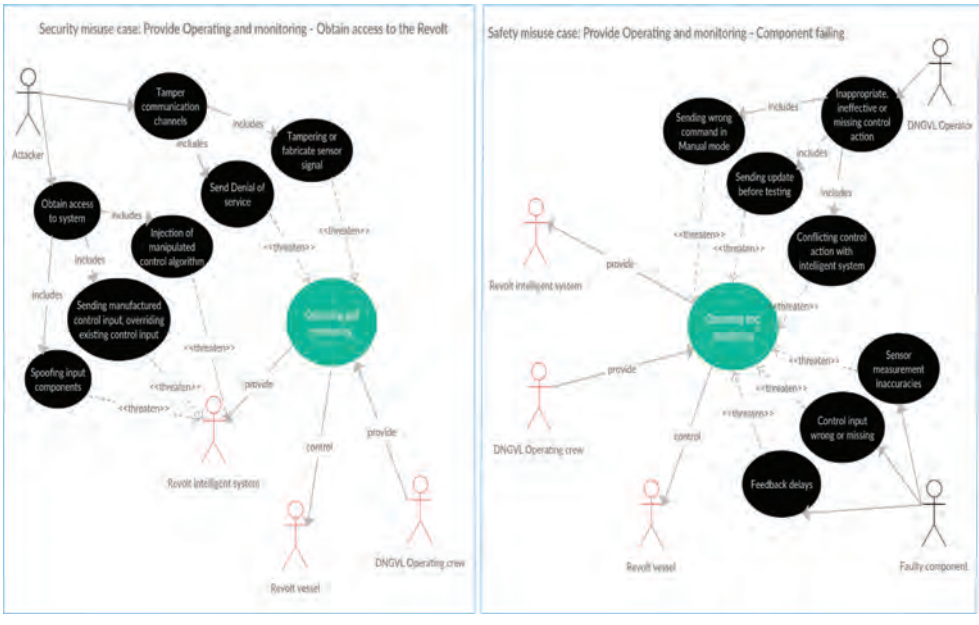

Figure 3. Examples of security and safety misuse cases.

Table 1. Effort spent on each method.

FMVEA		STPA and STPA-Sec		CHASSIS	
Activities	hr.	Activities	hr.	Activities	hr.
System level analysis	5	Define unacceptable losses	7	Elicitation functions and services	4
Selection of component	3	Identify hazards and safety constraints	5	Use case diagram	9
Identify functions of component	10	Create functional control structure	30	Safety misuse case diagram	9
Failure Mode, Vulnerabilities and Effect Analysis	27	Identify hazardous control actions	20	Security misuse case diagram	9
Risk assessment	10	Identify causal factors and scenarios	20	Final misuse case with mitigations	15
		Identify mitigations	23	Misuse Sequence Diagram	8
				Failure Sequence Diagram	8
				Fill in HAZOP table	20,5

looks at the operative picture and identifies unsafe system operation. STPA analysis covers not only the physical system, but also human operators and actors. One hazard example identified by STPA is "setting route for shipment and launch position when the shipping dock has not permitting the action, because other ships are dispatching at the same time". STPA can identify such hazards due to its use of process model variables to identify hazardous control actions, which generates scenarios that otherwise would be omitted. Another advantage of STPA is that it does not assume or need the fully designed observability in the system from the beginning, and this can possibly be achieved through several iterations. We usually find out some UCA based on the preliminary design of the system. When we explore casual factors of UCA, we may find new constraints or requirements for observability and control to handle the identified accident causes, or new need to obtain proof that the accident causes will not practically occur. However, the challenge of STPA plus STPA-Sec analysis (John P., 2013) is that it relies heavily on enumerating process control variables. If many process control variables are present, the analysis can be time consuming.

Compared to FMVEA and STPA, the strength of CHASSIS is that it helps us find hazards that are related to operation sequences. One example hazard identified by using CHASSIS is "the operator performs operations on the Revolt before having done security and safety procedures, and the Revolts components are having feedback delays and commands are executed too late". The weakness of CHASSIS is that it relies more on expert judgement than FMVEA and STPA. As observed in (Schmittner et al., 2015), the possible risk could be that "*if a CHASSIS analysis is repeated by a new group, due to the differences in the experts, new viewpoints can be introduced that change the results*." A restriction of CHASSIS we identify is that its starting point is the use case. If the use case is too broad, steps that follows in the process might be difficulty to perform.

4.7 *Comparisons of security issues identified*

FMVEA security analysis uses STRIDE classification. The identified security threats are limited to threat targeted at single component, e.g., wireless connection is targeted to jamming. When using FMVEA, the safety and security analysis can be done independently. Thus, safety–security interactions may be overlooked.

CHASSIS identifies threats and vulnerability using misuse cases. The hazards identified by CHASSIS are mostly related to operation and use of the system, e.g., the communication system might have vulnerabilities that could lead to modification of system files. By integrating security misuse cases and safety misuse cases, it is possible to analyse safety–security interactions. However, like the safety analysis, the possible weakness of CHASSIS is that it relies heavily on expert knowledge. Thus, the analysis results may not be replicable.

The security analysis of STPA-Sec focuses on identifying security vulnerabilities that may lead to unsafe control actions. For example, providing CA2 (control the speed of the vessel) too late from shore to the boat when the WIFI connection is jammed. Comparing to FMVEA, the strength of STPA plus STPA-Sec is that it focuses more on

safety–security interactions. However, the limitation of the STPA-Sec is that the security analysis focuses mainly on vulnerability that can be the casual factors for safety hazards. The security vulnerabilities, which may lead to information leakage or privacy issues, but will not lead to safety hazards, may be overlooked. The study (Schmittner et al., 2016) proposes to enhance STPA-Sec with more focus on losses related to confidentiality. In our study, we list "loss of information" as an accident and find out some threats that can lead to this loss. However, STPA plus STPA-Sec method use enumeration of process control variables to identify possible information loss. If certain security vulnerabilities, e.g. improper encryption of stored data, are not reflected directly in existing process control variables, the vulnerabilities may not be identified in the analysis. Thus, we believe that integrating STPA-Sec with more security oriented analysis methods, e.g., misuse cases or threat modelling, can be beneficial.

5 DISCUSSIONS

5.1 *Comparison with related studies*

The study (Schmittner et al., 2015) compared FMVEA and CHASSIS. Our study included STPA and STPA-Sec in the comparison.

- Level of abstraction: CHASSIS is a quite high-level approach. It can be applied in early requirement and concept phase, when a system is not clearly defined and little information is known. In contrast, FMVEA needs at least a list of system elements and connections between the elements to generate meaningful results (Schmittner et al., 2015). STPA plus STPA-Sec requires information of the hardware, the network nodes, the network input/output lists to identify process control variables and unsafe control actions.
- Replicable analysis results: CHASSIS depends more on expert knowledge. In contrast, FMVEA and STPA will more likely provide comparable results, even if the analysis is performed by different persons.
- Reusability of analysis artefacts: All three methods use guidewords. FMVEA uses failure modes and STRIDE classification. STPA plus STPA-Sec uses guide words proposed in (Schmittner et al., 2016). CHASSIS uses HAZOP keywords. In all three methods, the quality and completeness of the keywords will strongly influence the quality of the analysis.
- Scope of analysis: FMVEA and STPA plus STPA-Sec depend to a higher degree on the accuracy of the system model and control structure. For CHASSIS, "*it is possible to expand the consideration of risk scenarios which do not arise directly from the system model* (Schmittner et al., 2015)."
- Suitability for a risk rating: FMVEA targets at rating the risks. STPA plus STPA-Sec and CHASSIS focus mostly on generating a list of possible safety and security issues rather than rating them. A possible combination of the method is to perform STPA plus STPA-sec or CHASSIS analysis to identify hazards and then use FMVEA for quantitative comparisons of certain hazards.
- Adaptability to changing context: It is easier for CHASSIS to consider different usage scenarios and changing environment than FMVEA, because CHASSIS is less formal and focuses on high level analysis. STPA plus STPA-Sec and FEMVA analyses results need to be updated when the system design changes.

5.2 *Applicability of the methods for analysing autonomous systems*

Autonomous systems have different levels of autonomy. Based on our observations of strengths and weakness of the three methods, we propose applying different methods for analysing systems with different levels of autonomy.

- For systems with high automation, STPA plus STPA-Sec may be more applicable than FMVEA to analyse interactions between systems, and interactions between systems and environment.
- For systems with many sensors, STPA plus STPA-Sec may be more applicable than CHASSIS. CHASSIS focuses on sequential messages. In contrast, STPA deals with fusions of sensor messages that come at the same time better. However, STPA plus STPA-Sec also needs to be improved. The current STPA proposed in (John P., 2013) is limited to analyse single control action. For many cyber-physical systems and autonomous systems like autonomous boat, some control actions are mutually dependent and might be issued in pairs. For example, in emergency cases, the boat needs to change course and slow down at the same time to avoid collision. Our solution for analysis mutually dependent control actions is to add the control action as a process control variable of another control action, if another control action has dependency with it. For example, in the table to analyse control action CA3 (i.e. control the course), the CA2 (i.e. Control the speed) is added as process control variables with values "speed up" and "slow down".
- For autonomous system with high level intelligence and learning capability, none of the three methods will be sufficient. AI will make it harder to review the system due to its increasing "black

box" and "black code" nature and its learning capability. For those systems, STPA plus STPA-sec or CHASSIS analysis may outperform FMVEA, because the operational level is the same regardless of system implementation. STPA and CHASSIS are good at analysing the operational safety with the system interaction. For autonomous systems with learning capability, however, it is necessary to have continuous verification along with the learning.

5.3 *Limitations of the study*

One main limitation of this study is that the safety and security hazards identified by this study may not be complete. It is because the completeness relies much on the domain knowledge and the guide words. However, the purpose of the study is to compare the three methods rather than to identify all hazards of the system. We believe that, even if other researchers identify slightly more security and safety hazards than us or identify different hazards from Revolt, our observations of the main differences of the three methods are still valid.

6 CONCLUSIONS AND FUTURE WORK

Many security and safety co-analysis methods have been proposed from academia and industry. However, few empirical studies have been performed to compare and evaluate the methods. In this study, we have evaluated three methods using an autonomous boat, called Revolt, as a case study. Results of the study show advantages and disadvantages of each method. Our future study is to extend and strengthen existing methods to analyse safety and security issues of intelligent and complex control actions of autonomous systems. In addition, we need to check the validity of the method, based on observing performance and incidents of the Revolt system.

ABSTRACT: This contribution is intended to observe special features presented in physical assets for defence. Particularly, the management of defence assets has to consider not only the reliability, availability, maintainability and other factors frequently used in asset management. On the contrary, such systems should also take into account their adaptation to changing operating environments as well as their capability to changes on the technological context. This study approaches to the current real situation where, due to the diversity of conflicts in our international context, the same type of defence systems must be able to provide services under different boundary conditions in different areas of the globe. At the same time, new concepts from the Industry 4.0 provide quick changes that should be considered along the life cycle of a defence asset. As a finding or consequence, these variations in operating conditions and in technology may accelerate asset degradation by modifying its reliability, its up-to-date status and, in general terms, its end-of-life estimation, depending of course on a diversity of factors. This accelerated deterioration of the asset is often known as "obsolescence" and its implications are often evaluated (when possible), in terms of costs from different natures. The originality of this contribution is the introduction of a discussion on how a proper analysis may help to reduce errors and mistakes in the decision-making process regarding the suitability or not of repairing, replacing, or modernizing the asset or system under study. In other words, the obsolescence analysis, from a reliability and technological point of view, could be used to determine the conservation or not of a specific asset fleet, in order to understand the effects of operational and technology factors variation over the functionality and life cycle cost of physical assets for defence.

1 INTRODUCTION

Throughout history, technological advances have always been applied in armed conflicts to allow certain superiority against the enemy. Such conflicts have served in many cases as fields of experimentation to validate progress that, subsequently, have had their application in the civilian world and vice versa. Identically, today's conflicts apply technology, where the digital transformation becomes more and more present. In fact, there is a historical constant where the same means used to create wealth, are those used for warfare, and vice versa [1]. I.e., there are dual-use technologies, so that the developments and commercial innovations take advantage to the military sector and vice versa. To this fact, it must be added that enemies can also have these high-tech devices easily.

Many functions from gadgets that emerged before, keep its purpose now, adapting them to the new circumstances, both operational and technological. In the case for example of an armoured vehicle, the basic characteristics that emerged during the First World War (protection, mobility and

firepower), are the same that are expected currently, though, with the own technological advances of today. These basic functions are seen nowadays in continuous development and improvement according to the new technologies that are emerging to meet specific operational needs. To such functions it is added now a fundamental property as the reliability of the systems themselves, as well as other concepts such as availability, maintainability and safety. This contribution deals with these technical characteristics from the standpoint of a military asset, introducing terms such as obsolescence and useful life of these systems, and also relating the effect on these assets and their characteristics of new technological tools included under the concept of industry 4.0.

2 CONCEPTS OF ASSET MANAGEMENT AND ITS ADAPTATION TO THE CASE OF DEFENSE

2.1 *RAMS parameters of an asset and its life cycle cost*

Reliability, availability and maintainability are parameters used in assets management whose analysis is usually known by the acronym in English of RAM. Frequently, it is added the S of security and/or safety, although some authors referenced it as sustainability, and hence the acronym results as "RAMS analysis".

- Reliability: capacity of the system not to fail, i.e., the probability that the system complies with what is expected of it
- Availability: proportion of time that the asset is useful to be used (in principle, it does not have to be operational, although it can be considered also an operational availability of the asset)
- Maintainability: ease of the asset to keep its normal operation, i.e. it would be inversely proportional effort in maintenance activities
- Safety/security: features set of measures that are taken to avoid and prevent accidents, or protect from illegal activities

Apart from the a. m. concepts, stricter definitions can be found in the references [2], [3] or [4]. These terms are closely linked to the concept of useful life, which is associated with the time during which the system continues fulfilling its functions [5]. Over the useful life of an asset, it must maintain and keep its value. Each of the stages of the life cycle of an asset will have some associated costs being finally life cycle cost the sum of all these costs. In other words, a life cycle cost analysis must take into account: costs initial acquisition of the physical asset (covering the costs of development and investment); operational costs; maintenance costs (planned, corrective as well as overhauls); and the costs associated with the divestiture of assets or dismantle the installation. If the asset is still used beyond than expected, this latter term, instead of a cost may be considered a Residual value (if for example is sold to a third party). All of the above are often treated from the standpoint of an industrial physical asset, which tend to have a certain operating profiles, to a greater or lesser extent, under controlled environments.

From the perspective of a military asset, they will find themselves under the paradigm of having to deploy to different environments, with changing mission profiles and where logistics is critical to maintain its performance. I.e. when a machine is acquired for a production process, this process can be more or less predictable or stable, while in the case of an asset for defence, it should be added the uncertainty of mission (surveillance, defence, humanitarian support… and other profiles), the conditions of operation that will be used (deserts, icy areas, forest, urban locations...), and of course technological change. Consequently, the estimation of lifespan for an industrial asset does not have to coincide in a military system. This end of life of an asset is known as obsolescence, which can slow down if redesigns and updates throughout the life of the asset are considered.

2.2 *Obsolescence and modernization of an asset*

The term "obsolescence" was used for the first time in relation to basic products [6], [7]. However, it has been employed in the industrial environment [8], [9], relating to functional factors (changes in use), economic (cost of continuing to use it, regard the cost of replacing it with an alternative), technological) efficiency of technology assets, in comparison with the new alternatives available), or social (trends of users, changes in legislation or regulations of health and safety...) [10], [11]. These asset shifts changed its durability and obsolescence [12]. Therefore, there are tangible factors, such as the functional and economic factors more related to the depreciation of the assets, and intangible factors such as technological and social, more subjective or prospects-related to the market [13].

Accordingly, maintenance activities are linked to the functional and economical obsolescence, preserving the value of the asset in a physical sense and combating the economic depreciation of own assets. In this sense, there is a time-dependent relationship between the obsolescence and the analysis based on reliability according to functional and economic factors [14] (life cycle costs). In other words, maintenance should be assessed by comparing the assets value regarding the cost involved

in repair or replacement. In this analysis, it may be the case that the decision to repair the asset results in disproportionate expense to preserve the value of the investment [15]. On the other hand, the modernization activities will be more closely linked to combat social and technological obsolescence.

In both cases, an improvement in maintenance and/or the possibilities of a modernization has to go exclusively through direct changes on the asset itself. It can be also related to assure the execution of tasks, training, spare parts and tools distribution, logistics required for the coordination of all aspects etc... allowing the system to be available and in operation as long as possible, maintaining and implementing its performance during its lifetime. I.e. new technologies not only can and must influence improvements on own assets, but also on the integrated logistics support provided to it.

3 INNOVATION IN MILITARY ASSETS

As seen in the previous section, with a view to slowing down the obsolescence of a military asset, it can be considered incorporating modernizations (on the assets and/or on its logistical support) taking advantage of the new technologies that now are at our disposal. It is important to emphasize that these advantages are not only applicable to the own assets, but they can facilitate and improve all those activities that surround system and needs that are essential to keep it in "life". With that intention, it is relevant to deal with the industry 4.0 concept, providing a panoramic view of possible applications in the military assets, focusing on the possibilities in terms of logistic support integrated with a view to improving precisely the reliability, availability, maintainability and safety of assets for the defence.

3.1 *Evolution to the "4.0"*

The origin of the term industry 4.0 refers to the fourth Industrial Revolution, understanding that the first arose when machine steam at the end of the XVIII century, the second when we implemented the use of electricity and manufacture in series in the last third of XIX century, and the third Industrial Revolution to that when automate factories began already in the s. XX century. Today, the fourth Industrial Revolution has to do with the digital transformation applied to the industry in the search for connectivity and operational excellence. It was named for the first time in a study conducted in Germany in 2011: "Smart Manufacturing for the Future", Germany Trade and Invest [16]. Associated with the term industry 4.0 are usually define 9 technologies such as the ones shown in the following table (Table 1).

Apart from these nine technologies, sometimes are added some others such as vehicles or autonomous or unmanned aircraft (drones), new materials (Graphene), artificial intelligence, digital platforms... having their place in the nine

Table 1. Technologies associated with the industry 4.0 concept.

Technology	Description
Robotics and computer vision	• Cooperative and autonomous robots. • Numerous integrated sensors and interfaces standardized.
Additive manufacturing and 3D scanner	• 3D printing, especially for prototypes and spare parts. • Decentralized 3D installations to reduce inventory and transportation distances. • Flexibility of forms, quickly not to use tools, cost savings
Augmented and virtual reality	• Augmented reality for maintenance, logistics and all kinds of operational procedures. • Supporting information display, for example, through smart glasses.
Simulation and modelling	• Simulation of value networks (flows). • Optimization based on data in real time from intelligent systems.
Horizontal and vertical integration	• Integration of data between companies based on standards of data transfer. • Precondition for a fully automated value chain (the company customer, the plant management)
Industrial Internet (IoT. Internet of things)	• Network of products and machines. • Multi-directional communication among objects in the network. • Cyber-physical Systems
Cloud computing	• Management of huge volumes of data in open systems. • Communication in real time for production systems.
Cybersecurity	• Operation in networks and open systems. • High level of networking between machines, products and intelligent systems.
Big data and data analysis	• Complete evaluation of the available data (for example, ERP, SCM, CRM, and data of machine). • Support and optimization in real time for decision-making

mentioned categories. All previous technologies have applications without a doubt in the military sphere. In this sense, one of the first objectives of digitization can be precisely:

- To support the concept of life cycle of military assets.
- Determine the needs of services and infrastructures in the evolution of the means for the defence.
- Study the incorporation of management software mass of data that allow the use of artificial intelligence methods.
- Evaluate trends.
- Get lessons learned.
- Control and manage the asset lifecycle and engineering.

In general, the inclusion of the concept of logistics support 4.0.

I.e. apart from the operational improvements that may benefit the assets themselves, first advantage is that assets management can be improved for the defence in maintenance (corrective action and scheduled inspections), in the management of spare parts and material (supply of spares, tools and consumables in time and place), in the adaptation of systems to operational requirements, control of assets configuration (design modifications) and, in general terms, the determination, evaluation and improvement of support along the life cycle through the support updating capabilities of the army.

3.2 *Technological trend of Defence 4.0*

The first half of the XXI century is characterized as a period of great political, social and ecological changes (translation of the geopolitical focusses, increase of the world population, consumption of large amounts of resources, effects on the biosphere...). All this happens in a highly globalized world and parallel to the highest scientific and technological transformation of history [17]. This context implies complex scenarios with increased uncertainty where the effect of technology cannot be ignored. Recent times correspond to the most technologically advanced in the history of mankind, driven by the digital revolution, but also by biology and nanotechnology [1]. In the digital realm, a growing convergence of cyber, physical and biological domains appear with more complex and higher value-added products and services. Therefore, at conventional operating environment: land, sea and air; it must be added now the virtual or cyber space (Figure 1).

In general terms, it is found an increasingly globalized combat environment more connected and with greater presence of digitized and automated means that (making a comparison with the industry) could be called "Defence 4.0". All this obliges the armies to a better adaptation to the changes because there are factors that radically transform the character of the war fighting. The Defence sector must therefore nourish of the digital revolution in aspects such as connectivity in real time (internet of things, "low cost" sensing), the collaborative robotic (drones, autonomous vehicles, 3D printing, exoskeletons), the Automation (augmented and virtual reality, artificial intelligence, Big Data, processing in the cloud...).

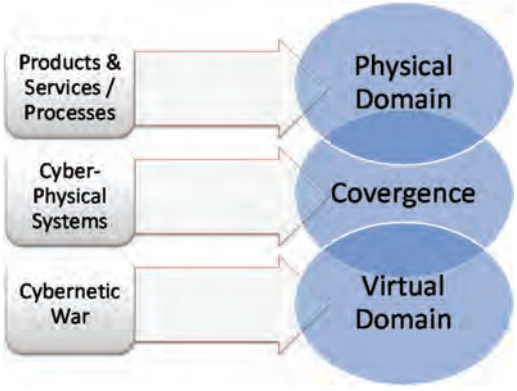

Figure 1. New operational environments.

The application of these technologies must take into account the platform on which it is incorporated (aircraft, vehicles, weapons, general equipment systems...), means for implementation (software, hardware...), as well as logistics and tactical elements (equipment of support, training and simulation systems, digital stands for technical documentation, mission planning systems...) [18].

4 CONCLUSIONS

Today, advances in technology and changes in operation environments oblige the designs of assets for the defence to be flexible and to evolve with the life of the system. In other words, the conservation of a fleet of military assets updated and the fulfilment of operational demands require redesigns and upgrades throughout the life of the items, as well as to streamline everything related to their logistical support. In order to emphasize those scientific issues addressed along this paper, it is relevant to explore the current willingness of industries, together with universities and research centers to collaborate and constitute a kind of community of interest in the area of maintenance [19], logistics support [20] and, in general terms, the integration of technological solutions [21], in

order to overcome the problem of obsolescence in the defense sector.

As it has been observed throughout this document, the application of technologies associated with the industry 4.0 concept, is without doubt a great help to increase the usefulness and efficiency of assets, improving both its operation and maintenance. For example, large data collection allows scheduled maintenance according to the different mission profiles, reducing costs by preventing unnecessary actions, and tasks etc. All intended to a result where it is increasing easiness, flexibility and immediacy of the spare parts, an improvement of maintenance policies, customizing them, as well as other aspects which, in summary, affect the parameters of assets reliability, availability, maintainability and safety.

As future lines of action and research, it is suggested the development of unified and simplified protocols for analysis and work processes. Depending on the case, it will be desirable to observe the applicability of methods of artificial intelligence (Machine Learning, Deep Learning), framed initially (for simplicity) in the concept of Integrated Logistic Support 4.0 for the establishment of decision-making processes, flow data and organizational structure that can certainly be implemented in the own assets ILS. As an academic added value, this paper stands aligned with the principles established by the current international defense sector, in the search for greater logistic efficiency [22] through an interconnected system among the members (Armies, Governmental Organizations and Companies from the allied countries), where innovation is encouraged and promoted [1], [16]. Finally, note that having operational armed forces requires today an advanced and competitive technological and industrial manufacturing. It should be a priority strategic objective for the industrialization and modernization of the defence sector.

Security risk and vulnerability analysis in military operational planning: The why's and how's

S. Malerud & H. Fridheim
Norwegian Defence Research Establishment (FFI), Kjeller, Norway

ABSTRACT: A military operational plan helps prepare the armed forces for future security challenges. Planning necessitates making assumptions about the future, and these assumptions constitute operational risks; possible negative operational effects in case the assumptions fail. Hence, a thorough risk analysis should be part of the operational planning process. In this paper, we propose a method for analysing operational risks and vulnerabilities in support of operational planning. In particular, we focus on risks related to assumptions about availability of critical capabilities. Using a bow-tie model where the undesired event is a capability gap, we explore likely causes and consequences by combining gaps with identified vulnerabilities. The outcome of the analysis is an overview of operational risks. The method is applied on an example within a fictive planning scenario. While developed primarily for military planning, the method is also relevant for security risk analysis in the civilian domain.

1 INTRODUCTION

A military operational plan is developed to prepare the armed forces for future security challenges. The future is inherently uncertain; hence, we should aspire to develop plans that are robust and adaptable both in the short-term and long-term perspective. This also necessitates making planning assumptions that are assertions about the future that underlies the plan (Dewar et al. 1993). Uncertainty and pertaining assumptions entail operational risks, which can be expressed as the combination of the probability that something goes wrong and the related operational consequences; negative effects on the operational effectiveness.

In order to facilitate development of relevant plans, we need to balance their desired properties, such as robustness, adaptability and flexibility, with the planning assumptions. This could be assumptions about the future threat environment and the availability of critical capabilities and resources to handle different situations. These assumptions are vulnerable to future changes, and thus, should be monitored and followed-up in order to ensure relevant plans.

Most military plans are developed following the Operational Planning Process (OPP) described in the Comprehensive Operations Planning Directive (COPD) (NATO 2013). COPD focuses on what to do, i.e. which planning products to produce, but not so much on how to do it. The COPD planning process results in comprehensive plans that include planning assumptions and risk assessments. However, the process usually stops short of identifying adequate indicators which can help determine when assumptions are violated or failed, i.e. when it is time to revise the plans.

There are various sources of uncertainty to include in the planning process, e.g. adversaries' intentions and capabilities, own and allied capabilities and the properties of the operational environment. In order to develop relevant plans, all these sources need to be considered. Ignoring uncertainty and associated risks is not a viable option. According to Walker et al. (2013), ignorance may reduce the ability to take timely corrective actions and increases the risk of missing emerging opportunities.

In order to support development of relevant plans, we need to explore uncertainties, vulnerable planning assumptions and possible consequences if assumptions are violated. This information can be obtained by a risk and vulnerability analysis. Hence, in this paper we discuss how risk and vulnerability analysis can support development of relevant plans.

For this reason, we propose a method for risk and vulnerability analysis based on the well-known bow-tie model; see for instance Aven (2015) and Rausand & Utne (2009). The starting point is an initiating, undesired event, and the model is used to explore likely causes for and possible consequences of this event. The model is a multi-method approach, which means applying different combinations quantitative and qualitative methods that

work well together to solve the problem. This makes the method flexible and adaptable to user requirements.

The proposed method can be applied to support development of relevant plans by testing the validity of planning assumptions: What happens if planning assumptions fail or are violated? The output of this analysis supports development of more adaptable plans, and it enables decisions about the need to either revise an existing plan or develop a new one. Further, the method can be used to analyse risks and vulnerabilities in support of plan development following the Operational Planning Process (OPP). The result of the risk and vulnerability analysis can be summarized in a risk picture providing necessary information for risk management.

In particular, we focus on risks related to capability gaps, i.e. gaps in the ability to perform a certain task or function. We explore likely causes and consequences by combining capability gaps and identified vulnerabilities, where we also assess the impact of barriers and implemented measures. The outcome of the analysis is an overview of operational risks that can be used to validate planning assumptions.

2 BACKGROUND

A relevant plan is one that is useful for its purpose, i.e. prepare for future decision making. Developing a relevant plan is not trivial, and it involves recognizing uncertainties and finding the right balance between robustness, adaptability and planning assumptions. Planning assumptions are necessary due to the irreducible uncertainties related to the future state of the world. Making planning assumptions is always challenging, because they have a direct influence on the relevancy of the plan. Hence, it is important to ensure that the assumptions are robust and relevant. The validity of assumptions is not static; it will change over time and depend on the planning time-horizon. It is more likely that the assumptions are valid in the short term than in the long term.

Some assumptions are more critical and vulnerable than others, i.e. violation or failure may have huge impacts on the operations covered by the plan. Thus, it is important to identify assumptions, both the explicit and implicit, and to assess how critical these are with respect to the plan. According to Rosenhead & Mingers (2001), a robust plan will perform satisfactory on selected assessment criteria across a wide range of plausible futures, i.e. be less vulnerable to changes (anticipated variations) in factors like the behaviour of adversaries and the operational environment. An adaptive plan is a plan that facilitates updating when new information becomes available.

2.1 *Assumption-based planning*

Dewar et al. (1993) introduce "Assumption-Based Planning" (ABP) as a way to make more robust and adaptable plans. ABP is not a tool for developing plans, but for improving the robustness and adaptability of existing plans by identifying and examining underlying planning assumptions. Events that violate the assumptions can originate from different sources, such as potential opponents/adversaries, the capability of own and allied forces, and the operational environment. ABP is about identifying and applying relevant signpost or indicators to detect changes in the vulnerability of planning assumptions that may have severe consequences for the operation. However, ABP does not give a clear recipe for how best to identify these signposts or how to determine appropriate threshold values.

Risk and vulnerability analysis may be a suitable approach to identify vulnerable assumptions and possible consequences if these are violated or fail. The bow-tie model provides a generic approach to risk analysis using an undesired event, e.g. a violated or failed assumption, to initiate an analysis of possible causes for the event and likely consequences. A vulnerability analysis is an integrated part of the bow-tie approach, supporting both the cause and effect analysis. We believe that a thorough risk and vulnerability analysis can support identification of signposts with pertaining threshold values, and relate these to consequences for the operation.

In this paper, our primary focus is on assumptions related to the availability and performance of own capabilities required to accomplish a specific mission. A typical undesired event in this context is a capability gap, i.e. the discrepancy between the capability requirement and available resources. However, assumption about the availability of required capabilities is only one of many assumptions that are usually made in a military contingency plan. Other assumptions are made related to the behaviour of the opponent/adversary, own Courses of Action (CoA) and properties of the operational environment.

For more information about ABP and related planning methods, see for instance Walker et al. (2013) which provides a review of planning approaches for adaption under deep uncertainty.

2.2 *Risk analysis*

An overview of risks is as natural part of planning and decision processes. In our definition, risk is associated with negative consequences of uncertainty; however, uncertainty may also introduce

emerging opportunities. In this case, the challenge is to exploit the "window of opportunity" in order to gain an advantage. This underlines the importance of being aware of uncertainties, planning assumptions and risks.

The bow-tie model provides a basis for developing more advanced and detailed risk analysis methods. According to Aven (2015), there are three main categories of risk analysis methods: simplified risk analysis (qualitative), standard risk analysis (qualitative or quantitative) and model-based risk analysis (primarily quantitative). All these categories are relevant to support development of robust and adaptable plans.

Regardless of the choice of method, it is hard to identify all the vulnerable planning assumptions and to assess their associated risks. A plan may contain many underlying assumptions, both explicitly and implicitly given, which need to be exposed. Further, it is necessary to develop relevant and plausible scenarios that include violated or failed assumptions. Based on this, it should be possible to assess the likelihood of a violated or failed assumption constituting an undesired event for the risk analysis. The next step is to assess possible consequences of the undesired event and in particular reveal events that may have a huge impact on the planned operations, i.e. a high negative influence on the attainment of objectives and effects. Lastly, the results of the risk analysis are to be presented in a risk picture suitable for making decisions about the relevance of the plan and the need for revision.

Thus, some basic requirements to the risk and vulnerability analysis in support of plan development are:

- Provide a structured approach to identify vulnerable assumptions.
- Identify likely causes for violated/failed assumptions.
- Identify possible consequences of violated assumptions.
- Identify indicators to detect violated or failed assumptions.

In the next section, we present our suggested method.

3 A METHOD TO SUPPORT DEVELOPMENT OF RELEVANT PLANS

Our method aims to combine ABP (Dewar et al. 1993) with a standard risk analysis. We use the requirements stated in the previous section as guiding principles for the method development.

Although the method is developed for analysing risks related to capability gaps, the approach is generic and can thus be applied to analyse other planning assumptions as well.

3.1 *Risk analysis*

Figure 1 shows the main steps of a risk and vulnerability analysis based on the bow-tie model (Aven 2015).

The first step is to perform proper problem structuring and framing. In order to produce relevant results, it is crucial to understand what decisions the results of the analysis should support. In addition, it is necessary to limit the scope of the analysis and determine the analysis object (system). Decision makers and stakeholders should participate in formulating the problem and determining the scope of the analysis.

In our method, an undesired event is any event associated with violated or failed planning assumptions. Various events and vulnerabilities can be underlying causes for the occurrence of undesired events like capability gaps. A violated assumption can result in reduced performance of an activity/task, which further can affect the outcome of the operation.

In the cause analysis we aim to reveal the causes behind an undesired event. There can be several causes for a capability gap, e.g. lack of relevant resources to fill the capability requirement, lengthy reaction times due to low preparedness of critical resources, or insufficient sustainability due to lack of fuel, food/water or manpower. In order to avoid or reduce capability gaps, barriers and functions are implemented. A probability estimate of the occurrence of a gap should include assessments of the effect of both vulnerabilities and barriers. The severity of undesired events varies, depending

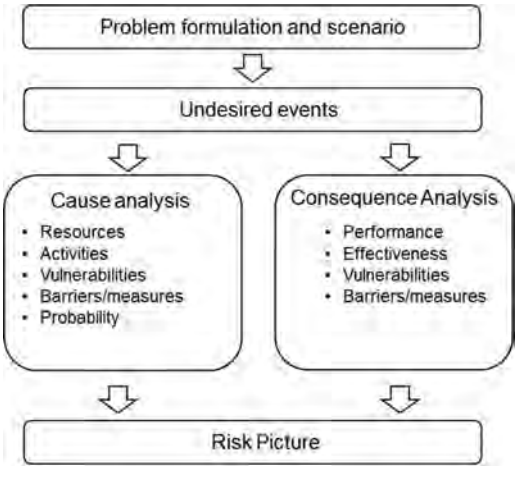

Figure 1. Risk analysis process.

on how critical the capability is for the operation. Thus, consequences depend on the scenario, the chosen Courses of Action (CoA) and the concept of operation.

The results of the cause analysis and the consequence analysis are combined in a risk picture that provides the required information to support the planning and decision process.

3.2 *Risk analysis of capability gaps*

Figure 2 gives an overview of the main components of the proposed method for analysing risks of capability gaps.

The method combines capability and risk analysis. First, we derive capability requirements and compare these to available resources. Identified capability gaps are further used as initiating events in a risk and vulnerability analysis, looking at the likelihood of occurrence of capability gaps and possible consequences for the outcome of the operation.

The different steps in Figure 2 are explained in more detail in the following. A possible application of the method is illustrated by an example.

3.2.1 *Problem structuring and scenario development*

Proper problem structuring and framing should be the first step of a risk and vulnerability analysis. Examples of questions we want to answer are: What is the purpose of the analysis? Who are the end-users? What are their expectations? Which resources are available for the analysis? Do relevant scenarios exist that can be adapted (Malerud & Fridheim 2013)?

Problem structuring can be done by informal discussions or by applying more formal methods and techniques, such as structured brainstorming, soft systems methodology or cognitive mapping.

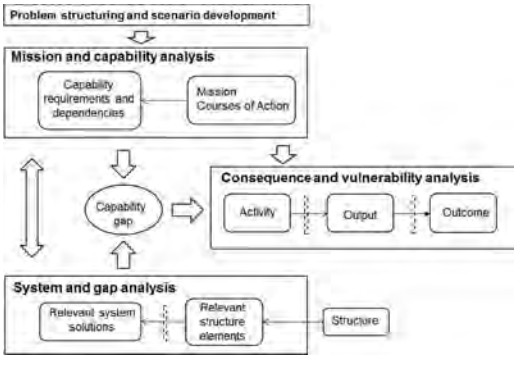

Figure 2. Method for analysing risks of capability gaps.

For an overview of problem structuring methods, see for instance (Rosenhead & Mingers 2001, Pidd 2003).

In this paper we use risk and vulnerability analysis to identify vulnerable planning assumptions and possible consequences if these are violated or fail. More specifically, we look at planning assumptions related to availability of critical capabilities. In Assumption-Based Planning (ABP), as presented in the background section, signposts are used as indicators for discovering when the vulnerability of an assumption is changed. It is particularly important to keep track of vulnerable assumptions that may have severe consequences for the planned operation.

In the example used to illustrate the method, we identify and analyse vulnerable assumptions about the availability of capabilities to handle small-scale operations as a part of daily, routine military operations. The actual plan is a contingency plan, which assumes access to capabilities necessary to perform specific tasks and functions in order to achieve the planned effects and objectives. Capability requirements are expressed using the following parameters: Capacity, reaction time, sustainability and interoperability. The plan covers small-scale crisis events at sea, and our task is to test and validate the plan in one particular scenario designed to challenge certain planning assumptions. Our focus is on capability gaps that may hamper or impede the planned operation.

Some relevant assumptions are:

- We are able to build a relevant situation picture to support situation awareness in a certain area of operation (AOO) at sea.
- We are able to react on, document (for forensic purposes) and handle an acute situation involving illegal fishing.

The scenario should in particular challenge the reaction time of critical capabilities and their ability to cooperate and exchange information.

Scenario development: Fit-for-purpose scenarios that challenge the planning assumptions are a premise for performing the risk and vulnerability analysis. Usually, a plan is developed for handling a scenario or a class of scenarios, thus there is a scenario base that can be adjusted to fit the purpose of the risk analysis. Otherwise, we need to develop new scenarios. We will not go into details with respect to scenario development here, but rather refer to Malerud & Fridheim (2016) which presents a method for developing fit-for-purpose scenarios. This method can be applied to develop new scenarios or adapt existing scenarios to fit the problems of the analysis.

Example scenario: Illegal fishing. Fishing vessels from a foreign shipping company X performs ille-

gal fishing in a Norwegian fisheries protection zone in the Barents Sea. In phase I, the illegal activity is discovered and triggers a response from Norwegian authorities. Surveillance units are allocated to the area to collect information and help build a relevant situation picture. In addition, units that are capable of ending the illegal activity are deployed.

In phase II, an inspection team from the Norwegian Coast Guard (CG) is restrained as hostages on a foreign fishing vessel. This vessel speeds up and heads for international waters.

This incident comes without advance warning, and the armed forces are performing daily, routine operations.

3.2.2 *Mission and capability analysis*

In the mission and capability analysis, information from a plan is used to develop a mission with effects, objectives and a desired end-state (what we want to achieve). A particular Course of Action (CoA) is developed comprising tasks and activities that needs to be performed in order to achieve the desired effects and objectives of the mission. Examples of effects and objectives for our scenario are:

- A relevant situation picture is established and maintained.
- The illegal activities are stopped and documented for forensic.
- The hostage situation is resolved and the hostage takers arrested.
- End state: Situation is back to normal.

An example of a CoA for handling this situation is to allocate necessary surveillance units to the area, allocate coast guard vessels (CG) to inspect and document illegal fishing activities, arrest vessels that don't comply, and finally to prepare for boarding of the vessel holding the hostages and to set them free.

Required capabilities are: In phase I: maritime surveillance, command and control (C2), action-team for boarding and inspection. In phase II: in addition to the above, action-team for hostage release.

In the following, we will focus on the maritime surveillance capability.

3.3 *System analysis*

As shown in Figure 2, the system analysis utilises a defined force structure as input, with Structure Elements (SE) such as CG vessels, surveillance aircrafts and maritime Task Forces (TF).

These SEs are combined into sub-systems to fulfil capability requirements. If a capability requirement is not entirely fulfilled, the result is a capability gap that might have impact on the operation. There are many sources that can cause capability gaps, e.g. lack of resources, loss/degradation or faults/defects of relevant SEs and low availability of SEs because they are busy doing other missions. Capability gaps arise when these sources are combined with vulnerabilities such as lack of redundancy, dependencies between capabilities, low preparedness and insufficient resilience. On the other side, barriers and mitigating actions may have been implemented to counter these deficiencies. Hence, both vulnerabilities and barriers should be considered in the gap analysis.

A part of the system analysis is to assess the performance of the SEs or sub-systems on the four performance parameters: capacity, reaction time, sustainability and interoperability. Input to these assessments can be expert judgements, historical data and simulations.

Gaps are identified by comparing system performance to capability requirements. Table 2 shows

Table 1. Capability requirements for maritime surveillance.

Task/activity	Capability	Requirement
Build and maintain a maritime situation picture	Maritime Surveillance	*Capacity*: surveillance aircraft + CG vessel *Reaction time*: Within 2 hours *Sustainability*: Duration of operation *Interoperability*: Ability to exchange information with other systems and to build a common operational picture

Table 2. Capability analysis of selected capabilities related to example scenario.

Capability requirement	SE/Sub system	Vulnerabilities	Gap
Maritime Surveillance	CG vessels Aircrafts Satellite	Dependency other capabilities Low redundancy Low preparedness	Reaction time Interoperability

an example of a gap analysis of the maritime surveillance capability.

A capability gap constitutes an undesired event that can have impact on the operations. It is possible to estimate the probability of capability gaps of varying severity, e.g. by using historical availability of resources and compare this to the capability requirements, or by assessments of Subject Matter Experts (SME). Probabilities can be expressed on a qualitative scale, e.g. high, medium and low. In this case the qualitative scale has to be defined, i.e. what is the meaning of a high probability. It is also possible to quantify the probabilities by applying methods to elicit probabilities, see for instance (O'Hagan et al. 2006).

The severity of consequences depends on the type and size of the gap. The gap may have huge or minor consequences dependent on the scenario and how critical the capability is.

In the next step, we assess possible consequences of capability gaps, with emphasis on gaps related to critical capabilities.

3.3.1 *Consequence analysis*

A capability gap results in reduced capability performance, and hence can have a negative effect on the output of an activity which further has negative impact on the achievement of effects and objectives of an operation.

Figure 3 shows an example of an event tree analysis of a gap in the maritime surveillance capability.

A moderate gap in the maritime surveillance capacity can result in reduced sensor coverage of the area of interest, delayed overview of the situation (slow reaction time), time periods with insufficient surveillance (sustainability) and inadequate common understanding of the situation due to insufficient interoperability.

The consequence analysis should comprise a thorough assessment of vulnerabilities that can lead to severe consequences, as well as associated barriers and mitigating actions that are implemented to avoid or reduce the consequences. Some examples of vulnerabilities are dependencies between capabilities, low level resilience, lack of alternatives and too high ambitions with respect to effects and timelines. At the branch points in the event tree model, identified vulnerabilities are compared to relevant barriers and mitigating measures in order to assess consequences for output and outcome of the activity/task. Such an event tree can be constructed for each capability gap.

Some relevant questions related to the event tree are:

- B: To what extent does the gap in maritime surveillance capacity cause a significant reduction in sensor coverage of AOI (vulnerabilities and barriers)?
- C: Does the reduced sensor coverage result in an insufficient situation picture?
- D: To what extent does an insufficient situation picture contribute to insufficient situation awareness?
- How severe is the gap with respect to achievement of planned objectives and effects of the operation (EH, H, M, L)? Insufficient situation awareness influences on the ability to make timely decisions.

The event tree is a suitable tool for assessing consequences. It can be supplemented by e.g. quantitative tools such as fault trees and Bayesian networks, see for instance Aven (2015).

3.3.2 *Risk picture*

Our main task is to identify and analyse vulnerable planning assumptions that can cause severe consequences if they are violated or fail. We have limited our scope to look at assumptions about the availability of relevant capabilities. The results of the risk analysis are combined and presented in a risk picture that is suitable for identifying and deciding on mitigating measures, in order to support decisions about the need for revising the plan. The risk picture contains a description of critical capability gaps, their probability of occurrence and possible consequences of the gaps for the operation (operational risks). Figure 4 shows how an operational risk picture can be presented for the example scenario.

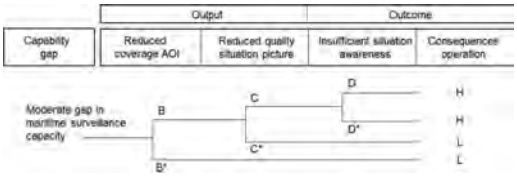

Figure 3. Example of an event tree of a gap in maritime surveillance capacity.

ID	Risk gap in maritime surveillance	Probability	Operational consequence	Mitigation
1	Capacity: Insufficient all-weather sensor coverage	L	L	More sensor units with relevant sensors. Prioritize sensor units
2	Reaction time: Sensor units insufficient reaction time	M	M	Increase preparedness of units
3	Sustainability: Sensor units don't have sufficient sustainability due to lack of logistics	L	L	N/A
4	Interoperability: Not sufficient interoperability between units	M	M	Invest in interoperable communication and information system. Collective training/exercises

Figure 4. Example of a risk picture.

4 DISCUSSION

In this paper we study the question: how can risk and vulnerability analysis support development of relevant military plans? What we want to achieve are robust and adaptable plans that help decision makers achieve overarching goals and objectives, as described in (Dewar et al. 1993 and Walker et al. 2013).

A plan will always, due to irreducible uncertainty, rely on a set of underlying assumptions. Making assumptions is necessary, but this should be done with great care because of the potentially huge consequences if the assumptions are violated or fail.

In Assumption-Based Planning (ABP) (Dewar et al. 1993), signposts are identified and applied to monitor if the vulnerability of a certain planning assumption is changed. ABP is one feasible approach to obtain more adaptive plans. It is, however not clear how signposts are identified.

Many military plans are developed using the COPD process (NATO 2013). COPD recognize the importance of adaptability and flexibility, however, it gives little guidance on how to achieve adaptable and flexible plans. In addition the COPD process lacks adequate measures for when and how a plan should be revised.

Hence, it is necessary to establish a method for detecting invalid assumptions that potentially can have huge impact on an operation. A proper risk and vulnerability analysis seems to be a promising line of approach.

This paper outlines a method for combining a capability and risk analysis to test the validity of planning assumptions, in particular assumptions related to the availability of critical capabilities for a military mission. Based on the bow-tie model, likely causes for a violated or failed assumption (capability gap) are explored. There are various sources that can cause a violated assumption, e.g. properties of the opponent/enemy, availability and performance of own and allied forces and properties of the operational environment. By identifying and assessing vulnerabilities, relevant barriers and measures implemented to reduce or avoid violation of assumptions, it is possible to obtain an overview of vulnerable assumptions and the likelihood that they are violated. This again will aid the development of signposts to monitor the vulnerabilities. This analysis relies on fit-for-purpose scenarios that challenge the planning assumptions. Ideally, one should test the planning assumptions in a wide variety of scenarios. However, in practice it is only feasible to include a few scenarios in the analysis. Thus, it is crucial to determine scenarios that cover different planning assumptions. To support this process, we suggest applying a scenario development method as described in Malerud & Fridheim (2016). Simulations may be a feasible approach to test assumptions in a larger set of scenarios and to identify the most challenging scenarios with respect to the assumptions.

In order to reveal which assumptions are most critical for achieving the objectives of the operation, it is necessary to perform a consequence analysis. We apply the proposed method to assess consequences of capability gaps by first considering how gaps influence on the output of the activity performed by the capability. Depending on the type and size of the gap, it will affect the output differently. This assessment also comprises the effects of identified vulnerabilities and barriers. In the next step, we assess consequences of reduced performance on the achievement of effects and objectives of the operation. Depending on how much the performance is reduced and the criticality of the capability, the gap will affect the outcome of the operation differently.

The proposed risk and vulnerability analysis is a multi-methodology that can adopt different combinations of methods covering the three main categories of risk analysis methods outlined in Aven (2015): simplified risk analysis which relies on qualitative methods, standard risk analysis which can be both qualitative and quantitative and model-based risk analysis which is mostly quantitative. The actual choice of method depends among others on availability of data and information, time and resources available for the analysis, and stakeholder expectations/requirements. This should be clarified in the initial problem structuring.

The example used to illustrate an application of the method is simplified and qualitative. However, it is possible to utilize more quantitative methods to enhance the quality of the risk analysis. Methods such as event trees, fault trees and Bayesian networks are promising candidates

Although the proposed method is only tested on simple cases, we believe risk and vulnerability analysis is promising with respect to support development of robust and adaptable plans. In order to refine and validate the method, we need to apply it on more cases involving real military contingency plans.

5 SOME FINAL REMARKS

We are currently not in the position to make any firm conclusions about the applicability of the method; the results are preliminary. However, we have gained some experiences that indicate that the method is appropriate for supporting development of relevant plans.

– It supports deriving signposts indicating when the vulnerability of an assumption changes.

– It can provide a risk picture comprising vulnerable planning assumptions, possible events/situations that can cause an undesired event (capability gap), and possible operational consequences if these assumptions are violated or fail (operational risk).
– It gives traceability between underlying causes for capability gaps and consequences for output and outcome of the operation.
– It provides a structured and traceable approach.

Although the method is developed to support military operational planning, we also believe it has a wider area of application, for instance to help develop robust and adaptable contingency plans in the civilian domain.

Security and availability on embedded systems

N. Burger, Y. Langeron, R. Cogranne & P. Lallement
University of Technology of Troyes, Troyes, France

ABSTRACT: With the fast-paced development of the Internet of Things and its applications within the emerging field of Industry 4.0 – decentralizing decisions by remotely monitoring data and automata – the issues of security and reliability of the whole communication pipeline between the connected devices taking part in this smart industry become crucial. In such context of embedded systems, microcontrollers are widely preferred over microprocessors as they are cheaper, smaller and less energy consuming. Unfortunately, the implementation of security features on microcontrollers, such as signing and ciphering functions, can largely reduce the availability of embedded systems because these functions are energy consuming and computationally complex. Thus, a trade-off has to be found between the prescribed level of availability and security. It is important to note that such a trade-off greatly depends on how the embedded systems will be used, how they are supposed to communicate between each other and if a central node with high computing resources is available. For instance, a common architecture typically consist of several embedded systems communicating up and down with a unique server. Indeed, this architecture is used in several areas where a monitor must supervise and treat data, which is the reason why this setup is chosen. The present paper aims at proposing a method to reach the right trade-off between security and availability, depending on the available resources. However, this problem is difficult to address because of the complexity to measure the security or the availability of a system. Solutions featuring those characteristics and a generic approach are presented to find the most suitable trade-off, in the use case of Industry 4.0.

1 INTRODUCTION

Embedded systems communicate between each others since the beginning of computer engineering. Today, these objects communicate on a network larger day after day: the Internet. For several years now the expression "the Internet of Things" is used. However, the expression "embedded systems" regroups many things: Smartphones, automobile electronics, sensors, and miniaturized computers like Raspberry. These objects have different functionalities, hence different computational power. For example, a communicating sensor embedded in a mechanical piece has physical constraints. Components such as microcontroller, battery, antenna, etc will be impacted by these constraints. If a Smartphone, because of these constraints, is less powerful than a computer, a communicating sensor will be much less powerful than a sensor. These constraints alone can define connected objects and their issues (Agrawal & Das 2011).

The eco-system of embedded systems changed drastically since their emergence. Embedded systems were *connected* to a physical interface, that was possible to physically secure. But with the more and more numerous communicating objects—with a server (for supervision purposes) or with other objects—physical security to access an object is not sufficient anymore (Sagstetter et al. 2013).

Whether the communication is radio-based, wired, or other, it is necessary to secure data exchanges. Security is a word that brings together many concepts. These concepts can be split in three categories:

- Confidentiality: The data are exchanged without anyone being able to understand it.
- Integrity: A modification of the exchanged data is detectable.
- Authentication: The data are signed by an emitter. The emitter can not repudiate the message. Another entity can not impersonate the emitter.

These three categories cause several needs that embedded systems must meet. Regardless of the system, the tasks answering these needs will take time and energy. Moreover, embedded systems will have different options to answer these needs, depending on their capabilities.

Comparing all the possible embedded systems outweighs the scope of this paper. That is why this study will focus on a specific restraint embedded system based on a small, procedural, real-time micro-controller with a transceiver. Possible applications, for a micro-controller like this, can be mass production of communicating sensors for the industry 4.0 or home automation.

2 PROBLEM AND CONTEXT

2.1 *Security definitions*

Authentication, integrity and confidentiality are based on mathematically complex functions. From an emitter point of view, authentication can be answered by a signature algorithm (S), integrity can be answered by a hash algorithm (H), and confidentiality can be answered by an encryption algorithm (E). From a receiver perspective, authentication can be answered by a verification algorithm (V), integrity can be answered by the same hash algorithm (H), and confidentiality can be answered by a decryption algorithm (D).

These functions take some time to execute:

- T_s: the time taken by S to sign a message
- T_h: the time taken by H to hash a message
- T_e: the time taken by E to encrypt a message
- T_v: the time taken by V to verify a signature
- T_d: the time taken by D to decrypt a message

Moreover, security also influences autonomy because these functions use computational power, hence energy, and reduce the autonomy of an embedded system. A balance must be found between security and energy consumption, reliability and real time constraints (Jiang et al. 2017). Nevertheless this study will focus on the availability of the receiver from a real-time situation perspective. Autonomy, influenced by the energy consumption of the cryptographic functions, is discarded in this paper.

2.2 *Embedded systems secured communications*

Let's take two embedded systems as in Figure 1: an emitter and a receiver. The emitter must:

- 1. Hash its message
- 2. Sign the hash of its message
- 3. Encrypt its message

The computing time for the emitter will be

$$T_{em} = T_h + T_s + T_e \tag{1}$$

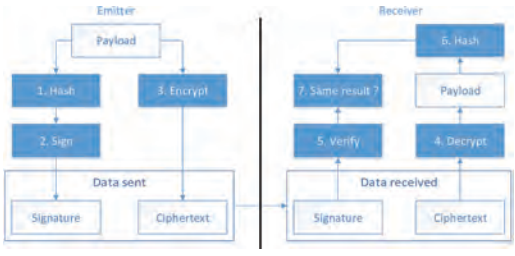

Figure 1. RSA signature.

And the receiver must:

- 4. Decrypt the message
- 5. Hash the message decrypted
- 6. and 7. Verify the signature and compare with the has previously calculated.

The computing time for the receiver will be

$$T_r = T_d + T_h + T_v \tag{2}$$

The signature (emitter side) and decryption (receiver side) have to be done with a private key. The receiver must be able to communicate with any emitter, and because of memory limitations, it is not possible to store the keys of all the emitters on the receiver memory.

A private key, k_{1d}, is used on the receiver for decryption: only the receiver can decrypt the messages from the emitter. And these messages were encrypted with the public key k_{1e} on the emitter.

Another private key, k_{2s} is used on the emitter for signing: only the emitter can sign its own messages. These signatures will be verified by the receiver with the public key k_{2v}. Two couples of keys are then needed: $K_1 = (k_{1e}, k_{1d})$ and $K_2 = (k_{2s}, k_{2v})$.

The receiver potentially manages many emitters. For example, a receiver in a nuclear power plant receives messages from hundreds of emitters. Once the messages received, they must be proceeded quickly so the data are supervised in real-time.

When the receiver receives too many messages at the same time, it will lead to message losses because the receiver will be busy to decrypt and verify the messages.

This study offers some methods to approach and quantify these *too many messages* and *at the same time* variables.

3 APPROACH AND METHODOLOGY

3.1 *Security level and algorithms*

First, some variables need to be fixed: the security level chosen is the most secured in the sense it manages the confidentiality, the integrity and the authentication of the data.

Not all messages in real life need to be so secured, but for the purpose of this article, the problem is simplified to focus on the workload of the receiver. Indeed, the receiver will be busy a certain amount of time to check these three security parameters. First to calculation of this duration is first needed.

RSA-1024 bits with SHA1 is chosen, mainly for the simplicity of the implementation, thanks to a C Microchip library. Each algorithm is set to its specific functions:

- *S*: RSA-1024 bits sign
- *H*: SHA1
- *E*: RSA-1024 bits encrypt
- *V*: RSA-1024 bits verify
- *D*: RSA-1024 bits decrypt

The RSA functions of encryption-decryption can be considered the same than the RSA signature-verification ones since the mathematical operations are the sames (Pawar & Ghumbre 2016). Indeed, in our case, the only difference is the key used for each operation:

- Encryption and decryption:

$$m^{k_{1e}} = c(modn) \tag{3}$$

$$c^{k_{1d}} = m(modn) \tag{4}$$

- Signature and verification:

$$m^{k_{2s}} = s(modn) \tag{5}$$

$$s^{k_{2v}} = m(modn) \tag{6}$$

The PKCS standard is used for the decryption and verification (on the receiver). So the function is mathematically optimized. Moreover, to balance the workload on the receiver, smaller exponent are used on its side, so the workload will be more important on the emitter for one ciphering or signature. Then, the workload per message is smaller on the receiver than the emitter, but the receiver manages several messages.

That is why equations 4 and 6 take a smaller amount of time than equations 3 and 5.

Using a smaller exponent as a private key on the receiver side for encryption may be a security issue: attackers can guess more easily the private key if they suppose it is a small exponent.

3.2 *Embedded systems definition*

The embedded system is an important variable on this problem. A modest micro-controller has been chosen to amplify the workload of both the receiver and emitter. Choosing a micro-controller means fixing the CPU speed, the Program Memory and the RAM. Each of these three variables can influence the security in some ways, because of memory limitation for example.

The measurements were conducted on a dsPIC30F3014 from Microchip with the specifications described in Table 1.

An output of the micro-controller was set to 1 during the operation, so the amount of time spent by the micro-controller to do each operation can be checked.

Table 1. dsPIC30F3014 specifications.

Parameter	Value
Architecture	16-bit
CPU Speed (MIPS)	30
Memory Type	Flash
Program Memory (KB)	24
RAM (KB)	2

3.3 *Variables*

Let's note T_r the total duration needed for the receiver to verify the security (see 2), T_{em} the duration between two emissions of the same emitter, and N the number of emitters.

Other duration, like time to send data to a central server, time to read some input on the receiver, time to read the message from the antenna can influence the availability of the system. However, these functions were voluntarily omitted to simplify the problem and to expose how security specifically influences the availability (Jiang et al. 2012).

From these data, the number of messages a receiver can treat without being overload can be determined, depending of the security (more specifically the time used for it):

$$N = \lfloor T_{em}/T_r \rfloor \tag{7}$$

4 RESULTS AND DISCUSSIONS

4.1 *Measurements*

In the Figure 2, it is shown that with a specific T_r and T_{em}, the receiver is totally busy. Graphically, it is visible that after 10 emitters, the receiver will miss some messages.

The assumption that messages follow each other was done to simplify the problem. Real life emitter can send messages at the same time, overlapping each other time frame. A CSMA/CA-like can be implemented by introducing an alea between each messages but itwould eventually return to this simple case of receiver overload.

The execution times of the different operations are referred in Table 2 and were given by an oscilloscope.

The total duration of unavailability for the receiver when receiving a message is

$$T_r = 6.8 + 6.8 = 13.6ms$$

The minimum time frame for an emitter between two message emissions is:

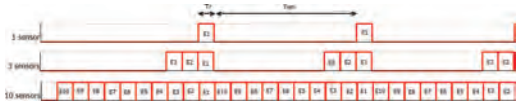

Figure 2. Receiver process time occupation.

Table 2. Operations and execution times.

Operation	Execution time
RSA 1024 signature + SHA1	158.4 ms
RSA 1024 verification + SHA1	6.8 ms
RSA 1024 encryption	159.2 ms
RSA 1024 decryption	6.8 ms

$$T_{em} = 158.4 + 159.2 = 317.6ms$$

If emitters never sleep and continuously send messages to the receiver, a message will be received each 317.6 ms. It can now be determined that the number of emitter a receiver can manage in optimal scenario where messages are sent one after another is:

$$N = \lfloor T_{em} / T_r \rfloor = \lfloor 317.6 / 13.6 \rfloor = 23 \quad (8)$$

Thus, 23 emitters can be associated to a receiver.

4.2 *Comparisons and improvements*

This result can be adapted to other scenario. For example, time measurements with RSA-2048 bits will probably take more time for both emitters and receivers and thus, change the number of emitters N.

Totally different encryption/decryption and signing/verifying algorithms can be used and compared on this embedded system. For example, a combination of AES and RSA will probably give a different N.

This comparison tool can be used to compare embedded systems instead of algorithms. For example, a measure done with AES128-CCM (symmetric solution of encryption + integrity + authentication) on a CC2538SF53 microcontroller supporting of Hardware acceleration for cryptography gave us a computing time of 210 μs (encryption) and 120 μs (decryption).

Symmetric algorithms, however, give a hard time for key management. This paper doesn't take into account this complexity, but some engineers could use the asymmetric algorithms to exchange a symmetric key.

This means that several type of messages will then be exchange: some encrypted with RSA, some with AES for example. That will imply different duration for these messages but it can be easily implemented on this method.

5 CONCLUSIONS

These results can be used to determine how many sensors can be attributed to a receiver on a specific area. Methods such as a header containing the ID of the sensor can help the receiver to know if it must verify the message or ignore it and thus, save time.

If an industry needs to deploy 30 sensors for instance, in the case studied previously, two receivers will be used.

Moreover, this method can be used to compare micro-controllers, and it can help embedded systems designers to better choose their components, regarding their needs.

More research can add other constraints on the equation, like the impact of security on the battery of the emitter (receivers are supposed to be plugged on a power source). This way, embedded systems designers will be able to choose their level of security depending on the real time and autonomy requirements.

Constructing a method for classification of complex infrastructures for security threats: A case study of Norwegian ISPS port facilities

K. Brattekås, J.A. Bruvoll & M. Maal
Norwegian Defence Research Establishment (FFI), Norway

J.F. Aae & A. Breivik
Norwegian Coastal Administration, Norway

ABSTRACT: When an unspecified terrorist threat against Norway was identified in the summer of 2014, the security level was heightened at all of Norway's 600 plus International Ship & Port facility Security code (ISPS) ports. A type of classification system was necessary in order to identify which ports required security measures dependent on the different types of situations which could potentially arise. However, classifying infrastructures by criticality is a complex task with little guidance available. The main challenge was how to decide which level of protection the facilities would require. We evaluated whether the ad hoc approach, used to return security levels to baseline, was a good approach, and if there were other best practices available. Furthermore, we asked how the more than 600 different facilities could apply the same classification system. This paper proposes an approach for how to arrange different port facilities into "security profiles". A general threat assessment was made, based on a literature review and contact with security authorities, in order to determine what kind of scenarios would be relevant for the ports. We then continued to map the different types of ports, and common denominators for security issues. Through the literature review, workshops and input from the Norwegian Coastal Administration, we developed value-based categories for criticality. The findings in this paper can help clarify and present solutions which might help practitioners overcome challenges related to assessing security and threats to their facilities. The approach presented in this paper may also be a useful framework for other critical infrastructures to help select categories for ranking or classification.

1 INTRODUCTION

Knowing which infrastructure is the most critical or most exposed in security incidents is a great challenge, and there are few systematic methods available. Several approaches have been developed to identify and assess critical infrastructures over the years, yet classification and prioritisation of asset or value protection remains a difficult task given the occurrence of security threats or risks. In this paper, we present a method developed to classify port facilities into different security profiles.

This method may also be a useful framework for other types of infrastructure when it comes to assessing criticality. Even though the method presented in this paper is customised for the nature, rules and regulations of the maritime sector, the broader framework and the mindset may be applicable for further use in other infrastructure classifications. This paper aims to present the background for – and development of – this methodological framework.

Port facilities play a key role in the global maritime transportation, as over 90 percent of the world's trade is freighted by sea (IMO, 2017). Ships, engaged in international voyages, which hold an International Ship Security Certificate (ISSC) can only be served by ISPS-approved port facilities creating a security network for global maritime transportation.

The Norwegian Defence Research Establishment (FFI) and the Norwegian Defence Estates Agency (NDEA) conducted a study in order to develop a user-oriented method for classifying Norwegian ports and port facilities. The study provided guidance in relation to the risk-based supervision conducted by the Norwegian Coastal Administration (KYV), and on how to determine the maritime security level in Norwegian ports and port facilities, particularly if the general threat level was increased. The focus for this article is the latter, where we have developed a method for classifying port facilities based on their criticality.

Various categories for criticality were developed in this study, which included ranking tables. Examples of categories developed include the number of annual passengers, the type of goods being stored and transported, and the port facility's strategic importance. Eight ranking tables were used for each

port facility to determine the overall score, and thus determine which security profile the port facility belonged to (security profile 1 is low criticality, 2 is medium criticality, and 3 has high criticality).

It was also recommended that KYV base their risk-based supervision on the ports' security profile as well as the Port Facility Security Assessments (PFSA).

2 BACKGROUND

In the summer of 2014, the general terror threat level in Norway was raised by the Police Security Service (PST) (PST 2014). The terror threat was high, but unspecified, and due to the raised threat level, KYV decided to raise the security level for all Norwegian port facilities to security level 2 from 24th July 2014. This resulted in increased costs and workloads at each port, and when the threat level continued to stay high, KYV started to lower the security level to normal (security level 1) by the end of July, depending on the features of each facility.

Following this situation, KYV wanted a more substantiated method for determining the ports' inherent security classification in order to better differentiate the security levels for incidences when the general threat level is raised, or where certain threats are specified. With this background, FFI and NDEA worked in 2015 and 2016, in close collaboration with KYV, to develop such a method.

2.1 *The ISPS code and the SOLAS convention*

Several international and national laws and regulations apply to ports and ships in Norway. The ISPS Code was created as a result of the terrorist events in the USA September 11 2001, and was adopted by the International Maritime Organization (IMO) in the Safety of Life at Sea (SOLAS) Amendments in 2002. The objective of the ISPS Code and amendments was to enhance international maritime security.

The ISPS Code Part A, and some of Part B, is applicable for Norwegian regulations. The Code applies to port facilities that operate the following ships in international traffic: passenger ships, cargo vessels over 500 BT, moveable drilling rigs and special ships (SPS). All ships with ISSC are considered to be in international traffic. The ISPS framework is not applicable to war ships, military auxiliary vessels, ships in state-run, non-commercial operation, fishing vessels, ships without propulsion machinery, primitive wood ships and pleasure vessels (IMO 2003 and IMO 2012).

As described, the ISPS Code describes three security levels for port facilities (IMO 2012: 34–36). KYV is responsible for changes in security level, and notification of the Port Security Officers and Port Facility Security Officers (PSO/PFSO) about changes in their operation areas. All port facilities are required to have a Port Facility Security assessment (PFSA) and, in some cases, a Port Facility Security Plan (PFSP).

2.2 *General threat assessment*

The authors conducted a literature study and a general threat assessment where trends in the maritime sector were described. The analysis was based on trend reports from the NCIS (Kripos), the PST, and the Norwegian Intelligence Service as well as FFIs research reports and international databases of terrorist incidents. We also had a conversation with PST on general threat trends in Norway, and the KYV headquarters presented their incident log with various types of threats and security incidents in their sector.

The literature study consisted of reports concerning Norwegian sea transport risk assessment (Eggereide et al 2007; Rutledal 2002a and Rutledal 2002b), as well as a report describing maritime threat trends (Tønnessen 2007) and a threat assessment done by PST in 2013. International sources and databases (RAND 2006) were used to identify international incidents relevant for the general threat assessment. The threat assessment includes considerations about terrorism, intelligence/espionage, sabotage and other crime. Piracy has been left out due to the scope of this study focusing on Norwegian ports.

It is worth noting that there is wide academic agreement regarding the high uncertainty with security related risks, and, in particular, terrorism risk (Aven 2015; Bruvoll, 2017; Fischhoff 2002; Renn 2008; Jore and Njå 2012; Weiss 2007; DSB 2014; NSM 2016; Busmundrud et al. 2015; Maal et al. 2016). This will of course impact risk analyses and assessments where these risks are addressed. The traditional way of assessing risk, where the parameters likelihood and consequence result in an estimated, quantitative risk score, can be less expedient for security related events (Jore and Njå 2012; Aven et al. 2004; Renn 2008, and Pettersen and Engen 2010). Maritime terrorism has been a declining trend in the Northern hemisphere in the last years, and one of the main recommendations from the general threat assessment was to also focus risk assessments on other security threats and not just terrorism.

3 SCOPE

The general threat assessment that was conducted in the original body of work will not be further described in this article. This article focuses on the

method developed, and the preconditions for the choice of approach.

3.1 *Definitions*

Value assessment has the purpose of mapping the organisation's values (sometimes also referred to as "assets"), and considers which of these are most important for the organisation's mission and deliveries. This requires systematic review of which consequences would happen if the values are affected (NSM 2016:11).

According to Norwegian Standard 5830 the term *value* is defined as "a resource that if affected by unwanted influence will cause a negative consequence for the ones owning, managing or benefiting from the resource" (NS 5830:2012). A *threat* is defined as a "possible unwanted action that can have a negative consequence for a port facility's security" (ibid.). *Vulnerability* is defined as "lacking ability to resist an unwanted event or restore a new stable condition if a value is affected by unwanted influence" (ibid.).

3.2 *Port facilities and ports*

A port facility is described as land, buildings, facilities and other infrastructures used in port operations, including quays, terminal buildings, loading, unloading and transhipment facilities, and storage and administration buildings (KYV, 2011).

A port is defined as areas that are for use by vessels that load or unload goods or transport passengers as part of maritime transport or other business activities (ibid.). A port may contain several port facilities within its perimeters.

4 METHODS

The methods were based on reviews of primary and secondary literature. Furthermore, the authors held several workshops with relevant national and regional stakeholders in the Norwegian Coastal Administration.

4.1 *Literature review*

The primary literature reviewed consisted of 24 risk assessments from selected port facilities from all regions in Norway as well as a classification guide for ISPS facilities developed in Denmark (Danish Transport Authority, 2015). This primary material gave unique insight into the main threats, as well as the diversity in Norwegian port facilities. Furthermore, the Danish example gave a baseline for a best practice method. The secondary literature studied ranged from relevant rules and regulations, to academic theory about risk, risk based supervision and vulnerability, as well as previous reports and threat assessments about maritime security.

4.2 *Workshops and interviews*

Several workshops were conducted with relevant stakeholders and users from all the regions where KYV are situated, as well as more limited workshops with selected stakeholders. This was to gain an overview of the diverse ports and port facilities in Norway, as well as ensure the user perspective throughout the study. The representatives from KYV also provided important expertise for the study.

Semi-structured interviews were conducted with experts outside of KYV for the threat assessment and risk based supervision.

4.3 *Validation*

When the first draft of the methodology for classifying port facilities was done, KYV were able to test the framework at several facilities, and give feedback on whether the framework would be applicable or required further adjustment. This was an iterative process where every draft of the classification system was circulated and considered for improvements in order to ensure sufficient validation of the system.

4.4 *Limitations*

The number of port facilities regulated by the ISPS code in Norway is more than 600. Thus, assessing all of them individually was out of scope for this study, and an approach based on "types" of ports was selected and done on a general basis in order to include all ISPS port facilities.

The analysis has included risk for intentional acts (security). Considerations regarding ICT-security or personnel security were not included.

5 CLASSIFICATION OF CRITICALITY

Categorising all Norwegian port facilities is highly demanding and very complex, as the facilities are very different. It is a balance between too broad categories and too narrow categories. After several takes, it was recommended that the port facilities themselves should determine which security profile they are, based on certain criteria. It is recommended that the PSO/PFSO is involved in the classification, which can then be quality assured by KYV. Based on this classification, KYV can identify some common values linked to the total score and security profiles of each port and its facilities.

The classification method consists of eight different assessment categories which all constitute a point score. The categories are all described quantitatively (by numbers and points) and by a qualitative description that may influence which profile the port facility belongs to in order to classify criticality.

5.1 *Applied research and best practices*

As previously described, the original framework that was used to lower the security level of the port facilities to security level 1 in 2014 was inadequate. The new framework needed to consider and include features for all the port facilities in Norway, and also adhere to the ISPS Code and existing best practices. Hence, the starting point included the rules and regulations, combined with regional experience from Norway and the best practice framework from Denmark.

5.2 *Categorising port facilities*

According to the ISPS Code part B, 15.5-10 the identification and consideration of important values and critical infrastructure is a process that needs to consider the potential for loss of life, the port's economic significance, symbolic value and presence of government installations. This is reflected in the damage assessment form, where the consequence classes are (i) down time/operative ability, (ii) environment, (iii) life and health and (iv) reputation. From these parent categories, we developed some sub categories to assess criticality/importance, as presented in Figure 1. This was necessary as the users needed more specific reference points to assess the different port facilities.

5.2.1 *Environment, life and health*

The ISPS Code reads that the main focus should be to "avoid death or damage". According to the Norwegian Security Act (Sikkerhetsloven 1998), one should consider if there is a potential hazard for the environment or the population's life and health. Therefore, we have used the category "number of yearly passengers" to capture how many passengers could be affected. The number of employees in a port facility was also included to capture how many people are present daily.

It was also important to see how events in a port facility could affect the life and health of the population situated around the area. Therefore, we added the category "port facility proximity to populated places". Populous areas can be places where many people are convened, such as industry areas, infrastructure such as train stations, residential areas etc. Another element is the presence of dangerous goods and hazardous materials at the port facility, which could have consequences for environment, life and health. The category for hazardous goods and substances captures this aspect. These categories are visualised on the left side of Figure 1.

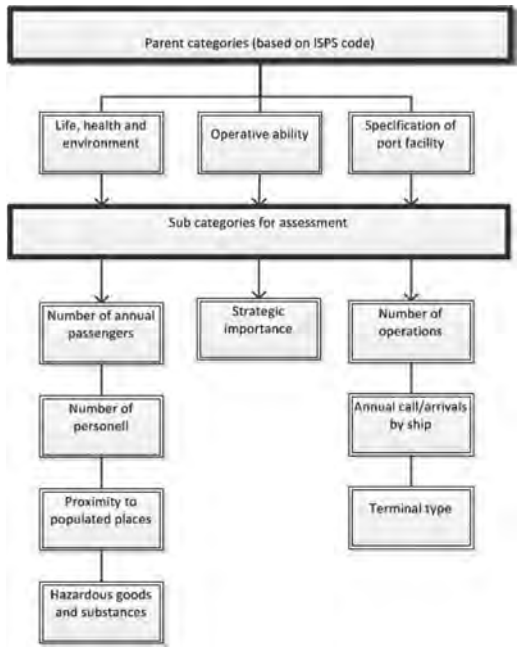

Figure 1. Categories for assessing criticality.

5.2.2 *Operative ability*

In the centre of Figure 1, the category "strategic importance" was included. According to the ISPS Code part B/15.6 it is important to consider if the port facility can still function without the given asset (or value), and in which degree it is possible to restore normal operations quickly. Downtime for the entire operation or delays in important deliveries can result in substantial costs. Addressing how some ports/port facilities can have such critical deliveries to society, is essential since any downtime will have impacts on society. This is why we added a category for strategic importance and redundancy. This is connected to national security and sovereignty, as well as critical infrastructure.

Today, there is no agreed method to assess whether the organisation is a critical infrastructure, and qualitative, knowledge based considerations are necessary. According to the Security Act, one needs to consider if downtime can have consequences for national security and defending the country, as well as critical societal functions for civilians. The assessment questions that addressed this aspect were: (i) Does the port facility have

import and export goods of strategic importance? (ii) Is your port facility the only one that has specialised operations or has special tools and facilities (e.g. a type of cables that are only produced/delivered for a certain port or goods for supply safety)? (iii) Does the port facility have strategic importance for the Armed Forces and proximity to defence installations (such as critical equipment like RoRo and LoLo (roll-on-roll-off and load-on-load-off))? (iv) Is the port facility a previously "national designated port"?

5.2.3 *Specifications for port facilities*

From a societal perspective, it is important to identify ports that are bigger and have more traffic than others. The sub categories "number of operations in the port facility" and "expected annual calls/arrivals by ship" cover this dimension. The thought was to also capture the complexity including actors, operations etc. that is ongoing in the port. We have also included "terminal type" with categories for different types of cargo. The categories were developed together with KYV, and include a ranking of different goods: (i) dry bulk, one-terminal facilities for timber, stone, gravel, asphalt, scrap iron etc., (ii) bigger goods and bulk facilities and groupage, (iii) containers and LPG, (iv) supply bases, oil- and gas production and cruise, (v) RO/PAX (roll-on/roll-off passenger) for international traffic, ferry terminals for international shipments. The reasoning for this weighting is based on classified threat assessments and what could be seen as attractive targets for a threat actor. These categories can be seen on the right side of Figure 1.

5.3 *Assessing and ranking criticality*

After workshops with KYV, we developed a general model to assess and rank criticality. The ranking tables associated with each category collect all the quantitative information. Several of the threshold values in the tables are based on Danish best practice adjusted to Norwegian conditions. KYV has tested the model on port facilities they have great knowledge of, and have returned with input regarding threshold values. However, we also included a field for each ranking table where the assessments should be described.

KYV also specified two conditions for the classification. If a port facility has more than 200 000 yearly passengers (score 5, red colour), the port facility will automatically end up in security profile 3 "high criticality". The other condition is tied to the category "terminal type". If the port facility has RO/PAX (score 5, red colour), the port facility will automatically end up in security profile 3 "high criticality".

As mentioned, the method for classification is based on both quantitative and qualitative assessments. The quantitative data should be relatively easy to collect through the PFSAs, as well as the KYV regional personnel and PFSOs' local knowledge.

The quantitative assessment will lead to a total score, which implies the criticality of the port and port facilities. Risk assessments for security related risks are difficult to manage solely based on quantitative approaches, so it was deemed necessary to supplement these with discretionary assessments. The qualitative assessments can both increase and lower the total score based on the quantitative assessments. They are meant as a supplement where e.g. quantitative numbers cannot describe the complexity or simplicity of the systems. Under each ranking table, there is a field where the qualitative assessments should be described. Including this will achieve a more holistic overview of the different ports and port facilities. The combined quantitative and qualitative data provides grounds for a nuanced overview in order to make an informed decision about the final security profile. Table 1 is one example of a ranking table including quantitative and qualitative assessment.

The security classification should make the process for raising and lowering the security level for different port facilities and ports more effective during and after changes in threat level. However, it is preferable to have continuous, updated information about the threat level and types of threats if available. The responsible stakeholders, such as KYV and PFSO/PSOs, should stay updated on openly accessible threat assessments from the relevant authorities.

The score for the port facility must be considered against the scores of the other ISPS port facilities in the port. The highest score in a port will affect the overall score for the port. This is also in terms with EU Port Security Directive 2005/65/EC.

The following figure shows the different categories explained in this chapter, and is a visualisation that will be further described in chapter 6.

Table 1. Example of a ranking table.

Ranking table Number of personnel in the port facility					
Number	<50	51–150	151–300	301–500	<500
Score	1	2	3	4	5
Describe the assessment	*Ex: There are normally around 20 persons in the port facility on a daily basis. However, during July this number will be 60 as there are more tourists and boats visiting. We have assessed that the port should still score 1.*				

6 USING THE METHOD

The first six ranking tables that should be completed use a score from 1 to 5, and the last two use a tripartite score, 0-3-5. However, the assessment criteria for each table differ. The quantification of the categories was done in close collaboration with KYV, who has extensive knowledge about the different types of facilities.

To better describe the step-by-step method for the users, we created a fictional port facility, "Hjertvik port facility", based on several real PFSAs. This example will also be described here in order to explain the approach.

The starting point for using the method is to count the "number of operations" in the port facility, which entails number of operations, people associated with the various operations etc., ranging from one to more than five. In the Hjertvik example, there were four operations in the port facility, which gave a score of 4 points.

The second step of the classification is to determine the "port facility proximity to populated places". This is described as proximity to populations or crowded places (cities, villages, industries, bases, installations with symbolic value and other infrastructure). This is measured in kilometres/metres ranging from less than 300 metres to more than 3 kilometres. Hjertvik port facility had more than 3 kilometres to the nearest densely populated area, which gave a score of 1 point.

As the third step, the "number of annual passengers" should be accounted for. The expected numbers should be filled in on a scale from less than 1000 to more than 200 001, and if the port facility does not handle passengers, the score is 1 (green). In this category, it should also be considered whether this is seasonal. The Hjertvik port facility did not handle passengers, and hence got a score of 1 point.

Fourth, the "number of personnel working daily at the port facility" should be counted based on the expected number on a scale from 0 to more than 200. Hjertvik had 21–50 people working on a daily basis, and got a score of 3 points in this category.

The fifth step is to assess the "expected annual calls/arrivals by ship" on a scale from less than 50 to more than 500. At Hjertvik, the annual arrivals were 51–150, and they got 2 points in this category.

Sixth, the "terminal type" should be described. This was done by examples for different scores: Does the terminal handle wet bulk, dry bulk, containers, general cargo, gas, building, RO/PAX and maintenance, as described in chapter 5.3.2. If the port facility handles different types of goods, the starting point is the type of cargo that gives the highest score. Here, Hjertvik had containers and LPG (liquefied petroleum gas-wet bulk), and ended up with a score of 3 points.

The seventh step includes "hazardous goods and substances". The term "hazardous substances" is used for any substance that may constitute an unreasonable risk to the health and safety of the operators, personnel or the environment if it is not handled and processed properly by storage, production, processing, packing, use, destruction or transportation. When assessing the dangers that may be potentially harmful to humans, the HazMat "diamond" is often used (United Nations 2011 and 2015). The scores were determined by consequence scores from the HazMat diamond, and whether the hazardous substances are stored in, or in proximity to, the port facility. Hjertvik had several types of dangerous goods and got a score of 5 points.

The eighth, and last, step is to determine "strategic importance". In this category it should be assessed whether the port facility has strategic significance for national security and sovereignty (e.g. territorial sovereignty and integrity, national freedom of action, relations with other states, democratic governance). It is also important to consider the importance of the port facility in the market and if it is of national symbolic value. In addition to the description, we prepared several guiding questions to help with this category, as described in chapter 5.2.2. The three scores were: no impact on national security and sovereignty, strategic import/export, uniqueness in operations, and importance for the armed forces, or a previous "national designated harbour". Hjertvik port facility did not currently have strategic importance, and hence got a score of 0 points.

In order to summarise the port facility's overall security profile, the point scores are added together and placed in the security profiles presented in Table 2.

Hjertvik port facility got a total score of 19 points, and ended up in "Security profile 2: Medium criticality", which is visualised in yellow in Table 2.

6.1 *End user experience*

During the spring of 2017, KYV completed the classification of all ISPS-approved Norwegian port facilities by applying the described classifica-

Table 2. The port facility security profiles.

The port facility security profile	
Security classes	Score
Security profile 1: Low criticality	7–16
Security profile 2: Medium criticality	17–24
Security profile 3: High criticality	25–40

tion method. KYV employees who have their main occupation in port security conducted the work, in association with PFSO when needed. Even though the aim was to make the PSO/PFSO determine what security profile they are, only to be quality assured by KYV, KYV ended up doing most of the classifications due to the familiarity with the method.

The method has a step-by-step approach making it intuitive to conduct, and does not require comprehensive knowledge about security risk assessments. Yet, it requires a joint interpretation of the ranking tables and their initial questions. During the process, KYV experienced that the questions were perceived differently among those who conducted the classification. This entailed that more or less similar port facilities could be assigned unequal security profiles.

As a response to this, KYV had to make some further refinements for how to understand the different ranking tables. For example, in the ranking table showing the number of operations in a port facility, KYV had to specify that operations in this context are related to the main ship-port activities. This means that a port handling container ships and dry bulk ships has two operations. For future use, a more accurate definition of each ranking table would improve the reliability of the method. Another remark is that classification must be considered as a continuous process. KYV has completed classifications of all Norwegian port facilities, but a change in a port facility's operational pattern can also entail change in the security profile.

Overall, the method provides a time efficient framework that applies to all Norwegian port facilities. Decision-makers in KYV are now provided with a simple, yet efficient tool when a situation calls for an increased security level in port facilities.

7 CONCLUSION AND RECOMMENDATIONS

In this paper, we have described a method developed to classify Norwegian port facilities and ports into different security profiles. This paper describes our approach and limitations to the study, as well as the data that has been analysed.

In the study, categories to assess criticality have been developed, with appurtenant ranking tables. Eight ranking tables are used for each port facility in order to determine what score they get, and thereby which security profile they belong to (security profile 1 is low criticality, 2 is medium criticality, and 3 has high criticality). Following this, the port facility's score must be compared with other ISPS port facilities in the port. All ISPS port facilities in a port must be dimensioned after the highest score in a threat situation.

We also described general threat trends in the maritime sector, focusing on the categories terrorism, intelligence/espionage, sabotage and other crime, and recommend that KYV stay updated on the available threat information in order to determine relevant security levels.

It is recommended that the security profile classification is used as one of the baseline information sources upon which KYV carry out their risk based supervisions. The frequency of supervisions should be considered with regard to both the criticality of the port facility and experiences from previous supervisions. The basis for the supervision should be well embedded, and the port facilities (e.g. PFSO/PSO) should be involved in the process of classification and risk assessments.

The approach presented here is a case that can be used as an example for other infrastructures as well. The background for the classification is rooted in a more general way of assessing consequences of security incidents, and may also be applicable to different kinds of critical infrastructures. Lessons from this case can also be relevant to consider for critical infrastructure owners or operators who are unsure of how they should address classification.

Mobile data interception in 4G via diameter interconnection

Silke Holtmanns

ABSTRACT: The IP Exchange (IPX) connects telecommunication networks with each other. It enables features like roaming and data access while traveling. Designed as a closed network it is now opening up and unauthorized entities now misuse the IPX network for their purposes. The interconnection networks suffer from many Signaling System No 7 (SS7) protocol attacks. Advanced operators now use Diameter based LTE roaming. We will illustrate how under certain network configurations an attacker can collect sufficient amount of insider information and then modify the subscriber profile to change the access point configuration in different core network nodes and by that place himself in the middle of the data traffic path for the user. We will close with recommendations on how to prevent such an attack.

1 INTRODUCTION

It is taken for granted that we can use our phone for data and calls when abroad. We rarely consider what happens in the background when we switch on our phone after our arrival in another country. You connect to a network that knows at that point of time nearly nothing about you, still in the end you can make calls, access your webmail and twitter and are being charged on your home-network bill. This is all possible because operator networks communicate through private signalling networks, i.e. an Interconnection Network. All network operators in the world are connected through it with each other, sometimes directly, sometimes indirectly via service providers.

The first Interconnection Network was the so called Nordic Mobile Telephone Network between Norway, Finland, Sweden and Denmark [1] in 1981. At that time most network operators were state-owned and there was trust between the partners. The main goal was to enable services for their users. They designed protocols and messages to serve that goal. The Signalling System No. 7 (SS7) is a network signalling protocol stack used worldwide between network elements and between different types of operator networks, service providers on the interconnection and within operator networks. It was standardised by the International Telecommunication Union, Telecommunication Standardisation Sector (ITU-T) more than 35 years ago [2].

At that point of time, security was not the main de-sign concern, as the usage of SS7 was considered to be only in a closed network between trusted partners. Later with VoIP and other IP services being handled by mobile devices it was necessary to use an IP based Interconnection network for mobile operators, this lead to the IP Exchange network (IPX) and it has been sup-ported and partially standardized by the GSMA Association since 2004.

2 DIAMETER BACKGROUND

Diameter is the evolution of the SS7 and its Message Application Protocol (MAP) [3] protocol that is used within and between the 4G Long Term Evolution (LTE) networks. LTE uses the Diameter protocol and the Session Initiation Protocol (SIP) for communication between the network elements inside a network and between networks. We will focus on the diameter part of the network in this article. In a Diameter based network architecture all elements are connected via an IP interface. The network nodes all support the Diameter base protocol specified in IETF RFC 6733 [4]. In Diameter each interface has its own application interface specification which is defined separately

in a different specification document and specifies application specific additions to the base protocol.

To connect two LTE diameter based operators together, often an IPX or interconnection service provider is used. Smaller operators utilize IPX service providers and aggregators to be able to offer their customers a large roaming selection. Operator networks usually deploy a Diameter Edge Agent (DEA) that resides on the border of the network as the first contact point for messages coming over the interconnection link. The most important nodes from the security point of view are the Home Subscriber Server (HSS) which holds the subscriber profile information and the Mobility Management Entity (MME) which takes care of the user's mobility (often combined with a Visitor Location Register VLR).

Diameter based communication can be secured using Network Domain Security NDS/IP as specified in 3GPP TS 33.210 [5] i.e. IPSec (Figure 1). However, even if IPSec is implemented in many core network nodes and separate gateways (e.g. SeGWs) it is commonly not used i.e. the Figure 1 is wishful thinking in most cases. The reason for that are manifold. Since this is an international network, the question of the trustworthy root certificate authorities, revocation list, certificate chains, trustworthiness of self-signed certificates, key generation etc. becomes a political one. In addition, there are Interconnection Service Providers i.e. messages often traverse several "hops" between the operators. The routes between operators are chosen based on costs, therefore, the realm based routing to and from an operator might be different. The support of security would require the creation of a large Public Key Infrastructure, including dynamic certificate status validation, which goes along with some substantial investments also for player who did not invest in security in the past (as the IPX network was closed). And some operators just don't have the financial resources or expertise to secure their network communications to their partners. We will focus on the usage of Diameter on the S6a/S6d between HSS and MME as specified in 3GPP TS 29.272 [6] and the Sh interface between the HSS and an IMS application server as specified in TS 29.329 [7] and TS 29.328 [8].

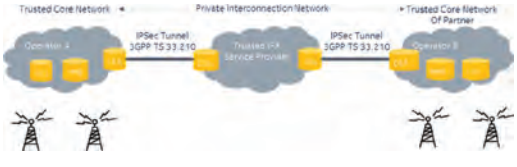

Figure 1. Interconnection between LTE operators using Diameter with NDS/IP security.

Diameter is constantly extended also for 5G and IoT (Internet of Things) connected devices. Even though Diameter is a different protocol that what is used within SS7, the underlying functional requirements e.g. authenticating the user to enable a IMS-SIP based session setup, transferring user information etc. remain much the same so there are many similarities in the messages used for Diameter and the SS7 MAP protocol messages. However, there isn't an exact one-to-one mapping for each MAP message to each Diameter command and vice versa.

3 RECENT SECURITY BREACHES

For SS7 many attacks via the Interconnection link are known and observed e.g. location tracking, eavesdropping, SMS interception, fraud, DoS, One-time password theft, credential theft, unblocking of stolen phones etc.

The first interconnection vulnerabilities were published for the 4G Diameter protocol:

- Location tracking [9], [12].
- Denial of Service/Fraud [10], [12].
- SMS interception [11].

Recently, an interesting GPRS data attack was observed during a live assessment, where a modification of the CAMEL profile of the user was manipulated [13] (Figure 2). We are doing a different type of profile modification, but it was inspired by the approach of [13].

In this attack, an incoming SS7-MAP Insert Subscriber Data (ISD) packet was detected being sent to the SGSN that a subscriber was currently attached to. Within the ISD packet the subscriber profile was modified with these specific CAMEL settings:

1. A GPRS-CSI Trigger Point was set, this set GPRS-TriggerDetectionPoint to a value of 11 (pdp-ContextEstablishment)

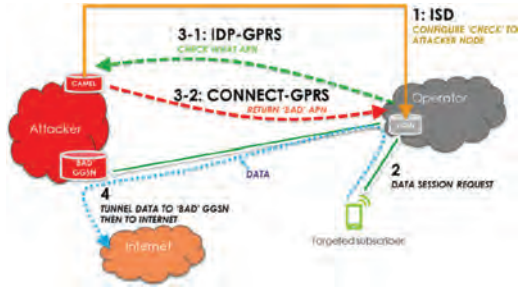

Figure 2. Data interception for GPRS [13].

2. A gsmSCF-Address was set, this is the SS7 Node address that the SGSN was to send any resultant CAMEL packet to. This SS7 address was the same as the source of the ISD packet (a SS7 Node based in another con-tinent)
3. DefaultGPRS-Handling was set to 0 (continueTransation)

The overall effect of this trigger point was to instruct the SGSN to inform the attacker node of any PDP context establishment procedure started by the sub-scriber, i.e. if they tried to use the Internet or set up a data connection. At this point the attacker node, having received the IDP-GPRS would override the APN indicated by the user (i.e. the one that is stored in his phone), with its own APN in its CONNECT-GPRS response.

The purpose of setting DefaultGPRS-Handling field by the attacker is if the attacker node did not respond, then the SGSN would continue to use the original APN, this removes the need to generate an explicit response each time, and reduces the attacker traffic.

The main obstacle for an attacker is to gain access to the private Interconnection network. In theory, this should not be possible for a private individual or an attacker, however the legal rules for network operators for renting out access to the interconnection to service providers differ between countries, and some IP-using nodes are attached and visible on the Internet (e.g. GGSN nodes via shodan.io [18]). Therefore, attackers with sufficient technical skills or financial resources have found ways to breach the privacy of the network. The GSMA Association has provided their members with a set of protection measures for SS7 and Diameter interconnection security. That those attack vectors are also very likely exploited in practice can be seen from the information contained in the leaked e-mails of HackingTeam [14] from 2013, which state that they are developing at that time already exploits for LTE/Diameter.

4 ATTACK DESCRIPTION

The attack we will describe has three major phases, which are independent of each other. Each of those phases has some assumptions on the configurations and also some variants and alternatives which an attacker may apply to reach the final goal of data interception.

We assume that the network does not have a signaling aware filtering software deployed at the edge of the network, typically represented by a Diameter Edge Agent (DEA) or a Diameter Routing Agent. Our assumption on the Diameter edge node is that it was placed there by the operator under the presumption, that it runs as a sort of router between trusted entities in a private and closed network.

The attacker is in possession of the phone number of the victim (MSISDN) and has access to the Interconnection network.

For attack preparation, the attacker acquires information about the network operators he wants to attack and about the network node he pretends to be. Operators that offer roaming have a so-called IR.21 document, this document describes various details of their architecture to enable the configuration for the roaming connections with their partners. Those IR.21 documents are not public documents and should be only used by the roaming partners for proper configuration of the roaming interface, nevertheless, some of them can be found on the Internet. In addition, operators also often use blocks of addresses for their nodes. Both IR.21 leakage and block usage make it easier for an attacker to brute force e.g. SGSN attacks.

The attacks are based on results obtained from specifications defining the behavior of the nodes and the test network that is usually used to verify correctness and security of new software code / updates for real operator networks before the new software is rolled-out.

4.1 *Subscriber data harvesting*

4.1.1 *Getting the IMSI*

The first step for an attacker is gather information about the user. He starts by obtaining the user's International Mobile Subscriber Identity (IMSI). This user identifier is needed for core network communication, but is also needed as critical information to base subsequent attacks on. There are several ways of obtaining IMSIs. One can set up a false base station and just call all devices in the area to send them their IMSI. Alternatively, a WIFI access point which is able to issue a EAP-SIM call to the device [15] or using the SS7 MAP SRI_SM (Send Routing Info for Short Message) command [16].

We will focus on how to obtain the IMSI via Diameter based Interconnection, as we assume that the attacker does not want to travel to his victim. The attacker impersonates a Short Message Center (SMSC) i.e. he claims to have a SMS for a user and he wants to deliver it and needs therefore the "contact details" from the users Home Subscriber Server (HSS), which contains all the important subscriber information elements (Figure 3). This is a common and valid roaming scenario.

For that purpose, the attacker sends a Diameter Send Routing Info for (Short Message) SM Request to the HSS of the user's operator.

This message contains the MSISDN (phone number) of the user. In response, the HSS will provide a Send Routing Information for SM Answer

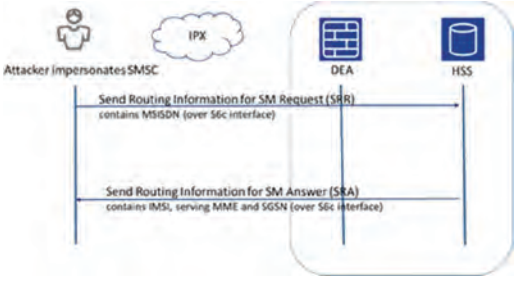

Figure 3. IMSI Retrieval using SMSC impersonation.

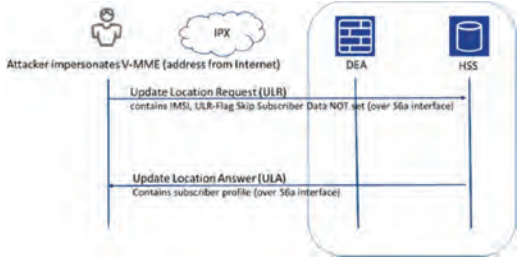

Figure 4. Profile extraction using ULR.

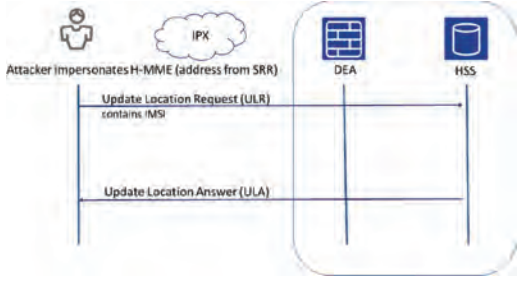

Figure 5. Setting back the MME to "old home MME".

with the IMSI and the serving nodes for the user i.e. serving MME and Serving GPRS Support Node (SGSN). The information will then later be re-used in the 2nd step of the attack.

It should be noted, that between the "harvesting of the IMSI" and the actual usage of the IMSI in attack years may go by. For some cases e.g. in IP Multimedia Subsystem IMS the IMSI is not even needed at all e.g. in the User Data Request (UDR) message.

The second piece of information the attacker craves is the subscriber profile. The subscriber profile contains detailed technical information and key attributes about the subscription the user holds.

4.1.2 *Subscriber profile retrieval*

4.1.2.1 From MME

The attacker is now in possession of the IMSI of the user, the serving Mobility Management Entity (MME). The next step is the attacker can perform a location update i.e. the attacker claims, that this user has "landed" in his network. For this he makes a Diameter Update Location Request (ULR) over the S6a interface according to 3GPP TS 29.272 [6], using the information obtained in the previous IMSI retrieval attack (Figure 4).

In this location update request he does NOT set the ULR-Flag "Skip subscriber data", this indicates to the HSS that the MME requests a fresh copy of the subscriber profile for synchronization purposes, which is a common roaming scenario. The HSS then sends back an Update Location Answer (ULA). This answer contains the requested subscriber profile.

We assume that once an attacker holds a complete subscriber profile of a user of one operator, he can deduct the operator specific details of the structure of the profile, and then figure out how to make a fake entry look real for this or another subscription. In Figure 5 a subtle attacker would also reset the MME back (assuming again that the DEA does not properly differentiate between internal and external originated traffic, in a really fully trusted and closed network this kind of differentiation would not be needed).

If the network has a very basic filtering in place i.e. H-MME messages should not come via interconnection link, then this setting back does not work, but for the main attack itself this 'extra' setting back of the MME is not needed, it is only a way for an attacker to reduce the risk of being noticed.

4.1.2.2 From HSS

An alternative method is to request the information from the HSS, this though is more difficult for Diameter. It may be possible as IMS networks usually deploy many Application Servers (AS) and not all of them reside directly in the core network. The Sh interface is between an Application Server and the HSS and is specified in TS 29.329 and TS 29.328 [7], [8] and should be used as a network internal interface only.

But, an operator has usually many application servers and not all AS services might be provided by that operator himself. They might be provided by the mother company of that operator or some other service provider, then the Sh interface becomes an interface that is open on the interconnection link (might not be visible, but still processes Sh messages).

In the case that the DEA passes Sh messages to the HSS (e.g. if the operators uses an application

server that does not reside directly in their network), the attacker can send a User Data Request (UDR) request message, which then returns the user profile. In IMS, this message can be populated with the MSISDN only as a user identity and the returned user profile would contain also the IMSI (Figure 6).

Below in Figure 7 a snapshot of such an update request and the corresponding answer in Figure 8:

As the Application Server would be on the other side of the DEA, the HSS would see only the IP address of the DEA and any IP address access control list for IMS Application Servers would not work, as that IP address control mechanism was designed for AS that reside in the same core network.

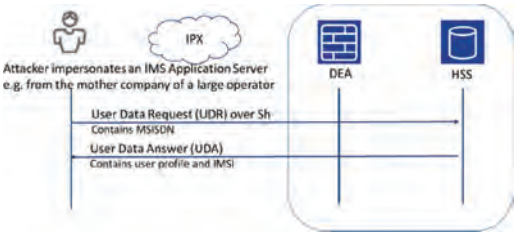

Figure 6. Subscriber profile and IMSI retrieval using UDR over Sh.

Figure 7. A UDR request containing a full profile.

Figure 8. UDA user data answer “ok”.

4.2 *Inserting the false access point node*

Depending on the different possible network configuration and on the target data communication, the attack discussed in this paper has several flavors. We will now outline how to place modified APN settings in various nodes.

4.2.1 *GPRS—profile modification in serving GPRS Support Node (SGSN) and MME*

The attacker aims to modify the subscriber data stored in the Serving GPRS Support Node (SGSN). From here on, the attack follows the discovery of [13] and evolves it to a Diameter attack. The attacker pretends to be the users home HSS issuing an Insert Subscriber Data Request (IDR) to the serving SGSN. The serving SGSN information has been obtained as outlined above or an attacker just brute forces all SGSNs of that operator or by extracting the subscriber profile.

The serving node information is part of the subscriber profile i.e. MME/VLR and SGSN. This malicious IDR message contains the subscription data AVP (attribute value pair) of type grouped. In particular, the subscription data contains:

– GPRS Subscription Data
– Access Point Network (APN) Configuration Profile (with APN con-figuration details)

In [13] based on SS7, the CAMEL settings were modified directly. In the LTE case this approach does not work, as the S6d interface does not support SGSN CAMEL subscription data. But this obstacle can be circumvented, by directly modifying the APN-Configuration-Profile AVP in the SGSN, which contains the APN-Configuration AVP (TS 29.272 [6], section 7.3.35) in the subscriber profile in the IDR diameter message.

APN-Configuration: = <AVP header: 1430 10415>
{Context-Identifier}
{PDN-Type}
{Service-Selection}

The Context-Identifier in the APN-Configuration AVP uniquely identifies the 4G Evolved Packet System (EPS) APN configuration per subscription. Each APN profile configuration can contain several APN configurations, therefore an attacker can set specific fake APNs for GPRS, EPS etc. TS 29.272 (section 7.3.34 and 7.3.35). Service Selection contains the name of the subscribed APN in use (Figure 9).

Depending on the deployed filtering the placement of a false APN in the SGSN is harder, while the user is in his home network. There the attacker would need to know the address of the home-HSS (potentially again from leaked IR.21 documents),

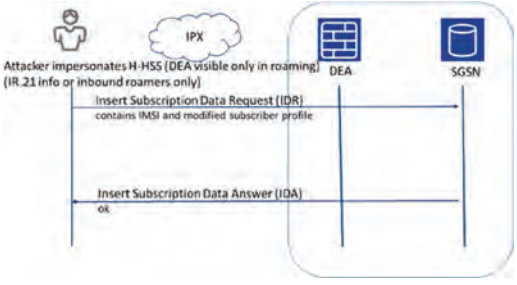

Figure 9. Placing of modified profile in the SGSN.

but that address is "less public" then for example a DEA address.

There are two "flavors" to this IDR attack. If the user is roaming and the serving SGSN resides in the visited network, then the attack has high chances of succeeding. The attacker, when sending the IDR with the malicious APN, would impersonate the Home-HSS, but due to roaming the visited network would only see the DEA address of the home network (which can be spoofed by setting the origin realm and origin host), as the message answer to the IDR does not really need to go through it is no issue to spoof the origin. The DEA address could be found from various IR.21 documents on the Internet or brute forcing the operator ranges.

Also, the network would not even have the lowest of all checks i.e. it does not check, if a message arrives on the interconnection edge which claims to come from an internal node. Therefore, the attack is considered harder, when the target user is not roaming. The modified profile would stay active until the SGSN synchronizes again with the HSS and indicates that it would need a fresh profile.

4.2.2 *Profile modification in HSS Using Sh*

An alternative method is to do subscriber profile modification in the HSS via the Sh interface. It is for an attacker very interesting to change the "master copy" of the subscriber profile which resides in the HSS, we will describe how in a not very well secure network that might be achieved. An attacker can pose as an Application Server and send a Profile Update Request (PUR) message to the HSS (Figure 10). This "synchronization message" can contain a modified subscriber profile i.e. it would have a modified APN settings. Actually, an AS is not supposed to touch that part of the subscriber profile, but the specification does not mandate fine grained profile processing on the HSS side. So depending on the implementation, the HSS will just process the incoming profile data, regardless if it is "transparent" profile data or not.

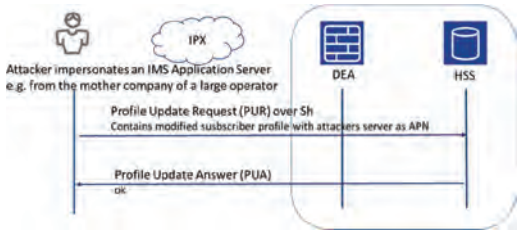

Figure 10. Update of profile in HSS using Sh interface and PUR message.

4.3 *Modification of APN settings in HSS using S6a*

The main focus of this paper is to highlight the risk that comes by an unprotected IMS Sh interface. But it should be noted, that parts of the attack can also be performed using other interfaces, like the S6a interface.

The update location message over the S6a interface allows the MME or SGSN to include a dynamic APN information to restore the Packet Data Network Gateway (PDN GW) data in the HSS e.g. for the case that a reset of the HSS has occurred and the APN information need to be restored (for detail see TS 29.272 [6] 5.2.1.1.2). The active APN AVP configuration element, contains the list of active APNs stored by the MME or SGSN, including the identity of the PDN GW assigned to each APN. The attacker would fill then in his APN information (Figure 11). The following information is required to be present:

- *Context-Identifier: context id of subscribed APN in use*
- *Service-Selection: name of subscribed APN in use*
- *MIP6-Agent-Info: including PDN GW identity in use for subscribed APN*
- *Visited-Network-Identifier: identifies the PLMN where the PDN GW was allocated (which would be the network the attacker has rented its access from)*

For the case that the above approach is not working the second alternative is to use a Wildcard APN by inserting the following information:

- *Context-Identifier: context id of the Wildcard APN- Specific-APN-Info: list of APN-in use and related PDN GW identity when the subscribed APN is the wildcard APN*

4.4 *Redirection of user*

When the user now requests data services, he would first use the APN configuration in the terminal. This APN configuration would not match the one

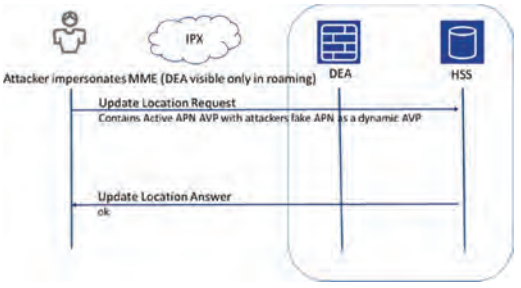

Figure 11. APN insertion with ULR over S6a.

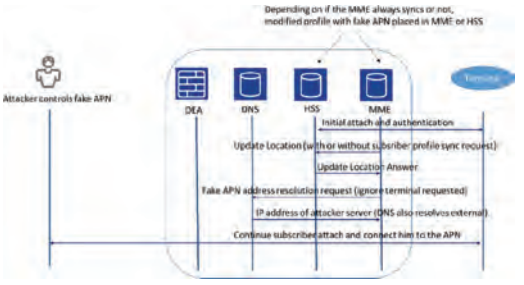

Figure 12. DNS resolution message flow.

subscriber profile in the SGSN/MME. There is an error process for this, as the basic assumption of the net-work would be that there is a misconfiguration in the user terminal. This assumption comes from the times, when the user had to manually configure their terminals. Therefore, the SGSN (GPRS) / MME (EPS) contacts the operators DNS using a NAPTR query to resolve the corresponding APN configuration to the attacker's node and the GTP (GPRS Tunneling Protocol) is established to the attackers GGSN.

Any profile modification in the SGSN and also in the MME are of "temporary nature", as those nodes synchronize with their Home-HSS at some point of time. Those synchronization configurations are operator dependent and depend on how much load usually a HSS has. If an operator has a of load on his HSS, those synchronization will be rarer. The attacker has to do some try-and-error to see, if it is sufficient to change only the MME subscriber profile or if he needs to change it in the HSS.

In some products exist the feature for such an error case to configure a default APN in the APN remap tables, but those remapping approaches can potentially be "tricked" by modifying the entry in the HSS/HLR. Also, there exist SGSN which attach automatically a "mncXXX.mccXXX.gprs" before sending out the request (similar for EPS), which would make such an attack difficult, but this kind of automatic attachment is not part of the mandatory standard processing TS 29.303 [17] and behavior and is a product specific extension.

It should be noted, that an operator should deploy different DNS for internal and external resolutions or at least different DNS views based on the requestor, but for efficiency reasons this is not necessarily always done. Note however, that even if different DNS are in place for both internal and external, and the internal DNS only contains entries of home and roaming partner APNs, it is possible that the malicious APN resolved could be resolved from the domain of a trusted roaming partner that has provisioned the malicious APN (to the attacked network). After all, the attacker needs to have some entry vector into the interconnection vector and that means he is "in some operator" already. This though, is a more complex and invasive method.

With those different approaches to modify and update the APN_Configuration_Profile AVP in the subscriber profile and setting it to the APN an attacker server, the attacker can vary his attack strategy according to configuration of the victim. The attacker does not know, if the MME would synchronize or not, so he would try and error, if he needs to modify the APN setting in the MME or in the HSS. When then a normal flow takes place and the DNS is serving internal and external requests, then the MME would redirect the terminal to the attacker's server (Figure 12).

In general, profile modification and data interception attacks pose a real threat and were observed in the wild for GPRS and therefore, we expect that with the advances in technology towards LTE, the attackers will extend their attack portfolio to cover also those attacks.

5 PROTECTION MEASURES

This article outlines, that an attacker is not bound to one technology or protocol choice when attempting to intercept data and modify the user profile via the interconnection link.

Attacks can be modular in structure and the attacker would have a toolbox depending on the encountered actual configuration of the victim network. From this toolbox he can use a mix-and-match approach to achieve his goals by combining several potential typical deployment weaknesses in Diameter networks. We validated in our test network specification conformant messages and nodes and their behavior under the different configurations. The main point of this article is to show that an information leakage and "harmless looking" configuration weaknesses in one interface combined with typical roaming messages can lead to a data breach.

The countermeasures are dependent on the actual deployments, but the following general recommendations would make this kind of attack harder:

- Interface checking at DEA i.e. the DEA should not answer Sh messages and related messages need to be blocked and logged.
- If the network relies use an Application Server outside of the core network security zone, then this should be secured with a direct certificate secure tunnel and explicit certificate based access control and authentication.
- Usage of whitelists and location-distance checks at the DEA (e.g. for S6a interface) and deploying a dedicated protocol aware signaling firewall for it.
- Validation if a reset procedure was done before executing a dynamic APN in an ULR message. In addition validation of the source of the update location i.e. if the this update location for this particular user is feasible (location-distance-travel-time-checking).
- Deployment of a dedicated DNS for internal queries only and put it behind the firewall e.g. multiple DNS servers or DNS views for each domain; Alternatively, no shared DNS configurations/physical DNS servers for trusted and untrusted domains.
- DNS security i.e. protection against cache poisoning and internal DNS should not be in front of the firewall.
- IMSI based address resolution (to avoid automatic resolution of attacker address).

These methods would make the described attacks at least much harder, if not impossible.

ACKNOWLEDGMENTS

This work was partially funded by the SCOTT project. The SCOTT (www.scott-project.eu) has received funding from the Electronic Component Systems for European Leadership Joint Undertaking under grant agreement No 737422. This Joint Undertaking receives support from the European Union's Horizon 2020 research and innovation programme and Austria, Spain, Finland, Ireland, Sweden, Germany, Poland, Portugal, Netherlands, Belgium, Norway.We would also like to thank the security group in GSMA which drive the improvement of the interconnection security. In addition, the authors would like to thank Tobias Engel from GSMK for his valuable feedback.

Finding your aim—choosing your game

T. Grunnan & H. Fridheim
Norwegian Defence Research Establishment (FFI), Kjeller, Norway

ABSTRACT: There are many ways to conduct crisis management games and exercises, with many formats to choose from. A recurring challenge is to find the most useful format for reaching the specific objectives of a given game or exercise. We have conducted a Limited Objective Experiment (LOE) to study organizational uncertainty related to this and to look at ways to support game and exercise planners. The experiment shows that precise aims and objectives are important for choosing suitable formats for games and exercises. Additionally, it shows that planners need guidance and support tools to make the right choices, even when the aim is specified. This is likely related to uncertainty associated with terminology, methodological biases and the fact that there are numerous available games and exercise formats. The findings are relevant to practitioners within both the fields of security and safety.

1 INTRODUCTION

There are many ways to conduct crisis management games and exercises and many types and formats to choose from. Relevant formats include table tops, seminar games, wargames and full-scale exercises. A recurring challenge is to find the most useful format for reaching the specific objectives of a given game or exercise. In our experience, there are often uncertainties within organizations on how best to do this.

Handbooks on wargaming and exercise planning are often descriptive, in the sense that they explain how to set up and conduct various types of games and exercises (DHS 2013, MSB 2014, Burns et al. 2015, NVE 2015, DSB 2016, MOD 2017). The handbooks often take the form of instruction manuals, teaching the reader to plan and conduct a game or an exercise. However, Grunnan & Fridheim (2017) shows that planners and decision-makers often are unaware of how choices in both design and execution affect the results from games and exercises. Handbooks often describe what to do, but to a lesser extent why a particular format or type is the best for a given purpose, what works and what will not.

In this paper, we will expand on our previous research (Grunnan & Fridheim 2016, Grunnan & Fridheim 2017, Fridheim et al. 2017) and argue that finding the aim of an activity is essential and a pre-requisite for choosing the right type of game or exercise to support it. However, we often notice that game/exercise planners are uncertain of what the most suitable format is, even when aims and objectives are given. The uncertainty is partly due to the bewildering array of overlapping and contradicting terms related to gaming and exercises, partly due to methodological biases of planners. Thus, we have started work on how to manage this uncertainty, using our own organization as a case. We have conducted a Limited Objective Experiment (LOE) to study whether the perceived uncertainty is real or not. We have also looked at possible tools to support game or exercise planners in choosing the right formats. This paper describes our initial findings.

The target audience for the paper is anyone involved in game/exercise planning, for example contingency planners, exercise planners, military planners, crisis managers, and consultants. In addition, the findings are relevant for decision-makers, researchers and analysts who use games and exercises as a method to investigate a problem and collect data.

2 BACKGROUND AND THEORY

2.1 *The organizational challenge*

The Norwegian Defence Research Establishment (FFI) has a long history of planning and conducting games and exercises, both generally to support analysis in running projects and specifically for various military and civilian customers. There is a wide range of activities that fall within the terms "games" and "exercises", but their purpose can roughly be divided in two:

1. Learning: Activities where the main purpose is to provide learning and training for the participants, so they are better prepared to make decisions in the future.

2. Analysis: Activities where the main purpose is to collect or develop data and information which can support future decisions.

While there are many activities that can support these purposes, they have several common features, similar to the elements of a wargame as listed in (MOD 2017):

- Aims and objectives for the activity
- Players/participants and their decisions
- A scenario and a setting that provides an immersive environment for the participants
- A simulation of the real world
- Rules, procedures and adjudication of decisions
- Data to create the scenario and the simulation
- Supporting personnel and subject matter experts
- Analysis and data collection

Although customer feedback on the conducted games and exercises at FFI is generally good, there are still areas for improvement. We have run a simple in-house problem-structuring session to help identify the challenges that must be addressed to develop more relevant and useful games and exercises in the future. Here we observed an uncertainty within the organization on which game and exercise types are best suited to support different purposes. Given the huge variety of possible formats, which should be chosen to give the most relevant answers and outputs for any given aim and objective?

Some of the causes for this uncertainty were identified to be:

- There is no common understanding of the terms related to "games" and "exercises".
- There is too little collaboration in the planning and conduct of games and exercises. Instead of sharing knowledge with each other, different project groups have established local practices and approaches.
- There is a practical approach to planning and conduct of games and exercises, instead of an academic one. The main goal is often to find a format that works given available resources, without considering options to find the best approach.

These causes are not uncommon for FFI. For instance, the lack of collaboration in exercise planning and conduct is also identified in OECD (2014), where local practices are described to be "…knowledge as a canon best passed on through mentor-mentee communication and informal apprenticeship or their designs as proprietary trade secrets best left undocumented and un-diffused".

2.2 *Games or exercises?*

The terminology related to games and exercises has long been subject to debate, and there are several definitions of both terms, with none being universally accepted. How you define the terms also depends on your area of work. Of interest to FFI is the difference between military and civilian approaches.

The military often uses the term wargaming or war gaming (tellingly, there is no consensus on whether the words should be combined or separate). One widely used definition of wargaming is from Perla (1990): "…a warfare model or simulation that does not involve the operations of actual forces, in which the flow of events affects and is affected by decisions made during the course of those events by players representing the opposing sides". The basic components of this definition are identified by the US Naval War College (USNWC 2017): "War-games involve PEOPLE making DECISIONS in a context of competition or CONFLICT (with themselves, other people, or their environment)". Exercises may differ from wargames in the sense that they use actual military forces instead of simulated ones (Simpson Jr 2015).

On the civilian side, one definition of exercises is made by the Department of Homeland Security (DHS 2013): "An exercise is an instrument to train for, assess, practice, and improve performance in prevention, protection, mitigation, response, and recovery capabilities in a risk-free environment." The same publication defines a game as "… a simulation of operations that often involves two or more teams, usually in a competitive environment, using rules, data, and procedures designed to depict an actual or hypothetic situation. Games explore the consequences of player decisions and actions". While this is in line with the definition of wargaming above, the military separation between the real (exercises) and the simulated (games) is muddled when DHS classifies games as a "discussion-based exercise technique". A similar approach is made by the Norwegian Directorate for Civil Protection, who defines "game exercise" as one of four exercise formats in their guidelines for planning, conduct and evaluation of exercises (DSB 2016).

At FFI, one result of these terminology uncertainties is that different terms are used about similar activities, and vice versa. On the military side, a tabletop discussion could be labelled as a seminar game. A similar activity on the civilian side could be classified as a crisis management exercise. However, for all practical purposes, these are the same activities, with the same aims and objectives, using similar formats. This confusion adds to the uncertainty of choosing the right game or exercise format for any given purpose.

2.3 *Choosing your game or exercise style*

There are many different styles of games and exercises available, and naturally, there have been

many attempts at categorizing them. Related to wargaming, a recent and widely used categorization is made by Pournelle (2017). He identifies six wargame categories, depending on the purpose of the games (creating knowledge, conveying knowledge or entertainment) and whether they address structured or unstructured problems, see Table 1.

Within the six categories, Pournelle (2017) identifies four major styles of operational wargames: Seminar games, matrix games, free kriegsspiel and rigid kriegsspiel. These styles get less creative, more predictable and provide more analytic rigour from left to right. In general, the effort necessary to arrange the games also increase from left to right.

Within these general styles, you will find various types of wargames. Mouat (2017) lists several types, mostly depending on how the operational environment is represented: Computer wargame, map wargame, board wargame, seminar wargame, sand table wargame and "soft issues" wargame (matrix game).

Related to exercises, DHS (2013) categorizes exercises as either:

- Discussion-based, Seminars, workshops, tabletop exercises and games.
- Operations-based, Drills, functional exercises and full-scale exercises.

Similar to Pournelle's game styles, the operations-based exercise categories are more effort-intensive than the discussion-based.

Within the range of styles, opinions naturally differ on which is the most suited game/exercise format for a given aim or objective. In many cases, the choice of format is subject to less thought than it should be. As discussed in (Grunnan & Fridheim 2016), customers often decide on a particular exercise format without finalizing the exercise goals. Similarly, game and exercise planners are very much subject to the "law of the instrument", as expressed by Maslow (1966): "I suppose it is tempting, if the only tool you have is a hammer, to treat everything as if it were a nail." The result is that old habits die hard when game and exercise planners re-use the methods they are familiar with, without considering new or improved approaches for the given problem.

Table 1. Six wargame categories (Pournelle 2017).

Problem	Creating knowledge	Conveying knowledge	Entertainment
Unstructured	Discovery games	Education games	Roleplaying
Structured	Analytic games	Training games	Commercial kriegsspiel

Similar effects can be noticed at FFI, where those working on the strategic and operational level tend to go for simpler discussion-based formats, while those working on the tactical level usually reach for more rigid formats with support of modelling and simulation. In many cases, this is a natural consequence of the problems that are to be studied, but not always.

In summary, it may be emphasized that there is need for more clarity on terms, as well as a need for tools or frameworks that enable us to choose the right game or exercise format for a given purpose.

3 METHOD

In this chapter, we explain the methods we have used in order to identify and manage uncertainty related to matching aims and objectives with suitable game and exercise formats. We have combined initial problem structuring with a simple Limited Objective Experiment.

3.1 *Problem structuring*

In order to 1) identify relevant challenges, and 2) demonstrate and discuss which game/exercise format is suitable and applicable for given purposes, we conducted two problem-structuring sessions in-house. The first session was a brainstorming session where the aim was to identify different formats/types of games and exercises, as well as to identify critical factors and criteria for matching formats and objectives.

After the initial problem structuring session (described in chapter 2.1), we used a creative technique called «Starbursting» (NATO 2017). The technique is used to generate questions about a problem, and it provides a useful structure for getting started with a research topic. We drew a star with six points and wrote who, what, why, when, where and how at each point. In the middle we put the topic of discussion, how to find the best format of a game or exercise in order to reach specific objectives. We systematically went through the six points, brainstorming possible questions. Afterwards, we organized and prioritized the questions.

The final step was to formulate a plan on how to proceed, based on an analysis of the findings. The questions laid the foundation for further literature studies and the organization of a seminar with a simple experiment. Starbursting is an effective method, especially in the early phases of a project, since many people find it easier to raise questions than to find answers (NATO 2017).

3.2 *Limited objective experiment*

The next stage was to conduct a Limited Objective Experiment (LOE). A LOE is a narrowly scoped, analytically focused assessment or validation event. We invited 24 researchers and military officers at FFI to take part in the experiment in the context of a half-day seminar. The participants' experience and expertise related to games and exercises ranged from no experience to much experience, see Table 2 in Chapter 4.2.

The seminar had three objectives. First, we wanted to strengthen internal competence and awareness of what games and exercises are and how they can be used at FFI. The authors presented a range of formats for games and exercises, using real examples. Second, we wanted to facilitate more collaboration on games and exercises across the organization, to enable learning and strengthen the quality of future games and exercises. Finally, and most importantly, we conducted the LOE with the participants, to study the perceived uncertainty related to game and exercise formats. In addition to being a competence-enhancing measure, the presentations and discussions were mood setters intended to prepare the participants for the experiment.

The purpose of the LOE was two-fold: First, we wanted to study whether the uncertainty we thought was present in the organization actually was there. Second, we wanted to see if a simple supporting form would help participants select the format of a game or exercise, when the aims and objectives were given.

The participants were given a form with the title: "How to choose the format of a game/exercise". On one page we described three cases. They were inspired by actual assignments FFI had received in the past. On the flip page, there was a form with boxes to fill out, as shown in Figure 1. The figure is a matrix with two dimensions, operational environment and adjudication. Operational environment is defined by the authors as "how the operational environment is represented in the game or exercise", i.e. how reality is simulated. Adjudication is "the process of judging how the game progresses and develops when the participants make decisions". The figure had these two dimensions represented on each axis. On each of the axes there were a number of values associated with the current dimension, 8 for adjudication and 6 for operational environment. Combinations of one value from each axis would constitute a format for a game or exercise.

Table 2. Participants' experience with games/exercises.

None	Little	Some	Much	Total
2	9	8	3	22

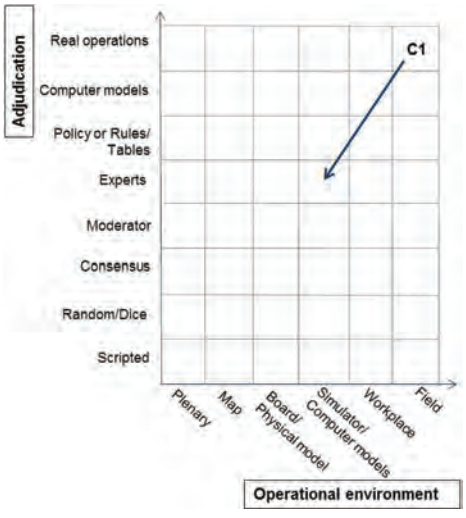

Figure 1. Example of form used in experiment.

The participants were asked to write C1, C2 or C3 in the figure where they would intuitively place cases 1, 2 and 3. When everyone had filled out the form, there was a short break to mingle and reflect, discuss and interact with the other participants. After the break, participants were allowed to make changes with an arrow to a new format they considered more appropriate, see example in Figure 1. Finally, the form was submitted to the organizers.

4 FINDINGS

In this chapter, we present the three cases we used in the experiment, before we describe and discuss the findings. The results from each case are presented in figures. The participants had the opportunity to modify the answers they made initially, and these changes are described in writing. We comment on the overall results, and we discuss how various factors may have impacted on the results from the experiment.

4.1 *Three cases*

The three cases chosen for the experiment were inspired by assignments given to FFI in the past. They have been conducted as games or exercises by researchers at the institute, including the authors, but not by the participants in the experiment.

The participants were asked to read the description of the cases and note in the form which game/exercise formats they intuitively would choose related to the two dimensions, operational environment and adjudication.

4.1.1 *Case 1 – Bilateral ministerial game*

As part of strengthening their bilateral cooperation, ministries in two countries want to carry out a wargame with a crisis in the Arctic region. The purposes of the game are:

1. Gain insight into the countries' strategic thinking, threat assessment and action in a potential crisis.
2. Help improve understanding of situational awareness and explore opportunities and limitations for cooperation in crisis and war.

4.1.2 *Case 2 – Internal wargame*

As part of internal learning processes, a research organization wants to conduct a wargame for its employees. The scenario is a bilateral conflict between two countries, which ends in a military attack on one of the countries.

The purpose of the game is to assess the two countries' practices and courses of action in different phases of the conflict, based on a given Order of Battle (i.e. available forces).

4.1.3 *Case 3 – Educational wargame*

A ministry is to participate in an annual international crisis management exercise. In order to prepare for the exercise, the ministry wants to conduct an internal game. The purposes of the game are:

1. Develop work methodology and procedures internally, within and between the various elements of the crisis management organization.
2. Prepare the players for the scenario and key issues related to the international exercise.
3. Exercise the ministry's crisis management procedures in relation to processes in international crisis management organizations.

4.2 *Experience with games and exercises*

24 employees took part in the experiment. However, the sample for "experience in games or exercises" is 22, as one participant did not fill out the table, and another marked both little experience with exercises and much experience with games. 9 participants had little experience with games or exercises, 8 participants had some experience, three had much experience, while two had no experience at all. This is shown in Table 2.

In the forms, a few answers differed considerably from the others. We examined these outliers and found that they were made by participants with no experience.

4.3 *Results*

The results in Figures 2–4 show the intuitive responses from the participants on which combination of adjudication and operational environment they would choose for the three cases. The results are their immediate reflections, based on their own skills and knowledge and on the information that was given to them in a presentation before the experiment. The number of respondents varies from case to case, due to incorrect use of the form.

4.3.1 *Results – Case 1*

For Case 1 – Bilateral Ministerial Game, 10 of 24 participants chose a *plenary* format for the operational environment, as shown in Figure 2. *Map* was the second choice, with 8 respondents finding this environment the most suitable for the given case.

Adjudication based on *consensus* between players was the preferred format for both *plenary* and *map* operational environment, with a total of 10 responses. Another preferred adjudication method was *moderator,* with 7 responses. No respondents chose *simulator/data models* as the operational environment or *scripted* and *policy or rules/tables* as means of adjudication for case 1.

Four participants made changes for Case 1 after the break. One participant changed the adjudication method from *consensus* to *scripted*, but kept *plenary* as the operational environment. One changed the operational environment from *workplace* to *plenary*, but kept *moderator* as a mean of adjudication, and another changed the operational environment from *board game* to *simulator*, but kept *computer models* for adjudication. The last modification was a change made on both axes, from *real operations—field* to *policy or rules/tables—workplace*.

4.3.2 *Results – Case 2*

Map was clearly the most preferred format for operational environment for Case 2 – Internal Wargame,

Figure 2. Results from Case 1.

Figure 3. Results – Case 2.

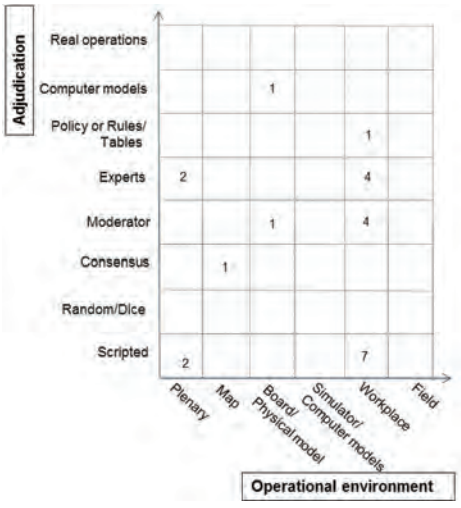

Figure 4. Results – Case 3.

with 13 of 24 respondents choosing it, see Figure 3. *Simulator*/*Data model* followed with 6 participants finding this environment the most suitable. Nobody chose *plenary* or *field*, the two "extremes" on the operational environment axis, and nobody chose *real operations* as a possible adjudication method.

Adjudication by *experts* was the preferred method with 9 responses, while *computer models* followed with 7 responses. *Experts* were chosen as the most preferred adjudication method in combination with a *map* operational environment, among four other choices. Nobody chose *experts* in combination with *simulator*/*data model*, which, evidently, was related to *computer models*.

After the break, five participants modified their responses for Case 2. Four of the changes were made from the combination *experts* as mean of adjudication and *map* as operational environment. Two of these kept *experts*, but changed *map* to *simulator*. Two others kept *map*, but adjusted the method of adjudication to *consensus* and *computer model*. One participant kept *computer model* for adjudication, but changed operational environment from *simulator* to *board*.

4.3.3 *Results – Case 3*

For Case 3 – Educational Wargame, 16 of 23 respondents chose *workplace* as the ideal operational environment, see Figure 4. No one preferred *simulator* or *field* for this case. *Scripted* adjudication was preferred with 9 answers, followed by *experts* which got 6 answers.

Four participants made changes after the break. All of them kept their initial choice of operational environment, but changed the method of adjudication. Two participants changed adjudication from *expert* to *scripted* and one participant changed from *moderator* to *scripted*. These participants' preferred operational environment was *workplace*. The last participant had *map* as operational environment, but modified the method of adjudication from *consensus* to *scripted*. The modifications strengthened *scripted* as the favorite mean of adjudication for case 3.

4.4 *Summary of results*

When combining the results from all three cases, represented in Figures 2–4, we find that the most popular choices for operational environment overall are *map*, *workplace* and *plenary*. *Field* is not considered particularly suitable for the cases. The most preferred adjudication method overall is the use of *experts*, followed by *moderator,* and *consensus* and *scripted* share the third option. The choices on the adjudication axis are more spread out than the ones on the operational environment axis.

The preferred choices in the experiment matched well with the formats used in the real games that the three cases were inspired by, see Table 3. The three means of adjudication used in the real games were *moderator*, *experts* and a *scripted* design, whereas the operational environment used were *plenary* sessions, *map* and *workplace*. The participants were presented the actual formats used after the experiment was completed, and they were able to comment on the differences.

In the experiment, the preferred combination in Case 1 was adjudication by *consensus* and a *plenary* representation of the operational environment. As shown in Table 3, the format for adjudication used in the real game was *moderator.* This was the second most popular choice in the experiment. For Case 2 and Case 3, the preferred formats in the experiment were similar to those used in the actual games.

Table 3. Actual formats used in real games.

	Case 1	Case 2	Case 3
Adjudication	Moderator	Experts	Scripted
Operational environment	Plenary	Map	Workplace

Overall, the experiment results correspond very well with real choices. However, Figures 2–4 show that the results were largely spread out, which indicate some uncertainty in the answers and that the participants intuitively thought differently.

4.5 *Discussion of results*

Various factors may have impacted on the results from the experiment. They are discussed in the following.

4.5.1 *Selection of cases*

There were similarities between the real games that the three cases were based on, in the sense that they were all discussion-based and tabletop-oriented. More rigorous games supported by models and simulations were not included, and having these as cases in the experiment could have provided clearer trends. However, we decided to choose cases that are representative for the assignments that the authors have worked on, where we knew the rationale behind the real choices of formats. Thus, it was interesting to see how a larger group of participants would respond to three tabletop-oriented cases. While the overall results from the experiment matched well with the real formats, individual responses were spread out across possible formats.

A major challenge with the cases is that they include several different objectives in the same assignment. This makes choosing just one format, or combination of adjudication and operational environment, difficult. This is especially relevant in Case 3. These challenges were present when FFI received these tasks from customers, and the participants also found this challenging when filling out the form. They gave feedback on this matter in the break between the two sessions. In reality, game and exercise planners often receive assignments with different objectives. Unlike the experiment, real assignments are often accompanied by an order or expressed wish for the type or format the customer wants. That brings us back to the initial scope of the paper: We argue that finding and defining the purpose is crucial for the choice of game or exercise, but that there is a need for supplementary guidance to find the most suitable format.

The cases could also have been presented with more detail, and the participants had little time to reflect on the cases and their choices. However, we were looking for the initial reactions from a group of researchers/officers interested in games and exercises. The results provide good indications that there is uncertainty within the organization about how best to match aims and goals with the myriad of available formats for games and exercises.

4.5.2 *Selection of dimensions*

In the experiment, we used two dimensions in the form to help choose game formats, adjudication and operational environment. The two dimensions illustrate the tradeoff between feasibility and robustness/complexity in game or exercise planning, where effort and necessary resources generally increase along the axes. It is more work involved to run a simulator than a plenary session, and data models are more resource-intensive to use for adjudication than a moderator. At the same time, the analytical rigor of the results will likely improve along the axes. This is in line with the categorizations and classifications referred to in Chapter 2, and therefore, it was natural to use these factors in the experiment.

In the experiment cases, we did not include how much time and resources were available for planning and conducting the games. In reality, time and resources are important entry values (Grunnan & Fridheim 2016), and the experiment participants commented on the lack of this information when discussing their selections. In other words, our form does not cover all relevant factors for choosing game formats. However, it gives the opportunity to quickly assess alternatives, preferably in dialogue with the client (Grunnan & Fridheim 2017).

4.5.3 *Selection of values*

The selection of values for the two dimensions in the form, presented on the axes in Figures 1–4, is influenced by the fact that both games and exercises are covered in the same form. Due to the uncertainties regarding terminology as discussed in Chapter 2, we have added values related to both games and exercises. Terms such as rules, tables, models, dices, maps, boards and simulators are often related to (war) games, while real operations, experts, moderators, workplace and field are often included in exercise vocabularies. There is a possibility that merging games and exercises in the same set-up may have confused the respondents and made them more uncertain.

4.5.4 *Number of participants*

It would have been beneficial to have more participants attending the experiment. Still, 24 participants is a fairly large number when reflecting on the number of experts working on this topic within the organization. Table 2 in chapter 4.2 shows an even distribution of experienced and less experienced participants.

5 CONCLUSION

The LOE shows that purpose should guide the choice of format for a game or an exercise, and it is therefore important to be precise when defining aims and objectives. A clear and precise task or assignment will make choosing an appropriate format easier (Grunnan & Fridheim 2017). However, our experiment indicates that even though you know the purpose, different people will still instinctively choose different formats. This is likely related to the uncertainty related to terminology, methodological biases and the fact that there are numerous games and exercise formats to choose from. Therefore, it is useful to have a quick support tool to assist the planners, like the form used in our experiment and shown in Figures 1–4. Although our findings demonstrate that there was a good match between the formats chosen in the experiment and the actual choices used in real-life, there was also a large spread of answers for each case.

The LOE is a pilot study, as it is the first time we have tested our ideas on this topic on a group of researchers. We carried out a first impressions session at the end of the experiment. The form (or matrix, as it was referred to by some participants) was especially considered useful for expanding the range of possibilities in the planning phase. The challenge is to choose formats when factors such as time and resources are included. For instance, which formats are best for a one-day or a week-long event respectively? Also, the participants found it difficult to choose only one format, especially in the cases which had several objectives in the assignment text. Often there is a need for different formats to cover all objectives, and this is not easy to visualize in one form.

There are many possibilities for future research on this topic. In coming experiments, it is possible to make adjustments such as adding more cases, choosing other dimensions in the form, and analyzing results from experienced and unexperienced participants respectively. Furthermore, for internal organizational use, we recognize that there may be a need for an internal classification of different game/exercise formats and their overall strengths and weaknesses for different purposes.

While the exercises and games covered by the paper are mainly related to security challenges, our findings are relevant also for more safety related issues. The form used in the experiment provides an opportunity to evaluate and discuss options and formats independently of the subject area.

ACKNOWLEDGEMENTS

The authors would like to thank our colleague Alf Christian Hennum for his review of the paper.

Optimizing security patrolling scheduling in chemical industrial parks by using game theory

L. Zhang & G.L.L. Reniers
Faculty of Technology, Policy and Management, Safety and Security Science Group (S3G), TU Delft, Delft, The Netherlands

ABSTRACT: Protecting chemical clusters from intentional attacks has been a hot topic during the last decade. Besides intrusion security countermeasures such as cameras, entrances control etc., patrolling also fulfils an important role in the security of chemical facilities and industrial parks. Current patrolling strategies in industry are mainly single-plant driven and purely randomized or based on the patroller's preference. Such an approach in a chemical industrial park is on the one hand not able to cover the more hazardous facilities more than the less hazardous plants within the park, and on the other hand is not able to deal with strategic (intelligent) human adversaries w.r.t. terrorism. This paper therefore investigates a game theoretic model for optimizing the schedule of patrolling in chemical clusters. The industrial defender and the intelligent/adaptive attackers are modelled as two players in the game. The defender aims at increasing the probability of detecting the attacker, by randomly but strategically scheduling her patrolling route. The attacker aims at causing maximal consequences with highest success probabilities, by choosing a proper attack time and a proper target. The model is further illustrated by a case study.

1 INTRODUCTION

Since the unfortunate 9/11 attack, the protection of critical infrastructures has been an urgent topic, both in academia and in practice. Chemical industries have an important role in modern society. They provide materials for human being's daily necessities such as clothes, food, energy, etc. However, chemical facilities may also pose huge threat to modern society. The sadly Bhopal disaster (toxic gas leakage), among others, caused more than 3000 deaths and life-long suffering for over 300,000 [1]. In the security aspect, the malicious attack to a chemical plant in France reminded people that there is a possibility of a successful attack to chemical facilities. An investigation carried out by Orum and Rushing [2] concluded that a successful attack to a top 101 dangerous chemical plant in U.S. may result in more than one million casualties.

Furthermore, due to economic and management reasons, chemical plants are nowadays geographically clustered, forming chemical clusters, e.g., the Antwerp port chemical cluster, the Rotterdam port chemical cluster etc. Besides intrusion security countermeasures within each plant, patrolling is also scheduled, for securing these chemical facilities. The patrolling can be either single plant oriented, which is scheduled by the plant itself, or multiple plants oriented, which should be scheduled by a multiple plant council (MPC) [3]. Both types of patrolling have a drawback of not being able to deal with intelligent attackers. Some patrollers follow a fixed patrolling route, and the attacker thus can predict the patroller's position at a certain time. Other patrollers purely randomize their patrolling, without taking into consideration the hazardous level that each facility/plant holds, and the attacker can attack more dangerous facilities/plants since all the facilities/plants are equally patrolled.

Game theory has been introduced to the security domain to optimally allocate security resources. In a security problem, the attacker (human beings) is able to plan his attack according to the defender's defence, while the defender knows the fact and thus she can also defend accordingly. This procedure is called the 'intelligent interactions' between the defender and the attacker. Game theory was invented to model strategic decision making in multiple actor systems, thus it perfectly fits the necessity of modelling the 'intelligent interactions' in the security domain. Tambe and his co-authors [4] employed game theory for optimizing patrolling of protecting ferries, of protecting wild animals etc. Alpern and his co-authors [5] theoretically studied the optimization problem of patrolling in a graph. Amirali et al. [6] introduced a game theoretic model for optimally scheduling pipeline patrolling. No literature has investigated the use of game theory to optimize patrolling in chemical clusters, neither for the single plant patrolling nor for the multiple plants patrolling.

This paper proposes a Chemical Cluster Patrolling (CCP) game, which answers the question how to optimally randomize the patrolling, to better secure a chemical cluster, by using a game theory model. The reminder of this paper is organized as follows: Section 2 briefly demonstrates the CCP game. A case study is introduced in Section 3 and the results of the case study are given in Section 4. Conclusions are drawn in Section 5.

2 THE CHEMICAL CLUSTER PATROLLING (CCP) GAME

2.1 *Graphic modelling*

A chemical cluster can be descript as a graph $G(V, E)$. The vehicle entrances of each plant and the cross points of the vehicle road form the nodes of the graph. The vehicle roads between different plants (to be more specified, they should be "between different entrances") are modelled as edges of the graph. Furthermore, all entrance nodes which belong to the same plant are modelled to be full connected, which means edges also exist between every two nodes in these cases.

Based on the graphic model, the chemical cluster patrolling can be descript as a graphic patrolling problem: 1) a patroller (team) starts her (In this paper, we denote the patroller/defender as she/her/her, and denote the attacker as he/him/his.) patrolling from a node (the base camp); 2) she moves in the graph; 3) when arriving a node, she may decide whether to stay at the node for a specific period of time t_k^p (i.e., patrol the plant) or not (i.e., move to another plant without patrolling the current plant); 4) after a period T, the patroller terminates the patrolling.

A directed patrolling graph pG(pV, pE) is defined based on the graphic model of the chemical cluster. A node of pG is defined as a tuple of (t, i), in which $t \in$ denotes time dimension and $i \in \{1,2,\ldots,|V|\}$ denotes a node in graph G(V, E) (i.e., a plant (entrance) in the chemical cluster). Node (t, i) means that at time t the patroller arrives or leaves node i. A directed edge of pG from node (t_1, i_1) to node (t_2, i_2) therefore means that the patroller moves from node i_1 at time t_1 to node i_2, and arrives at t_2. Figure 3 shows the patrolling graph of the case study.

2.2 *Game theoretic modelling*

A game theoretic model consists of players, strategies, and payoffs.

Players

Players of the chemical cluster patrolling (CCP) game are the patroller team and the potential attackers. The CCP game is a two players game and both players are assumed with perfect rationality.

Strategies

An attacker's strategy consists of three parts: i) which plant to attack; ii) when to attack; and iii) what attack scenario to use, thus can be expressed as:

$$s_a = (t, i, k_i) \tag{1}$$

In which t denotes the attack start time, i represents the target plant, k_i is the attack period (e.g., 7 minutes) which should be determined by both the attack scenario and the target plant.

A mathematic formulation of the defender's strategy is shown in Formula (2).

$$s_d = \prod_{(s,e)\in pE} c_{s-e} \tag{2}$$

In which c_{s-e} denotes the probabilistic number assigned to the edge (of pG) from node s to node e, $\prod$ denotes the Cartesian product of all edges in pG (i.e., all $(s,e) \in pE$).

An important property of these probabilities is that, for each node (of pG), the sum of all the income probabilities must equal the sum of all the outcome probabilities. Formula (3) illustrates the abovementioned property.

$$\begin{aligned} sP_{pv} &= \sum_{in\in\{s\in pV|(s,pv)\in pE\}} c_{in-pv} \\ &= \sum_{out\in\{e\in pV|(pv,e)\in pE\}} c_{pv-out} \end{aligned} \tag{3}$$

Payoffs

Formulas (4) and (5) define the patroller and the attacker's payoff, in which f is the probability that the attacker would fail, and if the attacker failed, the patroller gets a reward R^d (e.g., obtaining bonus) and the attacker suffers a penalty P^a (e.g., being sent to prison). If the attacker succeeds, the patroller suffers a loss L^d and the attacker obtains a gain G^a.

$$u_d = R^d \cdot f - L^d \cdot (1-f) \tag{4}$$

$$u_a = G^a \cdot (1-f) - P^a \cdot f \tag{5}$$

Computing the f

The probability that the attacker would be detected can be calculated by Formula (6), in which f_{cpp} denotes the probability that the intrusion detection systems (IDS) in the target plant would detect the attacker, f_p is the probability that the patroller would detect the attacker

$$f = 1 - (1 - f_{cpp}) \cdot (1 - f_p) \tag{6}$$

Note that f_{cpp} is a plant-specific parameter (a number belongs to [0,1]). While f_p can be calculated by Formula (7), in which r denotes the overlap situ-

ation of that the patroller's staying in the plant and the attacker's intrusion and attack procedure, σ_r is the detection probability of situation r. Furthermore, the probability that the patroller would be in situation r is denoted as τ_r.

$$f_p = \sum_r \sigma_r \cdot \tau_r. \tag{7}$$

Denote the defender's strategy in a vector form as $\vec{c}$. It is worth noting that τ_r would be a linear polynomial of $\vec{c}$, and f_{cpp} and σ_r are user provided parameters. Therefore, f is a linear polynomial of $\vec{c}$ as well.

Stackelberg equilibrium

In the CCP game, the attacker is assumed to be able to collect information of the patroller's patrolling route. A Stackelberg equilibrium $(s_d^*, s_a^*) = (\vec{c^*}, (t^*, i^*, k_i^*))$ for the CCP game is a defender-attacker strategy pair that satisfies the following condition:

$$(t^*, i^*, k_i^*) = argmax\{u_a(\vec{c}, (t, i, k_i))\} \tag{8}$$

$$\vec{c^*} = argmax\{u_d(\vec{c}, (t^*, i^*, k_i^*))\} \tag{9}$$

Formula (8) reflects that observing the defender's strategy $\vec{c}$, the attacker would play a strategy which will maximize his own payoff (i.e., a best response). Formula (9) represents that the defender can also work out the attacker's best response to her strategy, thus she plays accordingly.

3 ILLUSTRATIVE CASE STUDY

Figure 1 provides the layout of a chemical cluster from the Antwerp port (data source: Google map). There are 5 plants in this cluster, indexed as plant 'A', plant 'B', and so forth. The yellow dot lines demonstrate the vehicle routes, and the patroller only drives on the vehicle route. Figure 2 shows the graph model of the cluster shown in Figure 1.

Figure 1. Layout of a chemical park in Antwerp port.

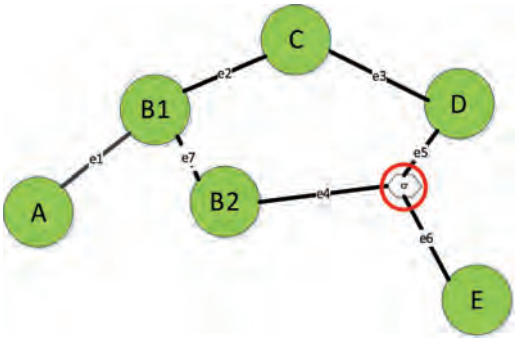

Figure 2. Graphic modelling of the chemical park.

As we may see, each plant (i.e., 'A', 'C', 'D', 'E') in Figure 1 is modelled as a node (with the same name) in Figure 2. The cross point of the vehicle road between plant 'D' and 'E' in Figure 1 is also denoted as a node in Figure 2 (i.e., node 'cr'). Moreover, plant 'B' has two vehicle entrances, and two nodes (i.e., nodes 'B1' and 'B2') are used in Figure 2 to denote the two different entrances of plant 'B'. Edges 'e1' to 'e6' reflect the vehicle roads between different plants, while edge e7 is added between node 'B1' and 'B2' because these 2 nodes belong to the same plant and hence should be full connected.

We set: $t_1^d = 2, t_2^d = 3, t_3^d = 4, t_4^d = 3, t_5^d = 2, t_6^d = 2$, and further set $t^p('A','B','C','D','E') = [9,7,6,5,7]$. t_i^d represents the driving time of edge 'ei' in Figure 2. For instance, t_1^d is the driving time from node 'A' to 'B1'. $t^p('X')$ denotes the time needed to patrol plant 'X'. If the patroller may have multiple patrolling intensity in a plant, then the t^p should not only be a number, but be a set of numbers. In this paper, we only consider one patrolling intensity in each plant and all the temporal data are unified in minutes.

Table 1 shows the time of moving from one node to another node. For instance, from node 'A' to node 'B1' needs $t_1^d = 2$ minutes. It is worth noting that i) numbers in the diagonal denote the time needed to patrol the plant, e.g., patrolling plant 'A' needs $t^p('A') = 9$ minutes; ii) the number from one entrance node to another entrance node of the same plant (e.g., from node 'B1' to 'B2') also represents the time needed to patrol the plant. Case (ii) means that the patroller comes into and leaves the plant from different entrances.

Figure 3 shows the patrolling graph pG for the chemical cluster shown in Figure 1, with the data in Table 1 and further assume a patrolling time T = 30. Patroller's base camp is assumed close to the cross road node, thus 'cr' is chosen as the patroller's base camp.

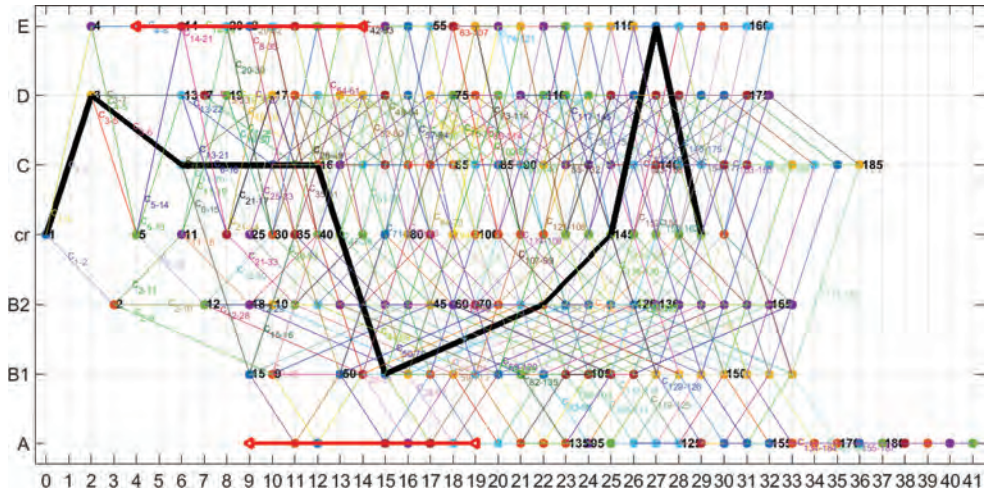

Figure 3. Patrolling graph of the illustrative example.

Table 1. Superior connection matrix for Figure 2 with the illustrative numbers.

	A	B1	B2	cr	C	D	E
A	9	2	∞	∞	∞	∞	∞
B1	2	7	7	∞	3	∞	∞
B2	∞	7	7	3	∞	∞	∞
cr	∞	∞	3	∞	∞	2	2
C	∞	3	∞	∞	6	4	∞
D	∞	∞	∞	2	4	5	∞
E	∞	∞	∞	2	∞	∞	7

In Figure 3, the x axis denotes the time dimension, while the y axis represents the different nodes in Figure 2. Therefore, any coordinates in Figure 3 can be a possible node for pG. As we may see, node 1 (at the left hand side of the figure) in Figure 3 is (0, *cr*), and it means that at time 0, the patroller starts from her base camp (i.e., 'cr'). Thereafter she has 3 choices: i) to come to plant 'B' (more accurately, entrance 'B2') with a driving time t_4^d, and reaches node 2; ii) to come to plant 'D' with a driving time t_5^d, and reaches node 3; and iii) to come to plant 'E' with a driving time t_6^d, and reaches node 4. Subsequently, at new nodes (e.g., 2, 3, or 4), the patroller has the same choice problem, that is, to patrol the current plant or to come to another plant. In Figure 3, the indexes of some nodes and the weight of some edges are not shown, for the clarity of the figure.

Table 2. Model inputs.

	R^d	L^d	G^a	P^a	f_{cpp}
'A'	1	16	10	3	0.45
'B'	1	11.2	6	3	0.3
'C'	1	14	8.3	3	0.42
'D'	1	12	7.1	3	0.45
'E'	1	15	10	3	0.5

For example, the bold (and black) line in the figure, denotes a patrolling route as: '*cr*' → '*C*' → *C*' → patrol plant '*C*' → '*B1*' → patrol plant *B*' → leave plant '*B*' from '*B2*' → '*cr*' → '*E*' → '*cr*'.

Finally, when time comes to the end of the patrol, the patroller terminates the patrolling and comes back to her base camp. In this research, to keep the continuity of coverage of each plant, the patroller is required to prolong their patrolling in the plant until that the next patroller team might be able to arrive the plant. For instance, in Figure 3, though the patrolling time is set as $T = 30$, however, the patrolling in plant 'A' is not stopped until $t = 41$. The reason is that, the shortest time that the next patrolling team can arrive plant 'A' (from 'cr') is 11 (By following a path '*cr*' → '*B2*' → '*B*1' → '*A*'). If the current patroller team does not prolong their patrolling, and the next patroller team starts at time 30 and stars from their base camp (i.e., 'cr'), then plant 'A' will definitely not be covered during time (30, 41). This approach may increase the patroller's workload. However, if we set T slightly smaller than the patroller's real workload, the problem will be solved. For example, if a patroller team's workload is 240 minutes per day, and we may set $T = 220$.

For the sake of clarity, only one type of attacker and only one attack scenario is considered. Further assume that the intrusion and attack procedure of the employed scenario would last for 10 minutes. For instance, the two horizontal bold dot red lines in Figure 3 represent attack strategies that attack plant 'A' start at time 9 (the line at below) and attack plant 'E' start at time 4 (the line at above), with an intrusion and attack period of ten time units, respectively.

Table 2 gives the model inputs, i.e., the defender's reward (loss) of (not) detecting an attacker; the attacker's gain (penalty) from a (not) successful attack; the probability that the intrusion detection system (IDS) can detect the attacker. The probability that the patroller can detect the attacker (i.e., σ_v) should also be provided by security experts. However, in this paper, we simply assume that in each time unit, if the attacker and the patroller stay in the same plant (i.e., overlap), there is a probability of 0.05 that the attacker would be detected by the patroller.

4 RESULTS

4.1 *Stackelberg equilibrium*

Figure 4 shows the Stackelberg equilibrium (SE) of the case study. The black (and narrow) lines demonstrate the patroller's optimal patrolling strategy. The associated numbers on the line denotes the probability that the defender will take this action. For instance, $c1 = 0.22747$ means that at time 0, the patroller should drive to node 'B2' at probability 0.22747. Furthermore, in patrolling practice, if the patroller arrives at a node in the figure, the conditional probabilities of following actions can be calculated as $cP = c/sP$, in which c denotes the probability assigned to the edge, sP_v denotes the probability that the patroller would be at the node. For instance, the probability that the patroller would arrive at the red node $(6,'C')$ in Figure 4 is $sP_v = 0.41734$, and the conditional probabilities that she should take the 2 actions are $cP_1 = 0.4979, cP_2 = 0.5021$.

Table 3. The patroller's actions that may detect the attacker.

Edge	τ	Overlap	σ
25	0.00220	[9,13]	0.20
41	0.09935	[9,16]	0.35
85	0.11143	[11,18]	0.35
159	0.09935	[16,19]	0.15
186	0.00220	[17,19]	0.10
206	0.11143	[18,19]	0.05

Table 4. Comparison of the CCP strategy and the purely randomized strategy.

Edge	Overlap	τ_c	τ_{rc}	σ
82	[11,19]	0.1926	0.0046	0.4
98	[12,19]	0.1942	0.0139	0.35
156	[15,19]	0	0.0019	0.2
176	[16,19]	0	0.0071	0.15
196	[17,19]	0	0.0024	0.1
216	[18,19]	0	0.0039	0.05
425	[9,10]	0	0.0100	0.05
430	[9,11]	0.3358	0.0274	0.1

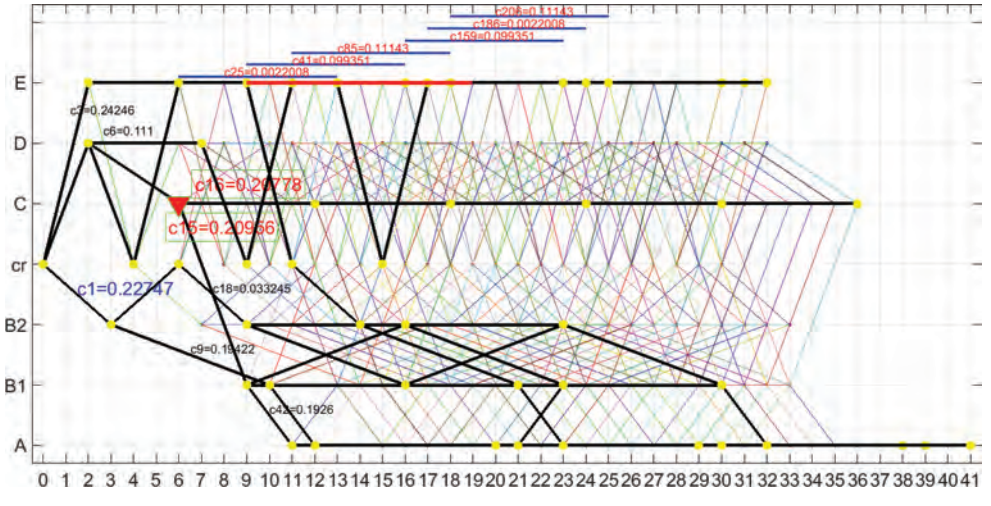

Figure 4. The optimal patrolling strategy and the attacker's best response (Stackelberg equilibrium).

The attacker's best response in the SE is to attack plant 'E' at time 9, as shown in the figure as a red bold line. The short lines above the attacker's best response line represent the defender's patrolling actions which would have overlap with the attacker's strategy. Table 3 shows detail information of these patrolling actions.

Based on the result in Table 3, we have that: $f_p = \sum_r \tau_r \cdot \sigma_r = 0.089101$, $f = 1-(1-0.5)*(1-f_p) = 0.09491$, $u_a = 2.88311$, $u_d = -6.24074$.

4.2 *Comparing to random patrolling*

In the current patrolling practise, patrollers may randomly schedule their patrol route. This situation, one looks at Figure 3, is simply assigning the same probabilities to edges that start from the same node. For instance, at the starting node (i.e., (0,'*cr*')), the patroller would come to plant (entrance) 'B2', 'D', and 'E' at the same probability, and the probability is 1/3.

In the case study, if the defender would purely randomize her patrolling, then the attacker's best response would be attacking plant 'A' at time 9. The attacker and the defender would obtain a payoff of 4.0653 and –8.2393, respectively. Comparing to the result of the CCP game, the defender suffers a higher lose.

Table 4 illustrates the differences between the CCP strategy and the purely randomized strategy. The 'Edge' column in Table 4 shows the edges in the patrolling graph that have an overlap with the attacker's strategy (i.e., attack plant 'A' at time 9). The overlap column illustrates which period of the attack procedure is overlapped by the edge. The 'c' and 'rc' column show the probability that the patroller will go the edge, resulting from the CCP game and from the randomized strategy respectively. The sigma column shows the probability that the attacker will be detected by the patroller by this edge and it is simply calculated as 0.05 multiplied by the overlapped time units. According to the result in Table 4, we can calculate the probability that the attacker would be detected by the patroller (see Formula 7), and the results are: $f_p^c = 0.17860$, $f_p^{rc} = 0.01183$. These results reveal that the CCP strategy has a higher probability of detecting the attacker at plant 'A', and thus transfers the attacker's best response target from plant 'A' to plant 'E'.

5 CONCLUSION

Terrorism has been a global problem. The chemical industry can be an attractive target for terrorists, due to the existence of hazardous materials. A chemical cluster is formed by multiple chemical plants, and can be of extra interest for attackers.

Besides intrusion security countermeasures of each plant, security countermeasures at the cluster level are also recommended. The current patrolling in chemical clusters are either single plant based or purely randomized, being economically not efficient and theoretically not optimized. The security adversaries are human beings, and they may learn the patroller's daily patrolling routes and plan their attack accordingly.

This paper therefore proposes a chemical cluster patrolling (CCP) game. The CCP game generates randomized but strategic patrolling routes for the cluster patrolling team. The intelligent interactions between the patroller and the potential attackers are modelled in the CCP game. An illustrative case study shows that the patrolling routes generated by our CCP game outperforms the purely randomized patrolling strategy.

Perception of security and use of public travel modes in an urban Norwegian public

T. Rundmo, A.-M. Kummeneje & T. Nordfjærn
Norwegian University of Science and Technology (NTNU), Trondheim, Norway

ABSTRACT: The aim of the study was to examine judgement of security problems when using public transportation. A self-completion questionnaire survey was carried out among representative samples of residents in six Norwegian urban areas (n = 1047). Respondents who most frequently use public travel modes assessed the security problems to be larger compared to less frequent users. Frequency of use as well as past personal experience of a security problem enhanced the assessment of future probability of experiencing such an event. Perceived risk consistency was also measured and a median split on both these variables was carried out and four groups emerged. The first group was a group of risk insensitive respondents, the second group consisted of risk inconsistent respondents, the third consisted of risk consistent respondents and the fourth was risk sensitive respondents. Travel mode use and personal experience of a security-related problem were positively associated with risk sensitivity.

1 INTRODUCTION

More knowledge is needed to understand how future choices could be moved into a more pro-environmental and safe direction by use of public transport as well as walking and cycling. The current study focuses on the role of perception of security risks by use of public travel modes. Several studies carried out previously have examined perceived risk related to security (probability of violence, acts of terror, etc.) in public transport. Roche-Cerasi, Rundmo, Sigurdson and Moe (2014) showed that there were differences in overall perceived risk evaluations between frequent users of private and public travel mode users in representative samples in Paris and Oslo. The group including those who most frequently used public travel modes perceived the probability of experiencing violence and acts of terror on public travel modes to be larger compared to those who most frequently used car. Frequent public travel mode users were also found to be more worried about security issues on public transportation. In a representative sample of the Norwegian public, Rundmo, Nordfjærn, Iversen et al. (2011) also reported differences in perceived risk evaluations and worry with regard to criminality and acts of terror on public travel modes when comparing a group of respondents who used public travel modes most frequently with a group of respondents who most frequently used private motorised travel modes. Frequent users of public transport perceived the security problems to be more probable compared to frequent users of own car. Nordfjærn, Şimşekoğlu, Lind et al. (2014) showed that perceived risk evaluations and worry related to terrorism, sabotage, theft, harassment and other uncomfortable episodes, as well as violence significantly predicted travel mode use.

The studies presented above primarily examined the role of perceived risk and worry in travel mode use. Accordingly, the current study also hypothesises perceived risk evaluations and worry to be significant predictor variables of travel mode use, i.e. use of public travel modes versus car. In addition, perceived risk evaluations have been distinguished from risk sensitivity (Sjøberg, 1996). Risk sensitivity is the general tendency to perceive all risks as large or small. Consequently, risk sensitivity is linked to perceived risk. The current study aims to examine coincidence between perception and sensitivity in risk judgements.

Rundmo and Moen (2006) showed that perceived risk evaluations in various types of transport were significantly associated. Those who perceived the risk to be large concerning one type of transport also perceived the risk to be large in other areas, and vice versa. Sjöberg (1996, 2004) found that risk amplification-attenuation was a significant predictor variable of personal as well as general perceived risk evaluations. The risk amplification-attenuation framework attempts to explain the process by which risks are amplified, receiving public attention, or attenuated, receiving less public attention. In a random sample of the Swedish public, Sjøberg (1996) showed that risk sensitivity was a significant predictor vari-

able of general perceived risk evaluations among other factors, e.g. trust in authorities, attitudes, and the pooled original psychometric dimensions (see Fischhoff, Slovic, Lichtenstein et al., 1978). In these studies perceived risk evaluations and risk sensitivity were distinguished and measured as two different constructs. However, if risk is rated to be high in one domain it is more likely to be rated as high in another domain, which implies risk sensitivity. Thus, it could be that risk sensitivity is identical to perceived risk evaluations.

In the current study risk sensitivity is conceived to be pooled perceived risk evaluations. While risk evaluations have been found to be equal to hazard perception (Rundmo & Nordfjærn, 2017), risk sensitivity adds to the understanding of the concept by introducing an element of perceived risk that is a general tendency in risk perception which is independent of the object that is perceived. Thus, perceived risk evaluations consist of two elements. The first is linked to the characteristics of the object that is perceived (i.e. subjective assessment of the probability of experiencing a negative event and judgement of severity of consequences if it should occur) and a general characteristic reflected in the sensitivity of risk in general. Risk sensitivity should also be distinguished from perceived risk consistency. Respondents may vary in risk sensitivity, i.e. the level of perceived risk when judging a number of risk sources, as well as in risk consistency, i.e. how consistent or stable the risk level of all the sources is perceived. The current study hypothesises that risk sensitivity and risk stability significantly predicts travel mode use. The current study aims to investigate the role of priority of security and risk sensitivity in use of public travel modes versus car among an urban public. An additional objective is to discuss the relationship between risk perception and risk sensitivity.

2 METHODS

The results of the current study are based on a self-completion questionnaire survey carried out among residents above 18 years of age in the six most urbanised areas in Norway (n = 1043). The response rate was 18% A total of 1043 respondents (18%) replied to the questionnaire. The respondents were asked to assess the occurrence probability of a security problem on a seven-point evaluation scale ranging from 'not at all probable' to 'very probable' (see also Rundmo et al., 2011). Transport mode use was measured by asking the respondents about their weekly ordinary use of transport modes. The questionnaire also contained questions about the demographic characteristics of the respondents, including gender, age, level of education and car access. They were also asked about whether they themselves had been victimised due to a security-related problem when using public transportation and how they prioritised security measures to prevent theft, harassment and acts of terror.

3 RESULTS

The respondents assessed the probability of "theft" and "harassment" to be larger compared to the other types of security problems that were measured. The probability of "sexual assault" and "terrorism" was perceived to be low. A MANCOVA aimed to examine differences in the respondents' assessment of probability for experiencing security problems in such transport was carried out (significant differences shown in bold). Those who most often used public travel modes were compared to those who most frequently used car. There was a significant overall difference in judgement of security problems (Wilks' $\lambda = .95$, $p < .001$). Gender, age group and educational level were covariates in the analysis. The frequent public travel mode users perceived the probability of security problems in general to be larger compared to the group of frequent users of private motorised travel modes. This was the case for assessment of the probability for "theft" ($F = 9.17$, $p < .01$), "sexual assault" ($F = 7.68$, $p < .01$), "harassment" ($F = 7.20$, $p < .01$), and "terrorism" ($F = 9.37$, $p < .01$). There were also tendencies, however not significant, in the same direction for assessments of "blind violence" and "sabotage". Thus, respondents who most frequently used public travel modes assessed the security problems related to use of such modes to be larger compared to less frequent users.

The respondents were also asked to assess the probability of "being too late at work" due to public travel mode delay. In this case the group difference was in the opposite direction. Those who most seldom used public transportation assessed the probability of delay to be larger when using public travel modes compared to the cluster group of frequent users of such modes ($F = 12.33$, $p < .001$).

It could be argued that "being too late at work" is not a security problem in line with the other security problems in public transport. While the other items have to be conceived as the probability of outside inflicted damages, the probability of "being too late at work" is either caused by the traveller or by the operating travel company. In this case it is not a problem inflicted to a victim during the travel. Most often the consequences are more trivial compared to other security problems concerning public transportation. The internal consistency of the judgements of risk sensitivity measured

on a single dimension was satisfactory ($\alpha = .839$). When excluding the item "being too late at work", the reliability improved marginally ($\alpha = .859$). There were large and significant positive associations between the probability assessments of the security problems, i.e. those who assessed one security problem to be large also tended to assess the other security problems in the same way and vice versa, indicating the presence of risk sensitivity. The coefficients varied between .15 and .65.

In addition to probability assessments the respondents were also asked whether or not they had been exposed to one or more security risks when using public transportation during the last five years. A total of 14.5 per cent reported that they had experienced themselves either "theft", "sexual assault", "harassment", "terrorism", or "sabotage" during this time period. Thus, in addition to frequency of use of public travel modes, the respondents' previous experience of public travel mode security hazards have to be taken into consideration. A MANCOVA was carried out to examine the differences in probability assessments of public travel security problems due to risk exposure (frequent users of public versus private transportation) and previous personal experience with security problems when using public transportation. As shown there were significant differences in the judgement of probability due to previous hazard experience (Wilks' $\lambda = 0.87$, $p < .001$).

A median split on risk sensitivity as well as risk stability was carried out and four groups emerged. The first group consisted of respondents who scored low on risk sensitivity as well as on risk consistency ($n = 342$). In addition to rating the probability as low they were characterised by a low Sd, indicating that they judge the overall probability to be low, i.e. consistent low score. This group could be defined as consisting of risk ignorant respondents. The next group consisted of respondents who rated some of the risks to be large and at the same time their evaluations were characterised by a low Sd ($n = 152$). This group was characterised of risk instability and consisted of risk steady respondents. The third group of people who rated most of the probabilities to be low, however, was characterised by a high Sd, indicating a variety in judgements ($n = 188$). This group was entitled risk fluctuating respondents. Finally, there were respondents who rated the probability of all risks to be high, and consequently the group was characterised by a low Sd ($n = 351$). This group was entitled risk sensitive respondents. A total of 52.2 per cent of the respondents scored high on risk stability and 48.7 per cent on risk sensitivity.

The number of risk sensitive female respondents were larger than expected by statistical inference compared to male respondents $\chi 2 = 30.06$, $p < .001$. There were also more risk sensitive respondents than expected among those who had a vocational practical education and a university education less than 3 years. The number of risk insensitive respondents were larger than expected by statistical inference among those who had a university education lasting for more than three years compared to the other groups, $\chi 2 = 23.71$, $p < .05$. The age groups were also compared and risk sensitivity decreased by age, $\chi 2 = 28.71$, $p < .01$.

The respondents were also asked to rate how they prioritized security in transport, i.e. how important it was for themselves. This evaluation included the importance of implementing countermeasures to prevent theft, harassment and terror. The results showed a significant overall difference in priority of security due to risk sensitivity, Wilks' $\lambda = .96$, $p < .001$, gender, Wilks' $\lambda = .7$, $p < .001$, educational level, Wilks' $\lambda = .97$, $p < .001$, and age group, Wilks' $\lambda = .97$, $p < .01$. However, there were no significant differences in priority of security due to past security risk experience, Wilks' $\lambda = .99$, NS. Risk ignorant and risk steady respondents prioritised security measures to a lower extent compared with risk fluctuating and risk sensitive respondents.

The Post Hoc tests showed that there were no statistically significant differences between the security priorities of the groups of risk insensitive and risk stable respondents. The tests showed an identical pattern of differences for all the three assessed factors. The priority of security measures in the risk sensitive group differed significantly from all the other three groups. However, both the two last groups (the groups of risk steady and risk sensitive respondents) differed significantly from risk fluctuating and risk sensitive respondents, $p < .001$. This was the case for priority of countermeasures to reduce the risk of theft, harassment as well as terror. Of note, there were no significant differences between the security priorities of the risk fluctuating and risk sensitive respondents. The pattern was the same for all the three prioritised areas. Thus, risk fluctuation and risk sensitivity seems to enhance the priority of security measures to reduce the risk of theft, harassment as well as terror. Risk perception varied due to previous risk security experience. However, there were no significant differences in priority of risk reduction measures due to past experience of security problems in public transport.

The next step was to examine how priority of security and risk sensitivity predicted travel mode use. Hierarchical and k-means cluster analysis was carried out separately for leisure and work travels to identify mode user groups. The first group consisted of those who most frequently used public transport and the second group consisted of respondents who mainly used car. The same cluster groups emerged for leisure as well as work travels.

The first analysis concerned leisure travelling. As expected the first block consisting of demographic variables, distance from home to the nearest public transport point, and car access significantly predicted leisure travel mode use ($\chi 2 = 213.74$, $p < .001$). Adding priority of security significantly improved the model ($\chi 2 = 16.05$, $p < .05$) and adding risk sensitivity as the final block added further to the explained variance ($\chi 2 = 4.03$, $p < .05$).

When all the blocks were adjusted for in the model, level of education (OR = 1.36, $p < .001$), annual income (OR = 0.67, $p < .01$), and car access (OR = 0.02, $p < .001$) significantly predicted travel mode use. Annual income and access to car were negatively associated with use of public transportation. Gender, minutes to walk from home to the nearest public transport point and previous personal experience with security hazards was non-significant predictor variables. In the second block the significant predictor variables were priority of security against theft (OR = 1.80, $p < .05$) and harassment (OR = 1.41, $p < .001$). Priority of countermeasures to reduce theft was largest among frequent car users and countermeasures for reducing harassment was prioritised among public travel mode users. Finally, the probability of belonging to the group of frequent public travel mode users were larger when risk sensitivity increased (OR = 1.24, $p < .05$).

Concerning work travels, the predictor variables of the first block also significantly predicted work travel mode use ($\chi 2 = 57.62$, $p < .001$). This was also the case for the third block ($\chi 2 = 4.37$, $p < .05$). However, the predictors of the second block seemed not to be equally important for mode use on work travels ($\chi 2 = 1.53$, NS) compared to leisure travels. The significant predictor variables in the final analysis were annual income (OR = 0.69, $p < .05$) and access to car (OR = 0.25, $p < .001$) from the first block. Risk sensitivity also significantly predicted mode use (OR = 1.28, $p < .05$). The prediction of leisure travel mode use (Cox & Snell's $R2 = 0.35$, Negelkerke's $R2 = 0.49$) was more successful than predicting mode use on work travels (Cox & Snell's $R2 = 0.11$, Negelkerke's $R2 = 0.20$).

4 DISCUSSION

The current study showed that priority of security and risk sensitivity was significant predictors of travel mode use among an urban public when demographic factors were controlled for. In studies carried out previously (e.g. Sjøberg, 1994, 2004) risk sensitivity was conceived to be a predictor of "risk perception". However, risk sensitivity is the tendency to perceive all risks to be high and risk insensitivity the opposite. Explaining a large percentage of the variance in "perceived risk" (Sjøberg, 1996, 2004) could partly have been caused by the use of risk sensitivity as a predictor variable which is coincident with the criterion variable. Rundmo and Nordfjærn (2017) found no support of fit of the data to a model where risk perception was conceived to be a formative construct of subjective assessments of probability and judgement of severity of consequences. Subjective judgements of risk should be conceptualised as perceived risk assessments when the judgements are not considered to be a formative construct.

The current study was restricted to examining the probability component of the perceived risk evaluations. In future research the role of severity of consequences should also be included. This could add to explained variance in prediction of travel mode use. Sjøberg (1999) as well as Rundmo and Moen (2006) showed that the subjective judgement severity of consequences if a negative event should occur was a more significant predictor of demand for risk mitigation compared to the probability assessment. Studies carried out previously have shown that subjective assessments of risk and judgement of severity of consequences may predict worry and worry has been found to be associated with demand for risk mitigation in transport (Rundmo & Moen, 2007) as well as mode use preferences (Nordfjærn et al., 2014; Rundmo et al., 2011). Probability assessment was found to be rather insignificant for such demands. The current research did not aim to re-examine the role of worry in travel mode use. It is interesting to note that the assessment of the probability-component of risk sensitivity alone contributed significantly to prediction of travel mode use (public transportation versus use of car).

The results of the current study showed that the same set of predictor variables explained a significantly larger proportion of explained variance in leisure travel mode use compared to work travel mode use. There could be several explanations for this. Most obvious is that the freedom to choose travel modes could be different on the two types of travels. It may be that the freedom of choice is larger for leisure travels compared to work travels. As expected access of private travel modes was an important predictor of travel mode use. In addition, the power of this predictor variable was significantly larger for travel mode use on work travels compared to leisure travels, indicating that it may be easier to choose other travel modes for leisure travels. Also demographic factors seemed to be of less importance for travel mode use in leisure time than for work travels. Other possible explanations, which could be further investigated, include possible differences in the role of habits. Because work travels could have a more repetitive nature than

many travels conducted during the leisure time, habits could play a larger role in mode use on these travels (see also Bamberg et al., 2003).

In this study, perceived risk evaluations and risk sensitivity have been considered to contain the same data of evaluations of probability assessments and judgement of severity of consequences. Consequently, the concepts of perceived risk evaluations and risk sensitivity are unquestionably woven together. They are two parts of the same intuitive evaluation of risk; a direct assessment of probability of an event with negative consequences and the stability or consistency in the evaluation of various risk sources. The first element may vary because it relates closely to the hazard or object of evaluation. The second element is not primarily related to the object, but is a general tendency influencing on the direct evaluation of risk. This element consists of two elements. The first is risk sensitivity, i.e. judging a set of hazards or risk sources on a continuum varying from high (indicating risk sensitivity) to low (indicating risk ignorance). The second element is risk stability, which varies from high (indicating risk stability) to low (indicating risk flexibility). Perceived risk evaluation is only the "basis material" for calculating risk sensitivity. Therefore, risk sensitivity is the main concept, covering the perceived risk evaluations, including intuitive judgments of probability as well as severity of consequences across a set of risk sources.

Further research should examine predictors of risk sensitivity as well as risk stability in further detail. It could be interesting to investigate how aspects of subjective risk judgements not directly associated with characteristics of the risk source influence judgement. Therefore, research on risk sensitivity should be given priority, not the mere analysis of single hazard or risk source evaluation. Further investigations could focus on associations between personality variables and risk sensitivity, which in previous research have been found to be associated with risk perception as well as risk-taking behaviour. Such behaviour has been connected to personality factors e.g. sensation seeking. Another hypothesis is that attitudinal factors, e.g. attitudes towards risk-taking and risky behaviour, may stabilise risk sensitivity on a high or low level, working more or less independently in the judgement of single hazards or risks. The current study showed that priority of security also was associated with travel mode use. The relations between priority of security, personality factors and risk sensitivity should be investigated more thoroughly in future research.

A systematic classification scheme for cyber-attack taxonomy

ABSTRACT: Development of digital and network technology has led to a big change in the industry, especially in ICS (Industrial Control System) and SCADA (Supervisory Control And Data Acquisition) system. The components of analogue in facilities are changed into digital components and new facilities of ICS and SCADA systems are composed of various digital instrumentation and control systems. Because of these changes, the security of ICS and SCADA system became an important factor in the industry. Nevertheless, there are few researches on cyber-attack taxonomy for ICS and SCADA systems. Even though some papers and researches suggested a cyber-attack taxonomy, it was not enough or comprehensive for industrial oriented ICS and SCADA systems. Therefore, in this paper, the classification scheme is proposed to classify the cyber-attack taxonomy of PLC (Programmable Logic Controller), DCS (Distributed Control System), and network equipment, which are core components of ICS and SCADA systems. In this paper, cyber-attack is subdivided into foot printing/scanning, password cracking, spoofing, sniffing, hijacking, MITM (Man In The Middle), virus, DoS (Denial of Service), backdoor installation, and hiding files. These ten cyber-attack categories are related with cyber-attack scenario, which is composed of prior preparation, gaining access, maintaining access, and clearing tracks. The grouped categories mentioned above were subdivided according to the characteristics and principles of cyber-attack. The subdivided cyber-attack access path is classified into physical/network, internal/external, and accidental/intentional access. After that, the detailed method of access is investigated. The consequences that can be caused by cyber-attacks are defined as disclosure, modification, destruction, and interruption. Finally, the prevention and mitigation of cyber-attack suggested the specific ways to reduce or escape the damage of cyber-attack consequence.

1 INTRODUCTION

In the ICS (Industrial Control System) and SCADA (Supervisory Control And Data Acquisition) system, the analog instrumentation & control device is being replaced by the digital instrumentation & control device because the digital control system provides better control accuracy and ease of maintenance. However, digital control systems have problems that are subject to cyber-attack. An example of the seriousness of the situation is Stuxnet, which was discovered in 2011, which has caused great damage to the Iranian nuclear infrastructure and major industrial infrastructure in China [1]. This example implies that ICS & SCADA systems, which have closed networks with air gap, are no longer safe from cyber-attack.

Therefore, a new digital instrumentation & control device with cyber security function is required to protect from malicious cyber-attack. In order to apply a new measurement control device with cyber security function to ICS & SCADA system such as nuclear power plants, a compatibility test for cyber security must be performed along with the development of design requirements. In order to conduct a conformance test for cyber security, a systematic classification of attack types and a cyber-attack taxonomy investigation including the latest attack types should be preceded. Most of the preceding cyber-attack taxonomy and researches focused on IT (Information Technology). However, this classification scheme is not suitable for ICS & SCADA systems that are composed of closed networks with air gap and take into account the characteristics of the equipment such as DCS (Distributed Control System) and PLC (Programmable Logic Controller). Therefore, this paper suggested a systematic classification scheme for cyber-attack taxonomy that selectively considered the characteristics of ICS & SCADA systems. The paper classified the cyber-attacks as foot printing & scanning, password cracking, spoofing, sniffing, hijacking, MITM (Man in the middle), virus, DoS (Denial of Service), backdoor installation, and hiding files according to the general cyber-attack scenarios. Then, each category of attacks is subdivided into detailed attacks, access means, result of cyber-attack, vulnerability,

and defense of cyber-attack. In addition, the classification of cyber-attack taxonomy can be applied to identify the attackable digital devices such as DCS, PLC, and network device and the interval of cyber-attack test such as DCS to network device, DCS to PLC, and so on.

2 BACKGROUND

2.1 *General cyber-attack process*

As mentioned above, this paper classified ten categories of cyber-attack. Before the systematic classification scheme for cyber-attack taxonomy, a brief description of the ten categories of cyber-attack is first presented.

Foot printing & scanning is the preliminary task of gathering information about the system to be attacked. Password cracking is the attack that extracts passwords through various methods and means, and can gain full access rights to the system through password cracking. Spoofing is the word meaning cheat, which allows spoofing on any connection that exists on the Internet or locally. Sniffing is an act of peeping packets exchanged by other parties on the network, similar to the dictionary meaning of 'sniff'. Session hijacking is a cyber-attack technique that steals and accesses another person's session state. MITM is the way of intercepting and exchanging information between two parties communicating with each other. A computer virus is a type of malicious software program that can replicate itself by modifying other computer programs and inserting its own code.

A DoS is an attack that causes an attacker to deplete the resource of target so that the user is no longer able to receive services for the resource used by the attacker. Backdoor installation is the method of passing through authentication, ensuring remote access. Hiding files is a process that clears the trace of the attack and deletes the related log to avoid tracing and also hides key files or information for later use or for confidential use of information stored in the victim system.

2.2 *Digital assets for ICS*

Analyzing the digital devices is necessary to make relationship between cyber-attack type and a digital asset. This paper analyzed PLC, DCS, and network device, which are core components of ICS & SCADA systems.

2.2.1 *PLC*

The PLC is a digital control device that can store commands and perform control algorithms that can perform various functions such as logic, operation, counting, and sequential processing to control various types of machines or processes. The PLC is basically the central processing unit that manages and controls all the functionality, a process input / output for exchanging signals, a memory for storing programs, a power unit for supplying electricity to the PLC, and other peripherals [2,16]. The differences between PLC and analog type relays are shown in the Table 1.

2.2.2 *DCS*

The DCS divides one central processing unit to distribute various functions. The overall system configuration is connected to each computer with a small number of central processing units via a communication network. DCS is developed to replace the PID (Proportional Integral Derivative) controller and generally controlled the complex process. The basic feature of DCS is to distribute the process control functions to several computers to improve the reliability and minimize the ripple effect in the event of an error. In addition, it facilitates data processing and operation management by concentrating information, driving operation, and management functions of distributed computers on the Distributed Operate Console. The basic components of the DCS are a CPU (Central Processing Unit) that performs data in real time, a data highway, LAN (Local Area Network) connecting a communication line, a signal input/output unit, an interface for power supply, and a power supply for supplying power [2]. The comparison between PLC and DCS is shown in the following Table 2.

2.2.3 *Network*

The network has a fieldbus, which is a type of digital network system. The fieldbus has been developed to digitally replace analog signals, providing high accuracy and reliability. The fieldbus is a path for transferring network data from the field where PLC-based control equipment exists to the network system between equipment. In addition, there are fieldbus as a controller subnetwork that digitizes/network connection between analog type control devices and field devices, and sensor bus which is a network that transmits sensor signals at high speed. The fieldbus as a controller subnetwork is also classified as a FA (Factory Automation) system and a PA (Process Automation) system. The fieldbus requires only one signal line to transmit signals to the main cable to which a plurality of cells can connect, thereby reducing the wiring cost. It is not only makes it easy for the operator to identify all the devices included in the system, but also facilitates mutual operation between individual devices, thereby lowering the maintenance cost and ensuring reliability. In addition, it has an advantage that system performance

Table 1. Differences between Relay and PLC.

	Relay	PLC
Control method	Hard Logic	Soft Logic
Control function	• Relay (AND, OR by serial/parallel) • Timer • Counter (The function is limited and enlarged according to size)	• Relays (AND, OR, NOT, etc.) • Up/down counter • Arithmetic operation • Logical operation • Transmission (Function is limited and can be enlarged)
Control element	• Reed switch (Limited lifetime, low speed control)	• Solid contact (High reliability, long lifetime, high speed control)
Change content	Disconnection and rewiring of wire	Change through program change
Construction period	• Control panel production after specification • Prolonged inspection and commissioning period	• Specification can be made in parallel with assembly of hard decision • Reduced inspection and commissioning period
Integrity	Difficult to repair	High reliability and easy maintenance
Scalability	Difficulty in expanding the system	• Easy to expand system • Transmission of work information is possible by connecting with computer
Size	Difficult to miniaturize	Possible to miniaturize

Table 2. Differences between PLC and DCS.

	PLC	DCS
Control target	Unit control	Process system
Constitution	PLC	• PLC • Distributed I/O • Touch panel
Response time	Fast (relatively) Suitable for situations requiring real-time action	Late (relatively)
Scalability	Manage thousands of I/O	• Manage hundreds of thousands of I/O • Suitable for advanced process control
Complexity	Impossible to request PLC based control system	Better than PLC
Process change	Suitable for processes that are not frequently changed	Ideal for complex or coordinated analysis that combines large amounts of data

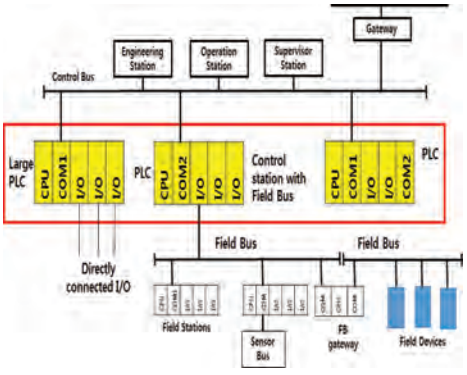

Figure 1. Typical structure of PLC.

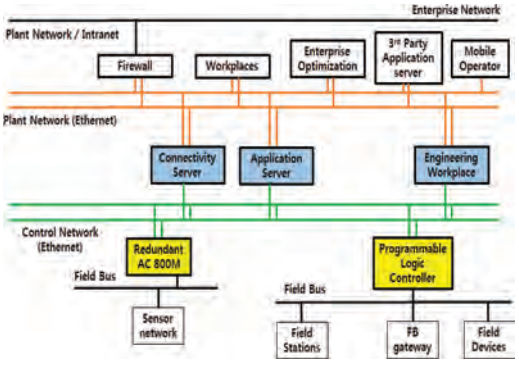

Figure 2. Structure of DCS.

can be improved by facilitating the information collection of field devices. Typical types of these field buses are Modbus, Interbus, Profibus, RS232C/RS485, and Ethernet TCP (Transmission Control Protocol)/IP (Internet Protocol) [9].

3 CLASSIFICATION SCHEME FOR CYBER-ATTACK

3.1 *Subdivision of attack categories*

This paper classified cyber-attack scenario as four stages: prior preparation, gaining access, maintaining access, and clearing tracks [18].

Prior preparation for cyber-attack includes information that target IP range, namespace, vulnerability, and protocol. Gaining access is to bypass access controls to gain access to the system. Maintaining access is retaining ownership of the system. Clearing track is the activities carried out by an attacker to hide malicious acts.

The step after classifying the cyber-attack in terms of cyber-attack scenario is to further subdivide the cyber-attack. The reason for subdivision of cyber-attacks is that even if the basic principles of cyber – attacks are the same, the conditions and vulnerabilities for the cyber-attacks are different, and the attack results and countermeasures are not the same accordingly. Also, if the cyber-attack is further subdivided and complementary measures are taken, it can be a more stable system. As a typical example, password cracking can be subdivided into keylogger attack, dictionary attack, hybrid attack, brute-force attack, and precomputed Hashes attack.

With these definitions, ten types of attacks were matched to the cyber-attack scenario and Table 3 shows their relationship.

Table 3. Cyber-attack scenario with corresponding attack.

Cyber-attack scenario	Corresponding Attack
Prior preparation Gathering information for attack	Foot printing & Scanning Spoofing, sniffing, MITM
Gaining access Bypass access controls to gain access to the system.	Password cracking Hijacking, DoS
Maintaining access Retain ownership of the system	Virus, Backdoors
Clearing tracks The activities carried out by an attacker to hide malicious acts	Hiding files

3.2 *Classification scheme for cyber-attack*

Generally, the cyber-attack scenario proceeds as follows. In the prior preparation stage, the attacker will identify the attack target information, attack through the designated access, and achieve the desired result. After that, security vendors will develop a defense. This paper focused on the general cyber-attack scenarios and selected items to be considered in the attack classification system as method of access, outcome, vulnerability, and defense. The Figure 3 shows the overall flow chart of cyber-attack taxonomy.

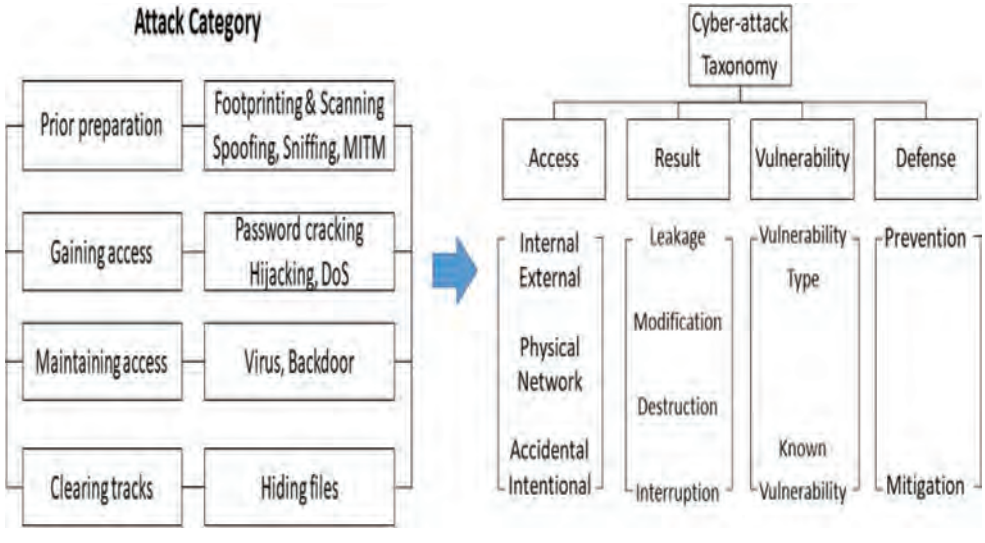

Figure 3. Flowchart of cyber-attack taxonomy.

3.2.1 *Access means of cyber-attack*

The first of the cyber-attack classification is the access of cyber-attack. The ICS & SCADA system is disconnected with the external network, so usually attack of internal is mainly considered. However, in consideration of recent ICS & SCADA system accidents such as Stuxnet, external attacks are also importantly considered as the accessible path of cyber-attack. After distinguishing internal/external attack, considered access of cyber-attack is physical access which include USB or CD and network access which using communication network [4]. This can be used to determine whether physical security is required or network and software security is required to increase the security of system. The last one considered is whether an attack is intentional or accidental. Considering only intentional attacks, there is a limit to the availability guarantee. Therefore, in order to provide a high level of availability and security for ICS operation, accidental access such as misconfiguration of ICS components and ICS equipment failure are considered [2,7].

3.2.2 *Attack result from cyber-attack*

The next classification is based on attack result. In order to derive the attack result, ten cyber-attack categories are considered which were earlier mentioned. For example, in the case of foot printing & scanning, the purpose is to leak data by secretly viewing the data. In the case of DoS, the goal is to destroy the system by putting the system and server in a saturation state. In the case of MITM, the purpose is to modify the data between the client and the server. Considering purpose of the remaining cyber-attacks, the results of the attack are classified as leakage, modification, destruction, and interruption [7].

3.2.3 *Vulnerability with cyber-attack*

The next classification is based on the vulnerability. With the development of information technology, the complexity of software has increased and vulnerabilities have also increased. Vulnerability is a flaw that can be security threat in hardware or software and can be exploited directly by a hacker or as a means of spreading a virus or malicious program [15]. As a result, some countries have databased vulnerabilities and have developed countermeasures against them. This enables early response to specific cyber-attack. This paper also considered vulnerability as one of the classification items, so that it can be used for early response by matching with vulnerability in case of specific cyber-attack. List the vulnerabilities of the software used in ICS and SCADA systems and investigate where the software is used to know anticipated cyber-attacks in the system and use them for countermeasures and mitigations in case of cyber-attack. In addition, the newly discovered vulnerabilities can be continuously matched and added to the cyber-attack, which can effectively upgrade and supplement the system. Vulnerability databases include USA's NVD (National Vulnerability Database), Japan's JVN (Japan Vulnerability Notes) and CNVD (China National Vulnerability Database). In this paper, NVD based on NIST (National Institute of Standards and Technology), which is widely used, is selected and shown in Table 4 [15].

3.2.4 *Defense from cyber-attack*

The last classification is the defense from cyber-attack. There are two kinds of method to reduce the damage from cyber-attack. One is the prevention of cyber-attack and the other is the mitigation of the cyber-attack [17].

Considering typical vulnerabilities of ICS is a way to prevent cyber-attack. Typical vulnerabilities of ICS are unauthorized protocols, aged hardware, vulnerable user authentication, vulnerable file integrity checks, vulnerable Windows operating systems, and undocumented third party relationships [13].

Table 4. Example for usage of cyber-attack taxonomy.

Attack Category	Subdivided Attack	Definition of Subdivided Cyber-attack				Defense		
		RST hijacking is a kind of TCP/IP hijacking in which RST packets are injected. ... (Omitted below)				The countermeasures of RST Hijacking are to reduce the SYN-received latency, or to block RST packets at the router or firewall. … (Omitted below)		
Session Hijacking	RST Hijacking	Access Method (1)	Access Method (2)	Attack Method & Condition	Attackable OS, CPU, S/W	Attack Result	Known Vulnerability	Vulnerability Type
		Internal External	NA: TCP/IP	TCP vulnerability (3-handshake)	OS: Window ver, Linux 3.2.24	Interruption	CVE-2002–1778	Other

The prevention of the cyber-attack which derived from ICS vulnerabilities are antivirus, firewall, one-way gate, and media control. Antivirus is the use of signature-based engines with solutions to detect and treat malware. Firewall is used to allow and block information transmitted during data transmission between ICS networks. One-way gate is a method of establishing a physical unidirectional environment to intercept the intrusion when linking infrastructure network and external network data. Media control is the disconnection of an interface control device such as a USB connected to an ICS network [15]. There is mitigation as a way to reduce the damage after the cyber-attack. Treatment and mitigation is the method needed to normalize the system after a cyber-attack. Treatment and mitigation are various like as vulnerability. As mentioned above, the mitigation is linked with vulnerability and can be used for early response after cyber-attack. With these classifications, Table 4 shows the example of systematic classification scheme for cyber-attack taxonomy.

3.3 *Example of cyber-attack taxonomy utilization*

The surveyed cyber-attack taxonomy can be used to determine attack target, attack area, and test method considering the principles and characteristics of PLC, DCS, and network device of ICS/SCADA system proposed in 2.2. PLC, DCS, and network devices used in the actual industrial field vary, and security performance and vulnerabilities are also different. The PLC, DCS, and network devices mentioned in this paper are assumed to have general performance and characteristics.

An example of cyber-attack, which shows the usage of cyber-attack taxonomy, is the RST hijacking. RST hijacking is a kind of TCP/IP hijacking in which RST packets are injected into the network approach. RST Hijacking can observe the communication between the client and the server as well as TCP session hijacking. Also, it is possible to extort the session using the trust and the session using the TCP. This attack exploits the weaknesses of the TCP three handshake method, which can cause the device to overload and stop functioning similar to a DoS attack. By applying the information of the cyber-attack taxonomy investigated to the ICS & SCADA system, the attackable device can be selected by the DCS and the network because RST hijacking is intended for communication between client and server like DCS. It is expected that the test interval in the cyber security test can be between DCS and network. It means that knowing of the particular cyber-attack, which occurs in a particular section of the ICS and SCADA system, can reduce the effort and cost of defending and mitigating from cyber-attack. Also, if many cyber-attacks are systematically classified and accumulated like RST-hijacking mentioned above, the user or operator will be able to quickly recognize the type of attack when an arbitrary cyber-attack is applied. It means that the user or operator can take action quickly.

4 CONCLUSION & FUTURE WORK

This paper classified cyber-attack scenario as four stages such as prior preparation, gaining access, maintaining access, and clearing tracks matched with the ten categories of cyber-attack such as footprinting, scanning, password attack, spoofing, sniffing, hijacking, MITM, virus, DoS, backdoor installation and hiding files. Then, ten kinds of cyber-attacks are subdivided and classified into access means, result of cyber-attack, vulnerability, and defense according to the classification scheme for cyber-attack. Access of cyber-attack can be classified with internal/external, physical/network, and intentional/accidental. Result of cyber-attack can be classified with leakage, modification, destruction, and interruption. Vulnerability of cyber-attack is based on NVD and it can be used for early response from cyber-attack when it combined with defense of cyber-attack. Defense of cyber-attack can be classified with prevention and mitigation. Through this classification system, the cyber-attacks and the possible intervals in ICS are exemplified. Future works include further subdivision of the ten categories of cyber-attack, and using it to prove possible attacks and attack intervals through penetration testing in a cyber-attackable experimental environment.

Organizational information security culture in critical infrastructure: Developing and testing a scale and its relationships to other measures of information security

T.O. Nævestad & S. Frislid Meyer
Institute of Transport Economics, Oslo, Norway

J. Hovland Honerud
University College of Southeast Norway, Norway

ABSTRACT: The aims of the present study are to 1) develop and test a scale measuring organizational information security culture, and 2) examine its relationships to other aspects of information security. The study focuses on an organization providing critical infrastructure. We developed the scale by conducting qualitative interviews (N = 22) and three focus groups (N = 15) in an organization providing critical infrastructure, and by reviewing previous research on culture in organisations. Based on our literature review and the interviews, we chose to measure organizational information security culture by reformulating one of the few existing general organizational safety culture questionnaires. We first tested the questionnaire in a small pilot survey, and then conducted a questionnaire survey (N = 323) including all departments in the organization. Our examination of the factor structure of the scale indicated two factors. Regression analyses indicate that our adapted GAIN-scale, measuring organizational information security culture is the most important variable influencing information security behavior in the model.

1 INTRODUCTION

1.1 *Background*

Information security is often defined as protection against breaches of confidentiality, integrity and accessibility. This applies to information that is oral, written or electronic. Confidentiality refers to ensuring that only those who are authorised to access information, accesses it. Integrity refers to protecting the accuracy and entirety of information and processing methods. Accessibility refers to ensuring that authorised users have access to the information and associated equipments when necessary (Report to the Storting 29. 2011–2012).

Ruighaver et al (2007) assert that it was not until the start of the century that scholars began to recognise the importance of organizational information security culture for information systems security in organisations. The importance of culture for security and safety has also gained recognition in the Norwegian society in recent years. One of the most important conclusions of the report of the investigation commission following the terrorist attack in Oslo and Utøya, July 22. 2011 was that future efforts to secure sensitive objects (e.g. people and critical infrastructure) and information should focus on culture, focusing especially on the acknowledgement of risk and leadership.

The study organization is a provider of critical infrastructure in Norway. As a provider of critical infrastructure, the study organization is obliged to follow the requirements of the Security Act ("Sikkerhetsloven") when it comes to preventive safety work, which includes safety analyses, securing objects, information security and safety drill. Based on these requirements, the study organization decided to map and analyse their own organizational security culture. Critical infrastructure means the facilities and systems that are completely necessary to maintain society's critical functions, which in turn meet society's basic needs and respond to the population's need for a perception of safety (NOU 2006).

1.2 *Aims*

The aims of the present study are to 1) develop and test a scale measuring organizational information security culture and 2) examine its relationships to other aspects of information security.

1.3 *Research on culture in organisations*

1.3.1 *Organisational information security culture*

Although Ruighaver et al. (2007) note that the organisational security culture concept has gained recognition, they also underline that there is

lacking consensus when it comes to how the concept should be defined and conceptualized (cf. Chia et al., 2002). Additionally, they also assert that in spite a large amount of research on organisational security and how it should be improved, this research only focus on certain aspects of security and not how these aspects can be analysed as part of a larger organisational culture.

Based on this understanding, Ruighaver et al. (2007) choose to draw on organisational culture research in their analysis of security culture. This approach is similar to that applied by scholars studying organisational safety culture, who analyse safety culture as a focused and safety relevant aspect of the larger organisational culture (e.g. Hale, 2000, Haukelid, 2008, Antonsen, 2009). Based on this, we may also analyse security culture as "security relevant" aspects of the larger organisational culture, define and conceptualising using models of organisational culture (e.g. Schein, 2004). In this paper, we suggest that the research on information security culture could learn from the research on safety culture. Nosworthy (2000) asserts for instance that one of the key challenges of information security culture implementation is how to educate the people of the organization to successfully implement the requirements of the information security policy. A lot of effort has been put in to understand this in safety culture research, discerning between formal (structure; safety management system; procedures, training, routines etc.) aspects of safety and informal aspects (culture) (Antonsen, 2009). Additionally, Knapp et al. (2006), depict the top management support as a significant predictor of an organization's security culture and level of policy enforcement. This also reflects a key finding in organizational safety culture and safety culture research, and thus it is relevant to also draw on the knowledge gained in these research fields.

1.3.2 *Organisational culture*

The influential scholar Schein defines organizational culture as: "(...) a pattern of shared basic assumptions that the group learned as it solved its problems of external adaptation and internal integration that has worked well enough to be considered valid and, therefore, to be taught to new members as the correct way to perceive, think and feel in relation to those problems." (Schein 1992: 12). According to Guldenmund (2000: 222–225), organizational culture has the following characteristics: 1. It is a construct in the sense that it is an abstract, not a concrete concept, 2. It is relatively stable, 3. It has multiple dimensionality, in the sense that it can be described in many different ways, 4. It is shared by groups of people, 5. It consists of various aspects, which means that several different cultures can be identified within organizations, depending on the issue at hand, 6. It constitutes practices, 7. It is functional. Guldenmund describes organizational culture in the following manner: "Overall, organisational culture is a relatively stable, multidimensional, holistic construct shared by (groups of) organisational members that supplies a frame of reference and which gives meaning to and/or is typically revealed in certain practices." (Guldenmund 2000: 225).

As the research on organizational safety culture seems to have been through many of the challenges that the organizational security culture research now is facing, we draw on the experiences of the former, e.g. when it comes to analyzing security culture as a focused aspect of organizational culture.

1.3.3 *Organizational safety culture*

Even though the concept of safety culture has become popular since it first was introduced in the wake of the Chernobyl accident in 1986, it is not well understood (Reason, 1997). Safety culture scholars may disagree on a range of different issues, but they seem to agree that the research on safety culture and its relationship with safety is fragmented and unsystematic (e.g., Cox & Flin, 199, Pidgeon, 1998, Hopkins, 2006, Guldenmund, 2007; Choudry et al., 2007; Glendon, 2008). In spite of this disagreement, most scholars seem to agree that safety culture refers to shared and safety relevant ways of thinking or acting that are (re) created through the joint negotiation of people in social settings (Nævestad, 2010a), and as noted as safety-relevant aspects of organisational culture (Hale 2000). The element of safety culture that can be measured is often referred to as safety climate. Thus, safety climate can be conceived of as "snapshots", or manifestations of safety culture (Cox & Flin, 1998). Quantitative measurements of safety culture can provide leading indicators of safety and consequently offer predictive assessments that enable safety improvements without having to wait for accidents or incidents to happen (Antonsen, 2009). Senior management commitment to safety is the most studied and best-documented characteristic of a good safety culture, independent of sector (Flin et al. 2000; Guldenmund 2000).

2 METHOD

Our methodological approach is based on a literature review conducted in 2012, interviews (N = 22) and focus groups (N = 15) in 2014 and survey in 2014 (N = 323).

2.1 *Interviews and focus groups*

We started with the qualitative part of the study before conducting the quantitative survey, so that

we could form a picture of key issues concerning safety and security work at the study organisation. This is important because we had to adapt the security culture questionnaire, and because it gave us the opportunity to add questions that are central to safety and security work at the study organisation to the questionnaire. We have conducted 22 in-depth interviews, primarily managers, and one group interview with 3 respondents. Focus groups, primarily employees: 2 focus groups with a total of 12 persons. This makes a total of 37 in-depth interviews.

We used a semi-structured and relatively open interview guide based on the safety and security culture topics from the safety culture index. Our point of departure was topics related to information security and the protection of critical infrastructure. The interview guide had to be open so that we could depend on the interviewees' understanding of how different features of the organisation culture in the study organisation have had and can have consequences for safety and security.

The interviews were built up around the following main topics: 1) In general about the department's and respondent's responsibility and roles, 2) Security focus, and relation to safety in the information security, HSE safety, deliverance reliability, 3) Organizational framework, management lines and communication, 4) Safety culture issues; safety, training, expertise, procedures, etc.

2.2 *Literature review*

The literature review was originally conducted as part of another project (cf. Nævestad & Bjørnskau 2012), but we nevertheless draw on it in the present study, as it also was relevant to the present study, and as our choice of safety culture scale for the present study was based on it. This is based on our mentioned ambition to learn from the safety culture literature when measuring and understanding organisational information security culture.

In this review, we conducted literature searches for articles and reports that document experiences with different safety culture measurement tools. We conducted searches through two key scientific databases, "Science direct" and the ISI web of science. A search for "Safety climate" in "abstract/title/key words", "safety climate scale" and "safety climate questionnaire" in scientific publications (primarily referenced journal articles, but also some books) for all years, gave everything in all 249 results. The next search we made from the scientific database "ISI-Web of Knowledge". Here we searched for articles with "safety climate" in title or subject, for all years, and received 458 hits.

The scales were reviewed according to the following criteria, whether: 1) they are based on a solid scientific approach (e.g. based on previous research and existing theory, have been validated in several studies), 2) they are universal, 3) they are) user-friendly; do not include too many themes and questions, which are understandable for people who are not researchers and 4) A key criterion has been that the themes and the items in the scales are in accordance with the key results of the interviews and focus groups. Our review resulted in 11 scales that we perceived as relevant enough to be evaluated systematically against these criteria.

In the present study, we choose to reformulate one of the few existing universal organizational safety culture scales, the GAIN-scale for safety culture, into an organizational security culture scale. The GAIN scale was chosen first, as our previous literature review, conclude that this is one of very few universal safety culture surveys (Nævestad & Bjørnskau, 2012). Thus, the wording of each item can be adapted to different sectors (and presumably also to security) without obviously altering the particular aspect which that item measures. Thus, the scale has the potential to be developed as a generic measure.

Second, the scale was chosen, as it is founded on a relatively solid scientific foundation. It must be noted that we ended up recommending another scale in the above mentioned 2012 review. In this review, we chose the NOSAQ-50 scale (Kines et al., 2011), over the GAIN-scales (GAIN, 2001), as this had been subjected to a more systematic literature review. We have however conducted several studies using the GAIN scale since 2012 (e.g. Nævestad & Bjørnskau, 2014, Nævestad et al., 2017, Nævestad, 2017), subjecting it to exploratory and confirmatory factor analyses, and we have also analyzed the relationship between the scale and safety outcomes (e.g. Nævestad, 2017). The scale has also been used to study and compare safety culture in different transport sectors like road, rail, helicopter and aviation (Bjørnskau & Longva, 2009).

Third, the scale was chosen, as it is relatively easy to use. The GAIN-scale has for instance considerably shorter than the NOSAQ 50; it has only half the items. Additionally, the questions are relatively short, and it is relatively easy to change and adapt the wording to information security culture.

2.3 *Survey*

2.3.1 *Sample characteristics*

A total of 323 individuals responded to the survey, from 11 different departments, giving a response rate of 56%. More than 90 per cent of the respondents are permanent employees and seven per cent are hired consultants. We also see that seven per cent are section or department managers. It should also be mentioned that more than 50% those who responded to the survey had been employed by the

study organisation for five years or less. This is a relatively high percentage. It explains that more than 40 per cent of the respondents have been employed by 3–5 other business in their working life before the study organisation. Almost a quarter of those who responded have however been employed for more than 20 years. This is an approximate reflection of the actual distribution in the study organisation, but respondents with the shortest seniority are overrepresented. 56 per cent of the respondents are above the age of 46. This is interesting, considering that around half have seniority of five years or less. 61 per cent of the respondents are men and 66 per cent have graduated from university/university college.

2.3.2 *Pilot survey*

As we developed several new questions in the survey which had never been tested before, we conducted a small pilot study (N = 12) directed at personnel in the study organisation to obtain feedback and assess how the questions worked. In the pilot study we received some useful feedback, including that we should use the term "my immediate supervisor" rather than "my department manager" in the survey on safety culture and information security culture

2.3.3 *Survey topics*

The survey contains mainly questions about ten topics. It first contains a set of background questions (e.g. gender, age, education, experience, level) that were sent to all respondents. In addition, three short indexes follow with questions about three different types of security related to information security, HSE safety and deliverance reliability. The questions are identical and have the same scale so that we can directly compare the meanings of the three forms of safety and security in the study organisation. Furthermore, the questionnaire 13 contains questions about attitudes and behaviour regarding information security culture.

2.3.3.1 Background variables

The survey also includes questions on demographic background variables and various performance targets related to safety. The background variables include information on: 1) gender, 2) age, 3) education, 4) seniority, 5) employment in other businesses, 6) level in the organization and 7) employment status in the organization (permanent, hired). These background variables are only presented at the enterprise level.

2.3.3.2 The GAIN scale

Global Aviation Information Network (GAIN) is a voluntary association of airlines, manufacturers, trade unions, governments and other organisations in aviation. The GAIN questionnaire contains 24 questions concerning (we excluded one of the original questions, because of the wording):

1. Management's attitude to and focus on safety:

Man 1: My immediate supervisor discovers employees who fail to take sufficient considerations to information security in their work
Man 2: My immediate supervisor often praises employees for maintaining information security
Man 3: My immediate supervisor is aware of the most important information security issues in the company
Man 4: My immediate supervisor often discusses information security issues with the employees
Man 5: My immediate supervisor is personally involved in activities to improve information security
Man 6: My immediate supervisor postpones tasks/activities if information security is not sufficiently ensured
Man 7: My immediate supervisor considers information security to be very important in all tasks and activities
Man 8: My immediate supervisor does everything he/she can do to avoid breaches of information security

2. Employees' attitudes to and focus on safety:

Emp 1; My colleagues do everything they can to avoid breaches of information security
Emp 2: Employees encourage one another to safeguard information security
Emp 3: Employees usually report all breaches and irregularities related to information security that they experience at work

3. Reporting culture and reactions to incident reporting:

Rep 1: Those who pursue breaches of information security in the business attempt to find the real causes rather than just blaming the employees
Rep 2: There are routines and procedures at my workplace so that I may report information security-related breaches or irregularities
Rep 3: After a breach of information security, measures are implemented to prevent this from happening again
Rep 4: All irregularities and information security issues that are reported are remedied in a short time
Rep 5: Everyone has plenty of opportunities to forward suggestions related to information security

4. Safety training and education:

Tra 1: Employees in my company are provided with adequate training in the secure use of ICT systems (e.g. e-mail, storage, encryption)
Tra 2: All new employees are provided with adequate training for tasks and the secure use of ICT systems (e.g. e-mail, storage, encryption)
Tra 3: Everyone is provided with sufficient feedback on how the enterprise is performing with regard to information security

Tra 4: Everyone is informed of any changes that may impact information security

5. General questions concerning safety in the organization in question:

Gen 1: There are procedures that must be followed in the event of an emergency situation in my workplace
Gen 2: Information security in my business is better that in other businesses
Gen 3: Regular security audits are carried out
Gen 4:_Information security is generally well taken care of at my workplace

Respondents can rate the questions from 1 (totally disagree) to 5 (totally agree). Thus, a safety culture index with a minimum value of 24 (1 × 24) and a maximum value of 120 (5 × 24) can be compared across companies and sectors. According to GAIN (2001), organizations with a score of 93–125 points on the safety culture index have a positive safety culture, 59–92 indicates a bureaucratic safety culture and 25–58 indicates a poor safety culture.

2.3.3.3 Questions about information security
Based on the interviews (and literature review of organizational security culture scales, e.g. SjekkIT developed by NTNU and Sintef for the Norwegian National Security Authority (NSM), we also included 22 additional questions about information security in the organisation. These were themes representing special information security challenges in the organization.

3 RESULTS FROM INTERVIEWS AND FOCUS GROUPS

In the interviews, we discussed organisational security management with the key managers, and based on the interviews, we found that they perceived the five GAIN themes as important and relevant. Management and employee commitment for safety was perceived as key. The organisation had also developed a reporting system covering information security, and they were also engaged in several initiatives to educate employees in information security issues.

Based on the interviews and focus groups, we also developed 22 survey questions, reflecting the most important information security challenges in the organisaion. We included several untested questions among the 22, and we experienced that nine of these did not work because some of them had relatively large shares of "neither/nor" responses. The 13 questions on information security we ended up with after removing the 9 that did not work (of 22 questions in total) may be divided into the following topics. We unfortunately don't have the opportunity to present all here due to space considerations, but will nevertheless reproduce the topics and questions, as they are an important result of our qualitative surveys:

1. Knowledge/attitudes—information security:

We constructed an index for knowledge of and attitudes to information security with five questions. All of the questions have five values, such that the minimum value for the index is 5 and the maximum value is 25 (Cronbach's Alpha = 0.740).

In my work, I have a clear understanding of what the term information security means.
I have a clear understanding of what entails a breach of information security in my business.
I feel that I have adequate knowledge on the secure use of ICT systems (e.g. e-mail, storage, encryption)
All unfamiliar persons at the workplace are noticed, and one investigates what they are doing there.
When I am asked for information, I always think carefully about whether the information can be used for other purposes than originally intended.

2. Security assessment—PC and cell phone:

My cell phone contains sensitive information.
If I'm working on a PC from home, information security is just as high as it is at work

3. Classified information and accessibility.

We created an index of the following three questions on classified information (Cronbach's Alpha was 0.721):

I am well aware of which type of information that is sensitive and classified
I am well aware of who has access to various types of classified information
I take precautions when I come into contact with sensitive and classified information

The respondents were also asked to consider the following statement: "Considerations to information security (for example passwords to log on) impede my work".

4 RESULTS FROM THE QUANTITATIVE SURVEY

4.1 *Clear understanding of information security?*

The questionnaire that measures information security culture is based on the GAIN safety culture index, where the word "safety" is replaced by "information security." The questionnaire opened with definitions of information security and related sub-concepts.

4.2 *Organisational information security culture index*

We have combined the 24 statements with five response options on the five different aspects of information security in an information security culture index. The indexes for the departments correspond to the average scores for the respondents. Since we have removed a statement from the GAIN index, the minimum score will be 24 (24×1) and the maximum score will be 120 (24×5). Cronbach's Alpha for the 24 questions in the index is 0.913, which means very good agreement between the questions and that the index is very good.

Factor 1: Information security management and commitment	**Factor loadings**
Man 4: My immediate supervisor often discusses information security issues with the employees	0.774
Tra 4: Information security is generally well taken care of at my workplace	0.745
Man 7: My immediate supervisor considers information security to be very important in all tasks and activities	0.743
Man 6: My immediate supervisor postpones tasks/activities if information security is not sufficiently ensured	0.735
Man 8: My immediate supervisor does everything he/she can do to avoid breaches of information security	0.733
Rep 3: After a breach of information security, measures are implemented to prevent this from happening again	0.729
Man 3: My immediate supervisor is aware of the most important information security issues in the company	0.691
Man 5: My immediate supervisor is personally involved in activities to improve information security	0.678
Rep 4: All irregularities and information security issues that are reported are remedied in a short time	0.654
Emp 2: Employees encourage one another to safeguard information security	0.644
Man 2: My immediate supervisor often praises employees for maintaining information security	0.639
Emp 3: Employees usually report all breaches and irregularities related to information security that they experience at work	0.634
Gen 3: Regular security audits are carried out	0.615
Rep1: Those who pursue breaches of information security in the business attempt to find the real causes rather than just blaming the employees	0.598
Man 1: My immediate supervisor discovers employees who fail to take sufficient considerations to information security in their work	0.593
Emp 1: My colleagues do everything they can to avoid breaches of information security	0.591
Rep 5: Everyone has plenty of opportunities to forward suggestions related to information security	0.572
Gen 2: Information security in my business is better that in other businesses	0.548
Rep 2: There are routines and procedures at my workplace so that I may report information security-related breaches or irregularities	0.534
Tra 1: There are procedures that must be followed in the event of an emergency situation in my workplace	0.508

Factor 2: Information security training	**Loadings**
Tra 2: All new employees are provided with adequate training for tasks and the secure use of ICT systems (e.g. e-mail, storage, encryption)	0.691
Tra 1: Employees in my company are provided with adequate training in the secure use of ICT systems (e.g. e-mail, storage, encryption)	0.629
Tra 3: Everyone is provided with sufficient feedback on how the enterprise is performing with regard to information security	0.562
Tra 4: Everyone is informed of any changes that may impact information security	0.550

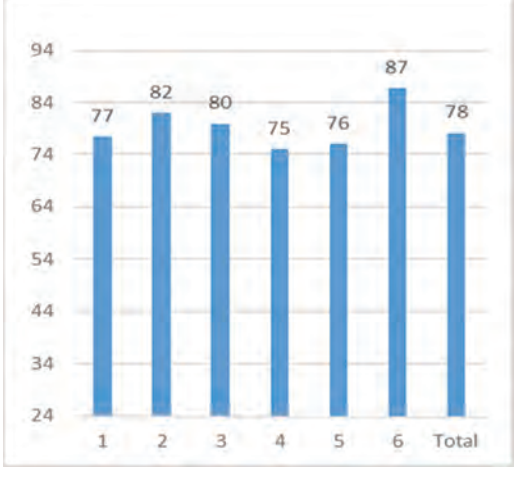

Figure 1. Mean scores on the GAIN index applied to organsiational information security culture. Departments in the study organisation. Minimum 24, maximum 120. (N = 249).

The figure shows that DEP 6 has the highest score and that DEP 4 has the lowest score. The difference between the highest and lowest score is more than 11 points. The differences between the departments are significant at the 1% level. We are careful of comparing the departments and in relation to the information security culture questions. The number of "neither/nor" responses indicate that the respondents are unwilling or incapable of considering the statements on the area, which may make it difficult to interpret the numbers. It also entails that respondents who have actually had an opinion are a minority for some of the questions. All in all, we therefore consider this index to be less robust than the others. This applies to all departments, except DEP 6.

The first topic in the index was "Immediate supervisor's attitude to and focus on information security." Here DEP 6 had the highest score, DEP 4 the lowest.

The second topic in the index is "Employees' attitude to and focus on information security." Once again DEP 6 had the highest score while DEP 1 had the lowest. The differences are significant at the 5% level. This should be interpreted in the light of DEP 1 having responsibility for following up such work, and is probably more critical in its assessment.

The third topic in the index is "Reporting culture and reactions to incident reporting." DEP 6 and DEP 2 had the highest scores, while DEP 4 and DEP 5 had the lowest. Differences were significant, of more than two points.

The fourth topic in the index is "Training in information security thinking." DEP 2 and DEP 6 had the highest scores, while DEP 1 had the lowest. The fifth topic in the index is "General information security issues." DEP 6 had the highest score, while DEP 1 had the lowest. The differences are significant at the 1% level.

4.2.1 *Exploratory factor analysis*

An Exploratory Factor Analysis (EFA) was conducted to examine the underlying factor structure of the 24 items in the sample. Although the original GAIN-scale for safety culture is comprised of five themes, we chose EFA as we apply it to a new topic; information security culture. Tests indicated that the items and the data were suitable for factor analysis. Bartlett's test of sphericity (approx. Chi-square) was 3380,834 ($p < 0.001$). The Kaiser–Meyer–Olkin's measure of sampling adequacy showed a value of 0.909. An unrotated principal component analysis (PCA) was used. We sat the cut off value of factor loadings equal to or above 0.40, as Matsunaga (2010) suggests that this perhaps is the lowest acceptable threshold on a conventional liberal-to-conservative continuum. Results showed five components with initial Eigenvalues higher than 1, which explained a total of 64.9% of the variance. The choice of the number of factors to retain was based on a combination of a) Eigenvalues, b) inspecting the scree plot for a bending point, c) inspecting the factor loadings in the component matrix, and d) conceptual and theoretical consideration. By inspecting the scree plot, a bend was relatively clearly identified between factor 5 and 6, indicating a five-factor solution. This is in line with the Eigenvalues. However, when looking at the factor loadings, we saw that all items loaded on the first component, while there were seven cross-loading. Four of these had lower factor loadings on the other factors than the first factor, and they were distributed on different factors. They were therefore kept in the first factor, with one exception. Three of the cross-loading items were all in the second factor, they had higher factor loadings in the second factor and they all concern security training. They were therefore attributed to a second factor. Additionally, one of the first mentioned cross-loading items had quite similar loadings in both factors (0.567 vs. 0.562), but as it matched the second conceptually, we attributed it to this factor.

Thus, based on our analysis of the factor loadings and a conceptual and theoretical consideration (the four latter items all concern information security training), we chose a two-factor solution, which explained a total of 50% of the variance, i.e. about 15% less than the three-factor solution.

4.2.2 *Regression analysis: What influences organisational information security scores?*

The information security culture scores vary according to conditions such as age, education and seniority, but we do not know which conditions that are most important to explain the variation in information security culture, or whether the effect we see from education is actually due to age or vice versa. We have conducted regression analyses to assess which conditions explain variation in the information security culture index.

We have used linear regression as the dependent variable is continuous. We add various independent variables in steps, so that we can assess their isolated effect on the dependent variables, i.e. when the values of the other variables remain unchanged. In this manner we can examine the effect of education controlled for age, for example.

We add the gender, age, education and seniority variables in the study organisation and department. We have converted the department variable to a dichotomous variable, i.e. with two values. The reason is that in regression analyses one cannot have independent variables that are at the nominal level, i.e. with values that are mutually exclusive, but which can't be ranked. The two values of the department

variable are 1) all other departments, 2) DEP 6. We have done this because DEP 6 had the highest score on the information security culture index.

We see that age contributes significantly and positively in 2; the older the respondents are, the better their information security culture score. In model 3 however, the age variable stops being significant, and that indicates that the age effect is actually due to it correlating with education. This means that younger respondents have higher education and a lower information security culture score and vice versa. Seniority does not make a significant contribution in any of the models.

Finally, we see that the department variable makes the strongest contribution in the regression analysis in Table 1. Belonging to DEP 6 predicts a positive score on the information security culture index. We already knew this, but in the regression analyses in Table 1 also show that this also applies when controlling for gender, age, education and seniority. We may therefore conclude that DEP 6's high score on the information security culture index is not due to underlying variables such as gender, age, education and seniority.

We see that the adjusted R^2 value, which indicates which proportion of the variation in the dependent variable that is explained by the independent variables significantly increasing in model 3 when education is included in the analyses, and that it increases by more than twice as much when department is included in model 5. The independent variables education and department explain 9.7% of the variation in the information security culture index.

4.3 *Regression analysis: What influences information security behaviour?*

We have conducted regression analyses to assess which conditions explain variation in the variable "I have never caused a breach of information security." This is a variable with five options from 1 (strongly disagree) to 5 (strongly agree). The overall "neither/nor" share is 26.3% for this question. What one answers here is probably to a certain extent dependent on whether one has a clear understanding of what information security is, or what it means for day to day work. The answer will also depend on how many opportunities one has to breach information security in one's work. We have used linear regression as the dependent variable is continuous. We add four independent variables in steps, so that we can assess their isolated effect on the dependent variables, i.e. when the values of the other variables remain unchanged. We add the gender, age and seniority variables in the study organisation and information security culture.

The table shows that seniority and information security culture contribute significantly to explain the variation in the variable "I have never caused a breach of information security." Both effects are positive. The positive effect of seniority means that

Table 1. Linear regression. Dependent variable: Organisational information security culture standardised beta coefficients.

Variable	1	2	3	4	5
Gender	–0,003	0,028	0,021	0,020	0,003
Age		**0,158****	0,105	0,076	0,034
Edu (Uni = 2)			**–0,185*****	**–0,157****	**–0,138****
Seniority				0,078	0,059
Department (DEP 6 = 2)					**0,244*****
Adj. R^2	–0.004	0.016	0.044	0.045	0,097

*p < 0,1; **p < 0,05; ***p < 0,01.

Table 2. Linear regression. Dependent variable: "I have never caused a breach of information security." Standardised beta coefficients.

Variable	Mod. 1	Mod. 2	Mod. 3	Mod. 4
Gender	–0,043	–0,042	–0,046	–0,051
Age		0,005	–0,070	–0,087
Seniority			0,159**	0,132*
Information security culture				0,192***
Adjusted R^2	–0.002	–0.006	0.010	0.041

*p < 0,1; **p < 0,05; ***p < 0,01.

the longer one has been employed by the study organisation, the higher the likelihood that one has not caused a breach of information security. This is perhaps somewhat unexpected, as one would assume that the longer one has been employed, the more opportunities (in terms of time) there have been to breach information security. It further means that there is reason to assume that the study organisation had scored somewhat higher on security culture if the distribution of respondents had corresponded to that in the organization: In the survey, 51 per cent of respondents had 0–5 years seniority, while in reality there are 38 per cent who have 0–5 years seniority in the study organisation. There is nevertheless no reason to believe that this possible skewness alters fundamental conclusions, as the difference is too small.

The effect of information security culture is however strongest, and this is the most important variable to explain variations in breaches of information security in the analyses. The higher the information security culture score is, the higher the likelihood that one has not caused a breach of information security.

We see that the adjusted R2 value, which indicates which proportion of the variation in the dependent variable that is explained by the independent variables, is negative in the two first models, but that it is at 1 and 4.1% in the last two. This happened when we included seniority and information security culture. These variables explain 4.1% of the variation in the variable "I have never caused a breach of information security".

5 CONCLUDING DISCUSSION

Learning from research on organizational culture and safety culture, we have adapted an organizational safety culture scale to measure organizational information security culture. Our examination of the factor structure of the scale indicated two factors. Regression analyses indicate that our adapted GAIN-scale, measuring organizational information security culture is the most important variable influencing information security behavior in the model.

How can we explain improvements in organizational information security culture in an organization providing critical infrastructure?

Institute of Transport Economics, Oslo, Norway

ABSTRACT: The aims of the present study are to 1) Compare results from a study conducted before and a study conducted after efforts to improve organizational information security culture in an organization providing critical infrastructure, and 2) discuss the results of the comparison. In this study, we compare the results of two surveys done over a period of just over two years; the first early in 2014 (N = 323) and the second late in 2016 (N = 446). Organizational information security culture was measured with an index which was made by adding the scores of respondents' answers to 24 items with answer alternatives ranging from 1 to 5. Thus, the minimum score of the information security index was 24 and the maximum score was 120. We found a statistically significant improvement in the index, comparing 2014 to 2016. Changes are discussed considering respondents' experiences with the implemented measures, sample characteristics and other methodological factors. We conclude that it seems that management implementation of measures aimed at improving organizational security culture has led to improvements.

1 INTRODUCTION

1.1 *Background*

Ruighaver et al (2007) assert that it was not until the start of the century that scholars began to recognise the importance of organisational security culture for information systems security in organisations. Information security is often defined as protection against breaches of confidentiality, integrity and accessibility. This applies to information that is oral, written or electronic. Confidentiality refers to ensuring that only those who are authorised to access information, accesses it. Integrity refers to protecting the accuracy and entirety of information and processing methods. Accessibility refers to ensuring that authorised users have access to the information and associated equipments when necessary (Report to the Storting 29. 2011–2012).

Throughout the report of the 22 July Commission, following the Oslo and Utøya terror attacks in 2011, leadership, culture and attitudes are emphasized as key challenges, both back in time and for the future. In the 22 July Commission's report, part VI "Learning, 19.9" (page 458) the Commission's main conclusion and recommendations are presented: The Commission's most important recommendation is that leaders at all levels of the administration work systematically to strengthen their own and their organisations' fundamental attitudes and culture in respect of: e.g. the acknowledgement of risk and leadership. Critical infrastructure means the facilities and systems that are completely necessary to maintain society's critical functions, which in turn meet society's basic needs and respond to the population's need for a perception of safety (NOU 2006).

1.2 *Aim*

The aims of the present study are to 1) Compare results from a study conducted before and a study conducted after efforts to improve organizational information security culture in an organization providing critical infra-structure, and 2) discuss the results of the comparison.

The study organization is a provider of critical infrastructure in Norway. As a provider of critical infrastructure, the study organization is obliged to follow the requirements of the Safety Act ("Sikkerhetsloven") when it comes to preventive safety work, which includes safety analyses, securing objects, information security and safety drill. Based on these requirements, the study organiza-

tion decided to map and analyse their own organizational security culture.

1.3 *Previous research on culture in organisations*

Although Ruighaver et al (2007) note that the organisational security culture concept has gained recognition, they also underline that there is lacking consensus when it comes to how the concept should be defined and conceptualized (cf. Chia et al 2002). Additionally, they also assert that in spite a large amount of research on organisational security and how it should be improved, this research only focuses on certain aspects of security, and not how these aspects can be analysed as part of a larger organisational culture (Ruighaver et al 2007). Based on this understanding, they choose to draw on organisational culture research in their analysis of security culture. This approach is similar to that applied by scholars studying organisational safety culture, who analyse safety culture as a focused and safety relevant aspect of the larger organisational culture (e.g. Hale 2000; Haukelid 2008 Antonsen 2009). Based on this, we may also analyse security culture as "security relevant" aspects of the larger organisational culture, define and conceptualising using models of organisational culture (e.g. Schein 2004).

The influential scholar Schein defines organizational culture as: "(...) a pattern of shared basic assumptions that the group learned as it solved its problems of external adaptation and internal integration that has worked well enough to be considered valid and, therefore, to be taught to new members as the correct way to perceive, think and feel in relation to those problems." (Schein 1992: 12). According to Guldenmund (2000: 222–225), organizational culture has the following characteristics: 1. It is a construct in the sense that it is an abstract, not a concrete concept, 2. It is relatively stable, 3. It has multiple dimensionality, in the sense that it can be described in many different ways, 4. It is shared by groups of people, 5. It consists of various aspects, which means that several different cultures can be identified within organizations, depending on the issue at hand, 6. It constitutes practices, 7. It is functional. Guldenmund describes organizational culture in the following manner: "Overall, organisational culture is a relatively stable, multidimensional, holistic construct shared by (groups of) organisational members that supplies a frame of reference and which gives meaning to and/or is typically revealed in certain practices." (Guldenmund 2000: 225).

As the research on organizational safety culture seems to have been through many of the challenges that the organizational security culture research now is facing, we draw on the experiences of the former, e.g. when it comes to analyzing security culture as a focused aspect of organizational culture. This also applies to management of culture. Knapp et al (2006) asserts for instance that top management support is a significant predictor of an organization's security culture and level of policy enforcement. Learning from the organizational culture literature, we may conceptualise this in terms of Schein's (2004) "six primary embedding mechanisms" that managers can use to shape culture is typical of the integration view:

1) What managers pay attention to, measure and control on a regular basis, 2) How managers react to critical incidents and organizational crises, 3) How managers allocate resources, 4) Deliberate role modelling, teaching and coaching, 5) How managers allocate rewards and status, and 6) How managers recruit, select, promote and excommunicate. It should however be noted that although organisational culture is a concept that often is examined with the intention to influence, organizational culture scholars give different answers to whether, to what extent and how safety culture can be managed, depending on their conceptualization of culture (cf. Nævestad 2010a). To conclude, the research on culture interventions in organisations generally indicate that safety culture change come about in the dynamic between "top-down" processes inititated from the management and "bottom-up" processes based in sub-groups (Olsen et al 2009).

2 METHOD

2.1 *Interviews*

We used a semi-structured and relatively open interview guide. Our starting point was topics related to information security, follow-up of safety and security work since 2014. The interview guide had to be open so that we could depend on the interviewees' understanding of how different organisational and cultural features of the study organisation have had and can have consequences for security. The interviews were built up around the following main topics: a) Reviews and measures related to security in the study organisation since 2014, b) The organisation's and employees' relationship to security. Security in everyday life, and as a topic of conversation, c) Clarity, management and rules related to security, d) Training, reporting/notification and risk assessments.

2.2 *Survey items*

The survey mainly contains questions about ten topics. It first contains a set of background questions, (e.g. gender, age, experience, education). that were sent to all respondents. In addition, the questionnaire contains 13 questions about attitudes and behaviour concerning information security culture.

We have chosen to not report results for these items here, as we wanted to focus on the development in the organizational security culture scale in 2014 and 2016, also comparing departments and measures implemented after the first measurement.

2.2.1 *The GAIN scale*

In this study, we choose to reformulate one of the few existing universal organizational safety culture scales, the GAIN-scale for safety culture, into an organizational security culture scale. Global Aviation Information Network (GAIN) is a voluntary association of airlines, manufacturers, trade unions, governments and other organisations in aviation. The GAIN questionnaire contains 25 questions concerning: 1) management's attitude to and focus on safety, 2) employees' attitudes to and focus on safety, 3) reporting culture and reactions to incident reporting, 4) safety training and education, and 5) general questions concerning safety in the organization in question. Respondents can rate the questions from 1 (totally disagree) to 5 (totally agree). Thus, a safety culture index with a minimum value of 25 ($1 \cdot 25$) and a maximum value of 125 ($5 \cdot 25$) can be compared across companies and sectors. According to GAIN (2001), organizations with a score of 93–125 points on the safety culture index have a positive safety culture, 59–92 indicates a bureaucratic safety culture and 25–58 indicates a poor safety culture.

The scale was chosen first, as the research on organizational safety culture seems to have been through many of the challenges that the organizational security culture research now is facing. Although Ruighaver et al (2007) note that the organisational security culture concept has gained recognition, they also underline that there is lacking consensus when it comes to how the concept should be defined and conceptualized (cf. Chia et al 2002). Additionally, they also assert that in spite a large amount of research on organisational security and how it should be improved, this research only focus on certain aspects of security and not how these aspects can be analysed as part of a larger organisational culture. Based on this understanding, Ruighaver et al (2007) choose to draw on organisational culture research in their analysis of security culture. We choose the same strategy in the present paper, drawing on the experiences of the safety culture literature, and choosing the GAIN-scale. The safety culture literature seems to have matured a bit more conceptually and methodologically, as it has employed the culture perspective in a few more years than the field of security research.

2.2.2 *Three types of safety/security/reliability*

In the 2014 interviews related to the first survey, we were given indications that many different types or nuances of safety and security are key in the study organisation. To assess the importance of, or the focus on these types of safety and security, we created four indexes with similar formulations of statements: one about information security, one about HSE, one about deliverance reliability (and one about security in connection with sensitive objects which is not reported here). The indexes consist of three statements:

I. My head of department considers ... to be very important
II. The study organisation's senior management considers ... to be very important
III. My colleagues consider ... to be very important

In the four indexes we replace ... with 1) information security, 2) protection of sensitive objects, 3) HSE and 4) deliverance reliability. All of the questions have five values, so the minimum value is 1 (totally disagree) and the maximum value is 5 (totally agree). The four indexes therefore have the same minimum and maximum values so that they can be compared to each other. In this way we can see what types(s) of safety and security managers and employees focus most on in the study organisation as a whole; in the various departments.

2.3 *Samples*

In this study, we compare the results of two surveys done over a period of just over two years; the first in the spring of 2014 and the second in the autumn of 2016. While we have used the same questionnaire, we added some questions to the last form. A total of 323 respondents responded to the survey in 2014, while 446 responded in 2016. The survey respondents are shown in Table 1.

2.4 *Analysis*

We calculate the significance of the differences in scores for all surveys. In this way, we examine the probabilities that the differences are due to statistical coincidences. This is done by calculating the

Table 1. Responses, number of employed and response rate per department in 2016, compared with response rates in 2014.

Dep.	Res.	Empl	2016	2014
1	84	112	75%	79%

4	38	54	70%	70%
4	115	162	71%	46%
6	84	109	77%	24%
7	13	17	76%	92%
8	24	28	86%	113%
Total	446	600	74%	56%

average scores' confidence intervals. These indicate the error margins of the average scores, i.e. the range which, with a given probability, contains the true number measured. When comparing average scores, we can generally say that the differences between them are statistically significant if they do not lie within each other's confidence intervals.

Probability is given as a percentage. This is also often given as a so-called P value. In choosing the confidence interval, you choose how much uncertainty you will accept. A 90% confidence interval means that you have decided on a 90% probability level, indicating that, on average, an error will be concluded in one of ten cases. A 95% confidence interval means that there is a 95% chance that the "true" risk number is within this range. We use confidence intervals of 90%, 95% and 99%, and we say that the differences are statistically significant at the 10%, 5% and 1% levels, respectively.

3 RESULTS

The questionnaire that measures information security culture is based on the GAIN organisational safety culture index, where the word "safety" is replaced by "information security." The questionnaire opened with definitions of information security and related sub-concepts. In order to map the respondents' relationship with information security in their work, we asked them to take a position on the statement: "In my work, I have a clear understanding of what the term information security means." The results show that all of the departments have an average score above 4 (= agree somewhat).

3.1 *Management commitment*

The immediate supervisor's attitude to and focus on information security is an index with eight questions, with a minimum value of 8 and a maximum value of 40. Cronbach's Alpha for this index in the data from 2014 was 0.911, which means very good agreement between the questions and that the index is good. The index is based on the following questions:

- My immediate supervisor discovers employees who fail to take sufficient considerations to information security in their work
- My immediate supervisor often praises employees for maintaining information security
- My immediate supervisor is aware of the most important information security issues in the company
- My immediate supervisor often discusses information security issues with the employees
- My immediate supervisor is personally involved in activities to improve information security
- My immediate supervisor postpones tasks/activities if information security is not sufficiently ensured
- My immediate supervisor considers information security to be very important in all tasks and activities
- My immediate supervisor does everything he/she can do to avoid breaches of information security

The score in 2014 was 26 points, while it was 29 in 2016. When we test the significance of the difference between the total scores for 2014 and 2016, we see that the differences are significant at the 1% level. The differences between the departments are significant at the 1% level in 2014 and 2016. This indicates that there are significant differences between the departments as to whether employees feel that their immediate supervisors focus on information security. DEP 6, DEP 2, DEP 1 and DEP 5 had the highest scores in 2016. In addition, we also see that all of the departments saw improvement in this index in 2016, especially DEP 1, DEP 2, DEP 6 and DEP 4.

3.2 *Employees' attitude to and focus on information security*

Employees' attitude to, and focus on information security is an index with three questions, with a minimum value of 3 and a maximum value of 15. In 2014, we measured a Cronbach's Alpha at 0.754, a high value considering that the index consists of three questions.

- My colleagues do everything they can to avoid breaches of information security
- Employees encourage one another to safeguard information security
- Employees usually report all breaches and irregularities related to information security that they experience at work

All of the departments saw an improvement on this index in 2016, especially DEP 1 and DEP 5. DEP 6 had the highest score again in 2016. The general improvement went from 10 to 11 points on the index. When we test the significance of the difference between the total scores for 2014 and 2016, we see that the differences are significant at the 1% level.

3.3 *Reporting culture and reactions to incident reporting*

Reporting culture and reactions to incident reporting is an index with five questions, with a minimum value of 5 and a maximum value of 25 (Cronbach's Alpha = 0.785 in 2014).

Those who pursue breaches of information security in the business attempt to find the real causes rather than just blaming the employees
There are routines and procedures at my workplace so that I may report information security-related breaches or irregularities
After a breach of information security, measures are implemented to prevent this from happening again
All irregularities and information security issues that are reported are remedied in a short time
Everyone has plenty of opportunities to forward suggestions related to information security

Again DEP 6 had the highest score in 2014 and 2016, followed by DEP 2. All of the departments regressed on this index in 2016, especially DEP 1, which noted a decline of more than 3 points on the index. The average decline for all of the departments from 2014 to 2016 was 2.1 points. This could be due to a learning effect and/or increased focus on what reporting means in the organisation (i.e. increased expectations), and/or an actual decrease. This change is statistically significant at the 1% level.

3.4 *Training/instruction in information security thinking*

Training/instruction in information security thinking is an index with four questions, with a minimum value of 4 and a maximum value of 20 (Cronbach's Alpha = 0.866 in 2014).

Employees in my company are provided with adequate training in the secure use of ICT systems (e.g. e-mail, storage, encryption)
All new employees are provided with adequate training for tasks and the secure use of ICT systems (e.g. e-mail, storage, encryption)
Everyone is provided with sufficient feedback on how the enterprise is performing with regard to information security
Everyone is informed of any changes that may impact information security

Again DEP 6 department had the highest score in 2016 (and 2014), followed by DEP 4 and DEP 1. All of the departments saw an improvement on this index in 2016, especially DEP 1, which increased by more than 4 points on the index. The average improvement for all of the departments from 2014 to 2016 was 2.4 points. This change is statistically significant at the 1% level.

3.5 *General information security issues*

General information security issues is an index with four questions, with a minimum value of 4 and a maximum value of 20 (Cronbach's Alpha = 0.720 in 2014).

There are procedures that must be followed in the event of an emergency situation in my workplace
Information security in my business is better that in other businesses
Regular security audits are carried out
Information security is generally well taken care of at my workplace

DEP 6 department again had the highest score in 2016 (and 2014), followed by DEP 1. All of the departments saw an improvement on this index in 2016, especially DEP 1, which increased by 3 points on the index. The average improvement for all of the departments from 2014 to 2016 was 1.4 points. This change is statistically significant at the 1% level.

3.6 *Index for information security culture*

We have combined the 24 statements with five response options on the five different aspects of information security in an information security culture index. The indexes for the departments correspond to the average scores for the respondents. Since we have removed a statement from the GAIN index (as the wording was unsuitable for the context), the minimum score will be 24 (24 · 1) and the maximum score will be 120 (24 · 5). Cronbach's Alpha for the 24 questions in the index was 0.913 in 2014, which means very good agreement between the questions and that the index is very good. Table 2.

We see that the DEP 6 department again had the highest score in 2016 and 2014, followed by DEP 2 and DEP 1. All of the departments saw an improvement on this index in 2016, especially DEP 1, which increased by 12 points on the index.

The average improvement for all of the departments from 2014 to 2016 was 9 points. This change is statistically significant at the 1% level. The differences between the departments are significant at the 1% level, both in 2014 and 2016.

If we are to transfer the GAIN scale values from organisational safety culture to organisational

Table 2. Scores on the index for information security culture per department in 2014 and 2016 (min = 24 points, max = 120 points).

Department	2014	2016
1	77	89
2	82	89
3	80	82
4	75	84
5	76	87
6	87	95
Total	78	87

information security culture, we see that none of the departments had a positive information security culture in 2014. However, in 2016 we find that DEP 6, DEP 2 and DEP 1 were within the part of the scale that we refer to as a positive culture. The limits for "positive organisational culture" range from 88 points to 120 points on the GAIN index. The moderate culture scale goes from 47 points to a maximum of 87 points, and scores below 46 points correspond to a poor culture.

3.7 *Questions about the department's follow-up of the survey in 2014*

We asked the respondents three questions about what actions their immediate supervisor has taken in his/her own department/section after the evaluation of the information security culture in 2014. We opened the questions with the text: "We want to know a little about what actions your immediate supervisor has taken in your department/section after the evaluation of the information security culture in 2014".

We made an index based on the three questions we have reviewed. All of the questions include six response options: 1 = totally disagree and 5 = totally agree and 6 = Have no knowledge about this. When we made the index, we removed the sixth response option. The index is based on the following questions:

- The head of my department/section has gone through the results of the evaluation with us
- My department/section has taken steps to improve the information security culture (e.g. focus on passwords and security-critical information) based on the results of the evaluation
- I am satisfied with how my department/section has worked on information security over the past two years

Table 3 shows the average index score for actions the immediate supervisor has initiated in his/her own department/section after the evaluation of the information security culture in 2014.

3.8 *Questions about training*

We asked the respondents three questions related to whether they have received useful information over the past two years that has increased their knowledge and awareness of information security:

- During the past two years I have received useful information (e.g. from security coordinator, manager, intranet) about what a secure password is
- During the past two years, I have received information (e.g. from security coordinator, manager, intranet) that made me more aware of strangers in our premises
- During the past two years, I have received information (e.g. from the security coordinator, manager, intranet) that has given me more insight into what security-critical information is

Since we, to some extent, assume that this information comes from the security coordinator, manager and intranet, we also refer to these questions as training in information security 2014–2016.

We made an index based on the three questions. All of the questions include six response options: 1 = totally disagree and 5 = totally agree and 6 = Have no knowledge about this. When we created the index, we removed the sixth response option.

Table shows the average index score for information security training in 2014–2016 in combination with scores for the action index in each department.

3.9 *Three types of safety/security/reliability*

Through initial interviews in the first survey we found that it was appropriate to distinguish between different types or nuances of security, safety and reliability in the study organisation. To assess the importance of, or the focus on these

Table 3. Index for actions the immediate supervisor has initiated in his/her own department/section after the evaluation of the information security culture in 2014. Minimum value: 3, maximum value: 15. (N=313).

types of safety and security in the study organisation as a whole, and in different departments, we created indexes with identical questions: one about information security, one about HSE, one about deliverance reliability and one about security in connection with sensitive objects. The index about sensitive objects was not included in 2016.

In line with what we have commented on, we see in Figure 1 that all of the departments did better on the indexes in 2016 compared with 2014. However, the improvement is greatest on the information security index.

This is interesting because in 2014 we concluded that the results indicated that little attention was paid to information security compared with the "primary task" of deliverance reliability and the more traditional focus on HSE. The fact that the respondents in 2016 deemed that the focus on information security is equally strong as for the other types of security can indicate that the study organisation's efforts to put this topic on the agenda has worked as intended.

3.10 *Interview results*

The organisation has carried out extensive changes in its organisation and practices during the period. The scope and significance of the changes are emphasised through interviews. Information security and HSE-related support and correction from colleagues seems to be a fairly consistent practice. They also seem to be topics that are the subject of conversations. This is well in line with the general increase in all types of security culture in the agency. There has been a strong focus on information security both internally in the organisation and through auditing, supervision and ownership requirements. Since 2014, a more clear "security organisation" has been established, to use the organisation's own term. Security organisation means roles, ownership, and processes related to security.

The security culture now seems more strongly rooted the higher one gets in the organisation. This is partly based on interviews, which quite uniformly point to a clear focus on security in the agency's top management, and more varied further follow-up. This also correlates with the fact that managers state to a greater degree than staff that security is being followed up.

4 CONCLUDING DISCUSSION

4.1 *Improvements and measures*

We saw above that DEP 6 scored the highest on the information security culture index, and in chapter we also saw that DEP 6 scored the highest on the index for managers' measures aimed at information security culture. This indicates a correlation between immediate supervisors' measures since 2014, and the information security culture score.

Figure 2 confirms the impression that good work on measures produces results in the form of high scores on the information security culture

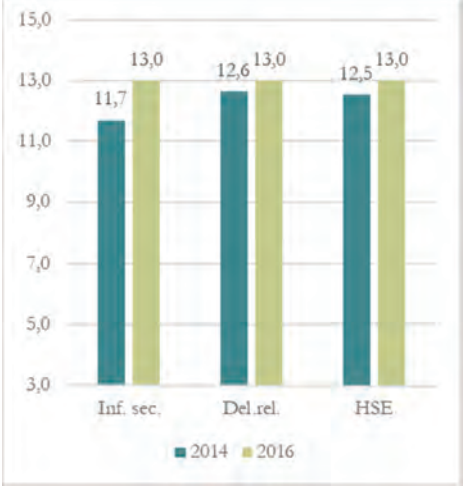

Figure 1. Total scores for the indexes for indexes on: Information security (N=323 and 446), Deliverance reliability (N=323 and 446), HSE (N=85 and 169).

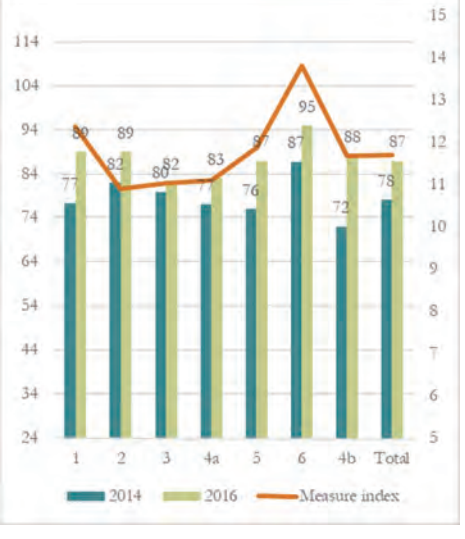

Figure 2. Information security culture scores in 2014 and 2016, for each department, including a measure index.

index. On the other hand, the impact of measures can also be assessed on the basis of which department has made the greatest improvement on the index from 2014 to 2016.

This result is in line with both the assertion of Knapp et al (2006), depicting the top management support as a significant predictor of an organization's security culture and level of policy enforcement. It is also in line with Schein's (2004) view on the possibilities to manage culture in organisations. As noted, he has coined "six primary embedding mechanisms" that managers can use to shape culture: e.g. what managers pay attention to, measure and control on a regular basis, how managers allocate resources. Thus, our study may indicate how organisations may improve their organizational security culture through cultural management. Moreover, the training measures also seem to be related to high security culture scores. Thus, this organization may provide an example of a possible solution to the key challenge addressed by Nosworthy (2000): how to we educate the people of the organization to successfully implement the requirements of the information security policy?

4.2 *Is the improvement of information security culture real?*

Hawthorne effect? We have seen an average increase of 9 points from 2014 to 2016 in the study organisation's information security culture index. This is a significant improvement that can be said to indicate that the study organisation's information security measures from 2014 to 2016 have produced good results. On the other hand, the improvement may be interpreted as a "measurement effect". This means that the improvement has more to do with the repeated survey than a real effect.

Such measurement effects can be due to numerous mechanisms. On a general basis, one can point to the so-called "Hawthorne effect," which indicates that being measured repeatedly produces improvement in the surveys because the researchers' focus per se causes the studied elements to do better in measurements. This is the "placebo effect" of intervention research, i.e., one can expect a certain amount of improvement in a repeated survey, only because the survey is conducted.

Learning effect? Another measurement effect that occurs in some cases is that the respondents learn from the first questionnaire and respond differently to the second questionnaire for that reason. However, this can yield both positive and negative outcomes; the respondents may think that they assessed their workplace too "harshly" when they think more about the topics from the survey and respond more positively the second time. However, they may also think that they assessed their workplace too "leniently" when they think more about the topics from the survey and respond more negatively the second time. This can result in lower scores in a repeated survey.

Noise. A third effect that can impact the second survey is that reorganisation, noise and the like make the respondents more negatively disposed to their workplace and the topics that are being measured and therefore show their dissatisfaction by giving negative answers. This would involve lower scores, which only applies to reporting culture.

We can perhaps conclude to some extent that the comparisons seem realistic, first since the results for the short indexes for safety, security and reliability also indicate a clear, increased focus on information security in the study organisation. In 2014, we saw a greater focus among managers and staff in the study organisation on deliverance reliability and HSE than on information security. However, in 2016 we see that the score for information security is at the same high level as deliverance reliability and HSE. Second, we saw a relationship between measures, training and security culture scores. Third, interviews indicate increased focus on information security in 2016 compared with 2014.

4.2.1 *Can the improvement be explained by sample differences?*

Changed scores should also be discussed in the light of possible sample differences in the two surveys. The respondent rate in 2016 was higher than it was in 2014. The fact that there were more respondents in 2016 may have influenced the answers given and the scores on the indexes we looked at. In 2016, the percentage of respondents who had been employed for 16 or more years was down five points compared with 2014. This should have indicated lower scores on the information security culture index, since we know that higher age and seniority yield higher scores. However, it should be pointed out that the increased shares without higher education in the 2016sample probably did not respond to the questions about information security culture, since this higher share was probably due to higher response rates from DEP 3.

It should also be mentioned that over half of those who responded to the survey had been employed by the study organisation for five years or less in both 2014 and 2016. This is a relatively large share. However, we do not know how many of the employees have been employed for less than two years.

Finally, it should be noted that an important difference between the departments' samples in 2014 and 2016 is that all of the departments in 2016 were given a code for "staff" that counts in the department's average. This is a small number of persons in each department, which usually includes

one supervisor and the rest staff. We considered removing staff from the comparisons between the departments in 2014 and 2016, but decided not to after a systematic analysis showed that the staff groups did not have higher scores than the sections in the departments.

Average scores for GAIN information security culture increase with the age of the respondents and decline with education. The difference is the same between the age groups in 2014 and 2016, and about the same for the highest and lowest level of education (14 in 2014 and 13 in 2016). There is no significant difference between the scores for men and women. Finally, we see that those with 11 and more years of seniority have significantly higher scores on the index than those with 10 or fewer years of seniority. The difference is 6 points in 2014 and 5 points in 2016.

4.2.2 *Information security culture scores with and without managers*

Since we also include managers in the survey, we will examine whether managers' responses pull the scores up or down in the various departments. The differences between the information security culture scores of staff, other managers and department and section managers were insignificant in 2014. In 2016, however, the differences were greater. Section or department managers consider the information security culture to be 6 points higher than staff do. This is interesting, but perhaps not unexpected, because section or department managers answer on the basis of their immediate supervisor, who is either the department manager or the study organisation's director. The results can therefore indicate that efforts and measures aimed at information security culture in 2016 are etter rooted at the management level than at the staff level. Similarly, this may indicate that efforts and measures are better rooted at higher management levels in the organisation, which correlates with statements from the interviews. However, the differences between the three groups within each measurement point are not statistically significant, so these results must not be accorded too much weight ($P = 0.14$).

5 CONCLUSION

We conclude that it seems that management implementation of measures aimed at improving organizational information security culture has led to improvements. Thus, our study may indicate how organisations may improve their organizational security culture through cultural management. It is important, however, to note that the study lacks a control group, and that it is impossible to rule out the influence of a possible Hawthorne effect. Additionally, we discuss whether sample characteristics may explain the observed improvements.

Pitfalls of machine learning for tail events in high risk environments

C. Agrell, S. Eldevik, A. Hafver, F.B. Pedersen & E. Stensrud
DNV GL AS, Norway

A. Huseby
University of Oslo, Norway

ABSTRACT: Most of today's Machine Learning (ML) methods and implementations are based on correlations, in the sense of a statistical relationship between a set of inputs and the output(s) under investigation. The relationship might be obscure to the human mind, but through the use of ML, mathematics and statistics makes it seemingly apparent. However, to base safety critical decisions on such methods suffer from the same pitfalls as decisions based on any other correlation metric that disregards causality. Causality is key to ensure that applied mitigation tactics will actually affect the outcome in the desired way. This paper reviews the current situation and challenges of applying ML in high risk environments. It further outlines how phenomenological knowledge, together with an uncertainty-based risk perspective can be incorporated to alleviate the missing causality considerations in current practice.

1 INTRODUCTION

In this paper we highlight some pitfalls to avoid in the design of Machine Learning (ML) applications for high risk engineering applications. We also propose some recommendations to consider in model development, and emphasize the introduction of causality constraints based on phenomenological knowledge.

1.1 *Background*

ML is recognized as one of the key enablers for the fourth industrial revolution[1]. In this setting it is often communicated as a tool that, together with increased access to data and computational power, can unlock a huge potential for increased efficiency, new insights and ultimately new revenue streams. Success stories of businesses that have disrupted entire industries are often shared to inspire investment in similar technologies. However, for operation of complex engineering systems in high risk environments, the new challenges that appear are often not clearly expressed.

Concerns have been raised regarding the reliability and trustworthiness of systems relying on Artificial Intelligence (AI) in general, and specifically related to the current main strategy of implementation. Knight (2017) emphasizes that "not knowing how the most advanced algorithms do what they do might become a serious problem as computers become more responsible for making important decisions". The problem of accidents in ML systems is discussed in detail in a paper led by Google Brain researchers Amodei, Olah, Steinhardt, Christiano, Schulman, & Mané (2016). Here the authors motivate the increasing need to address these safety problems by some general trends, one of which relates to the increasing autonomy in AI systems. "Systems that simply output a recommendation to human users, such as speech systems, typically have relatively limited potential to cause harm. By contrast, systems that exert direct control over the world, such as machines controlling industrial processes, can cause harms in a way that humans cannot necessarily correct or oversee."

In this paper we turn our attention towards the introduction of ML in design and operation of complex engineering systems in high risk environments. These are systems where today's methods for assessing risk relies heavily on understanding the underlying physical processes and our ability to model these. This is in contrast to e.g. mass production of components where more data-driven, statistically founded methods can be applied to estimate rates of failure.

We acknowledge the need for ML technologies to address increasing complexity of engineering systems, and the challenges that follow in quantifying uncertainty and risk based on detailed numerical simulation. However, this type of application reduces the tolerance for erroneous model behavior. Most of the methods applied in ML are based

[1]For a broader discussion see e.g. Lu (2017) and Dopico, Gomez, De la Fuente, García, Rosillo, & Puche (2016).

on historic statistical models, enhanced by recent breakthroughs in computer science. The assumptions, limitations and practical challenges of these statistical models still remain, and serve as recurring pitfalls in the digital era.

For a given application both the statistical and ML mindsets may have its advantages and drawbacks, but we argue that for the high risk engineering problems discussed in this paper, uncritical application of ML is unwarranted. We believe that experienced ML practitioners know this, and the main problem lies in how ML is communicated in the current digitalization boom, and how it is perceived by the increasing number of new practitioners in the field that may also be strongly incentivized to develop solutions for cutting costs through automation.

1.2 *Correlation and causation*

Most of today's ML methods and implementations are based on correlations, which we define in the general sense as *any statistical relationship, whether causal or not, between random variables*, i.e. the degree of which two or more variables tend to vary together.

"Correlation does not imply causation" is a well used phrase within statistics, and describes what still remains as one of the major pitfalls in the analysis of data. The importance of this distinction depends on the degree to which one intends to intervene, and the consequence of erroneous intervention. See e.g (Pearl 2010). For many ML applications this may not be significant. But for the use cases considered in this paper it plays an important role, and we will argue that causality constraints from phenomenological knowledge should be incorporated in ML models—to strengthen model performance for tail events, to increase model transparency, and to make it easier to falsify models that do not comply with observations.

1.3 *Structure of this paper*

Section 2 is included for readers that are unfamiliar or new to the field of ML, and gives a brief introduction to some core concepts and their relation to classical statistics. The experienced ML practitioner may jump directly to Section 3, where we propose a set of model properties that should be accommodated for ML applications in high risk, low probability scenarios. Going beyond model selection, some general pitfalls are highlighted in Section 4 which gives an example illustrating the use of ML for anomaly detection and space exploration in Structural Reliability Analysis (SRA). Finally, our conclusions and some final remarks are summarized in Section 5.

2 A BIT OF HISTORY

Often times discussions regarding ML and AI can become fairly opaque, colored by data science jargon, cognitive analogies and marketing buzzwords. This section will clarify the relation between ML and statistical methods by comparing the classes of ML problems with their statistical counterparts, and tracing their origins. This section will only briefly present the statistical background that underpin the main classes of ML methods. See e.g. (Hastie, Tibshirani, & Friedman 2001) for a thorough introduction, or (Domingos 2012) for a more informal description on how they are used in practice.

2.1 *A formal definition of machine learning*

Although the field of ML is often defined in cognitive terms, as giving computers the ability to learn without being programmed, a more formal definition often cited is the one by Mitchell (1997). "A computer program is said to learn from experience E with respect to some class of tasks T and performance measure P if its performance at tasks in T, as measured by P, improves with experience E." Further, ML is generally classified into two categories called supervised and unsupervised learning.

Supervised learning: For some unknown relationship between variables $\mathbf{x} \rightarrow \mathbf{y}(\mathbf{x})$ where N pairs of data are observed $\left\{\left(\mathbf{x}_i, \mathbf{y}_i\right)\right\}_{i=1}^{N}$, the goal is to estimate $\mathbf{y}^*$ for unobserved $\mathbf{x}^*$. Here, the experience E is the observed data, the task T is to predict $\mathbf{y}^*$ and P is usually a measure of the difference between the predicted $\mathbf{y}^*$ and the true value $\mathbf{y}(\mathbf{x}^*)$.

Unsupervised learning: The goal is to discover patterns in unlabeled data. For instance, based only on the x-values in the above example, $\left\{\mathbf{x}_i\right\}_{i=1}^{N}$, estimate the distribution over the data or identify clusters, etc. With the task T of clustering in mind, the experience E is still the observed data and P might be a measure on cluster compactness or separability.

2.2 *Machine learning and statistical modelling*

The increasing popularity of ML today may be credited to recent advancements within computer science, although most of supervised and unsupervised learning have roots in traditional statistical methods. An overview is illustrated in Figure 1. *Supervised learning* is based on *prior* knowledge, and covers regression and classification (discriminant analysis).

Regression considers a continuous dependent variable represented by a model function fitted to data. Assumptions are generally made about the data generation process, e.g. homoscedasticity (equal finite

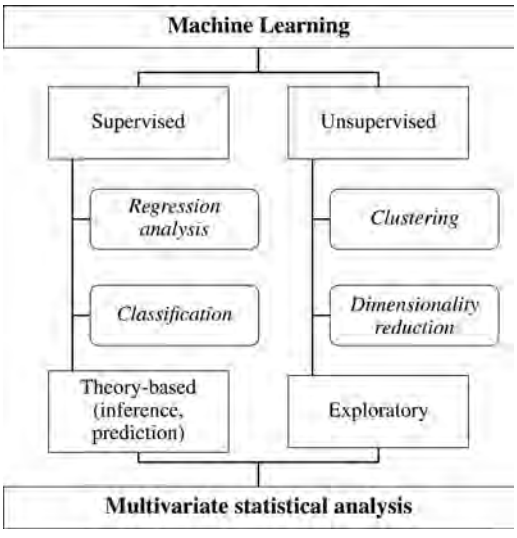

Figure 1. Machine learning vs. multivariate statistics.

variance), independence and normality. The earliest form of regression was the method of least squares, published by Legendre (1805) and Gauss (1809).

Classification or discriminant analysis has the same objective as regression, but where the dependent variable is discrete, and typically comes in a categorical form as labels from a finite set. Some of the earliest work was by Fisher (1936) leading to Fisher's linear discriminant function. Other popular methods are Logistic regression that dates back to Verhulst (1838), decision trees (Morgan & A. Sonquist 1963) and k-nearest neighbors (Cover & Hart 1967).

Note that due to the close link between these two categories of supervised learning problems, regression models may be altered to work for discriminant analysis and vice versa.

Unsupervised learning is related to data exploration problems. The main exploratory methods are often classified as clustering or dimensionality reduction.

Clustering analysis considers the task of grouping objects into sets (clusters) such that objects in the same set are more similar to each other than to those in other sets. No precise definition of a cluster exists, and this is one of the reasons why there are so many different clustering algorithms (Estivill-Castro 2002). Some popular alternatives representing different approaches to the problem of clustering are k-means (MacQueen 1967), hierarchical clustering (Sibson 1973), Gaussian mixture models using expectation-maximization (Dempster, Laird, & Rubin 1977) and Density-Based Spatial Clustering of Applications with Noise (DBSCAN) (Ester, Kriegel, Sander, & Xu 1996).

Dimensionality reduction is the procedure of reducing the number of input variables to a smaller set of principal variables. One fundamental approaches is principal component analysis (Pearson 1901), developed by Karl Pearson, considered the father of modern statistics.

The methods mentioned above is by no means a complete list, and the references cited are meant to give indications on early work on the different subjects as true origins are often debatable and outside the scope of this paper. A lot of research has gone into extending or improving on these methods since first invented, which has spawned the large variety of models and algorithms used in ML today. There are also other popular methods and widely used techniques within ML that can be placed in more than one category in Figure 1, e.g. artificial neural networks dating back to Hebb (1950) and using the backpropagation algorithm developed by Werbos in 1974.

2.3 *Model design vs. trial-and-error*

Many of the similarities between statistics and ML are just hidden behind different terminology. For instance, where we in ML refer to *features* in a model and that model *weights* are *learned* from data, a statistician would refer to *variables* in a model where data is used to *estimate* model *parameters*. But there are also some important differences in how the (same) models are used, and whether the main emphasis is on designing a good model or obtaining good prediction by trial-and-error.

In classical statistics, the focus is often on testing hypothesis of causes and effects and interpretability of the models applied. A common aphorism in statistics is that "All models are wrong, but some are useful". The analyst should know when the model will break, how it breaks, and if one can still use it anyways. The main goal is understanding the underlying mechanisms that drive the things we observe.

On the contrary, ML has more focus on predictive accuracy of models, with less attention towards model interpretation. Model selection is often based on trial-and-error through cross validation to evaluate goodness-of-fit criteria, where prediction accuracy is evaluated on data that was excluded in the learning process. Although the main goal is to obtain a good prediction, special considerations are made based on what the prediction is used for in a given application. For high risk applications for instance, false positives may be far worse than false negatives (or vice versa), and the model optimization can be weighted accordingly. Still, it is based on observing the desired behavior in future or excluded data.

Although science always has been concerned with both prediction and explanation, the different

philosophies have resulted in much debate between the statistics and machine learning communities. See for instance the discussion in Breiman (2001).

3 ML FOR HIGH RISK ENGINEERING APPLICATIONS

This section highlights some of the main challenges when using ML for high-risk and low probability scenarios. We continue by proposing recommendations to consider in ML model development to address these challenges.

3.1 *Tail events in high risk environments*

Three of the main challenges with ML applied to high risk and low probability scenarios are related to the following:

- **High risk reduces the tolerance for wrong predictions**. The consequence might be catastrophic.
- **Critical consequences often relate to tail events—for which data is naturally scarce**. This increases uncertainty and reduces the accuracy of predictions.
- **The ML models that are able to fit the data well are often opaque.** This makes the model less falsifiable, increasing uncertainty and reducing decision makers' ability to trust the model.

The first point relates to the decisions that are made based on model predictions. When the high risk is associated with a catastrophic consequence, the tolerance for a wrong prediction is clearly low. Moreover, severe consequences are often related to a rare event. This introduces additional uncertainty as data is scarce[2]. These first two points are in direct contrast to the typical ML applications today (e.g. non-consequential recommendation engines). In this respect, assurance of safety critical systems relying on ML is also recieving increasing attention, see e.g. Brandsæter & Knutsen (In press).

The last point on model opaqueness (lack of transparency) relates to quantification of model discrepancy and the ability to falsify models that do not comply with observations. The added uncertainty from model opaqueness may at first seem purely subjective. However, as we will see in the following section, addressing this by increasing model transparency may relax requirements on accuracy and vice versa.

[2]Scarce in the sense that the size of data is small compared to the number of relevant dimensions. This is because the event under consideration, e.g. structural failure, is rare and expensive to approximate by experiments.

3.2 *Recommendations on model development*

The challenges stated above will make any ML or statistics based model prone to erroneous, and potentially dangerous, use. However, many of the most common pitfalls in using such correlation based or data-driven methods may be avoided by proper model selection and design. To increase confidence in the safe use of ML models we propose some recommendations in this section.

For supervised learning, and when we want to use ML for prediction in general engineering applications, one should seek to adopt or develop models with the following attributes:

1. **Flexibility:** The models ability to represent a large class of functions.
2. **Constrainability:** The ability to impose model constraints based on phenomenological knowledge.
3. **Probabilistic inference:** Probabilistic representation of model output defined on the entire model range (i.e. the model output is represented by a distribution).

The first two concepts relate to the problem of underfitting and overfitting respectively. The third is important when the model is used in assessment of risk and reliability.

From an engineering perspective, **flexibility** is needed to capture the behavior of complex physical systems and their response. Most non-parametric models fulfill this requirement. The definition of "a large class of functions" in this context may not be precise, as it certainly depends on the problem at hand. A typical example may be all continuous or differentiable functions with a finite number of discontinuities.

Constrainability is beneficial for two main reasons. First, it reduces the possibility of overfitting the data, thus increasing the robustness and the performance for application on future data. This is particularly important for tail behavior problems where data is scarce. The second reason is that imposing constraints based on phenomenological knowledge reduces model opaqueness, i.e. increases transparency.

By a *transparent model* we mean that the relationship between model inputs and outputs can be meaningfully understood by humans, and that model characteristic properties and limitations of the model can be understood without explicit numerical computation. The most straightforward example is simple linear regression with linear basis, i.e. fitting a line. In contrast, for an opaque model, the model behavior can only be investigated through computation. These models are often referred to as black boxes, where the only way to fully characterize the model's properties is through

exhaustive computation; evaluating the model for *all* possible inputs.

The scientific method is based on the principle that any model, or hypothesis, should be falsifiable. All models, including ML models, are based on a set of assumptions. For a model or an assumption to be falsifiable, it must, in principle, be possible to make an observation that would show the assumption to be false. Thus, model transparency is important as it enables one way of falsification. ML models are typically falsified by observing poor accuracy. That is, observations are made that differ significantly from model predictions. However, understanding why such discrepancies occur is often difficult in an opaque model. If we assume that the observation is not erroneous (observed discrepancy is not related to noise), then the root cause might either be lack of relevant data, i.e. the model is built on too few datapoints close to the observed discrepancy—in which case a larger degree of uncertainty is expected. Or the root cause is related to violation of the underlying model assumptions—and the model must be changed.

In order to develop useful ML models for high risk applications, a compromise usually has to be made between model transparency and flexibility. To counteract the negative tradeoff of an initially opaque, but flexible model, we might impose constraints based on phenomenological knowledge related to causality. This can be thought of as "putting the black box inside a white box", i.e. enabling deduction of bounding model properties through the imposed constraints.

Figure 2 illustrates constraints in the form of boundedness, monotonicity and convexity. Three datapoints have been observed, and for simplicity we assume the data does not contain noise. This means that we are looking for an interpolation model, a function passing through all three points. The shaded areas show where the function cannot enter due to the imposed constraints. Hence, starting with the space of all functions passing through the three points, the constraints reduce the space of possible interpolation functions. Assuming that the constraints are based on phenomenological knowledge that hold in reality, the constrained models are less prone to overfitting (more robust). In the case where an observation is made within the shaded area, the model is falsified immediately as the assumptions behind the constraints do not conform with an observed outcome. Hence, by imposing constraints based on phenomenological knowledge, either a) performance is increased, or b) the model is falsified and the modeler learn something fundamentally new about the phenomenon studied, which can be applied in future modelling.

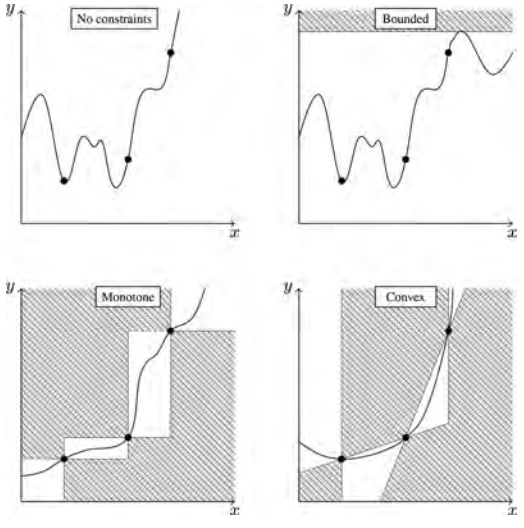

Figure 2. Effect of some different constraints for interpolation in data without noise. The interpolation function cannot enter the shaded areas.

The constrained models shown in Figure 2 may be restricted further by imposing multiple constraints, e.g boundedness and monotonicity or monotonicity and convexity. Note also that for noisy data, this means interpreting constraints in terms of probabilities using the assumed distribution of noise. The example is motivated by the more general class of constraints in the form of partial differential inequalities, for which phenomenological knowledge related to causal effects in various physical phenomena may often be available.

Practically, imposing constraints such as the ones illustrated in Figure 2 means translating the phenomenological constraints to constraints in the ML optimization algorithm. Many techniques exist for including constraints in ML through optimization, usually in order to obtain regularization effects, but we emphasize that developing the necessary links between these constraints and phenomenological knowledge will be highly beneficial. See for instance (Yu 2007) or (Maatouk & Bay 2017) for some examples and further discussion.

Probabilistic inference on the ML model output is needed for risk and reliability analysis applications. This means that the model output should optimally be in the form of a distribution. Model predictions in the form of fixed values and best estimates are not applicable. The dangers of expressing risk through expected values is well known, and modern definitions of risk usually relate to the distribution over possible outcomes. Hence, some quantification of prediction uncertainty is essential. It should be noted that this goes beyond the probabilities often used to report model accuracy for ML classifiers. The fact that an object is correctly classified 99% of the time might be insignificant if the outcomes of the remaining 1% is associated with severe consequences.

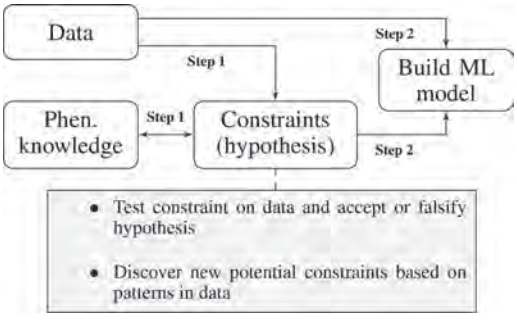

Figure 3. ML workflow with emphasis on constraints.

There is a traditional approach to this problem, where ML has played a role in mathematical models for calculation of risk and reliability. First, the models are scrutinized through human quality control to ensure that the model accuracy is sufficient or at least on the conservative side. This quickly becomes infeasible for higher dimensional models. Further, a single distribution representing the model uncertainty is often established from statistical analysis of prediction accuracy alone, assuming uniformly distributed data. This is no longer feasible for higher dimensional models or when the input data is far from uniformly distributed.

3.3 *Working with constraints*

Figure 3 illustrates of the workflow for building ML models with emphasis on constraints. For simplicity we ignore work on data cleaning and feature selection that naturally comes prior to model development.

Any hypothesis on model constraints coming from assumed causalities in the phenomenon under consideration must be tested to identify to what degree they hold in the observed data. Hence, the task of hypothesis testing is emphasized. There might also be valid constraints that are not immediately identifiable from phenomenological knowledge. It could therefore be valuable to search for possible constraints by unsupervised learning, to serve as hints to the modeler, and help identifying additional constraints before further testing and possible inclusion in the ML model.

This type of workflow will move the typical approach for building ML models today closer to traditional statistical modelling.

4 RELEVANT AREA OF APPLICATION – SRA

In this section we give a concrete example of an application area where ML is linked with engineering risk analysis – Structural Reliability Analysis (SRA), where the recommendations given Section 3 are highly relevant. In addition, we highlight two general pitfalls related to a common, but possibly misconceived, idea on how ML may be used in this context.

4.1 *Structural reliability analysis*

Structural reliability analysis, or SRA for short, is the fundamental building block of modern risk-based engineering methodologies. For a thorough introduction reference is made to Madsen, Krenk, & Lind (2006). The underlying theory combines structural analysis with statistics and probabilistic modelling to assess uncertainties of information that contributes to the probability of structural failure.

SRA may generally be described as the problem of establishing the probability

$$P\left(G(\mathbf{x}) \leq 0\right) \tag{1}$$

where $\mathbf{x}$ is a vector of stochastic variables, e.g. structural dimensions, material properties, loads and model uncertainties. The function $G(\mathbf{x})$ is referred to as the limit state, and is defined such that $G(\mathbf{x}) \leq 0$ if and only if the scenario represented by $\mathbf{x}$ results in structural failure, see Figure 4. In the literature the limit state is often presented as

$$G(\mathbf{x}) = R(\mathbf{x}) - L(\mathbf{x}) \tag{2}$$

where $R(\mathbf{x})$ and $L(\mathbf{x})$ represent the structural resistance, or capacity, and load effect respectively, although these are often not separable in practice.

The main tasks in a structural reliability analysis is to establish a suitable limit state function and distributions of all the input parameters, so that one may estimate the failure probability given by Eq. 1 and analyse the sensitivity of parameters and

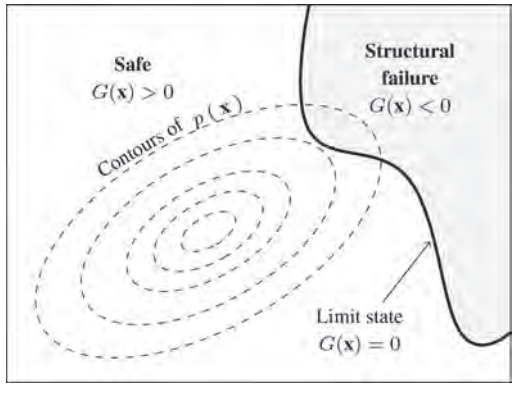

Figure 4. Illustration of SRA in two dimensions.

decisions that will affect the system. Informally, one might say that we use data and domain knowledge to establish the input distributions describing the current state of the system, and extrapolate to states where the system has failed using very limited data related to system failure in combination with advanced phenomenological simulations based on first principle physics.

4.2 *Machine learning in SRA*

Some of the key challenges in SRA today relate to the rapid increase in structural complexity of engineering systems, including more automation and software intensive control systems, together with a demand for higher system utilization and the need for more accurate and reliable models to support decision making under uncertainty. At the same time, ubiquitous sensor data provides new information that could potentially reduce the uncertainty if the information could be incorporated into the models.

In practice, this means that the function $G(\mathbf{x})$ in Eq. 1 and the distribution over the input space $\mathbf{x}$ will take a more complicated form. To cope with this, the technologies we now label ML can be useful, e.g. to address the following problems:

- Find $\mathbf{x}$: Establish distribution over $\mathbf{x}$ using all relevant data.
- Find G: Through data related to structural behavior, combined with data from past experience, experiments and simulations of structural failure, establish the limit state function that classifies all $\mathbf{x}$'s as *Safe* or *Failure*.

Note that in practice these two problems are generally intertwined, in the sense that inference about a model parameter (the $\mathbf{x}$'es) may only be observable through its effect on the system response. E.g. some $y(\mathbf{x})$ is observed, where the mapping $y(\cdot)$ is in our representation baked into the general function G.

The use of ML in SRA has traditionally been confined to smaller subcomponents where human quality control is possible, but for more complex systems this quickly becomes infeasible. The more general task of approximating functions like the limit state $G(\mathbf{x})$ using ML together with a limited number of realisations (experiments or numerical simulations) has received increasing attention over the last decades, within the field of Uncertainty Quantification (UQ). See for instance (Sullivan 2015). UQ aim to quantify the ML uncertainty introduced through approximation, as well as how uncertainty in input parameters propagates through such models.

4.3 *General ML pitfalls in SRA*

As for all ML applications, there are some general pitfalls to look out for. This section highlights some of the challenges related to how introduction of ML in reliability analysis is often depicted. This relates to a growing appetite for ideas like the following

- Due to the increasing instrumentation of systems, more data is available about the loads and structural behavior of systems at any time. By combining this with historical data from many other similar systems where the structural integrity is known (we know whether or not they have failed, and how), we could detect any abnormal behavior. With this information we could create warnings before potential failure occurs, and possibly also help the system back into normal operation.

Anomaly detection will probably play a larger role in risk assessment in the future, but there are some pitfalls that the industry needs to be aware of. The first relates to the quantification of the safety margin, which is often represented as a probability of failure or through some other metric relating the current physical condition with conditions corresponding to structural failure.

- For complex engineering systems, quantifying the margin of safety based on operational data alone is unlikely.

This statement might be obvious, from the many different ways a system may fail in practice and the assumption that these systems are designed not to fail. The next argument however is a bit more subtle

- From a data exploration perspective, when observing system states outside normal operation one might unknowingly have transitioned away from the default system behavior, leaving all previous observations biased, and possibly irrelevant.

This statement impacts the basic assumption in ML that future data will come from the same distribution as the data the model was trained on. This is illustrated by an example in Figure 5.

Following the SRA setting illustrated in Figure 4, we assume that the limit state is defined in terms of material over-utilization. Often the criteria for when ultimate failure occurs is difficult to express mathematically, and conservative approaches are applied by defining failure as some identifiable prior event. One such limit from material science is the yielding criteria of ductile materials such as steel. The stress-strain relationship of a material under some loading is linear up until the yielding point, and the material behaves elastic in this region. I.e. unloading the material will bring it back to its original unharmed state[3]. For continued loading beyond the yield point, the material will exhibit plastic behavior until rupture.

[3]Ignoring other failure modes such as fatigue.

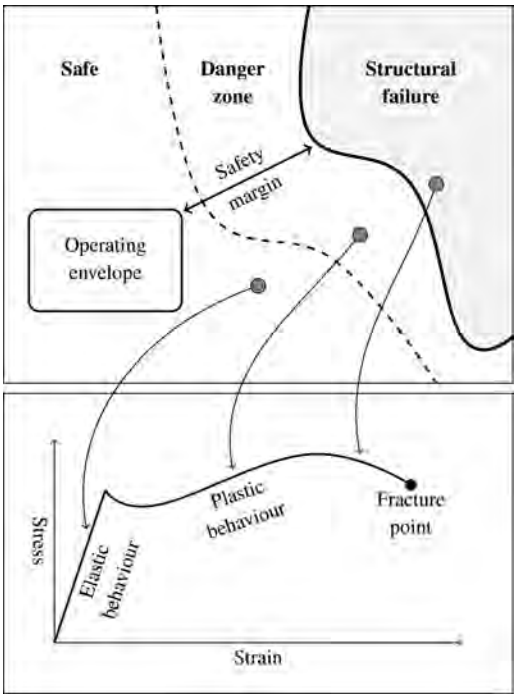

Figure 5. Illustration of structural response in different operating environments.

A limit state defined from the yield criterion can be illustrated as the dashed line in Figure 5, whereas the boundary of the structural failure set (black line) represents material fracture[4]. Imagine an anomaly detection agent that warns whenever the system behaves outside the normal operating envelope, and estimates procedures for moving the system back into normal operation. For elastic material response (leftmost point), the data used to train the model is still valid. But when materials are pushed closer to their limits, some properties are fundamentally changed. The elastic limit will change due to work hardening, and the stress-strain curve is no longer valid. Furthermore, when the material is over-utilized over a certain threshold, the reduction of load may initiate failure modes previously non-relevant, and uninformed decisions may be catastrophic.

This example is an oversimplification, but illustrates some challenges with introducing purely data driven agents. Due to the increased computational capacities and scientific models available today there is an increased push to utilise systems closer to their limits. In the above example this means allowing operation closer to the true failure limit, and compensating by increased control, uncertainty reduction, and more detailed understanding of the failure modes.

[4]For load controlled scenarios the top of the stress-strain curve represents maximum capacity. Unless the load is decreased the material will eventually fracture

5 CONCLUDING REMARKS

The field of ML is largely based on statistical methods, but with a focus that is shifted more towards predictive accuracy and with limited attention towards model interpretation and testing hypotheses on causes and effects.

For tail events in high risk environments the modeler is faced with additional challenges, as the tolerance for error is reduced and accuracy is needed in distribution tails rather than where the main bulk of data is. Because of this, opaque black-box type models are difficult to work with as the means for falsification may be limited to observations of future performance.

Therefore, research and development of ML models for such applications should be guided towards enabling incorporation of causality constraints reflecting the modeler's phenomenological knowledge.

ABSTRACT: In the context of Operation and Maintenance of wind energy infrastructure, it is important to develop decision support tools, able to guide engineers in the management of these assets. This task is particularly challenging given the multiplicity of uncertainties involved, from the point of view of the aggregated data, the available knowledge with respect to the wind turbine structures, as well as the varying operational and environmental loads. We propose to propagate wind turbine telemetry through a decision tree learning algorithm to detect faults, damage, and abnormal operations. The use of decision trees is motivated by the fact that they tend to be easier to implement and interpret than other quantitative data-driven methods. Furthermore, the telemetry consists of data from condition and structural health monitoring systems, which lends itself nicely in the field of Big Data as large amounts are continuously sampled at high rate from thousands of wind turbines. In this paper, we review several decision tree algorithms, we then train an ensemble Bagged decision tree classifier on a dataset from an offshore wind farm comprising 48 wind turbines, and use it to automatically extract paths linking excessive vibrations faults to their possible root causes. We finally give an outlook of a cloud computing based architecture to implement decision tree learning involving Apache Hadoop and Spark.

1 INTRODUCTION

Wind Turbines (WTs) maintenance and inspection relies on conventional techniques (Yang & Sun 2013), such as visual inspection, non-destructive evaluation and standard signal processing, trend analysis and statistics of data streamed from the Supervisory Control And Data Acquisition (SCADA). Specialized Condition Monitoring (CM) systems are only available on specific components such as the gearbox and main bearing (Hameed et al. 2009), while far forming part of the actual engineering practice (Grasse et al. 2011) Structural Health Monitoring (SHM) systems are deployed mostly for research purposes, or temporarily during the certification stage. In fact, there exists a dislocation between (i) data derived from CM systems (e.g. power output, rotor RPM), (ii) data obtained from specialized SHM (e.g. tower acceleration, strain on blade root), and (iii) specialized maintenance strategies of individual WT components. As a result, there are currently no holistic approach, and systematic, quantitative and automated tools for monitoring and diagnostics of WTs, for operation, maintenance (O&M) and decision making within their life-cycle. Towards this end, we propose to perform automated fault diagnostics and root cause analysis of faults on wind turbines (WTs) on the basis of decision tree classifiers. A decision tree is a predictive model that maps observations to their target values or labels. The key concept lies in running WT telemetry data through a decision tree learning algorithm for detecting faults, errors, damage patterns, anomalies and abnormal operation (i.e., end states). A decision tree essentially comprises a machine learning tool for classification of event outcomes. For a given initiating event, multiple end states are possible, linking each event to an associated probability of occurrence. Once built and trained, and given a new set of measurements, the decision tree may be used to predict end states and classify (discover) previously unknown end states. By examining the paths that lead to failure-predicting leaf nodes, one may distinguish the possible sources (root causes) of error. The remainder of this article is organized as follows. In section 2 we revisit the decision tree learning theory. In section 3 we

train an ensemble of bagged decision tree classifiers with the standard CART algorithm on a condition monitoring data set from the Lillgrund offshore wind farm comprising 48 wind turbines and use it to perform a diagnostics to elucidate the root cause of excessive vibrations. Finally, in section 4 we further our discussion to show how decision tree learning can be expanded to big data based applications for monitoring and diagnostics for wind turbines using the object-oriented based decision tree concept cite (Abdallah 2017).

2 DECISION TREES

A Decision Tree (also called Classification or Prediction Tree) is designed to classify or predict a discrete category from the data. Decision Trees (DTs) are a non-parametric supervised learning method used for classification (and regression). In the machine learning sense, the goal is to create a classification model (classification tree) that predicts the value of a target variable (also known as label or class) by learning simple decision rules inferred from the data features (also known as attributes or predictors). From Figure 1 an internal node *N* denotes a test on an attribute, an edge *E* represents an outcome of the test, and the Leaf nodes *C* represent class labels or class distribution.

Four reasons motivated us to work with decision tree classifiers. First, they can be learned and updated from data relatively fast compared to other methods. Second, they are visually more intuitive, simpler and easier to assimilate and interpret by humans/engineers. Third, unlike other classification methods, with decision tree classifiers one is able to perform data-driven root cause analysis of faults; one can trace a path from the end state (e.g. blade damage) to the initiating event (e.g. wrong parameters in control system), a way that follows the sequence and chronology of how events are interlinked. Last, it has been shown that

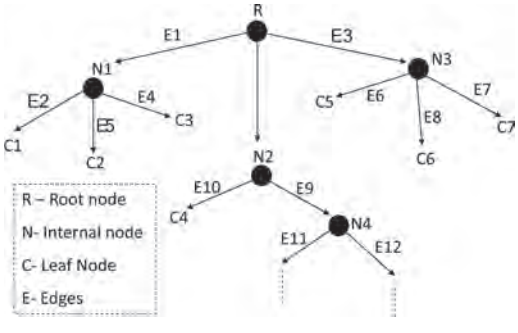

Figure 1. Graphical representation of a decision tree (DT) classifier. DT terminologies are also shown.

the accuracy of decision tree classifiers is comparable or superior (especially ensemble descision tree classifiers) to other models and in fact display the best combination of error rate and speed (Lim, Loh, & Shih 1997, Hand 1997, Lim, Loh, & Shih 2000, Caruana & Niculescu-Mizil 2006).

A decision tree is is a tree-structured classifier built by starting with a single node that encompasses the entire data and recursively splitting the data within a node, generally into two branches (some algorithms can perform *multiway* splits) by selecting the variable (dimension) that best classifies the samples according to a split criterion, i.e. the one that maximizes the information gain (Equation 1) among the random subsample of dimensions obtained at every point. The splitting continues until a terminal leaf is created that meets a stopping criterion such as a minimum leaf size or a variance threshold. Each terminal leaf contains data that belongs to one or more classes. Within this leaf, a model is applied that provides a fairly comprehensible prediction, especially in situations where many variables may exist that interact in a nonlinear manner as is often the case on wind turbines (Carrasco Kind & Brunner 2013). Algorithm 1 shows pseudocode of a generic decision tree learning algorithm.

Formally, the splitting is done by choosing the attribute that maximizes the Information Gain (I_G), which is defined in terms of the impurity degree index:

$$I_G(T,M) = I_d(T) - \sum_{m \in M} \frac{|T_m|}{|T|} I_d(T_m) \tag{1}$$

where T is the training data in a given node, M is one of the possible dimensions along which the node may be split, m are the possible values of M, $|T|$ is the size of the training data, $|T_m|$ is the number of objects for a given subset m within the current node, and I_d is the function that represents the degree of impurity of the information. There are three standard methods to compute the impurity index (I_d). The first method is by using the information entropy (H), which is defined by:

$$I_d(T) \equiv H(T) = -\sum_{i=1}^{n} f_i log_2(f_i) \tag{2}$$

where i is the class to be predicted, n is all possible classes, and f_i is the fraction of the training data belonging to class i. The second option, is to measure the Gini impurity (G). In this case, a leaf is considered pure if all the data contained within it have the same class. The Gini impurity can be computed inside each node using the following simplified equation:

$$I_d(T) \equiv G(T) = 1 - \sum_{i=1}^{n} f_i^2 \quad (3)$$

The third method is to use the classification error (C_E):

$$I_d(T) \equiv C_E(T) = 1 - \max f_i \quad (4)$$

where the maximum values are taken among the fractions f_i within the data T that have class i. Figure 2 shows the three impurity indices, for a node with data that are categorized into two classes, as a function of the fraction of the data having a specific class. If all of the data belong to one class, the impurity is zero. On the other hand, if half of the data have one class and the remaining data belong to the other class, the impurity is at its maximum (Carrasco Kind and Brunner 2013).

There exist several algorithms for training decision trees from data including *ID3, C4.5, C5.0, J48, SPRINT, FACT, FIRM, SLIQ, CHAID, QUEST, CRUISE, PUBLIC, BOAT, RAINFOREST, MARS, RIPPER and CART*. In the following we will briefly mention some ofthe more common algorithms. Ross Quinlan developed ID3 (Quinlan 1986) which stands for Iterative Dichotomiser 3, and its later iterations include C4.5 and C5.0. ID3 attempts to generate the smallest multiway tree. If the problem involves real-valued variables, they are first binned into intervals, each interval being treated as an unordered nominal attribute. C4.5 converts the trained trees into sets of if-then rules (Quinlan 1994) and improves on ID3 by allowing both discrete and continuous attributes, missing attribute values, attributes with differing costs, and pruning trees to avoid over-fitting are usually applied to improve the ability of the tree to generalise to unseen data. The accuracy of each rule is then evaluated to determine the order in which they should be applied. C5.0 is essentially the same as C4.5 but uses less memory and builds smaller rule sets while being more accurate.

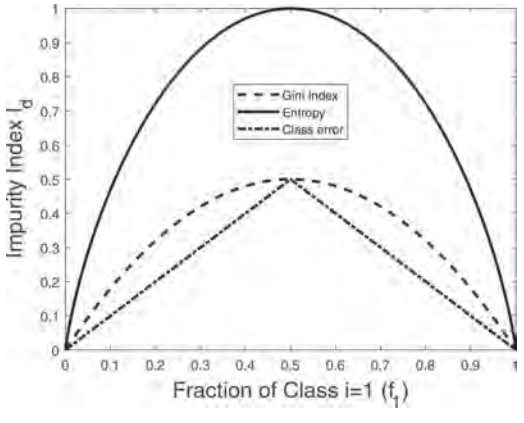

Figure 2. Impurity index I_d for a two-class example as a function of the probability of one of the classes f_1 using the information entropy, Gini impurity and classification error. In all cases, the impurity is at its maximum when the fraction of data within a node with class 1 is 0.5, and zero when all data are in the same category.

CART (Breiman, Friedman, Olshen, & Stone 1984) which stands for Classification and Regression Trees is very similar to C4.5, but it differs in that it supports numerical target variables (regression) and constructs binary tree based on a numerical splitting criterion recursively applied to the data instead of constructing rule sets.

According to (Lim, Loh, & Shih 2000) *C4.5* and *QUEST* have the best combinations of error rate and speed, but C4.5 tends to produce trees with twice as many leaves as those from Quest. QUEST is a binary-split decision tree algorithm for classification and regression (Loh & Shih 1997). It uses a significance test to select variables for splitting. An advantage of the QUEST tree algorithm is that it is not biased in split-variable selection, unlike CART which is biased towards selecting split-variables which allow more splits, and those which have more missing values.

CRUISE is one of the most accurate decision tree classifiers (Loh 2011) that is also efficiently capable of performing multiway splits. (Kim & Loh 2001) proposed CRUISE which stands for Classification Rule with Unbiased Interaction Selection and Estimation that splits each node into as many as subnodes, which precludes the use of greedy search methods. CRUISE is practically free of selection bias (Kim & Loh 2001) and is capable of integrating interactions between variables when growing the tree. CRUISE borrows and improves upon ideas from many sources, but especially from FACT, QUEST, and GUIDE for split selection and CART for pruning.

Finally a word about *RainForest* which is not a decision tree classifier per se but rather a framework. *RainForest* was proposed to make decision tree construction more scalable (same as *BOAT* which is in fact faster than *RainForest* by a factor of three while constructing exactly the same decision tree, and can handle a wide range of splitting criteria (Gehrke et al. 1999)). According to (Gehrke et al. 2000), a thorough examination of the algorithms in the literature (including C4.5, CART, CHAID, FACT, ID3 and extensions, SLIQ, Sprint and QUEST) shows that the greedy schema described in Algorithm 4 can be refined to a generic RainForest tree induction schema. In fact, most decision tree algorithms consider every attribute individually and need the distribution of class labels for each distinct value of an attribute

to decide on the splitting criteria. Rainforest is a comprehensive approach for decision tree classifiers that separates the scalability aspects of algorithms for constructing a decision tree from the central features that determines the quality of the tree. Rainforest concentrates on the growth phase of a decision tree due to the time consuming nature of this step RainForest, closes the gap between the limitations to main memory datasets of algorithms in the machine learning and statistics literature and the scalability requirements of a data mining environment (Singh & Sulekh 2017).

Next we present a demonstration of decision tree classifier learning based on a real-world SCADA data set from the Lillgrund offshore wind farm.

Algorithm 1: Pseudocode of a generic recursive decision tree learning algorithm.

```
DTClassifier (TR, Target, Attr);
  Input  : TR: training examples, Target:
           target label, Attr: set of descriptive
           attributes
  Output: DT: decision tree classifier
Create a Root node for the tree;
if TR have all the same label t_i then
    return a single-node tree, corresponding to
     leaf node with that label;
else if the set of attributes Att is empty then
    Return the single-node tree, i.e. Root, with
     most common value of Target in TR;
else
    pick an attribute A from Att (such that A
     maximizes I_G) and create a node R for it;
    for each possible value v_i of A do
        Let TR_{v_i} be the subset of TR that have
         value v_i for A;
        Add an out-going edge E to node R
         labeled with the value v_i;
        if TR_{v_i} is empty then
            attach a leaf node to edge E labeled
             with the target value = most
             common value of Target in TR;
        else
            call
             DTClassifier(TR_{v_i}, Target, Attr −
             A) and attach the resulting tree as
             the subtree under edge E;
        end
    end
    Return the subtree rooted at R;
end
```

3 DEMONSTRATION

Condition monitoring data from 48 wind turbines was collected over a period of 12 months and sampled every 10 minutes, across 64 channels. In total, more than 2.5 million records were available, of which 980 excessive vibration error events are recorded across all wind turbines. The error event of interest in this demonstration is *excessive structural vibrations*.

Data Pre-processing The first step prepares the data for the construction of the prediction tree classifier. Knowledge of the process is helpful in the elimination of parameters (features) that are not significant. The SCADA system recorded parameters can be grouped into the following categories: (i) system related data, e.g., turbine number and index, time stamp, are turbine specific and, therefore, can be excluded from the decision tree classifier training, (ii) operating performance parameters such as power output, pitch and rotor speed, (iii) environmental parameters such as wind speed and wind direction, (iv) temperature measurements for various components such as gearbox, bearings and generator, and finally (4) dynamics parameters such as tower top accelerations. The attributes chosen in this demonstration are shown in Table 1. The table includes both original sensor attributes such as maximum generator rotational speed over a 10min period (*GRpm_max*) and additional derived parameters such as the difference between max and min wind speed over a 10min period (*DMaxMinV*). We open a small parenthesis here. As with most pattern recognition methods, tree-based classification methods work best if the proper features are selected to start with; preprocessing by a data dimensionality reduction techniques such as principal component analysis (PCA) or independent component analysis (ICA) or optimal feature selection approaches such as the wrapper approach integrated with the genetic or the best-first search algorithms can be effective because they find important axes to be used as guideline for the selection of the features upon which a decision tree is trained. However,

Table 1. The attributes (features) used as input to train the decision tree classifier.

Attributes	Description
HSGenTmp	Mean temperature of gear bearing on generator side
Po_max	Max value of active power
DMaxMeanPow	Difference between max and mean active power
GRpm_max	Max generator RPM
DMaxMeanGRpm	Difference between max and mean generator RPM
Pi_min	Min collective pitch
DMaxMinV	Difference between max and min wind speed

in this demonstration we chose not to in order to test the limit of a decision tree classifier for fault diagnostics; for instance wind speed, power and RPM are strongly inter-dependent attributes, but for the same wind speed a wind turbine could be found operating at two different power output levels (during distinct time periods) or two different generator RPM levels, and both cases are considered normal operating modes. How so? Indeed this happens very often when a wind turbine has to de-rate the power output following a demand from the grid side or reduce the generator RPM under a specific noise or load control mode. The target variable *TurbineState* for classification is shown in Table 2. It can take two labels, *NoFault* indicating that the wind turbine is producing electric power under normal operating conditions, and *Vibr* indicating an excessive vibration fault resulting in the wind turbine shutting down, furthermore triggering a message to be send to the vibration support technical team (in order for some corrective action to take place).

Bagged decision tree construction The second step is the construction of the Bagged decision tree classifier. An ensemble of decision trees is often more accurate than any single tree classifier (Bauer & Kohavi 1999, Dietterich 1996). Bagging (Breiman 1996), boosting (Schapire 1990) and random forest are three popular methods of creating accurate ensembles. Previous research indicates that boosting is more prone to overfitting the training data (Freund & Schapire 1996, Opitz & Maclin 1999). Consequently, the presence of noise causes a greater decrease in the performance of boosting. Therefore, this study uses bagging to create an ensemble of bagged decision tree classifiers (using the standard CART algorithm) to better address the noise in the condition monitoring data. Other decision tree algorithms and ensemble approaches will be investigated in future work. This technique can be summarized as, (i) take a bootstrap sample from the data set, (ii) train an un-pruned classification tree and (iii) aggregate the trained tree classifiers. In more detail, Bagging predictors comprise a method for generating multiple versions of a predictor, each on random subsets of the original dataset, and fusing these into a unique final aggregated predictor. This aggregated predictor can typically be used for reducing the variance of a black-box estimator, by introducing randomization into the construction procedure and forming an ensemble (for proof refer to (Breiman 1996, Bühlmann 2012)). The bagging algorithm consists in (1) constructing a bootstrap sample $\left(X_*^{(1)},Y_*^{(1)}\right),\ldots,\left(X_*^{(n)},Y_*^{(n)}\right)$ by randomly drawing n times with replacement from the original data $\left(X^{(1)},Y^{(1)}\right),\ldots,\left(X^{(n)},Y^{(n)}\right)$ (2) computing the bootstrapped estimator (i.e. tree classifier) $\hat{g}_* = h_n\left(X_*^{(1)},Y_*^{(1)}\right),\ldots,\left(X_*^{(n)},Y_*^{(n)}\right)$ where the function $h_n(.)$ defines the estimator as a function of the data, and (3) repeating steps 1 and 2 M times, where M is often chosen as 50 or 100, yielding $\left\{\hat{g}_*^k, k=1,\ldots,M\right\}$ and the bagged estimator is $\hat{g}_{bagg} = \sum_{k=1}^{M} \hat{g}_*^k / M$. In theory, $M \to \infty$ if the bagged estimator is

$$\hat{g}_{bagg} = \mathrm{E}\left[\hat{g}_*^k\right] \tag{5}$$

In the machine learning and statistics literature, the two main performance measures for a classification tree algorithm are its predictive quality and construction time of the resulting tree. In this paper the predictive quality is given by the misclassification rate on the validation data set. As shown in Figure 4, the misclassification rate of the trained Bagged tree is less than 1% when the bag size is more than 10.

Fault diagnostics (offline) The final step uses the newly generated decision tree classifier (e.g. Figure 3) to create diagnostics for individual target fault classes, i.e. *Vibr*. One aspect of fault diagnostics deals with offline root cause analysis, which we will demonstrate here. When diagnosing faults, we are interested in identifying the root causes (or sequence of events) that lead to a large portion of the overall abnormal behavior, where the decision tree edges leading to faults become root cause candidates. In the literature, one can find a limited number of proposed programatic algorithms by which decision tree classifiers can be scanned/probed for root cause analysis (Solé, Muntés-Mulero, Rana, & Estrada 2017). One implementation is as follows (Zheng, Lloyd, & Brewer 2004):

1. Ignore the leaf nodes that correspond to normal operations (i.e. *NoFault*) as they will not be useful in diagnosing faults.
2. Identify, in the decision tree, all leaf nodes with the target fault class of interest, i.e. *Vibr*
3. Ranking: list the leaf nodes with the target fault class ranked by failure count to prioritize their importance.

Table 2. Target variable: *Turbine State*. Turbine state is defined in this demonstration according to two labels.

Class label	Description
NoFault	Normal operation, turbine is producing power, no faults
Vibr	Structural vibrations error resulting in: "Inform Vibration Support"

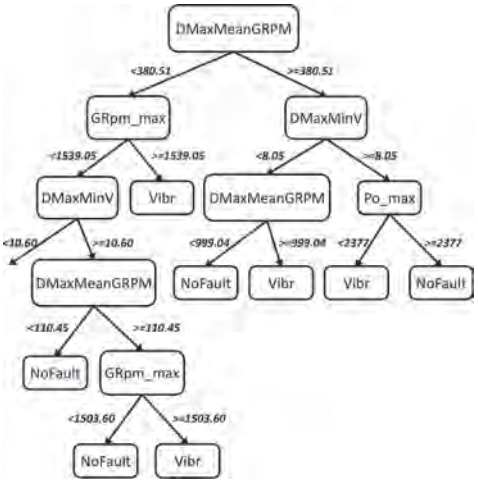

Figure 3. Part of the decision tree classifier based on the SCADA data from 48 wind turbines.

4. Noise Filtering: in diagnostics, we are interested in identifying the root causes that result in a large proportion of the overall faults. Thus we retain the leaf nodes accounting for more than a certain threshold of the total number of faults (e.g.) $threshold = 5\%$)
5. Extract traces (paths) containing the target fault leaf node (C), and all edges (E) and internal nodes (N) up to the root node (R).
6. Extract rules at each internal node of the traces
7. Node Merging: we merge nodes on a path by eliminating ancestor nodes that are logically subsumed by successor nodes.

Below is an example of an automated extraction of a sequential trace of events (root causes) from the trained decision tree classifier (see Figure 3), leading from the classified fault to the root of the tree:

$$Vibr \leftarrow 1503.6 <= GRpm\_mar < 1539.05 \leftarrow 110.455 <= DMaxMeanGRpm < 380.51 \leftarrow DMaxMinV >= 10.65$$

This sequential trace of events indicate that the fault *Vibr* can possibly occur when, over a period of 10 minutes, the maximum generator speed is in the range 1503.6–1549.05 *RPM*, the difference between max and mean generator speed is in the range of 110.45–380.51 *RPM* and the difference between the max and min wind speed exceeds 10.65 *m*/*s*. Note that it is not possible to infer from the data the time interval during which the large change in wind speed occured but it could well be an indication of agust or excessive turbulence over a short period of time resulting in the excessive vibration fault. Another example of an automated extraction of a sequential trace of events (root causes) leading from the classified fault to the root of the tree is as follows:

$$Vibr \leftarrow Po\_max < 2377 \leftarrow DMaxMinV >= 8.05 \leftarrow DMaxMeanGRpm >= 380.51$$

This sequential trace of events indicate that the fault *Vibr* can possibly occur when, over a period of 10 minutes, the maximum electric power output does not exceed, 2377 *kW*, the difference between max and mean generator speed exceeds 380.51 *RPM* and the difference between the max and min wind speed exceeds 8.05 *m*/*s*.

This approach to data-driven root cause analysis elegantly elucidates the traces of events that lead to a fault. These traces can subsequently be used by an engineer to design simulation scenarios to try and replicate the faults and to propose mitigating actions.

4 OUTLOOK: BIG DATA BASED MONITORING AND DIAGNOSTICS FRAMEWORK

So far we demonstrated how offline root cause analysis can be conducted via an ensemble based Bagged decision tree learning from SCADA data of 48 wind turbines based on the CART algorithm. In this section we summarize an outlook for a monitoring and diagnostics framework that would perform on big data and in real-time. The intent is for this framework to be deployed on a cloud such as Azure and scale as the volume of streamed data increases. Figure 5 shows an overview of the architecture of the framework. The main features of the framework include:

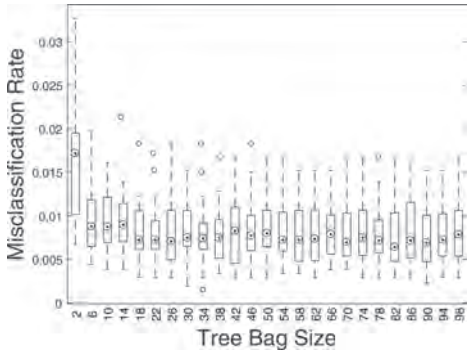

Figure 4. Misclassification rate of the validation set as a function of tree bag size.

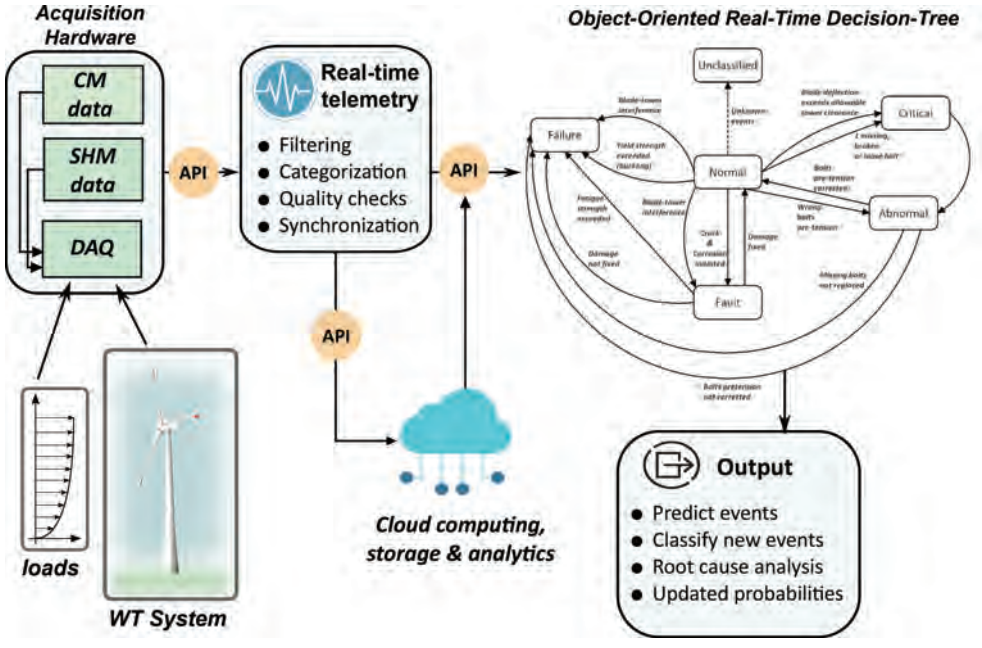

Figure 5. Graphical summary of the proposed framework decision tree learning with big data for fault diagnostics.

- Hardware-software package, able to acquire and fuse in real-time both condition monitoring (CM) (e.g. electric power output, rotor speed) and specialized structural health monitoring (SHM) data (e.g. tower accelerations, strains on blade) from WT components (e.g. blades, gearbox, tower, etc.).
- Computational core: object-oriented decision tree learning algorithm, Bayesian network (BN) based computation of probabilities and root-cause discovery algorithm (as demonstrated in the previous section).
- Distributed cloud based data storage and analytics of the high rate of real-time data streaming from the measuring unit on the WT, which interfaces with the real-time decision-tree software unit. Hence, the toolkit does not need to save data and do heavy computations on remote WT.
- Online user interface to visualize the output from the decision tree (decision support tool).

In the following we elaborate a bit more on: (i) the cloud computing, storage and analytics, and (ii) object-oriented decision tree learning aspects.

i. For efficient fusion of the large bulk of information made available from the condition and structural health monitoring systems constitutes a Big Data problem, as large amounts of data are continuously sampled at high and diverse rates from the WTs within a wind farm. Thus, the integration of a distributed cloud based data storage and analytics is a natural fit with consequent reduction in the cost of handling and manipulating of said data (see Figure 6). In the proposed framework, large scale storage of historical data from WTs is done via the Hadoop Data File System (HDFS). HDFS is a distributed file system that is fault tolerant and can load large volumes of data, in a distributed manner, even if any errors occurs. Telemetry and data acquisition is supported by Apache Kafka which is a distributed streaming platform that aims to provide a unified, high-throughput, low-latency methodology for handling real-time data feeds. Kafka is a fault-tolerant system, meaning that if any error occurs, published data would still be available in case the application or Kafka is stopped, is offline and then restarted. Thus, Kafka can be guaranteed not to miss any data that is issued from the wind turbines. Finally, for data processing purposes, Apache Spark is used. Spark is an in-memory fast and general engine for large-scale data processing. In addition, Spark can scale to thousands of machines in a fault-tolerant manner. These characteristics make Apache Spark very suitable to process and analyze the large volumes of data that are gathered from the wind turbines (Canizo, Onieva, Conde, Charramendieta, & Trujillo 2017).

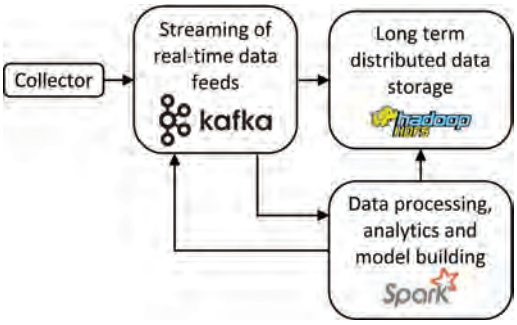

Figure 6. Cloud computing and storage.

ii. A priori Decision Trees are built first to serve the fundamental diagnostic tasks by combining engineering knowledge of the system, failure modes and domain knowledge. The dynamic decision tree classifiers are trained over time from wind turbine telemetry (CM & SHM data). The limitation in traditional decision tree classifiers appears when the component displays a behaviour with feedback (i.e., after a repair/update in the system) or for evolving systems (e.g. when new sensors are integrated or aging of the system), which implies a need to establish several decision trees based on the possible ordering of the events or based on new initiating events. One way around this is an innovation that we introduced in this framework in the form of object-oriented decision tree learning (Wyss & Durán 2001). To this end, a WT is viewed as a multi-layered system of objects (e.g. structure, controller, actuator, etc.) that are defined on the basis of abstract super-classes, attributed with specific properties and methods. Decision trees classifier are further mapped into Bayesian Networks for further assessment of the conditional probabilities (Bearfield & Marsh 2005, Jassens, Wets, Brijs, Van Vanhoof, Arentz, & Timmermans 2006). The integration of the object-oriented decision tree learning and BN delivers updated probability of occurrence associated with each event and end state, which would form a solid indicator of the risk of future failure of any given component.

5 CONCLUSIONS

We presented a review of several decision tree classification algorithms. We then demonstrated how data-driven and automated root cause analysis can be conducted via an ensemble based Bagged decision tree learning from SCADA data of 48 wind turbines based on the CART algorithm. Root cause analysis is here cast in the sense of programmatically discovering the sequence of events (paths) leading from a classified fault at the leaf, all the way to the root of the decision tree classifier. These traces can subsequently be used by an engineer to design simulation scenarios to try and replicate the faults and to propose mitigating actions. Finally, we briefly presented an architecture for a monitoring and diagnostics framework that would perform on big data. In particular we highlighted the need for cloud based storage and computing, and an innovative approach based on object-oriented decision tree learning that extends the traditional decision tree classifier concept. In the future, more concrete implementations and results of the proposed framework will be disseminated.

ACKNOWLEDGEMENTS

The authors acknowledge the support of the European Research Council via the ERC Starting Grant WINDMIL (ERC-2015-StG #679843) on the topic of Smart Monitoring, Inspection and Life-Cycle Assessment of Wind Turbines. We would like to thank Vattenfall AB for providing access to the SCADA data from the Lillgrund offshore wind farm.

Cyber physical systems implementation for asset management improvement: A framework for the transition

L. Villar-Fidalgo
Universidad Nacional de Educación a Distancia (UNED), Spain

A. Crespo Márquez, V. González Prida, A. De la Fuente, P. Martínez-Galán & A. Guillén
Universidad de Sevilla, Spain

ABSTRACT: The transformation of the industry due to recent technologies introduction is an evolving process whose engines are competitiveness and sustainability, understood in its broadest sense (environmental, economic and social). This process is facing, due to the current state of scientific and technological development, a new challenge yet even more important: the transition from discrete technological solutions that respond to isolated problems, to a global conception where the assets, plant, processes and engineering systems are conceived, designed and operated as an integrated complex unit. This vision is evolving besides a set of concepts that are, in some way, to guide this development: Smart Factories, Cyber-Physical Systems, Factory of the Future or Industry 4.0, are examples. The full integration of the operation and maintenance (O&M) processes in the production systems is a key topic within this new paradigm. Not only that, this evolution necessarily results in the emergence of new processes and needs of O&M, i.e. also, the O&M will undergo a profound transformation. The transition from actual isolated production assets to such Industry 4.0 with CPS is far from easy. This document presents a proposal to develop such transition adapting one iteration of the Model of Maintenance Management (MMM) integrated into ISO 55000 to the complexity of incorporating "System of Systems" CPSs maintenance. It involves several stages: identification, prioritization, risk management, planning, scheduling, execution, control, and improvement supported by system engineering techniques and agile/concurrent project management.

1 INTRODUCTION

Cyber-Physical Systems (CPS) is a widespread concept with several meanings, usually linked with embedded and connected systems.

The term cyber-physical systems was coined by Helen Gill in 2006 at the National Science Foundation in the U.S. to refer to the integration of computation with physical processes.

One of the earliest and referred papers describes them as "… are integrations of computation with physical processes. Embedded computers and networks monitor and control the physical processes, usually with feedback loops where physical processes affect computations and vice versa." (E.A. Lee 2008). In the early 2010's was defined as "transformative technologies for managing interconnected systems between its physical assets and computational capabilities" (Baheti & Gill 2011). It was a wider definition and avoids any technical description. The most recent release of Framework for CPS released by American National Institute of Standards and Technology (NIST CPS Public Working Group 2017) opens even more the definition: "... are smart systems that include engineered interacting networks of physical and computational components". But simultaneously the technical description needs a complete section –2.1 – of the document, and details in other section –1.1.2 – thirteen main differences with conventional product, system, and application design. This process of increasing the technical description extension while broaden the scope by shrinking the term definition and using vague words, reveals the complexity of these systems.

Despite this complexity, Industry will have to deal with the integration of CPS into their asset portfolio and their maintenance framework. It is a straightforward way to improve their performance in the global and competitive market that they face nowadays. The disruptive aspect of CPS in Operation & Maintenance of assets are two. The first one is their ability to share information & self-compare their behavior in an autonomous way as a community of equipment. For example: a network of CPS pumps will be able to predict the failure of one of their members based on shared information, without the intervention of higher level supervisors. The prognostics and health management has an open road ahead. The second disruptive aspect is

their ability to identify a misuse or improper use by human operators: two conveyor belts could compare themselves and rise a warning if one of them is overloaded while the other is underutilized. Unfortunate ly for maintenance personnel, most of their interventions will be over legacy and operating Systems of Systems interacting with human beings: plant operators, maintenance technicians, etcetera. Their intervention will have also to deal with the seven samurais (Martin 2004) systems: context, intervention, realization, deployed, collaborating, sustainment and competing.

This paper will propose a framework to introduce CPS assets and their philosophy for Operations & Maintenance in those real environments.

2 METHOD

Assuming a company that follows the Maintenance Management Model (Márquez 2007) as a framework for maintenance that fulfills the ISO 55000standard for asset management (Crespo & Parra 2018). The starting point for CPS integration in the asset portfolio should appear as a decision of phase 8 of an iteration (Continuous improvement and new techniques utilization): The company decision is to adopt the industry 4.0 concepts. In doing so it will implement Cyber-Physical Systems (CPS) as future assets and uplift the existent ones to this concept. Therefore, a new iteration in the complete Maintenance Management Model is proposed[1]. This iteration will also follow the Cyber Physical Framework. The actual target is to achieve the Function III (Cyber level) of the 5C level architecture for implementation of CPS (J. Lee, Bagheri, & Kao 2015), as a previous step to the full completion (Configuration Level) in future iterations.

It will be analyzed in the next paragraphs the eight phases of Maintenance Management Model as decision areas to implement our strategy regarding the inclusion of CPS in our asset portfolio. There will not be further references to "business as usual" activities of above mentioned framework related to maintenance process of the company.

3 PHASE 1: DEFINITION OF THE MAINTENANCE OBJECTIVES AND KPI'S

Along this phase there is a conceptualization facet: the main effort is to obtain the model that will satisfy our requirements under the distinct aspects of CPS framework: Functional, Business, Human, Trustworthiness, Timing, Data, Boundaries, Composition and Lifecycle. It is one of the phases deeply impacted by CPS implementation. During this phase, the decisions taken will determine the level I of the 5C architecture: The Smart Connection Level function with Plug & play, tether-free communication and sensor network as attributes.

Basic tool for this phase is Balanced Scorecard integrating not only economic performance and technical indicators of operation and maintenance but also project execution and Human factors of iteration to integrate CPS in the assets portfolio.

3.1 *Objectives to add*

1. CPS implementation policy. This policy should consider the importance of achieving tangible objectives of CPS as soon as possible, to engage the main stakeholders. So, assets to upgrade/ substitute must be carefully chosen; on later iterations under MMM it can be implemented the fully transformation of portfolio.
2. Maintainability, risk reduction, reliability and availability improvement to achieve by new/ uplifted CPS assets. Obviously, these parameters should be increased above the average.
3. Economic impact of overall operation. Capital expenditure should be considered carefully: In the future, the balance between investment and return obtained will be scrutinized for such technology change and can jeopardize further deployment.
4. Domains of CPS framework implementation should be identified; these are the areas of deployment in which stakeholders may have domain-specific (manufacturing) and cross-domain concerns (Energy, transportation). Groups of conceptually equivalent or related concerns will became the Aspects of the CPS framework of our interest.

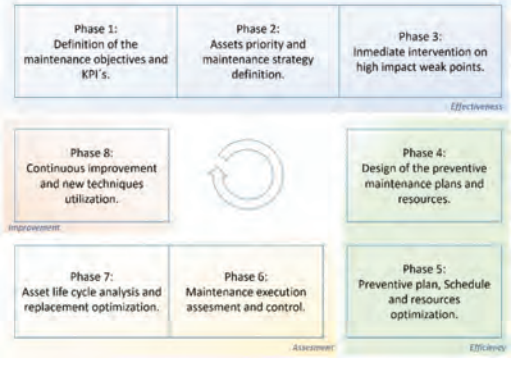

Figure 1. MMM schema.

[1]Only the new activities due to CPS are mentioned in the paper. The *business as usual* activities of the cycle are not included: refer to the original

Level	Function	Techniques	Attributes	System of systems action level
L5	**Configuration**	Resilient Control System (RCS):Action to avoid	• Self configure for resilience • Self adjust for variation • Self optimize for disturbance	DECISION
L4	**Cognition**	Decision support system (DSS): Prioritize and Optimize Decisions	• Integrated simulation and synthesis • Remote visualization for human • Collaborative diagnostics and decision making	
L3	**Cyber Physical Systems** (CPS)	Self-Compare	• Twin model for components and machines • Time machine for variation identification and memory • Clustering for similarity in data mining	DATA COLLECT
L2	**Data to information conversion**	Prognosis and Health Management: Self-Aware	• Smart analytics for component machine health. • Multi dimensional data correlation • Degradation and performance prediction	
L1	**Smart connection**	Condition Based Maintenance: Condition Monitoring	• Plug & play • Tether-free communication • Sensor network	

Figure 2. 5C level architecture (Lee et al.).

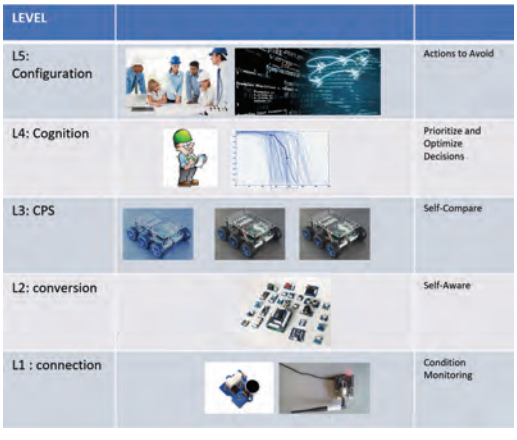

Figure 3. 5c architecture overview examples (Lee et al.).

3.2 *Identify the critical questions to be answered and key decisions to be taken*

1. New Stakeholders identification and documentation of their expectations. Consultants and technology providers are new stakeholders, but it should be also reexamined the old ones with new concerns: maintenance personnel and operators should change their approach to these systems improving their technical skills in software/hardware; it will imply new training. Report processes, command chain and IT systems will be also impacted.
2. Legal & safety concerns: Due to the recent development of CPS, there is a lack of regulation, but it will have a deep impact in the future for safety or environmental risky systems. The legislation will affect them and their crypto conditions to avoid any unintended access. The CPS framework has a full detailed coverage of this concerns and the assurance facet is described in detail.
3. Technological state of the art. Due to the lack of maturity, it must be evaluated which technologies will survive in a few years. Open standards will help to survive or, at least, to ease the transition to new ones in the future.
4. Identify leaders (internal and external) for new know-how transference and acquisition.
5. Other Standard, Policies, Directives and Procedures to be adapted. It has been mentioned the technological ones, but other business domains should be also considered. As an example: CPS themselves could inform of earned value to the project management software (units produced, finish of testing phase, finish of startup process…)
6. Cyber-level infrastructure and Machine-cyber interface.
7. ERP and Enterprise Asset Management software data flow impact.
8. Big data analysis systems and AI deployment.
9. Training of personnel.
10. Infrastructures, Special tools and test equipment needed or affected.

IT infrastructures play a key role in CPS systems. So, critical questions must be faced in this

stage as a decision-making breakdown structure for IT to be implemented in the CPS:

In the software level, the continuous evolution of information technologies is a risk factor and the use of open and standard methodologies for communications, like REST APIs with HATEOAS to exchange data, based on JSON or XML should be a priority. A wrong step in this direction could endanger the rest of the project by making CPS unable to communicate among them.

Regarding physical layers of communications (wired or wireless) it should be followed the same principle: looking for standard and open technologies. Of course, wired TCP/IP should be there, but wireless technologies are here to stay, and it is far more confusing the election:

Low-rate wireless personal area networks under IEEE 802.15.x or WIFI could be a reasonable decision for locally deployed systems.

For wide areas, it could be chosen between licensed LPWA technologies standardized by 3GPP (EC-GSM-IoT, LTE MTC Cat M1 and NB-IoT) or other commercial LPWA solutions: LoRAWAN or SigFox. These are closed technologies.

The future would pass through commercial 5G bands categorized into three generic services, namely, extreme mobile broadband, massive machine-type communications, and ultra-reliable machine-type communications.

3.3 *KPIs*

1. Human factors: strong leadership is needed, to overcome resistance and barriers, to change mindsets, to push through organizational change, to sustain investment, and to keep the team involved, specifically during the transition. Indicators over these soft factors will help to measure the pulse of the organization. It is important because the benefits of the CPS will appear after the integration of some of them: at the beginning of the process, only problems will arrive without any apparent benefit.
2. Speed of update in infrastructures, assets, etcetera: transition should be implemented fast enough to achieve evident benefits during the first stages, but avoiding over stress the organization (shutdown and start up production, new training, new processes, etcetera)
3. AI transition and assets peer to peer comparison. As one of the theoretically most disruptive changes that brings CPS, we should monitor the efficiency of this behavior through the economic impact in our organization. Installing only a modern gadget will fail as objective.
4. Earned Value management indicators (EV, CPI, SPI) are a good reference for any project to deploy CPS. It should also use the American Defense Contract Management Agency 14 points of Baseline Execution Index for planning and schedule. These are objective indicators of project's financial status, as one of the main concerns of the enterprise.

3.4 *Audits*

The use of audits will have two variants: the ones for control and continuous improvement according to MMM (MES, QMEM, etcetera) and specific ones to check the efficiency and effectivity of CPS implementation. These audits should focus on the incremental evolution of CPS upgrade: The added value of firsts units implemented should be audited against their objectives.

4 PHASE 2: ASSETS PRIORITY AND MAINTENANCE STRATEGY DEFINITION

Basic tool is Criticality Analysis, upgraded to include the risk of project—failure during implementation of CPS: It is needed to prioritize those assets with higher Return on Investment and lower technical risks. During the first iteration one of the highest risks is disaffection of CPS by main stakeholders. So, the asset to be upgraded at this early stage should be with high improvement-visibility, affordable capital expenditures effort, lower technological risk, easy to O&M in the near future.

4.1 *Determination of actions on actual assets based on risk factor analysis to:*

1. Replace/substitute for a new asset.
2. Uplift and improve the existent ones.

It will be scored using the concerns of CPS-FWK tailored accordingly. Without been exhaustive, in this first iteration it should be paid special attention to several concerns enumerated in the framework:

1. Functional: monitorability and communication.
2. Business: cost, time to market, utility and interoperability.
3. Timing: awareness and resilient time.
4. Boundaries: networkability, responsibility.
5. Composition: adaptability, constructivity and discoverability.
6. Lifecycle: procureability, deployability and mantenability.
7. Human: usability.
8. Trustworthiness: safety, reliability and cybersecurity.

These are, under author considerations, the key aspects to assure stakeholders engagement during the first iteration.

4.2 *Planning and scheduling to retrofit the assets. Based on the CPS 5C level architecture, with target of cyber level*

It will be used turnaround, shutdown and Outage operations to implement the new CPS assets or transform the legacy ones in CPS systems.

The authors recommend using Kanban agile practices embedded in a general schedule (Villar-Fidalgo, Espinosa-Escudero & Domínguez-Somonte 2016 & 2017), according to PMI® Agile Practice Guide (2017). The "product owner" value team might produce a roadmap to show the anticipated sequence of CPS to add or legacy systems to upgrade over the time. This planning will include conceptual, preliminary and detailed design, development, construction, M&O and disposal phases. This team re-plans the roadmap based on what the results are.

Due to the complexity of the CPS concept and lack of maturity, incremental and iterative changes during several iterations are preferable than a complete transformation in a single endeavor with waterfall planning and scheduling. Besides the intrinsic resilience and flexibility of a well-designed CPS will benefit this approach.

Agile-lean Kanban Method fits perfectly in particular steps of the proposal: Starts with current state, it is incremental, respects the current process, roles, responsibilities and titles. It will help dealing with overcoming requirements

The main adversary is that enterprise culture not always embrace leadership attitude at all levels.

4.3 *EV baseline evaluation*

This baseline will help to measure the performance of transition. The variances over baseline estimations will identify the need of upgrade the plan or maintain the initial target. Deviations off the baseline will not only affect the financial performance of the transition project but also stakeholder's engagement with CPS vision.

5 PHASE 3: IMMEDIATE INTERVENTION ON HIGH IMPACT WEAK POINTS

Basic tool is Failure Root Cause Analysis (FRCA), to look for high impact reliability enhancements and ensure a very effective definition of subsequent maintenance plan activities. Adding a new cause of failure is necessary, as it is recognized in CPS framework aspect of trustworthiness, based on security, privacy, safety, reliability and resilience of future CPS. The high complexity of network based software is a new factor to consider in the FRCA analysis over traditional physical, human and latent causes inherent to any kind of systems.

Nevertheless, it should be also intervened in high impact favorable assets to CPS transformation: those items which could lead to enhance the visibility of CPS advantages. A key reactor of high economical value deems for sure to be upgraded to CPS level, but their actual monitorization as a single asset with conventional SCADA and PLCs plugged to the network will dilute the improvement of such upgrade. On the other hand, a set of water flow pumps will not be as spectacular as the reactor, but their number and failure rate could make them ideal candidates to be upgraded if it is possible to achieve some good failure prognostics based on their shared data, including condition based on sensors and usage rate.

5.1 *Retrofit of highest priority assets to CPS level in first incremental iterations of schedule*

The priority will be based on:

1. Affordability of implementation and economic benefit for asset exploitation.

   Feasibility of full CPS application.
   Trustworthiness of implementation.
   Visibility of CPS enhancements.

5.2 *Data capture and data mining to extract the information, probably under "big data" considerations*

The first data extracted and initial behavior of CPS itself should follow the planned strategy. Otherwise will be necessary to adapt, preferably through agile methodologies, the next steps.

It should be achieved the maximum net benefits per system replaced/upgraded during the earliest stages of implementation, because of the priority criteria used. If the results are not the expected, it is an alarm signal that should draw attention to strategy or, at least, re-plan the implantation priorities. During this phase, it should be achieved the 5C architecture function 2: Data—to information Conversion Level. The attributes are smart analytics for component machine health with multi-dimensional data correlation and finally the degradation and performance prediction.

6 PHASE 4: DESIGN OF THE PREVENTIVE MAINTENANCE PLANS AND RESOURCES

Basic tool is Reliability Centered Maintenance: where operations and maintenance start to be influenced by CPS, depending on the level assigned in the risk plan and within the operational mode. It is far from the function 5 of 5C architecture: Configuration Level, with attributes of self-X of the

CPS, but it has information that, supported by new plans and their optimization, will take it to desired Function III of 5C architecture: the cyber level.

After implementation, the maintenance plan should be oriented to Condition Based Maintenance/Prognostic Health Management to exploit all the advantages of CPS. The CPS will probably rise overcoming requirements due to higher precision in sensors and data analysis (big data, M2M peer review), that will fine tune the detection of catastrophic failures. But this fine tune detection will increase the need of fast actuation: it will not only detect the normal worn of a friction bushing but the fast failure of an axle due to unexpected fatigue because of micro cracks (that CPS could infer due to misuse of the asset). The maintenance plans should also embrace the Agile philosophy.

7 PHASE 5: PREVENTIVE PLAN, SCHEDULES AND RESOURCES OPTIMIZATION

Basic tool is Risk-Cost Optimization considering the new opportunities that CPS brings. Use of self-compare behavior and machine to machine data exchange (peer monitoring) to identify the state of the asset portfolio and accuracy prognosis will allow to take advantage of dynamic planning and scheduling forecasting with optimal allocation of resources for maintenance and operation. The capacity of CPS to identify misuse or workloads unbalanced will also affect the production plans or operators training plans.

Again, the agile methodologies imbricated in high-level integrated master plan is a must: it should be ready to deal with overcoming requirements that need to be addressed on line. Baseline updates with a transition from original contour conditions (or "samurais") to updated ones will allow to measure performance without losing contact with the new reality. This way audits will continue delivering value.

8 PHASE 6: MAINTENANCE EXECUTION ASSESSMENT AND CONTROL

Basic tool is Operational Reliability Analysis, but it should not be forgotten specific aspects of transition phase: under a project environment with high-risk technological transition.

All the KPIs defined in phase 1 will help to control the evolution of the project and the impact in O&M operations:

1. Measurement, analysis and evaluation of earned value indicators for asset retrofit and start-up: cost and schedule through CPI, SPI, S-curves and Integrated Program Management Report.
2. Evaluation of indicators of actual performance in reliability, maintainability and future improvement based not only on probabilistic assessments, but also on truthful information and prognostics delivered by new CPS.
3. Evaluation of Risk with cost/benefit evaluation of mitigation plans.
4. CPS transition-speed and acceptance among stakeholders.

Finally, it will be needed to control the improvement achieved with CPS already installed. If we are not able to follow the baseline technical-plan, it should be reconsidered the overall project.

9 PHASE 7: ASSET LIFE CYCLE ANALYSIS AND REPLACEMENT OPTIMIZATION

This phase, as the first one, is deeply impacted by CPS. Basic tool is Life Cycle Cost Analysis, but it must include all the facets that new systems will bring to the asset portfolio.

It will face new cost-categories: software upgrades, trustworthiness analysis and developments, data networks deployment and maintenance, etcetera. Nevertheless, it can also achieve important savings: better use of systems by operators, higher accuracy in prognosis maintenance, lower supervision costs due to the "self-awareness" of CPS groups. Unfortunately, this kind of improvement will become very often incomputable because the traditional life cycle analysis has not included these factors. The maintenance team will have to struggle against skepticism to show the advantages of the CPS. This is one of the reasons to make key decisions and answer critical questions during the first phase: once the iteration is at this point, it should have evidences from CPS deployed to support the benefits to Life Cycle Cost, otherwise there will be only important capital expenditures and intangible benefits that could lead to disaffection of critical stakeholders like CFO's.

Another key aspect to highlight is the improvement in risk management and "probability/risk number" of CPS systems, due to a better knowledge of their health as a system.

10 PHASE 8: CONTINUOUS IMPROVEMENT AND NEW TECHNIQUES UTILIZATION

It will be necessary to analyze the targets from phase 1 achieved in the concluded iteration. If the result is satisfactory there will have two roads ahead: spread the CPS architecture to more assets or take another step with actual CPS towards

Function IV of CPS architecture: The Cognition Level. Probably the wisest decision in these times of technological immaturity is spread the CPS concept and study lessons learnt during the first iteration to smooth the continuous uplift / renovation of our asset portfolio.

The Function IV (Cognition Level) and V (Configuration Level) of 5C architecture have an intrinsic high degree of technological uncertainty that make them too risky under the engagement of main stakeholders. They should go through a System Integration Laboratory or prototype phase before the full integration in production assets.

11 DISCUSION

The architecture developed by Lee et al. (J. Lee et al. 2015) or the Framework released by NIST (NIST CPS Public Working Group 2017) are clear starting points for deployment of CPS in manufacturing industries. Nevertheless, these documents are focused on the CPS itself.

Our approach is a complementary and holistic view of the CPS implementation in a dynamic environment like the active enterprise. The Human Factor is a cornerstone during business transformation and should be included in the equation.

Another intended contribution is the necessary link between the sequential workflow of construction of a CPS with the iteration phases of the maintenance model and business itself.

12 CONCLUSIONS AND FURTHER DEVELOPMENT

This paper presents a framework to incorporate CPS, up to Function 3 of 5C architecture, in our asset portfolio with a holistic view and under a consolidated maintenance management model. The objective is to avoid early failures that discourage stakeholders from supporting this technology after the first iteration.

This work will continue with use cases evaluation and further iterations to achieve the Function V (Configuration Level) where all the advantages of CPS could be exploited in benefit of maintenance of full assets portfolio, and therefore the business objectives.

Automated train driver competency performance indicators using real train driving data

R.A.H. El Rashidy, P. Hughes, M. Figueres-Esteban & C. van Gulijk
Institute of Railway Research, University of Huddersfield, Huddersfield, UK

ABSTRACT: On Train Data Recorders (OTDR) are used within the GB Railways to collect data relating to train operations and the state of various train systems throughout a journey. These data include power and brake controller position and driver acknowledgement of signaling system warnings. This data could be used to assess driver competency but an assessment framework is required to extract the data sensibly. This paper proposes a train driver competency framework to define aspects that are related to train driver functions based on documents analysis, cab-rides and informal interviews. It also explores the utilization of OTDR in the quantification of the train driver competency framework by introducing a number of indicators under each aspect covered by the framework. The proposed indicators demonstrate to how OTDR data can be useful in routine systematic checks and pre-incident investigation, for example, identification of the deviation from recommended rules that may have safety implications. Furthermore, the data may allow for improved understanding of driver performance that in turn could allow the development of more effective safety management strategies. A number of numerical example presented to illustrate applicability of developed algorithm.

1 INTRODUCTION

On train data recorder (OTDR) offers an opportunity to understand the driver use of power, brake and safety systems during a journey. Despite the potential of OTDR data, it is not widely used to facilitate the automatic analysis of driver performance.

This paper presents a train driver competency framework based on official documents and reflecting the professional driving policies. It will also explore the use of OTDR data to quantify different areas covered by the proposed train driver competency framework to assess train driver performance aspects such as drivers' use of safety systems and braking, in addition, to derive indicators to measure the vigilance level of a driver.

2 AUTOMATED SAFETY ASSESSMENT

In the UK, current practice for assessing driver competence performance is in-cab riding by driver managers. A number of train operating companies use in-cab assessment to monitor drivers' operational usage of Driver's Reminder Appliance (DRA) (McCorquodale et al., 2002). In some cases, digital cameras implemented to record driver's action but they tend to be unpopular (RSSB, 2004). These techniques have their merits in assessing the driver performance as they supplied comprehensive details about the driver's behavior. However, drivers may behave differently under observation, limiting the potential for independent driver assessment. Add to that, the time and cost traditional methods hinder their use for continuous monitoring.

A number of research studies (Balfe, 2016; El Rashidy & Van Gulijk, 2016; Walker & Strathie, 2014; Green et al., 2011) explored the advantage of using OTDR source in different areas such as station duties, driver assessment and interaction with warning systems. Green et al. (2011) introduced a number of indicators to assess driver performance. They are:

- The speed at which power Notch 4 (out of a total of 4 notches) is selected when accelerating;
- The percentage of time in a braking sequence that the driver selects brake step 3 (out of a total of 4 steps);
- The of the train as it traverses a Train Protection and Warning System grid (TPWS) approaching a Permanent Speed Restriction (PSR);
- The speed through a PSR as a percentage of the maximum speed and the mean speed when the warning system (AWS) horn is received.
- Erroneous events such as wrong-side door release and system trips such as TPWS brake demand.

These indicators are compared with the average performance of the whole population of train drivers

to assess an individual's driving performance in relation to the cohort of drivers. The study introduced initial learning OTDR analysis but did not make use of all the available OTDR that related to the driver performance.

The aim of this paper is similar to the papers above: to assess driver performance in relation to safe driving of a train but we propose a more comprehensive framework.

3 METHOD

The method proposed in this work comprises of two steps, *viz.* developing a train driver competency framework and introducing a number of performance indicators to quantify elements of the framework using OTDR data.

3.1 *Train driver competency framework*

The framework is based on documents analysis, cab-rides and interviews.

Document analysis clarified the driver function and best practices in relation safe professional driving. For example, the professional driving policy (e.g. SWT, 2012; LM, 2009) was used to identify the recommended travel speed when approaching a red aspect and braking rules. The Rule Book – Train Driver Manual (GE/RM8000/ train driver) was also used to identify rules that the driver should comply with such as the use of safety systems.

To gain more knowledge about the driver environment and driver reaction under different situations, cab-rides were carried out. In addition, consultations, in the form of informal interviews, with a driver and a driver manager were conducted to discuss some operational issues and clarify some technical points.

Based on above processes the following aspects were identified:

- The driver handling of trains;
- The driver's compliance with rules;
- The driver's vigilance;

Under each aspect, a number of indicators were introduced, as presented in Figure 1, to facilitate the conversion of the conceptual framework to operational indicators that can be used to assess each aspect. Train handling aspect covers how the driver uses the brake system and the power system whereas compliance deals with rules in relation to driver's handling safety systems. The vigilance level of the driver has been assessed by a number of TPWS brake demands, wrong-side door release and percentage of instant cancellations of AWS horn.

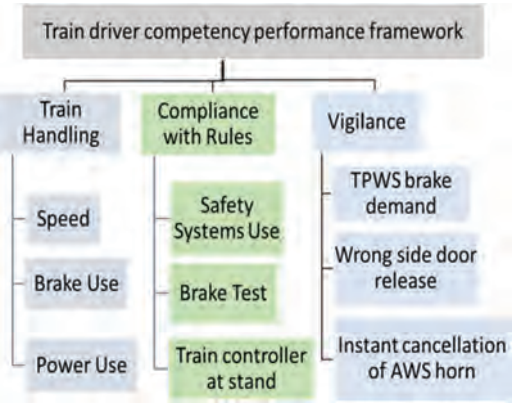

Figure 1. Train driver competency framework.

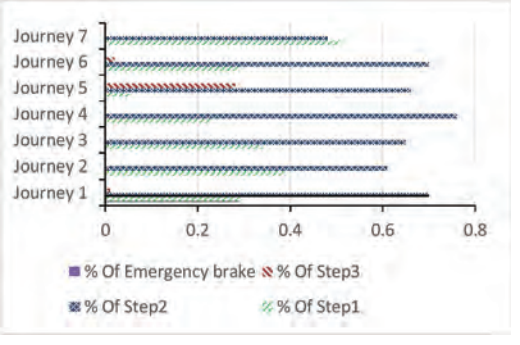

Figure 2. Brake use for a pair of origin-destination pair.

3.2 *Train driver performance indicators*

A bottom-up approach was implemented to develop train driver competency performance indicators (DCPIs) based on driver competency framework using OTDR data.

3.2.1 *OTDR data*

The OTDR data files used in this paper were supplied by Southern Railway. They are for the same route and the same day but different drivers to eliminate the impact of route conditions.

3.2.2 *Initial data handling*

The initial data handling process, presented in Figure 2, includes a number of steps as follows:

- Examine data types and format and correct them if needed. For example, the format of a relative journey time is converted from "+ 01h24 mn26 s 6" to "5066.6" seconds.
- Compress all variables that occurred at the same time in a single data row. Closer inspection of the

data showed a relative journey time record may appear more than once with different groups of variables (i.e. for the same time record, there was more than one input line from different data channels).
- Processing missing data using different logical processes, for example, filling the missing values of train distance with calculated distance based on the available time duration and train speed. This error checking is specific to the Class 455 data used in this study, although it is likely that all OTDR data will need similar error handling and cleaning routines to make it useable.

After this pre-processing, data analysis could commence.

3.2.3 *Detection algorithms*

A number of algorithms have been developed in the R software package to extract relevant indicators for each behavior aspect presented in Figure 1.

3.2.4 *Data analysis*

A number of algorithms have been developed in R to identify relevant scenarios for each behavior aspect presented in Figure 1 and, then, calculate the metric. The metrics are mostly the frequency, the averaging or maximum or minimum values. A number of standard statistical visualizations were used to present the results such as boxplots.

4 RESULTS

4.1 *Proposed DCPIs*

Table 1 a, b and c summarize DCPIs that developed in this work and shows the proposed performance metric and criteria for each indicator assessment.

4.2 *Safety related DCPIs examples*

This section gives a few numerical examples of DCPIs that can be related to safety rules or devices to illustrate the use of OTDR rather than detecting any trend or best practice rule due to the size of the used data sample.

Under the train handling aspect, braking behavior and speed at AWS horn approaching a red aspect are presented here as they are directly related to safety. For braking behavior, Figure 2 shows the percentage of each brake step use calculated by considering the travelled distance using each step. For example, in "Journey 5" the driver applied Step 2 (0.66) in addition to using Step 3 (0.28) as shown in Figure 2 due to the late use of the brake which may create a hazard condition under different circumstance such as low adhesive condition. It should be noted that use of brake Step 3 should be

Table 1. DCPIs based on OTDR data.

(a) Train handling

Aspect	Metric
Braking behavior.	Pattern recognition based on braking curve data
Use of brake-step 3 on approach to stations.	The maximum percentage of distance travelled using brake-step 3 per station during a journey.
Use of brake on approach to stations.	The percentage distance travelled using each brake-step.
Speed	The speed at AWS horn (mph) prior to a red aspect
	The frequency of train speed < = 3 mph when power Notch 4 selected during the journey
Use of power.	The percentage of distance travelled using power notches 1 to 4 (out of 4).

Wrong side door release	Number of wrong side door release
TPWS Demand application	Number of TPWS Demand application

minimized, as a good practice unless the driver had to use it due to low track adhesion.

For the speed, Table 2 presents the speed at AWS horn when the driver approaching a red aspect. A higher than normal speed when approaching a red aspect may cause a SPAD (signal passed at dangerous without authorization) or lead to a full brake application to stop the train at the correct location. For one train operator this is 20 meters in advance of the red aspect (LM, 2009). For the OTDR sample used in this paper all driver complied with this rule as showed in Table 2.

Under compliance with rules, braking test is checked as the brake test enables the driver to evaluate the performance of train braking system prior to the need to use it. Using OTDR data enables checking this rule prior to the driver first stop (due to a station or a red aspect). For example, Figure 3 shows that the driver carried out the brake test prior to the first AWS horn, in contrast, the driver presented by first AWS horn.

For vigilance aspect, wrong-side door release is presented. Releasing the doors on the wrong side of the train may have serious consequences as it could cause a potential harm to railway passengers. Only one of the journeys showed any instances that appeared to have wrong-side door release. This journey is shown in Figure 5 and is unusual in that the train appears to be stationary for most of the time. It is possible that this file shows a train under maintenance. Figure 5 shows door releases; on each occasion the right-hand side door (shown by the blue circles) is released shortly before the left-hand side door (shown by the red line). Because of the very short period between the two door releases, they appear to occur at the same time in the figure. Whilst this file does not appear to show an instance of an actual hazard—since the train did not appear to be moving—it nevertheless demonstrates that it is possible to use OTDR data to detect instances of wrong-side door release.

Table 2. Maximum speed at AWS horn prior to red aspect.

Journey Number	Number of red aspects	Maximum train Speed approaching a red aspect

5 DISCUSSION

Considering the growing interest in harvesting data sources such as OTDR, the development of DCPIs

that support that direction is essential. DCPIs proposed in this paper developed not only based the available data from OTDR but also supported by the official documents such as Rule Book and number of professional driving policy documents.

The technological approach described offers sensible solutions for the extraction of DCPIs from OTDR; it offers rapid analysis of the driver performance in contrast to in-cab-riding assessment by a driver manager that normally takes place every six months and only provides the opportunity for a driver to be assessed under a limited range of conditions. Furthermore, the in-cab-riding assessment may cause drivers to behave differently under observation, whilst DCPIs can be calculated without disrupting the driver.

DCPIs do not pass judgement about what is 'good' or 'bad' but illustrate how data is extracted in a sensible way from a huge dataset. For qualitative judgement, the allocation of indicators may need further discussion in the implementation stage to consider related parties point of view.

A few numerical examples of DCPIs are presented to illustrate the practicality of using OTDR to calculated DCPIs. However, the used data sample was very small to detect any trend or best practice rule.

6 CONCLUSION

In this paper, the train driver competency framework was introduced to outline the main areas of a driver function using documentary analysis (e.g. TOCs professional driving policy and the Rule Book), in addition to interviews and in cab-rides. A number of DCPIs have also proposed to assess driver performance under real-life conditions using OTDR data.

OTDR offers great sources to develop a comprehensive list of behavior aspects related to driver performance that can be determined from OTDR data.

ABSTRACT: During the last decade, increasing attention has been focused on environmental protection. For instance, the ecological effects of hydrocarbon releases in the sea are of paramount concern. One way to assess their environmental impact is to consider the amount of pollutant discharged. Effective early detection would help in revealing spills in advance and take the necessary mitigating measures to contain the released volume. Standards and guidelines are established for developing effective sensor networks in the subsea templates for monitoring purposes and data collection. Sensors provide a heterogeneous amount of information about the template they are monitoring. According to recent studies on risk assessment, the *level of knowledge* about a specific system is an intrinsic feature that should be considered during the assessment and evaluation phases for better managing potential increments of the risk level. The information provided by sensor networks may be used in this perspective. Sensors may be functionally placed in fault tree analyses and update the information about frequency deviation. The work in this paper is focused on risk management using such information from subsea sensor networks. A real reference case from the oil and gas industry located in an environmentally sensitive area on the Norwegian Continental Shelf is provided for testing the suggested approach. The case study refers to subsea monitoring of oil leakages from the wellhead templates. Insights from the case study highlight how sensor data analysis may improve risk management and support operational decision making.

1 INTRODUCTION

Dynamicity to risk assessment and management is a main challenge that today´s researchers have to face. A quantitative assessment of the level of risk for a production installation is required by law, but it is usually performed during the design phase. Effective support during operations is missing (Villa et al., 2016). The chemical and petrochemical industry requires tools and methods to update the risk picture on a real-time basis and then improving risk management (Paltrinieri and Khan, 2016). Different approaches have been suggested to dynamically update the risk level. Some of these are based on Bayesian networks (Khakzad et al., 2016, 2014) while others are proactive approaches based on indicators (Paltrinieri et al., 2016).

In this perspective, the Dynamic Risk Management Framework (DRMF) has been developed (Paltrinieri et al., 2014). Figure 1 shows the DRMF. DRMF focuses on the continuous systematization of information on new risk evidence. As shown in Figure 1, its shape opens the process to new information and early warnings by means of continuous monitoring. Side information is an input to each step of risk management through communication and consultation.

The available information provided by different sources, such as monitoring and control devices, but also training reports and audits, should be included and exploited when assessing the risk level during operations. As suggested by Aven and Krohn (2014), a new dimension to the definition of risk from Kaplan and Garrick (1981) should be

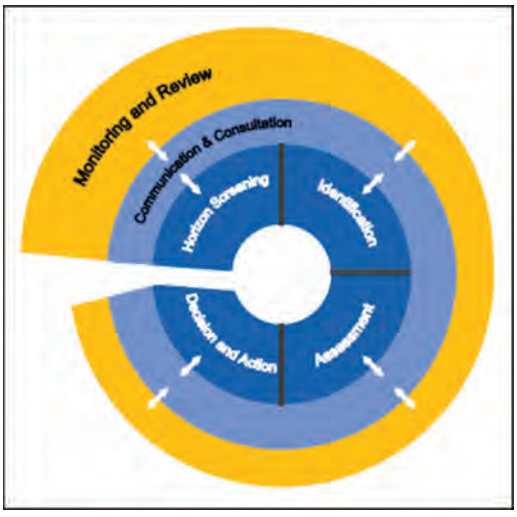

Figure 1. Dynamic risk management framework—clockwise (adapted from (Paltrinieri et al., 2014)).

added. As shown in Eq. (1), risk (R) is a function of the identified scenario (s), its probability (p), its consequences (c) and of what Aven and Krohn (2014) define as level of knowledge (k).

$$R = f(s, p, c, k) \tag{1}$$

The level of knowledge for a specific system is an intrinsic feature that should be considered during the assessment and evaluation phases for better managing potential increments of the risk level.

The information provided by sensor networks may be used in this perspective. Sensors may be functionally placed in fault tree analyses and update the information about frequency deviation. The current analysis in this paper refers to subsea detection networks.

Subsea leak detection is a considerable challenge for the oil and gas offshore industry, although the main concern for subsea templates is blow-out. As shown by Macondo (Deepwater Horizon Study Group, 2011) accident, the effect of a well blow-out due to the large amounts of spilt crude are catastrophic from human, environmental, economic and reputational point of views.

However, as oil and gas offshore production is moving north, towards sub-Arctic and Arctic areas, monitoring and control of crude oil spill are becoming critical issues. These areas are environmentally sensitive (Larsen et al., 2004) and specific requirements (DNV-GL, 2012) must be met during production. For instance, the Barents Sea area is recognized by the World Wildlife Fund (WWF) as critically sensitive from an environmental point of view (Larsen et al., 2004) due to:

- Naturalness;
- Representativeness;
- High biological diversity;
- High productivity;
- Ecological significance for species;
- Source area for essential ecological processes or life-support systems;
- Uniqueness; and
- Sensitivity.

The current development of large oil and gas templates in the Barents Sea may lead to severe pollution and increased risks of large oil spill (Bioforsk Soil and Environment, 2006), constituting a major threat to the biodiversity of this particularly sensitive area.

Detectors are required to show high sensitivity to small amounts of leaking hydrocarbons and to detect a spill in a reasonable time interval. This is the basis for early detection systems. The threshold value of a leakage rate to be detected by the sensors is a critical parameter that influence the choice and the cost of the device. Furthermore, the detectors have to be available and reliable when in place to effectively provide information to the topside control room. Fault logs' information may be gathered to evaluate to which extent the measurement by the sensor is trustable.

Moreover, it would be preferable to locate the leakage source through the detection system. Collecting information about where the template is spilling oil is useful for both intervention and consequent maintenance activities.

The contribution in this paper addresses the main challenges related to subsea oil detection coupled with risk management for a real case of an oil and gas Floating, Production, Storage and Offloading (FPSO) unit located in the Barents Sea. Available sensor network information is used to support risk management.

The paper is organized as follows: Section 2 provides some fundamentals of signal processing useful for a comprehensive understanding of how the subsea leak detector network works. The case study is extensively described in Section 3. The legislative requirements and both the subsea template and sensor network characteristics are included in this Section. The results of the study and their discussion are provided in Section 4 and 5. The paper ends with conclusions in Section 6.

2 FUNDAMENTALS OF SIGNAL PROCESSING FOR OIL DETECTION

The detection system purpose is to reveal hydrocarbon spills in the sea from the subsea equipment.

For the sake of simplicity, this work addresses the oil leakage event in a binary way: the presence of release is associated with the state H_1, while the absence with the state H_0. Sensors detect the presence (H_1) or absence (H_0) of oil leakage from the wellhead. A sensor's local detection is performed by comparing the registered signal with a fixed threshold.

Typically, distributed multiple sensors are in place to detect the oil leakage. Their number is defined as K and everyone is equipped with an acoustic transducer. Every i-th sensor makes a local decision, y_i, and this signal is transmitted to a fusion center (FC), which takes a (theoretically more reliable) global decision, d, about the presence or absence of the binary event. The global decision is derived by appropriately combining the received information on local decisions from different sensors. This type or architecture is defined as centralized and it is represented in Figure 2 (Salvo Rossi et al., 2016; Salvo Rossi and Ciuonzo, 2015).

Referring to Figure 2, the present study considers that the local decision from the i-th sensor, y_i, does not suffer of disturbance and signal attenuation while it is transferred to the FC. The signal transmitted to the FC from the i-th sensor is named r_i. For the assumptions made, the value of r_i corresponds with y_i.

Locally, at sensor level, four different decision situations may result considering a binary leak event. Such decision situations are summarized in Table 1. The present analysis assumes that every sensor senses autonomously the environment in a defined space cell to detect the presence or absence of a target (which in this specific case is the presence of oil leaking from the template).

The probability of detection (P_D), false alarm (P_F) and missed detection (P_M) are defined according to the equations 2–4:

$$P_D = p(y = H_1 \mid H_1) \tag{2}$$

$$P_F = p(y = H_1 \mid H_0) \tag{3}$$

$$P_M = p\left(y = H_0 | H_1\right) = 1 - P_D \tag{4}$$

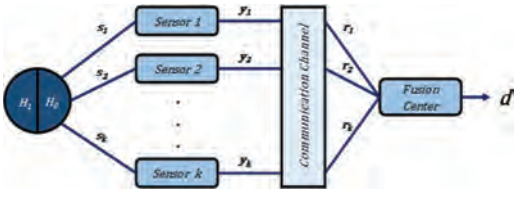

Figure 2. Distributed detection system (K sensors) with fusion center (adapted from Salvo Rossi and Ciuonzo (2015)).

Table 1. Detection and detection errors.

		DECISION	
		$d = H_0$	d = H_1
EVENT	H_0	Correct decision	Error type 2: False alarm
	H_1	Error type 1: Missed detection	Correct decision (detection)

The sensor local performance may be described by means of different parameters. The present work refers to P_D and P_F according to common practice in communication engineering studies (Salvo Rossi et al., 2016; Salvo Rossi and Ciuonzo, 2015). The present work assumes that sensors are independent from each other. Given this hypothesis, P_D and P_F are as well stationary and conditionally independent. The sensors within the network are assumed to have identical local performance (homogeneous network).

The detection system performance is evaluated in terms of the global probability of detection, Q_D, the global probability of false alarm, Q_F, and the global probability of missed detection, Q_M. They are defined according to the following equations 5–7:

$$Q_D = p(d = H_1 \mid H_1) \tag{5}$$

$$Q_F = p(d = H_1 \mid H_0) \tag{6}$$

$$Q_M = p\left(d = H_0 | H_1\right) = 1 - Q_D \tag{7}$$

The FC takes the final decision based on the received decisions and using a Fusion Rule (FR) (Javadi and Peiravi, 2013). This work applies the Counting Fusion Rule (CFR). The sum of sensor decisions is compared to a specific threshold at the FC to make the final decision (Javadi and Peiravi, 2013). The CFR is a simple and intuitive strategy to count the number of reported detections (Niu and Varshney, 2008), but it is far from the optimal performance (Javadi and Peiravi, 2013). However, it is suitable for the purpose of the current analysis as it does not require previous system knowledge and it provides a good basis for trade-off analysis.

3 CASE STUDY

As previously mentioned, this study focuses on the main challenges of subsea oil detection and risk management for a real case of an oil and gas Floating, Production, Storage and Offloading (FPSO) unit located in the Barents Sea.

For this reason, the study aims to evaluate if the facility detection system is able to:

– Improve subsea safety;
– Reduce environmental impact by controlling the released hydrocarbon quantities;
– Reduce the need for remotely operated vehicle (ROV) inspections.

In particular, the focus of this work is on early detection of oil releases in the subsea template on the seabed.

3.1 *Regulations and stakeholders*

Companies operating on the Norwegian Continental Shelf (NCS) are required to carry out environmental monitoring to obtain information about the actual and potential environmental impact of their activities (Norwegian Environment Agency, 2015). Different regulations set the requirements for the monitoring of petroleum activities. The regulations relating to conducting petroleum activities (The Activities Regulations) (Petroleum Safety Authority Norway, 2016a) dedicate Sections 52–57 to special requirements for environmental monitoring. These requirements include the monitoring of the water column and of the benthic habitats, as well as the establishment of an effective remote sensing system to detect and map acute pollution. The Management Regulations (Petroleum Safety Authority Norway, 2016b) require in Section 34 the operators to report the results obtained from monitoring of the external marine environment. These requirements have to be satisfied during oil and gas operations.

In 2014, a Joint Industry Project (JIP) led by DNV-GL was aimed at developing the best practices for designing and implementing detection systems (Leirgulen, 2014). Twenty key partners joined the project, including different operators, integrators and suppliers, as well as authorities, the Norwegian Ministry of Climate and Environment, and the Petroleum Safety Authority Norway (PSA) (Leirgulen, 2014). The JIP identified relevant functional requirements and general specification for a subsea detection system. The outcomes are included in the Recommended Practice F302 (DNV GL, 2016). The key functional requirements identified for the subsea detection system by DNV GL (2016) may be summarized as follows:

- Sensitivity to small releases;
- Responsiveness of the detection system;
- Availability and reliability of the leak detector;
- Ability to locate the leakage source.

Therefore, the detection system must satisfy the requirements set by the standard for oil detection in the subsea template RP-F302 (DNV GL, 2016). The standard sets qualitative requisites to be fulfilled. First, the Best Available Techniques (BAT) approach for leak detection has to be selected. RP-F302 requires a two-step BAT process where the firstly single techniques are assessed and then different configurations are compared to identify the most efficient in cost and risk reduction.

Anyway, the analysis of the different standards does not provide straightforward guidelines for the positioning of subsea leak detectors. Different configurations have to be assessed and redundancy margins to be guaranteed. The main purpose of the subsea network is to strain the detection of oil releases to unit.

Different actors are involved in the response when a subsea leak is detected. The topside operators have to gather relevant information and start preliminary mitigation actions. Moreover, the offshore personnel have to consult experts from the onshore department, and notify the coast guard and to the airborne in case their intervention is needed. From the topside, it is possible to monitor and control the amount of oil released from the subsea equipment. The production system needs a detailed and reliable picture of the situation in the subsea template in case there would be a need for shut-down. The economic impact of unplanned shutdowns can be severe for oil and gas companies (Oil and Gas IQ, 2014). Assessing the risk in a detailed way may allow minimizing time (and costs) of unnecessary stops of production. Moreover, the effectiveness of the subsea detection system is also critical for limiting the number of unplanned ROV inspections. ROVs are operated by a crew on board dedicated vessels and are usually used for maintenance activities on the subsea templates. ROV inspections are extremely expensive and especially dedicated expert personnel is required. A reliable sensor network able to identify releases due to mechanical failures would be helpful in eliminating the costs of unnecessary ROV inspections. With a detection system that works effectively and identifies (and eventually locates) the leakage sources, the number of required interventions from the topside would decrease, leading to a subsequent drop in operation costs.

In addition, different environmental organizations have raised their concern about oil and gas exploration and drilling, particularly in the sensitive Arctic and sub-Arctic areas, which are critical for biodiversity and ecological significance (Greenpeace, 2017). These organizations may affect public opinion towards the environmental protection policy of a company. The impact on reputation of oil and gas operators may be severe. For this reason, implementation of advanced and effective strategies and technologies for environmental protection should be a main priority for the operator company.

For all these reasons, the stakeholders of subsea oil and gas activities within Arctic and sub-Arctic regions may be the following:

- Offshore operator;
- Production system;
- Onshore department;
- Coast guard;
- Airborne;
- ROV operator;
- Sensor supplier;
- Petroleum Safety Authority Norway;
- Environmental protection agency; and
- Non-Governmental Organizations (NGOs).

3.2 *Subsea template overview*

The subsea template on the seabed is a critical area of the oil production installation where a high number of valves and joint points are located. These critical connections may be potential sources of oil leakage due to pressure increments during production disturbances and/or mechanical failures.

Sensors are placed in the template structure to early detect oil releases. Although different types of sensors may be available, this analysis refers only to acoustic oil leak detectors.

Figure 3 shows the physical elements needed for the detection of hydrocarbon leakage at the subsea wellhead and X-Tree (adapted from Røsby (2011)).

3.3 *Sensors characteristics and configurations*

According to RP F302 (DNV GL, 2016), there are no unique guidelines to locate the sensors in the distributed detection network. The only relevant requirement concerns the use of BAT approach for early detection of oil releases.

Two types of sensors are considered named Type A and Type B, respectively. They are set to work with the same P_F (equal to 10^{-2}) as common practice in telecommunication engineering studies. However, the sensors have different Receiver Operating Characteristic (ROC) curves and this results in different P_D. The more performing sensor (Type A) has a P_D of 0.90 and the other (Type B) of 0.50 (Salvo Rossi et al., 2016).

Table 2 summarizes the characteristics of the sensors.

Detection and its reliability are key parameters during oil and gas operations. Reliably assessing that a mechanical rupture has happened and that the template is leaking is critical in efficient ROV intervention management.

The sensors are placed in two different configurations. The area of interest is organized in structured square cell grids, as shown in Figure 4. The first configuration considers one single sensor for each grid cell defined in the sensed environment (namely, single configuration). In the second configuration, redundant N sensors monitor the presence (or absence) of the target of interest (namely, redundant configuration). Figure 4 is shown as representative.

The case study compares the detection performance of the distributed sensor network in two cases. The first scenarios refer to the single configuration using high-performance acoustic sensors in terms of detection probability (Type A). The second considers the redundant configuration applying theoretically cheaper and less performance sensors (Type B). The detection performance of the two sensors are described in Table 2. The single configuration uses one sensor of Type A for each grid node described in Figure 4. The sensor covers the

Table 2. Description of detection performance for sensors Type A and B.

Sensor	P_D	P_F
Type A	0.90	0.01
Type B	0.50	0.01

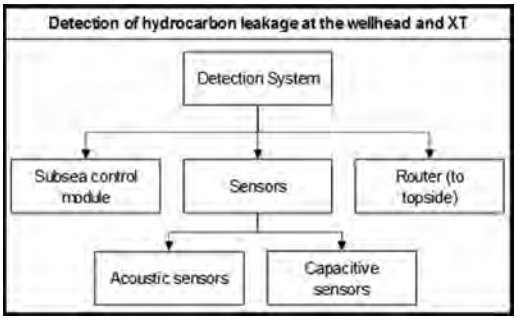

Figure 3. Detection system for the wellhead and X-Tree (adapted from Røsby (2011)).

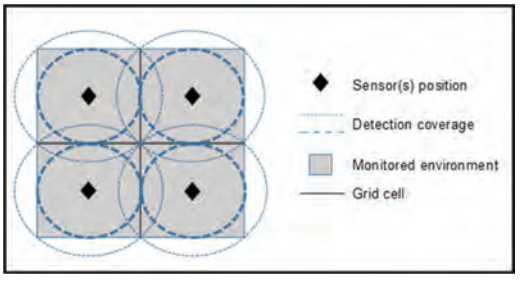

Figure 4. Sensor grid in the monitored environment.

entire grid cell and it sends its local decision about the presence or absence of oil release to the FC. The redundant configuration applies a number of N sensors Type B for each grid cells. The number N of sensors should be defined to approximately match the detection probability obtained with a single Type A sensor. The CFR is applied as fusion rule at the FC. The threshold is set conservatively to 1. This means that the FC conservatively takes a positive decision on the presence of oil leakage when at least one detector monitoring the grid cell sends a signal revealing the presence of the target.

4 RESULTS

The current analysis considers a release trend as the one shown in Figure 5. It is worth to noticing that the release behaviour has been adopted for demonstrative purposes. The sensors detect noises from the subsea template and they record them above a defined threshold. Some oscillations are recorded due to any pressure variation in the reservoir. In that case, the pressure is controlled and reset to its optimal value without any intervention from the topside (see the first 50 time steps in Figure 5). This trend may also be due to some slightly overpressure scenario developing in the first year of production, when the pressure in the reservoir is higher (Kansas Geological Survey, 2000). The oscillations may result in fatigue on mechanical components and induce a mechanical failure of some valve in the X-mas tree and wellhead. The template is then continuously leaking and it needs dedicated inspections and intervention.

The detection and false alarm probabilities are calculated using the fusion rule described in Section 2. Table 3 shows that a number of Type B sensors equal to 4 in the redundant configuration has been found to approximately match the detection probability obtained with a single Type A sensor.

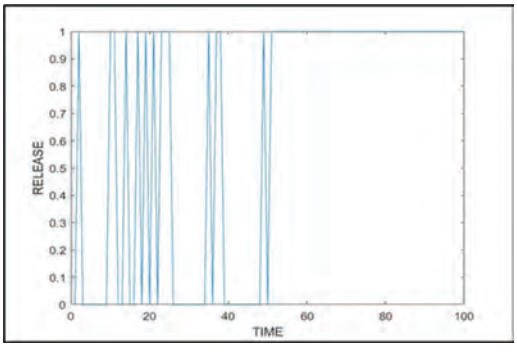

Figure 5. Assumed target trend for the present analysis.

Table 3. Detection performance of the subsea template system in two different configurations.

Configuration	SINGLE	REDUNDANT
Sensor type	Type A	Type B
Number for each grid cell	1	4
P_D	0.90	0.94
P_F	0.01	0.04

The P_D in the redundant configuration is slightly higher than the in the single configuration, while the P_F is four times increased.

5 DISCUSSION

Table 3 highlights a relevant increment of the detection system performance using redundant "cheap" sensors (Type B). The detection probability P_D for a single Type B sensor is 0.50 (see Table 2 in Section 3.3), but it is almost doubled in the redundant configuration (0.94). Moreover, this type of configuration slightly exceeds the single expensive Type A sensor P_D. Redundant configurations of Type A sensors may be also considered. However, the increment in detection performance would not be as relevant as in the case of Type B sensors as their performance is already high.

However, the redundant configuration as described in this work allows the increment of the false alarm probability P_F as shown in Table 3. This may have a negative effect on the organizational levels. False alarms may result in unnecessary unplanned ROV inspections and shut-downs with strong increments of operational costs. The fusion rule for the FC adopts a conservative approach with respect to leak detection for which the global decision is the presence of leak in case *at least* one detector emits a positive signal. That justifies a global P_F for the redundant configuration of four times the single value.

A more sophisticated decision rule should be implemented (Javadi and Peiravi, 2013). The sensor placement should be investigated and optimized to guarantee early detection and to track the oil spill movement in case intervention is needed.

The sensors detect noises from the subsea template and they record them above a defined threshold. Some oscillations are recorded due to any pressure variation in the reservoir. In such scenarios, the pressure is controlled and reset to its optimal value without any intervention from the topside. This trend may also be due to some slightly overpressure scenario developing in the first year of production, when the pressure in the reservoir is higher (Kansas Geological Survey, 2000). These oscillations may result in fatigue on

mechanical component and induce a mechanical failure of some valve in the X-mas tree and wellhead. The template may then continuously leak, needing dedicated inspections and intervention.

According to the results of the performed simulations, the number of missed detections is lower in redundant configurations. It is possible to identify and distinguish if the release is due to well fluctuations or mechanical failures by coupling the signal from the FC and pressure data. This allows recording of early warnings and use them for risk assessment and management. The analysis of near-accident data is a fundamental step in the framework to forecast likely accident scenarios. The information from sensor networks may provide a basis to the reactive update the risk picture of the installation with respect to subsea leakage risk. For instance, the data from sensors may be used as evidence in Bayesian inference network for updating release probabilities (Paltrinieri and Khan, 2016).

Reliable information from the subsea may also improve communication between different stakeholders and decision making processes.

6 CONCLUSION

The threshold leakage rate for the sensors defines its sensitivity and therefore its cost. High sensitivity (detection of lower leakage rate) results in highly sophisticated sensors with substantial cost. A solution would be the application of low cost redundant sensors located in a specific network in order to perform early detection. The decision about the presence of oil leakage into sea from the subsea template determines the need of intervention from the topside. Different (internal and external) stakeholders are involved in oil and gas facilities. A reliable subsea detection system may help avoid unnecessary intervention and improve the overall company risk management. Moreover, every intervention to the subsea template from the topside requires substantial costs that may be reduced with a reliable basis of information.

The analysis suggests the investigation of different sensor placement configurations in order to enhance early detection and oil leakage tracking. Further studies should be considered applying different and more specific decision fusion rules.

The information from decision making may be used in updating the risk picture of the installation and in improving the decision making process.

Ragnhild Eleftheriadis & Odd Myklebust
Sintef Raufoss Manufacturing, Norway

ABSTRACT: With the onset of Industry 4.0 several technological possibilities are offered in industry such as big data analytics, digital twin and augmented reality. The result is a more digitalised industry where faster and better decisions are possible. In long term this should provide a more reliable production with increased plant capacity and reduced downtime. To succeed with these possibilities a Cyber Physical Systems (CPS) must be established for the company. Currently, an own framework for CPS is under development and is expected to be tailored for Norwegian manufacturing. When building on the principle in Industry 4.0, big data capability with machine learning will be a fundamental model. Nevertheless, Industry 4.0 should also include other models for big data capability such as reliability modelling. The aim in this article is to present the current status of CPS framework and how it could be implemented in manufacturing industries. In particular, the article discusses and demonstrates the balance between machine learning and reliability engineering in big data analytics.

1 INTRODUCTION

The European competitive advantage is under pressure, where customer needs, such as improved delivery accuracy of products, have changed over time (Smart Industry, 2017). It might challenge the future industry in Europe how to implement and digitalize equipment and tools for a safe and reliable environment.

Several initiatives like platforms for Industry 4.0 have been established (Kagermann et al., 2013). Also national strategic initiatives have been established, like "Smart Industry" in Netherland (Smart Industry, 2017) and "Industry, greener, smarter and more innovative" in Norway (Ministry of Trade Industry and Fisheries, 2017) where the focus is adapting systems for data handling and digitalization. Several important elements can be related to Industry 4.0 such as predictive maintenance (McKinsey&Company, 2015). The benefit of predictive maintenance is improved reliability with application of the opportunities from big data and statistics where application of continuous real-time monitoring of assets, with alerts given based on pre-established rules or criticality levels (Pwc, 2017). It remains to investigate more in detail how reliability engineering methods also can be combined with big data analytics in order to improve the reliability of the production plant.

Another important element of Industry 4.0 is cyber-physical systems (CPS) (Kagermann et al., 2013). As an overall understanding, CPS are integrations of computation with physical processes (Lee, 2008). Since manufacturing is one essential application of CPS (Lee, 2008), the notion cyber-physical production systems (CPPS) is often used in manufacturing and production (Monostori, 2014, Lee et al., 2017, Hehenberger et al., 2016, Monostori et al., 2016).

Although the economic impact of applying the CPS in manufacturing is significant, computing and network technologies today may impede the progress towards this application (Lee, 2008). For example, the "best effort" in networking technologies make predictable and reliable real-time performance difficult. Nevertheless, certain efforts have been conducted where structures and architectures of CPS have been constructed, ranging from typical sketches with sensors and actuators (Lee, 2010), towards more generic architectures both as level based CPS (Lee et al., 2015) and CPS architecture with three dimensions (IEC, 2017).

Several challenges have been addressed for CPS, such as physical critical infrastructure that calls for preventive maintenance (Rajkumar et al., 2010). It has also been pointed out as a challenge to have a CPS architectures that are both "globally virtual and locally physical" (Rajkumar et al., 2010). Another challenge is need for standards (Chaâri et al., 2016). Although a pre-standard of CPS has been published (IEC, 2017) the industry has already started to test alternative architectures (Lee et al., 2017) in advent for a standard.

In Norway it is of interest to establish a CPS framework for Norwegian Industry. To create such a framework an ongoing competence project where framework, tools and implementation in demonstrators are in progress (Eleftheriadis and Myklebust, 2017).

The aim of this article is to present the current status of a Norwegian CPS framework and how it could be implemented in manufacturing and process industries.

To achieve this aim, following sub objectives are outlined:

1. Present existing elements for CPS architecture
2. Present existing CPS architecture for Norwegian manufacturing and process industry
3. Evaluate how it can be further developed based on existing CPS theory
4. Propose reliability-based analysis methods and technology for the CPS architecture
5. Discuss how the CPS architecture will be implemented in Norwegian industry.

The remainder of this article is structured as follows: In Section 2 existing elements for CPS architectures are presented. Based on these elements the Norwegian CPS framework is constructed in Section 3. In Section 4 three relevant CPS analysis methods and technologies are proposed and elaborated; life cycle profit (1), Safety perspective (2), and machine learning related to reliability engineering (3). Section 5 elaborates how the CPS framework can be implemented, while concluding remarks are made in Section 6.

2 EXISTING ELEMENTS FOR CPS ARCHITECTURES

To ensure successful application of the breakthrough technologies offered in Industry 4.0 in an organisation, a concrete architecture for CPS must be established. Today, there exist several architectures for CPS. In particular three architectures seem to be of relevance in Industry 4.0.

As a first example of CPS architecture, Lee et al. (2015) has proposed a 5-level CPS architecture denoted as the 5C architecture. This architecture provides a step-by step guideline in rolling out CPS in manufacturing with following levels:

1. *Smart Connection level.* Implementing the necessary instrumentation of machines, "plug & play" sensors, and wireless communication.
2. *Data-to-Information Conversion level.* The data collected from the sensors will be input-data for several models that provide information such as assessment of degradation.
3. *Cyber level.* At this level the digital twin of the plant is established and more advanced analytics is possible with assessment of fleet of machines.
4. *Cognition level.* To support the decision-maker to conduct faster and better decisions, proper presentation of the acquired knowledge is necessary. This level visualises e.g. future factory performance and key performance indicators.
5. *Configuration level.* This level provides feedback from the virtual world back to the physical world based on decisions conducted in level 4. This level also self-optimizes several properties of the plant.

Some successful case studies of the 5C architecture have recently been conducted both for ball screw health monitoring (Lee et al., 2017) and a wire rod machine (Rødseth et al., 2016b).

A second proposed architecture for CPS classifies the digitalization of Industry 4.0 into two types of value chains: Horizontal and vertical value chain (Geissbauer et al., 2014). The horizontal value chain comprises suppliers, the company and its customers, whereas the vertical value chain comprises activities in the company such as sales, manufacturing, service and product development.

A third proposed CPS architecture is "reference architecture model industry 4.0" (RAMI 4.0). Currently, a PAS (publicly available specification) has been developed for RAMI 4.0 (IEC, 2017). This specification does not fulfils the requirements for a standard, but is at least made available to the public. The core in RAMI 4.0 is to ensure cooperation and collaboration between technical assets which has a value for an organisation. RAMI 4.0 comprise a CPS architecture visualised with three dimensions:

1. *Layers*. In total six layers represent the information relevant for the technical asset: Business, functional, information, communication, integration and asset.
2. *Life cycle and value stream.* This dimension represent the life cycle of the technical asset.
3. *Hierarchy.* The hierarchy classifies the enterprise system into following categories: Connected world, enterprise, work centres, station, control device, field device and product.

RAMI 4.0 is developed from a more "Generalized Enterprise Reference Architecture Methodology (GERAM) which later was converted to three standards in late nineties. The GERAM was a extension of Computer Integrated Manufacturing (CIM) models which is an early enterprise or business model (Myklebust, 2002). The integration of GERAM and RAMI 4.0 from (Industrial Internet Consortium, 2016) shows the building block of a enterprise model that has interrelationships between organisational, process and product

structures. Members of the organisation are connected to process roles defining their work tasks. Competence are connected to process roles, goals are connected to the processes and products, and resources are connected to processes.

The GERAM later RAMI has a well-structured design and fit well with the generic demand of product, process and organisation. The link to the manufacturing system theory is therefore the last approach to include the product configuration and design process of disciplines like mechanics, cybernetic and material science on the physical side and planning activities, economical aspects and optimization processes on the logical side. Theoretically based on geometrical foundation and the methods within the theory that are related to concepts of connections. The analysis of the manufacturing systems is the prime area for the usage of this theory and is important to bring a science base into manufacturing. However how to succeed in developing, managing and operating such an enterprise model is still maybe the main challenge.

3 CONSTRUCTING A NEW CPS FRAMEWORK

Figure 1 presents the proposed CPS framework tailored for Norwegian manufacturing and process industry. With the motivation of establishing a value chain between vendor and the user (Geissbauer et al., 2014) a horizontal value chain has been outlined. In addition, inspired partly by the 5C architecture (Lee et al., 2015), a vertical value chain is also proposed to ensure that data from sensors will lead to smarter decisions. In total a CPS framework with two dimensions are developed.

The horizontal value chain consist of vendor (A), the production (B), and the customer where the end-product is consumed (C). At the vendor the asset is created and the support is provided from the vendor. The vendor can e.g. be a machine builder and supports with providing the maintenance programme. As pointed out by (Smart Industry, 2017) the maintenance could be totally outsourced where all maintenance activities are performed by the vendor and the machine is leased by the user. This will also require a more strategic alliance with the vendor (Batran et al., 2017). The production is where the asset, such as the machine is operated. At this location, an own maintenance management is located to ensure that the required technical condition of the asset is achieved with support from both internal and external maintenance resources. It is a crucial decision for the maintenance management to establish the most appropriate maintenance strategy relevant for the vendor. An important issue for the maintenance management to decide is the correct degree of maintenance outsourcing. The end-product is located at the customer where it is consumed. The customer value will be influenced by production where lack of maintenance can reduce the production assurance and result in late product delivery. Also a defect in production can be undetected and finally discovered by the customer. With application of real-time system, changes in customer requests will be ensured.

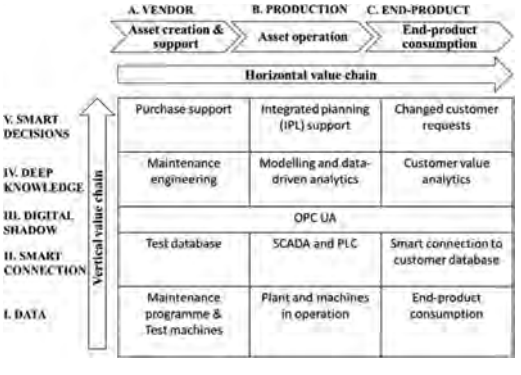

Figure 1. CPS framework.

The vertical value chain consist of six separate levels of data from assets (I) smart connection to assets (II), a digital shadow of the data (III), deep knowledge application (IV), smart decision application (V). At level I the asset is located that provides value for the organsiation. From the asset all relevant raw data is collected. The asset is not only the asset crated by the vendor such as the machine, but also other technical objects such as data servers, ERP-systems, algorithms and software programs. At this level the raw data is extracted from the physical assets, e.g. data capturing from a temperature sensor in a machine. The next level is smart connection (II) where data is extracted with SCADA and PLC systems and organized in databases such as ERP. To ensure that all databases can exchange data, an own level of OPC UA is necessary. In level IV, it will therefore be possible to apply deep knowledge analytics where databases at production and vendor can provide data-driven analytics in e.g. predictive maintenance.

In level V the deep knowledge analytics will support the decision maker with visualization and dashboards. This level can be considered to be a "digital advisor" for the decision maker. As an example in production, application of key performance indicators in integrated planning can support the planner to improve his future activities.

4 CPS ANALYSIS METHODS AND TECHNOLOGIES

4.1 *Life cycle profit*

Life cycle profit (LCP) is in this article defined as "*accumulated profit of a component or system over it's lifetime*". LCP presents the potential financial losses over the lifetime of a system due to the different time losses measured in overall equipment effectiveness (OEE) (Nakajima, 1989). The profit generated from the system after these losses is then LCP. Table 1 presents a proposed correlation between the time losses in OEE and LCP.

Figure 2 illustrates the LCP model, modified from Rolstadås et al. (1999). The area above the line x-x represents the time losses in accordance with Nakajima (1989). In addition, this area also distinguish between planned and unplanned maintenance. The reason for this distinction is that some of the planned maintenance require a shutdown of the machine and if necessary the production plant. If there are no time losses for the machine, it would be no area above the line x-x and maximum turnover would be achieved.

The area bellow the line x-x represents the costs that occurs during operation of the machine. In this model it is assumed that capital expenditure (CAPEX) is constantly scarred over the operation time. Both the maintenance costs and production costs will be decries in the start and increase at the end of the lifetime. The curve of line B-B will for the *bathtub curve* due to its characteristic shape and is due to the failure rate of the system over its lifetime (Sintef and Oreda, 2009, Rausand and Høyland, 2004). The bathtub can be divided into three specific phases:

- *Burn-in period.* This is an initial phase with high failure rate due to undiscovered defects. This is also known as "infant mortality".
- *Useful life period.* This phase is considered to be the useful period of the system where the failure rate is constant due to the maintenance activities.
- *Wear-out period.* In this phase, the regular maintenance activities can no longer keep the failure rate constant and it will decrease until the disposal of the system.

The LCP should be developed by the vendor with support from production in the CPS framework. With support from historical operations and loads it will be possible to achieve more accurate life cycle profit calculations.

Table 1. Time losses and LCP.

Time loss category	LCP element
Availability	Production Maintenance Resources
Performance	Degraded machine, energy loss.
Quality	Value of product before it is scrapped

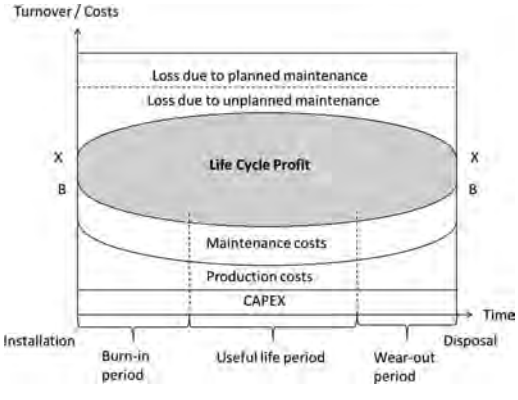

Figure 2. Life cycle profit model, modified from (Rolstadås et al., 1999).

4.2 *Safety perspective*

Regarding the safety perspective, following statements will be important:

- All corrective maintenance is deviation from required function.
- All maintenance activities will have a risk potential.
- Good maintenance is a pillar for effective and safe manufacturing and production.

The safety perspective will be of relevance of following situations:

- Accidents during maintenance
- Wrong type of maintenance
- Lack of maintenance

Table 2 presents a proposal of how these perspectives are relevant for the CPS framework.

4.3 *Machine learning and reliability engineering*

CPS plant position analytics in level IV with deep knowledge. It has been pointed by the European commission that intelligent maintenance systems based on condition prediction mechanisms with computation of remaining useful life (RUL) will increase reliability availability and safety (EFFRA, 2013). Furthermore, more sophisticated techniques for cause-effect and trend analyses are also

Table 2. Safety perspective in the CPS framework.

Safety perspective	Example of position of CPS framework	Example of Application in CPS
Accidents during maintenance	B. Production V. Smart decisions	Application of augmented reality.
Wrong type of maintenance	A. Vendor IV. Deep knowledge	Real-time notification to vendor in maintenance engineering.
Lack of maintenance	B. Production IV. Deep knowledge	Estimation of RUL in real-time with machine learning.

required. The deep analytics has been developed an integrated approach form machine learning and the need for zero defect manufacturing (ZDM). With intelligent sensor system ZDM can be operated for short term, medium term and long term decisions in the EU-project IFaCOM (intelligent fault correction and self-optimizing manufacturing systems) (Rødseth et al., 2016a). It has also been argued that maintenance could be one part of the IFaCOM concept. When advancing towards novel predictive maintenance technologies with reliability-based maintenance approaches, it is pointed out that this should include quality-maintenance methods as well as failure modes, effects, and criticality analysis (FMECA) (European Commision, 2016). Thus it is in this article of interest to investigate how FMECA can be balanced with big data analytics such as machine learning.

The maintenance model called deep digital maintenance (DDM) comprise an artificial intelligence module that tested remaining useful life (RUL) prediction based on dataset of degradation simulation run-to-failure data of jet engines (Rødseth et al., 2017). The output of the prediction model is the probability that RUL is more than 10 cycles in a specific point in time, denoted as $P_t(RUL > 10)$. One cycle is a magnitude for time, e.g. one week.

The prediction model should also include some error estimate to indicate the accuracy. Predictive maintenance should improve the maintenance planning capability in the organization where the plant capacity is increased as well as improved utilization of maintenance resources. The latter can be controlled by capacity overview (Liebstückel, 2014). Due to the operational conditions of degree of prediction in predictive maintenance and the available capacity of the craft technicians, the maintenance window needed by the maintenance planner will vary. Liebstückel (2014) has exemplified the

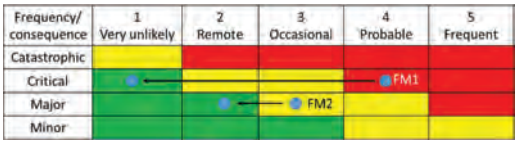

Figure 3. Risk matrix from FMECA, adapted from (Rausand and Høyland, 2004).

maintenance window to be 10 weeks when the planner shall conduct a capacity evaluation.

FMECA evaluates the risk of each failure mode and risk reducing measures. The risk of each failure mode may be positioned in a risk matrix shown in Figure 3 (Rausand and Høyland, 2004). The decision criteria for the risk matrix is as follows:

- *Red area.* The risk is unacceptable and risk reducing measures are required.
- *Yellow area.* Acceptable level of risk. The risk should be as low as reasonable as possible. Further investigations should be considered.
- *Green Area.* Acceptable level of risk. Only consider to keep the risk as low as reasonable as possible.

When the relevant failure modes has been evaluated in FMECA, it is further possible to evaluate to what degree implementation of machine learning in predictive maintenance can reduce the frequency of each failure mode. In the risk matrix, there are two failure modes denoted FM1 and FM2. The failure mode FM1 has non-acceptable risk whereas failure mode FM2 has acceptable but should still be investigate further for risk reducing measures. For both FM1 and FM2 predictive maintenance with machine learning is considered. To reduce the risk for FM1 to the green area, high accuracy in machine learning will be required. For FM2, it is not required the same accuracy in machine learning in predictive maintenance to reduce the risk to the green area.

Following criteria must be considered when evaluating the reduction of frequency due to implementation of predictive maintenance as risk reducing measure:

- The needed maintenance window and the accuracy of the trained data set.
- The similarity of operational conditions from the trained data and the predicted data.

5 ROLLING OUT THE CPS FRAMEWORK IN ORGANISATIONS

In a Norwegian perspective implementation of a CPS framework has to be followed up by guide-

lines and tools for fulfilling the expected impact. The Norwegian industry is probably one of the most organized labour markets in Europe and consist generally of small and medium size businesses. Where the labour policy for decades has been based on a tripartite cooperation between the government, trade unions and enterprise federations. The result is a flat structure where the involvement of skilled and self-dependent workers has been essential for competing in a global market.

The expectation of digitalizing Norwegian industry is therefore improved performance and a higher productivity. However, thru different maturity mappings, literature and surveys we can see the complexity in CPS and Industry 4.0 is broad. There is an image of a leadership which request for change, but do not find the right tools on one side. On the other hand, impatient workers with high digital competence and a mix match of equipment not prepared for digitalization. (Eleftheriadis and Myklebust, 2017)

A development of regulated safety and quality cultures is one of the benefit from such an organised labour where structure for reliable quality systems, preventive maintenance and management methods are implemented and where the improvement is a part of the organised culture.

6 CONCLUDING REMARKS

The aim of this article is to present the current status of CPS framework and how it can be implemented in Norwegian industry. With sound concepts of CPS theory a framework was proposed to be implemented for Norwegian industry which is both vertical and horizontal integrated. Also the analysis methods LCP and FMECA and different technological application for the safety perspective was recommended for the CPS framework.

The benefit of the CPS framework is that it can integrate all relevant data at sensor level up to decisions at plant level and at the same time connect the horizontal value chain including the machine builder, industrial user of the machine and the customer that consumes the end-product. As an impact for the industry it is expected that the value creation of this framework will be measured in terms of improved asset utilization with improved availability as well as improved product quality with reduced scrappage.

CPS plant will require parallel work with both vertical and horizontal integration of the CPS framework. Further work for the vertical integration will require specification of data capturing including establishment of a detailed specification of sensors that are to be applied in the project. For the horizontal integration, identification of interfaces in the horizontal value chain should be identified and mapping the value across companies.

Further work of the safety perspective would be to build a list of recommended application in CPS framework based on Table 2 and evaluate the reduction of risk. For the LCP, the horizontal value chain should be mapped when the vendor develops the LCP with support from production. The further development of FMECA would require more cooperation between the reliability engineering and machine learning. In detail, this would require simulation where the accuracy of the trained algorithms in machine learning calculates the failure rates as an input for the risk matrix.

For the implementation of the CPS framework, further work would require a detailed road map for Norwegian industry based on findings in demonstration of the CPS framework as well as involvement with several Norwegian companies within manufacturing and process industry.

ACKNOWLEDGEMENT

The authors wish to thank for valuable input from the research project CPS-plant.

Integrated analysis system for elevator optimization maintenance using ontology processing and text mining

M. Nagasaka & M. Sato
Corporate Research and Development Center, Toshiba, Japan

E. Kinoshita
Toshiba Elevator and Building Systems Corporation, Japan

ABSTRACT: In recent years, analysis methods using sensor data and record data acquired through the provision of maintenance services for social infrastructure equipment have attracted considerable attention. We focus on optimal replacement of elevator components. Features of elevators include that they move continuously for a long time without any operator and their proportion is high among social infrastructure equipment. We define five steps in the analysis of maintenance services for social infrastructure equipment. We have developed an analysis system consisting of life-limited component analysis, replacement planning simulations, and service performance analysis. The analysis system uses a combination of functionality of machine learning, such as ontology processing, text mining, and facility-type clustering in order to handle various types of facility data.

1 INTRODUCTION

In recent years, analysis methods using sensor and record data acquired through maintenance services for social infrastructure equipment have attracted considerable attention (Mobley, K. 2008, Narayan, V. 2004). Generally, social infrastructure equipment such as elevators and escalators require inspections and repairs by experts with special knowledge and skills. Experts visiting a site to maintain equipment usually prepare maintenance reports. In this paper we consider maintenance service data accumulated from elevators for a period of over twenty years.

Elevators are in continual operation without operators and are a very common form of social infrastructure equipment. Since there are various types of elevators installed in various building environments, it is important to consider these variations when analyzing the elevator data. Experts have compiled large datasets while providing elevator maintenance services. Elevators have thousands of components and database formats change over time, and there are also variations in how individual experts record maintenance data.

The remainder of this paper is organized as follows. In Section 2, we describe an integrated analysis system for maintenance optimization. In Section 3–5, we describe the elements of the system. Finally, we present conclusions in Section 6.

Figure 1. Integration of analyses for maintenance optimization.

2 FAILURE ANALYSIS

We define five steps in the analysis of maintenance services for social infrastructure equipment: (1) function diagnosis, (2) identification of factors that account for irregularities, (3) irregularity prediction, (4) maintenance planning based on predictions, and (5) verification of facility performance. The Plan–Do–Check–Act (PDCA) cycle is a widely known method for facilitating management tasks.

This study aims to improve maintenance services by developing data mining methods and simulation methods that consider the five analysis steps and the varied forms of elevator maintenance data. We pay particular attention to replacement planning for elevator components. We have developed an analysis system consisting of life-limited component analysis (Yano, T. et al. 2013) with statistical

survival analyses (Nelson, W. 2011), a naive Bayes model (Hsu, C.N. et al. 2000), and mixed survival analyses; replacement planning simulations with facility-type clustering; and facility and service performance analysis with a naive Bayes model and ontology processing using maintenance record data and troubleshooting data. To accommodate various facility data, the analysis system combines machine learning with functions such as ontology processing, text mining, and facility-type clustering.

3 CONSTRUCTION OF SURVIVAL MODEL

This section describes failure analysis in our system for diagnosing component failure, identifying equipment attributes that affect failures, and predicting failures. Survival analysis is generally known as a statistical modeling method for irregularities, commonly used in medicine, reliability engineering, and other fields. From the survival model of a component, we can calculate the probability of survival at a future time or after some number of uses following installation. Constructing a survival model requires "right-censored data," in which conditions are specified when the components are replaced. We used survival analysis to construct survival models of elevator components from maintenance records in order to apply those models to prediction of component failure. The maintenance records were composed of equipment master data, troubleshooting data, and regular operation data. However, to specify the conditions under which components were replaced, it was necessary to use handwritten reports of troubleshooting data, which used a variety of expressions to some extent.

To collect troubleshooting data associated with a target component, we use a naive Bayes model often used for text mining. Figure 2 shows a sample of troubleshooting data, which includes the date of occurrence, replacement component ID, trouble classification, treatment classification, and a detailed description. To allow the model to search for motor failure in troubleshooting data, we added "trouble classification" and "treatment classification" categories to the learning data as explanatory variables. Additionally, keywords such as "motor" and "electric mt" (mt: motor) in "detail description" are automatically extracted from maintenance reports in the troubleshooting data and added to the training data. A naive Bayes model is constructed from the data using positive and negative examples. The models can be used to search data sorted from high to low relevance and to select from among them based on a probability threshold parameter. Figure 2 shows how processing occurs. The naive Bayes failure search model thus uses threshold parameters to collect various component failure data.

We next describe construction of component survival models. The upper part of Figure 3 shows right-censored data for survival analysis, where the target component is replaced twice in equipment 1 and once in equipment 2. In the figure, "N" means normal and "F" means component failure at replacement. "N" is collected from regular operation data and "F" is collected using failure search model from troubleshooting data. The short line on the left indicates the start of maintenance service, and the line on the right indicates the analysis date on which the data were collected for survival analysis. There are only three cases (solid lines) in the component replacement database. Right-cen-

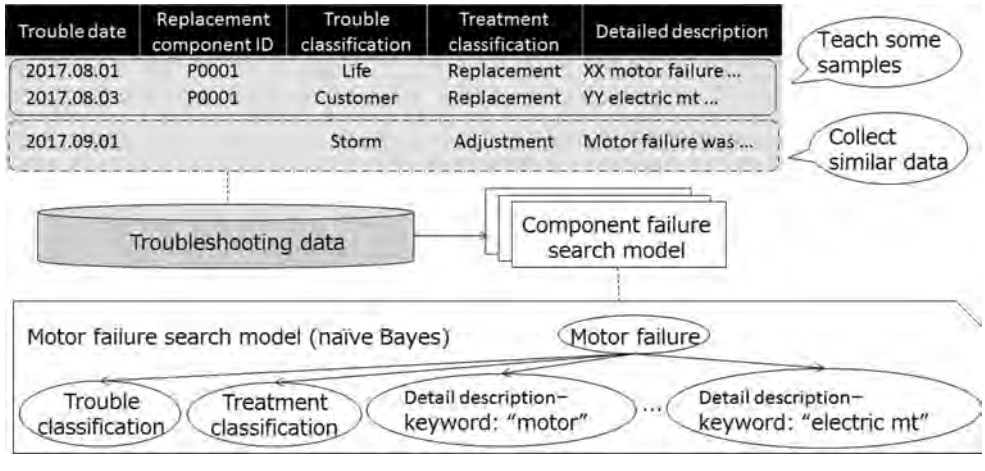

Figure 2. Component failure search model using text mining.

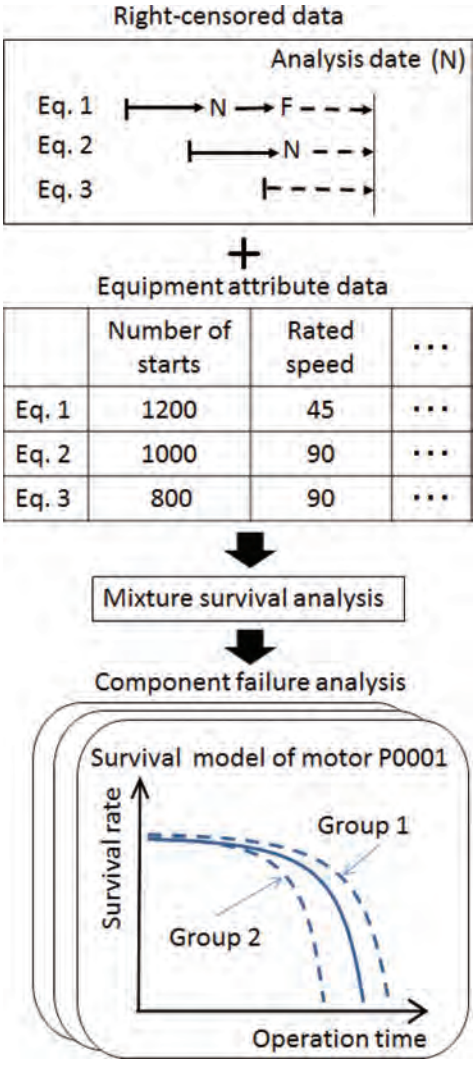

Figure 3. Censored data with attribute data, and survival models.

sored data must include six cases in addition to the above three cases, as indicated by the broken line. These three cases are assumed to be under normal conditions when we analyze the data. The solid curve in Figure 3 shows a survival model obtained from these right-censored data.

We adopt mixture survival analysis for components with many failure cases. Figure 3 shows differing equipment conditions such as number of starts and rated elevator speed. In this case, no components deteriorate over time over a fixed period. We thus split equipment into groups and create a component survival model for each group. A group consists of components with higher tendency to fail.

As described above, we specify component failure according to similar maintenance reports extracted using a naïve Bayes model. We generate right-censored data and conduct mixture survival analyses, and construct a survival model to predict irregularities and to identify factors that account for irregular functioning. We constructed about 100 fault-search models and about 2000survival models using the data mining methods.

4 MAINTENANCE PLANNING SIMULATION

This section describes the maintenance simulation used in our analysis system for maintenance planning. For maintenance planning using component survival models, we adopted simulation for estimating equipment maintenance costs and failure rate. This simulator should be able to accommodate various equipment types and components. Obtained simulation results can be applied to component replacement planning or budget management at individual branch offices.

Figure 4(a) shows an actual system in which users can visually grasp survival models. The left side of Figure 4(a) lists elevator type. When a user selects an elevator type, a list of components that make up the selected type is shown on the right. When the user selects a component from the list, a maintenance rule editor for that component is shown in the center. They can configure the maintenance rules for obtaining the desired simulation results and can set acceptable component replacement years through trial and error. The survival models of individual components are shown on the right. Component IDs and component names are shown in the maintenance rule editor. Users can specify the elevator types to which a rule applies. They can also configure replacement operations, component acquisition costs as replacement cost, and maintenance type, and can perform queries using elevator attributes or replacement years. By executing simulations after configuring the above items, lifecycle maintenance costs and component failure rates are calculated using the survival models, component ontology, and the elevator master data containing the attributes. Relations between equipment types and mounted components are organized as components in ontology data. Users can configure maintenance rules for obtaining the desired simulation results and can set acceptable component replacement years through trial and error. Other values (1) indicate maintenance costs for preventive maintenance:

$$\text{Replacement cost} = \text{Acquisition cost} + \text{Replacement operation cost} \quad (1)$$

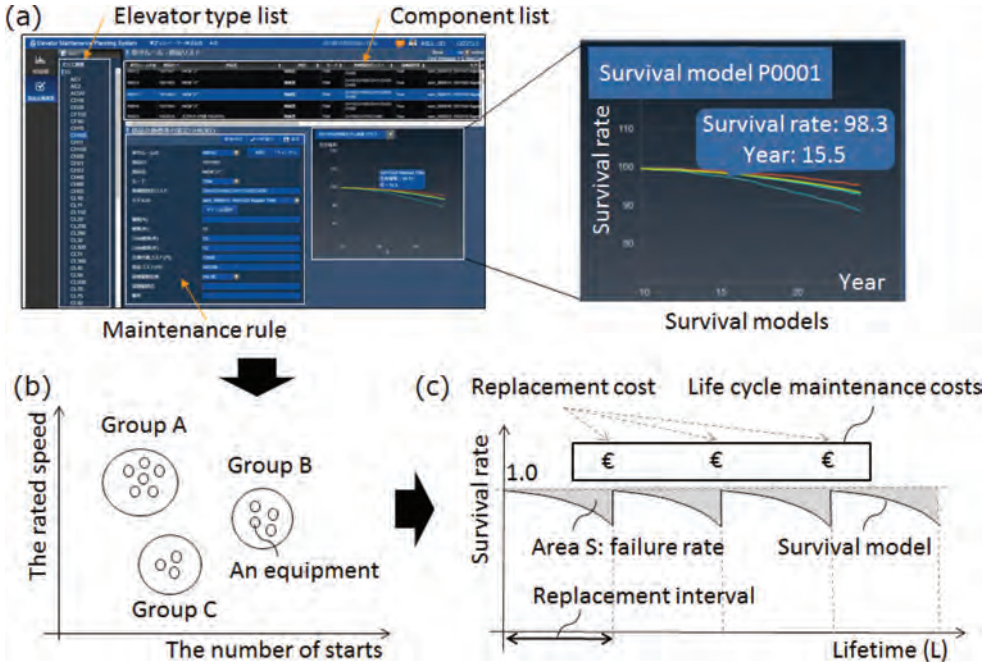

Figure 4. Life-cycle model and maintenance plan simulation. (a) Maintenance planning simulator. (b) Equipment grouping. (c) Life-cycle simulation.

To calculate simulation results rapidly for various elevator types, we previously used elevator master data to find groups with similar attributes and adopted these patterns for the principal elevator types. Figure 4(b) shows the simulation process for maintenance planning using equipment groups. When providing a simulation, it is necessary to know in advance the number of elevators belonging to a group and the patterns of principal types. It is also necessary to calculate the number of components attached to each elevator and to multiply this by the number of elevators to calculate the maintenance costs. After generating patterns for principle types, we proceed to life-cycle simulation. By using the above methods, we can perform simulation faster than by calculating the data for the elevator.

Figure 4(c) shows the calculation of life-cycle maintenance costs and component survival rates using the survival model. In the graph, the horizontal axis represents elevator life-cycle time and the vertical axis represents component survival rate. As the graph shows, the component survival rate gradually decreases. Area S represents the component failure rate, and dividing this by lifetime L gives the annual component failure rate. Costs are incurred at each replacement interval set by the users according to the maintenance rules. Life-cycle maintenance costs represent total costs.

Users can configure complex maintenance rules in the mixture survival model using attributes such as number of starts, and rated speed. Many elevator types require treatment of operation data from more than one hundred thousand elevators. There are too many elevator types to perform exact simulations for all types because of the amount of time needed. Therefore, we prepared about 10–20 typical groups using ontology processing to represent elevator types, principle patterns, and the number of standard components by elevator type. Users can configure the maintenance rules for obtaining the desired simulation results and can set acceptable component replacement years through trial and error. Utilizing these functions, organization staff can analyze information associated with component replacement based on actual maintenance data to determine repair and maintenance strategies. This is expected to aid with drafting plans for better maintenance services. By applying operation data such as those shown in Figure 4, users can analyze and update current maintenance records every day.

5 MAINTENANCE KEY PERFORMANCE INDICATOR ANALYSIS

As the previous section shows, we have focused on elevator component replacement planning

that uses cost and failure rate simulations based on a survival model. This section describes Key Performance Indicator (KPI) analysis applied to maintenance in our analysis system for checking facility performance of maintenance services to verify the consequences of a component replacement plan through simulation. Performance indicators need to include the number of component issues that arise when maintenance rule are changed. Down time, maintenance costs, and workloads are frequently used service indicators for maintenance. We developed analysis functions to calculate trouble incidence rates and component troubleshooting time.

Figure 5 shows the architecture of the maintenance KPI analysis system. These KPI analysis functions use maintenance records such as operating data, troubleshooting data, and equipment master data. Maintenance staff record regular inspections and maintenance reports along with troubleshooting reports describing situations of urgent site visits for unplanned maintenance. These data include handwritten reports as described in Section 3. Because there are various elevators types with tens of thousands of components each, the data analysis requires summarization methods. For this purpose, we prepared various ontology processes and failure search models using naive Bayes modeling.

Figure 6 shows a sample of the ontology processing function. The central table lists the replaced components. We created an equipment component ontology to determine equipment and components with higher tendencies for failure. The ontologies express thousands of component groups in four stages, allowing users to summarize large classifications such as "machine room" or "equipment type" or sub-stages lower in the hierarchy. This allows analysis of various component types among similar groups.

We also introduced a failure search model using a naive Bayes model to treat various handwritten texts. We showed a naive Bayes model for searching through troubleshooting reports of motor failure in Figure 2, and also adopted the model for searching for similar data in the maintenance KPI analysis system because the analyzed data includes handwritten reports. For example, natural disasters such as earthquakes have an effect on the operation of elevators, but are not a diagnosis of the operation. Therefore, we also constructed a naive Bayes model that can treat "earthquake" as a positive example. In fact, the ability to search for incidents of natural disasters allows users to analyze rates of incidence data and remove data that are related to natural disasters. Switching components to types with a longer life also decreased the rate of component failure.

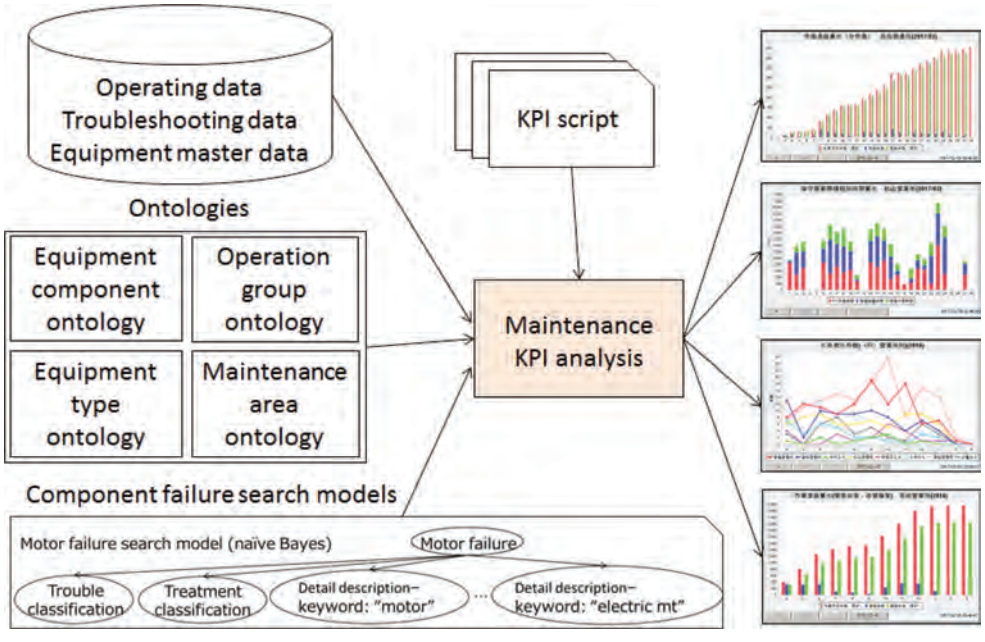

Figure 5. Maintenance KPI Analysis System with ontologies and component failure search models.

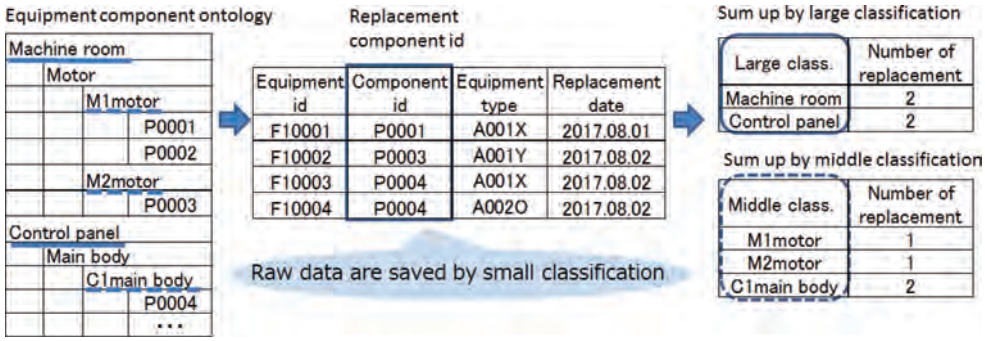

Figure 6. Adopting ontology data.

As stated above, we developed a maintenance KPI analysis system that prompts for updates to the policies and survival models. System functions include analysis of each group using ontology data and similar search models using naive Bayes models. At present, the system uses not only survival analysis components, but also visualizations of various maintenance service circumstances for optimization of field maintenance tasks. It calculates about 1000 KPIs for a few hours every night.

6 CONCLUSION

This paper described algorithms applied to elevator analysis systems for prediction-based maintenance planning. We described construction of failure analysis using a component survival model, and maintenance simulation that utilizes the failure analysis. In addition to the simulation, we also added a maintenance KPI analysis that optimizes maintenance by incorporating long-term maintenance records. The system is designed to include features such as application to various equipment types and long-term operation for social infrastructure equipment. In future research, we intent to investigate replacement planning based on maintenance planning simulations and elucidate factors in component degradation using maintenance KPI analysis with the aim of constructing and adopting an advanced survival model.

Safety enterprise architecture approach for a railway safety management system

S. Khan
Riyadh Metro, Hill International ME, Riyadh, Saudi Arabia

C. van Gulijk
Railway Research Institute, University of Huddersfield UK

ABSTRACT: This paper finds an extended set of railway Safety Management System (SMS) goals to manage safety compliance, technological complexities, operational uncertainties and business objectives in a holistic perspective using Enterprise Architecture (EA) approach. It also presents a comparative analysis of EA frameworks for implementation of a railway SMS. We call this system Safety Enterprise Architecture System (SEAS). In the technique, a set of selected capabilities based on the proposed railway SMS goals and system requirements are evaluated from legal, business and information systems perspectives. The SEAS approach establishes that the prevailing new technologies, evolving social realities and changing market dynamics has made the case of railway safety management more complex. Alongside regulatory compliance, it should also mandate explicit goals of standardization, innovation, business transformation, and IT alignment at all levels. It was found that at present not a single EA framework exists that suits the target SEAS approach entirely but the open group standard TOGAF comes closest.

1 INTRODUCTION

The Enterprise Architecture is a strategy to develop an IT backbone to support the safety infrastructure that comprises of railway's people, processes and systems in order to align safety objectives, business requirements and their complex interfaces through a structured IT system. For adequate application in railway safety, the architecture should cover all aspects of safety management by providing a 'whole system' approach to design, plan, delivery and control as part of a company business (Lodzinski et al. 2007 and RTS & TSLG. 2012). It should enable safety compliance, facilitate strategic decision making, support innovation and realize an effective business transformation (NAS 2014, Aier et al. 2016 and Cooney & Paxton 2016).

The innovation and business transformation for safety management systems are part of a continuous improvement process for Railway Undertakings (RUs) and Infrastructure Managers (IMs) alike, but it remains fundamentally based on their existing business functions and operations to remain in conformity with the legal requirements (Lodzinski et al 2007).

This paper describes an EA strategy to facilitate the IT business transformation in the organizational pursuit to institutionalized safety as inbuilt quality. The section 2 of the paper gives the EA overview, discusses some popular EA frameworks and explores railway safety management background. Section 3 list down the target SMS goals. Section 4 discusses criteria selection to examine the proposed strategy. Section 5 is the comparison table of some carefully chosen EA frameworks against the selected capabilities. Section 6 discusses the result and section 7 ends with concluding remarks.

2 BACKGROUND

2.1 *Enterprise architecture background*

The comprehensive introduction of EA terminology is down to J. A. Zachman from his paper title "A Framework for Information Systems Architecture.", published in the IBM systems journal where he presented his Zachman grid to provide EA ontology (Zachman 1987). An EA framework presents a skeletal structure to define suggested architectural artifacts, their relationships and characteristics. Every EA framework typically embraces a reference enterprise architecture, a planning and implementation methodology, guidelines tools and common vocabulary (Ahlemann et al. 2012). For various perspectives, several alternative EA frameworks have been proposed and evaluated by academics and practitioners, each with different scope and activities, to support all aspects of EA lifecycle (Dang & Pekkola 2017, Nikpay et al. 2015, Susanne

& Zellner 2015, Rouhani et al. 2015, Odongo et al. 2010, and Urbaczewski et al. 2006). The case of EA application to railway safety demands appropriate framework selection to ensure safety compliance in the very changing environment of technological complexities, operational uncertainties and evolving social realities.

Previous studies recognized that railways operational safety depends on several data-dependent systems including signaling, infrastructure management, rolling stock, organizational safety, culture and human factors. Many accident investigators agree that lack of linkage in between these systems contributed to the substandard control of multi-causal accidents (Kyriakidis et al. 2012, Silla & Kallberg 2011, Evans 2011 and Baysari et al. 2008). The studies also highlighted the weakness of railway SMSs in implementation especially in the area of information management, organizational structure, role & responsibility and competence management. It also observed significant deficiency of processes for design and improvement related to risk assessment (Shang et al. 2017). Ultimately, EA paves the way for better integration of overall data on the railway through alignment of its business with IT infrastructure.

2.2 *Enterprise architecture frameworks*

This paper assesses four major EA frameworks Zachman, TOGAF, DODAF and FEAF. They are selected on the basis of their popularity and customization. They are described in brief below.

2.2.1 *Zachman framework*

Zachman Framework (Zachman 1987, Sessions 2007) provides a concise way to structure and model enterprise architecture. It is a two-dimensional grid with a set of six perspectives or views and five basic interrogatives. A perspective constitutes a row that depicts role for a stakeholder of the project team. The various stakeholders are the planner, owner, designer, builder, subcontractor and user. The columns of the grid represent a characterization of information for each perspective through what-data, how-function, where-network, who- people, when- timing and why- motive. The rows and columns thus intersect to create cells where each cell is resulting in an architecture activity depending on the system's aspect for a particular stakeholder.

Zachman framework is the most comprehensive of the EA frameworks which offer a series of views and visualization support as a planning tool to help better selections between the alternative options. However, it does not focus on the EA development and governance mechanism. It also could not provide appropriate software tools configuration and alignment to the innovation and new social realities. The framework does not explicitly offer support for nonfunctional requirements and system development lifecycle. The Zachman framework, although self-described as a framework, is more accurately defined as a taxonomy for organizing architectural artifacts.

2.2.2 *TOGAF*

The Open Group Architecture Framework (TOGAF) is very comprehensive with regards to actual process involved (Magoulas 2012, Rouhani et al. 2013). TOGAF's view of an enterprise architecture consists of business, application, data and technical architectures. The most important parts of TOGAF is the Architecture Development Method (ADM) for process development, the enterprise continuum for various architecture views and the knowledge base repository for resources, implementation guidelines, templates and background information.

It provides appropriate strategy and governance supports for the designing, planning and implementing of an architecture based on the enterprise requirements. It utilizes appropriate models for both IT and enterprise activities. TOGAF-ADM is a step-by-step process performed in creating EA and consists of a preliminary phase, followed by eight transformation phases that guide the users through various levels of architecture maturity in a managed manner through the transition. TOGAF is flexible and allows phases to be performed incompletely, skipped, combined, reordered, or reshaped as per the stakeholder's requirement to fit any organization's needs. TOGAF views the world of enterprise architecture as a continuum of architectures, ranging from highly generic to highly specific. It document design rationale to trace design and architecture decisions.

TOGAF is lacking instructions to clearly describe the output specifications of each development cycle and missing the organizational role and responsibilities. Although strong on business and architecture perspectives, it is short in detail from planning and maintenance aspects.

2.2.3 *DODAF*

The Department of Defense Architecture Framework (DODAF) is developed by US defense to provide a holistic support platform for its agencies goals transformation. Its overall orientation is different in solving the EA issues. DODAF (Odongo et al. 2010) uses model templates to collect and disseminate information data on a specific issue resulting in a view or perspective. In DODAF 2.0 there are eight prescribed perspectives. Its architecture development process consists of six steps of context definition, scope, requirements, perspectives, development and application.

DODAF in acceptable manner supports the concept, modeling and process phases of EA life cycle. Its overall characteristics in the target system implementation reside in the same area with TOGAF with little lower in grade.

The issue with the framework is that there is no complete governance guidance, social, financial and technical analysis is available to support the system objectives. The lack of enterprise integration and software configuration support contradict its application in a dynamic environment. Also, it offers limited support to nonfunctional requirements of consistency, design traceability and verifiability.

2.2.4 *FEAF*

Federal Enterprise Architecture Framework (FEAF) of US government is to facilitate the shared development of common processes and information among US federal entities (Odongo et al. 2010, Sessions 2007). FEAF is based on Zachman framework, but refers only to the first three columns that represent what-data, how-function and where-network respectively and focuses on the top three rows presenting various perspectives to provide standard terms and definitions through Business Reference Model (BRM), Components Reference Model (CRM), Technical Reference Model (TRM), Data Reference Model (DRM), and Performance Reference Model (PRM) with each have unique goals. It uses architecture analysis, architectural definition, investment and funding strategy and program management plan as a four-step process for creating an EA.

FEAF is the most complete of all the methodologies discussed here. It has both a comprehensive taxonomy, like Zachman, and an architectural process, like TOGAF. It supports vision, strategy and knowledge base repository for EA planning. It allows flexibility in the use of tools and has standard practices for interoperability.

FEAF is primarily a framework for architecture planning rather EA development and maintenance. A part from system security, FEAF does not explicitly support other non-functional requirements and offer limited support on plan validation and traceability.

2.3 *Safety management background*

Different countries developed different railway Safety Management Systems (SMS) based on the operational circumstances and legal requirements. In Europe, the systems are guided by the Common Safety Methods (CSM) to be used as a solid basis to support the design and implementation of their SMS. The approach thus resulted in a number of SMSs but a reasonable degree of agreement can be achieved on what a standard SMS must cover. It shall contain all the processes and procedures describing activities related directly or indirectly with railway safety both at an organizational and operational level.

Although recent technological advances and development of railway SMS guidelines and standards assist operators to perform their duties efficiently, railway accidents still occur due to a complex interaction of its components systems and interface management shared between many actors functioning in fragmented collections of standalone or silo-based systems and processes. These silo systems include both older in house developed systems and a number of best available in the market commercial off-the-shelf solutions which are selected to meet their local business needs (Aier et al 2016, Clayton 2010, Cooney & Paxton 2016). Therefore, to couple the overall business with the current intelligent communication systems, sophisticated and extensible customer systems with cross-silo integration components are purchased at high cost without any future roadmap but only to provide opportunistic solutions to keep running the system. This approach literally lacks a holistic enterprise perspective of central IT functionality. The future highly automated railway operations anticipate innovation with information systems for business agility and safety requirements, leading to standardization and integration, at all levels. It is the enterprise architecture, SEAS, which can provide the desirable platform to deliver the greatest business value through reliability, interoperability and safety using a whole system unification of enterprise entities, railway systems and people.

3 SAFETY ENTERPRISE ARCHITECTURE

To appraise the proposed SEAS approach for a railway SMS in the ever-changing economic, regulatory and technical environments involves many considerations. A typical safety management system is driven by key guidelines originating from the CSMs for supervision, monitoring, risk evaluation, conformity assessment, and national legislations for effective safety management. Key elements of railway SMS are listed below (EU Railway Safety Directive 2004):

- Staff commitment
- Transition or migration
- Information management
- Emergency and crisis management
- Compliance assurance
- Accident/Incident reporting
- Continual improvement
- Gradual and step by step implementation
- Roles and responsibilities

- Competence management
- Change management
- Tools for monitoring
- Risk assessment and evaluation
- Strategies to achieve targets
- Documentation
- Assets management and maintenance
- Internal audits
- Standard Glossary

Implementation of these elements is essential for regulatory compliance and a railway SMS should establish specific targets and formulate relevant assessment criteria for achieving these targets to ensure the realization of safety complaint operations. A typical railway SEAS, in addition to these legal requirements, should achieve a number of other goals listed below as part of its strategic plan for a financially beneficial railway (NAS 2014, Tang et al. 2004, Aier et al. 2016, RTS & TSLG 2012, Lange & Mendling 2011, Lim et al. 2009, Magoulas et al. 2012, and EU S2R 2015). It will result in a blueprint for Safety Enterprise Architecture. Ideally, this blueprint should support the SMS independent of railway system geography, industry size, operational domain and architecture style.

- Regulatory Compliance
- Transparency
- Complexity Management
- Business-IT Alignment
- Configuration Management and Control
- Harmonization & Standardization
- Business Transformation
- Innovation
- Risk Control Measure for all risks associated with IM/RU, maintenance and assets management, subcontractors and other parties, reputational risks.
- Architecture Maturity
- Agility
- Soft aspects
- Standard Glossary

4 METHOD FOR CRITERIA SELECTION

This research is divided into foundation ground work, system requirements and SEAS capabilities identification and evaluation. For the purpose, a systematic literature review of relevant research articles was carried out. A set of research questions related to SEAS capabilities and framework selection are formulated and discussed with railway experts.

RQ1: What system aspects should be considered for SEAS?

In order to answer the first question, the SEAS can be divided into the following five aspects:

- Operational Safety: Railway SMS external goals are regulatory driven. The IM/RUs should fulfill community requirement to ensure safe railway operations through continuous improvement, adopting a system-based approach and assigning of responsibilities (EU railway safety directive 2004, Lodzinski et al. 2007, ORR 2015).
- Business Support: These are related to railway SMS internal goals related to cost reduction, new business initiatives, improve decision making, and risk management (Aier et al. 2011 and Lange & Mendling 2016).
- Information Technology System: This aspect is related to organization information resources, information systems, architecture tools, implementation models, software configuration and operating platforms (Urbaczewski & Steven 2006).
- Qualitative or Non-functional: It is the system ability that the characteristic of its offered service or a product satisfies the user's requirements. Therefore in railway SMS case we have to define the user's demands to understand the quality. Under the quality or non-functional aspects the following items are collected for EA framework analysis: interoperability, flexibility, reusability, scalability, standardization, Alignment, reduce risk, reduce complexity, integration, better and faster service, communication, innovation (Lim et al 2009).
- Social and Cultural: Safety has relative levels in relation to different situations and environments. Also the increasingly unreliable and demanding customers require through consideration in to which product or services to offer at any given time to ensure safety in operation as well mitigate reputation risks (Magoulas et al. 2012).

RQ2: What capabilities the proposed railway SEAS should have?

From the SEAS goals listed in section 3 in conjunction with required system aspects discussed in question 1 above, forty-two (42) capabilities are identified. The system should attain these capabilities through the best practices implementation by achieving set targets through gradual transformation and improvement of the system (Zamermann et al. 2015, Aier et al. 2016, Tung et al. 2004, Nikpay et al. 2017).

RQ3: Which of the EA frameworks is more relevant for railway SEAS implementation?

The question deals with the already established EA frameworks in various categories. These include Zachman from commercial frameworks, Open Group Architecture Framework (TOGAF) from open group frameworks, FEAF from government frameworks and Department of Defense Framework (DODAF) from defense frameworks (Jacco 2014, Nikpay et al, 2017). TOGAF is capa-

ble to be used as a general framework in any enterprise with modifications and therefore replaces GERAM and RM-ODP in that category. FEAF is the complete methodology with ZF-like classification and TOGAF like structural design process and excels over the TEAF in the federally developed frameworks category (Tang et al, 2004). DoDAF version 2.0 is an evolution of the C4ISR and NATO framework due to a limited application was dropped and replaced by DODAF.

Table 1. Comparison of EA Frameworks for SEAS.

CAPABILITY	ZF	TOGAF	DODAF	FEAF
Strategic Vision and Goals	H	H	M	H
Architecture definition	M	H	H	H
Architecture Development Process	M	H	H	M
Process Completeness	L	H	M	M
Architecture Verifiability	L	H	L	L
Transition Strategy and Plan	L	H	H	H
Tool Support	H	M	M	M
Information Reference Resources	H	H	L	L
Standardization	L	H	H	M
Step by Step guidelines	L	M	M	M
Continual	L	H	L	L
Architecture Evolution Support	L	H	H	H
Governance guidelines	L	M	L	M
Integrating enterprise systems	H	H	M	H
Business Alignment	H	M	M	L

Costing and Vendor Supporting	M	H	H	L
Meta model	M	L	M	M
Maturity Model	L	M	M	M
Enterprise Knowledge Base	L	H	H	H
Taxonomy Completeness	H	M	M	M
Vendor Neutrality	M	H	L	M

RQ4: How different frameworks are compared?

Three relative conformance levels (High, Medium and Low) based on the support each framework support to a capability are developed. If a framework explicitly supports a capability element in the table 1, it is marked as High (H), if partially support then marked Medium (M) and Low (L) in case of little or no support at all.

5 EVALUATION OF EA SYSTEMS

A SEAS capabilities list was developed as summarized in table 1 below based on the already done research in this area and produced here in citations. It provides a high level comparison and analysis of the selected EA frameworks.

From Table 1 outcomes of various frameworks are summarized based on the support they offer to the capabilities. In the current analysis, only considering the clearly supportive option (H) for suitable EA framework selection, ZF accrued 15 Hs, TOGAF has 30 Hs, DODAF has 16 Hs and FEAF has accumulated 13 Hs. In consequence, TOGAF, although does not meet overall criteria, emerged the most suitable preference.

6 DISCUSSION AND LEARNING

The current studies provide discussion platform for reconsideration of railway SMS goals and implementation approaches.

6.1 *Revamping railway safety management*

The current studies introduce business aspects and soft aspects of the railway safety management pursuit of attaining whole system approach. The typical safety management systems currently in sway in rail and metro industry rely on hard aspects to focus on safety compliance in supervision, monitoring, maintenance and improvement within their existing operational boundaries which is an inappropriate and outdated approach in the very changing environment. In today's world, the railway like all other safety-centric industries especially to mention, airline and space industries, is changing hands from public to privately operated corporations. The underlying drivers behind these handing overs are fundamentally based on business objectives. The market competition and survival threat compel every entity to deliver as per customer satisfaction with excellence in operations where safety matters at the center. We therefore suggest revamping of the European railway agency SMS wheel to cater for business objectives and soft

aspects in order to align with new social realities and market dynamics.

6.2 *EA framework selection*

EA implementation can be independent of any framework however it provides a roadmap and tools to capture requisite information and model them to avoid any panic. The results of the above comparison in perspective of railway SEAS objectives indicate that each enterprise methodology has its strengths and weaknesses and none of them is categorically complete. The Meta model, maintenance, dynamic and soft aspects are the issues which are not supported by all selected EA frameworks.

7 CONCLUSION AND FUTURE WORK

This paper presented EA application to an implementation of a railway SMS in order to develop SEAS. The new approach which is based on holistic perspective is to partner the safety regulatory requirements and business objectives of RU/IMs in a business transformation support in the face of system complexity, operational uncertainty and new social realities. The purpose of the paper is to evaluate different well- known EA frameworks methodologies to narrow down on the selection in order to support a future railway SEAS that is capable to shape norms and values of railway organizations. It also attempt to establish EA as the definitive solution and formulate parameters of a standard SEAS to ensure its optimal realization. Any of the existing EA frameworks can provide guidance for EA implementation to a certain degree and TOGAF scores higher in the case due to a number of distinctive capabilities. It uses architecture development in incremental step by step guidelines and supports the enterprise architecture modeling with detailed descriptions in order to effectively address critical business needs. The methodology also establishes a common set of risk and security concepts and demonstrates mapping to the implementation languages and tools leading to build a shared understanding and response strategies to ensure traceability and verifiability. Nevertheless it is not complete enough to meet the railway RU/IMs specific requirements in the area of business and socio-cultural alignment, risk management implementation and innovations support.

The SEAS goals set in this studies are not final and the related capabilities should evolve with architecture maturity. In the current assessment scheme all the capabilities are given equal weight irrespective of their risk exposure and manageability. In future studies some type of quantitative analysis will be considered based on relative scoring technique for EA framework selection.

A computer leaning approach to obtain safety information from multi-lingual accident reports

P. Hughes, M. Figueres-Esteban, R.A.H. El Rashidy & C. van Gulijk
Institute of Railway Research, University of Huddersfield, Huddersfield, UK

R. Slovak
Federal Office of Transport, Bern, Switzerland

ABSTRACT: Accident reports provide a valuable source of data for any safety management system. In multi-lingual jurisdictions, accident reports can be provided in more than one language. For example the Swiss transport authority collects accident reports that are written in either German, French, or Italian. The unstructured nature of free-text makes it difficult to extract information from large numbers of accident reports. Machine-reading of text is an emerging area of research, however there are few instances of information being extracted from text in more than one language.

This paper introduces an ontology-based interactive learning method between a human and computer software to identify safety-related information by analysing text written in three different languages. The results of the method were analysed by fluent speakers of each language, who rated the overall accuracy of the method to be 98.5%.

The method stores and processes the data in a NoSQL graph database, which provides a powerful tool to readily integrate the analysis with other data sources, for example train movement data, passenger census data, or even comparative data from other railways.

1 INTRODUCTION

A large amount of information that is useful to safety is contained in natural language text reports, for example accident reports, hazard reports, or safety audit reports. Whist these data sources can contain valuable information, it is not easy to extract the information. Human-reading of large amounts of textual data is slow and error-prone and, if the task is divided amongst a large number of readers, then differences in interpretation can occur. Machine reading of text is an emerging area of research which has the potential to provide useful information from large text sources, although there are still a number of problems to be overcome. No prior work has been found that has attempted to extract information from safety-related documents written in more than one language.

The Swiss Federal Office of Transport (FOT) collects textual data on safety incidents that occur on the nation's transport system. Switzerland is multi-lingual, and the text in the incident reports is provided in either German, French, or Italian. Each report contains information that could be useful to managing safety of the system, however no existing process is known whereby the information can be collated in a way that supports safety management.

This paper describes an ontology-based approach to obtain information from 5065 incident reports provided by the FOT. Incidents were classified into a number of categories including incidents that occurred: whilst passengers were boarding trains; whilst they were alighting trains; or as a result of passengers falling down stairs, caught by closing doors, or struck by falling baggage.

2 BACKGROUND

2.1 *Safety management of big data*

Modern approaches to safety management require organisations to collect information on accidents. It is very common for these data to include text that describes where and when the accident occurred; the context within which the accident occurred (for example weather conditions; activities that were taking place at the time); what injuries and damage resulted; what proximate and underlying causes led to the accident; what risk controls failed to allow the accident to occur; and recommendations to minimise and mitigate recurrence. The purpose of collecting such data is to support decision-making processes that consider information from different sources (for example safety-critical

work procedures, budget data, or legislative requirements) and take action to optimise safety management.

Professional safety management systems often collect information not only on accidents that have been observed, but also on incidents where safety risk controls have broken down but no injury or damage occurred, so called *near-miss* or *close call* events (Gnoni, Andriulo et al. 2013, Andriulo and Gnoni 2014, Macrae 2014). These accident and incident reports themselves can amount to a large quantity of data (Hughes et al., 2016a). Extracting information from these large data sources can be a challenge by itself; the problem is further complicated when the data is provided as free-text rather than structured machine-coded data. Combining data from such a large data source with data from other, potentially very large, data sources can be problematic. This data data management challenge is commonly referred to as *big data*. There is an emerging body of work describing the challenges of big data and techniques that can be used to extract useful information from the data. To obtain information that supports safety management, Van Gulijk et al. (2016) introduce the concept of Big Data Risk Analysis (BDRA), and describe the four *enablers* of BDRA:

- data and data-management,
- visualisation interface,
- analytics and software, and
- ontology and knowledge representation.

Figure 1 presents a schematic overview of the interaction of these enabling components. Each enabler is described below.

Data and data management is the initiating reason for BDRA. Modern organisations and their safety management systems collect large amounts of data with the intention of using these data to improve safety and safety management. Data may be collected from manual processes, such as workers completing forms as part of a safety-critical work process; from automatic systems, such as supervisory control and data acquisition (SCADA) systems; or from external sources, such as information on the internet regarding weather or traffic conditions. Collecting data on hazards, incidents and accidents is at the heart of modern safety management systems. The FOT has a database of thousands of reports describing all detected accidents on the transport network, including minor accidents, such as where a passenger fell over and sustained only very minor injuries. The data in the accident database is a valuable source of information that can be used to understand the causes of accidents and any underlying trends, and to determine actions that may minimise the likelihood of recurrence.

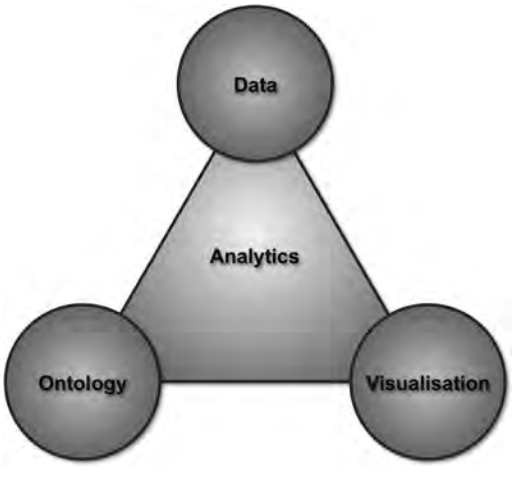

Figure 1. The four enablers of BDRA.

A *visualisation interface* is an essential component for understanding large data sources. Humans have a capacity for visualising concepts and their relationships, which is valuable for understanding big data sources which can contain thousands, or even hundreds of thousands of inter-related concepts. For example the safety management of an operating railway requires an understanding of concepts such as all types of rail vehicles including locomotives, carriages, wagons, and maintenance machines; all railway locations including track locations, stations, sidings, maintenance facilities; all organisations who operate within the railway including law enforcement organisations; users of the railway; routes and timetables *etc*. It is not feasible to expect staff who operate the safety management system to be able to visualise all these concepts and the multitudinous interactions between them without external support. Visual analytic tools facilitate the understanding of these concepts and include applications to help understand different categories of safety risks and the geospatial distribution of incidents and accidents. Such tools may even include visual causation models, such as bow-tie diagrams, that describe the chains of events that can lead to an accident and the risk controls that are in place to reduce the risk.

Analytics and software are the backbone of BDRA: modern data management systems are based on software and BDRA requires large software analytical capability such as that available on modern cluster computers or provided by cloud computing services. Several software services are required for BDRA in order to:

- store data in short-term stores and long-term archives;

- organise data into meaningful data units and transport it to the locations required for processing;
- pre-process data ready for analysis and format it as required;
- analyse the data to produce results that assist safety-related decision-making;
- collate results of the analytics and aggregate them as necessary;
- present the results—in a visual form—to analysts to allow understanding of underlying hazards, risks, controls, accidents and consequences;
- iterate through analysis depending on the findings of earlier analyses;
- store results of analyses to allow subsequent analysis to expand on the results of earlier work;
- oversee and coordinate all of the above processes and distribute computer resources in an optimal way.

The software tools to support these tasks may include traditional tools such as simple graphing tools and SQL databases, as well as technologies that have emerged in the past decade such as interactive visualisation tools, graph databases and massively parallel, distributed analytical tools.

Ontology is a structured method to classify entities within a domain and the interactions between them. An entity is any item that can have properties and interact with other entities. A simple example of an entity in a railway safety context are *trains* which have properties of rolling stock class, furthermore individual instances of trains have train numbers as properties. Trains interact with stations, track and passengers. Other examples of entities include tickets (which have properties such as valid dates and routes) and railway staff (who have properties such the job function and interact with people and organisations). Entities within an ontology may also be abstract, such as dates and times. Regardless of whether an entity is abstract or has a physical form, a defining feature of all entities is that they can be referred to by themselves; this differentiates them from *relationships* that require entities in order to be meaningful. An example relationship is that a passenger can *board* a train. Both the passenger and the train are entities that can exist by themselves. However the boarding relationship requires these entities to be present in order to be meaningful: boarding cannot occur by itself. The ontology provides a structure that allows data to be joined to the key entities that are relevant to safety management. For example as an instance of data, an accident report may be joined in an ontology to the station where it occurred; to the members of staff who responded; and to the date and time where it occurred. If the ontology contains an incident causation model, such as a bow-tie diagram, the accident report can also be linked to the particular risk control breakdowns that led to the accident and the outcomes that occurred. Individual stations in the ontology may be linked to the general concept of a station; individuals may be linked to the organisations for whom they work, and so on. In this way it is possible to structure queries of the data to request accident reports that occurred at particular stations, or at stations in general; or to identify staff responders from particular organisations. The ontology may also be linked to other data in the safety management system such as audit reports, or maintenance logs. In this way it is possible to identify accidents that occurred at stations where audits have not recently been performed; or accidents at locations where particular maintenance activities have occurred. Where the ontology contains dates or chains of causation, these entities can also be queried to extract precise and meaningful information to support safety management.

2.2 *Ontologies for data management and understanding*

Smith & Welty (2001) describe the traditional understanding of the word *ontology*, as being an ancient Greek concept that addresses the fundamental nature of reality. Aristotle established ten categories of reality *viz.*: action; habit; location; passion; position; quality; quantity; relation; substance or essence; and time (Ritter & Kohonen 1989). This ontology was established to address underlying questions in ancient Greek philosophy such as *what is real?* and *what can be said to exist?* A basic method for establishing an ontology can be considered in two stages: firstly observation and conceptualisation of the real-world domain; and secondly explicit formalisation of the of the identified concepts (Evermann & Fang 2010). Such a formalisation of the world into well-defined concepts that can be reasoned about in a meaningful way provides a framework that is well-suited to computational analysis of data (Searle 2006, Smith 1998). An open question in ontology research is the degree to which an ontology needs to be complete in order to support understanding and decision-making. The concept of a *naïve ontology* is discussed by Dahlgren (1995) which is an ontology that considers only objects and their classifications. For example a naïve ontology would consider a *passenger train* as being a type of *train*, which in turn is a type of *vehicle*. However such an ontology may not consider abstract concepts such as the concept of *lateness* in relation to a train running to a timetable. This *naïve* approach underpins the resource description framework established by the World Wide Web

Consortium as well as the approach taken by Noy & McGuinness (2001). Dahlgren (1995) asserts that the approach is sufficient to perform almost 80% of common-sense reasoning. Brewster and O'Hara (2007) argue that ontologies are particularly useful in well-defined domains such as individual organisations. Noy & McGuinness (2001) assert that the ontological approach to data management provides a valuable method to reuse domain knowledge. For example database queries can be stored within the ontology so that information found by one analyst can be found again later by other analysts. In this way the ontology adds to the amount of data that needs to be stored, but reduces the need for repetition of work.

2.3 *Ontologies for natural language processing*

Popping (2000) classifies natural language processing (NLP) techniques in three categories, which are in order of sophistication: *thematic*, *semantic*, and *network*. Thematic analysis considers the relative occurrence of words within the source text and can be used as a broad categorisation method to identify texts (such as accident records) that contain similar words and therefore may relate to the same broad themes. Semantic analysis expands the thematic approach by consider the function of words within a sentence (their *part of speech*, such as whether a word is a noun, a verb, or an adjective) to identify subject-verb-object triples. These triples provide the underpinning for complex formal ontology systems that develop from a mereology of objects or actions (Bateman et al. 2010; Bierwisch & Schreuder 1992; Miller & Fellbaum 1991; Ritter & Kohonen 1989).

Network analysis of text establishes the source text as a graph consisting of nodes (which usually represent single words) and edges (which describe relationships between the nodes such as co-occurrence of words within a single sentence). As such the network approach establishes a form of ontology of text within a document, although such an ontology is based on abstract concepts (using words as labels for objects) and therefore fundamentally differs from naïve ontologies which consider the nodes in the ontology as representations of the objects themselves. Miller and Fellbaum (1991) note that a disadvantage with network analysis can be the need for additional software tools such as graphing and network analysis tools, which can complicate the analysis if there is a need to transfer data between separate software products. The introduction of graphical text analysis tools introduces a new domain of research, for example as discussed by Figueres-Esteban et al. (2015).

For general text analysis, Miller & Fellbaum (1991) propose an ontology of 26 basic concepts, these concepts can be used to form a basis for domain-specific ontologies; they are:

- act, action, activity;
- animal, fauna;
- artefact;
- attribute, property;
- body, corpus;
- cognition, ideation;
- communication;
- event, happening;
- feeling, emotion;
- food;
- group, collection;
- location, place;
- motive;
- natural object;
- natural phenomenon;
- person, human being;
- plant, flora;
- possession, property;
- process;
- quantity, amount;
- relation;
- shape;
- society;
- state, condition;
- substance;
- time.

Finally, Van Gulijk et al. (2016) conclude their discussion of the use of ontologies in computer science by providing the following three counsels. Firstly there is no such thing as a perfect ontology; rather there can be a number of alternative ontologies that serve the same purpose. Secondly, effective ontologies are developed iteratively, perhaps as users interact with an ontology and seek more detail from it. Thirdly, ontologies that relate to physical objects are the easiest to create; ontologies that relate to abstract concepts can provide conceptual difficulties for both the ontology builder and the analyst using the ontology.

3 METHOD

Extraction of information from the text was performed in a process that consisted of four mains steps. The first step being the preparation of the data to allow for efficient completion of the later steps. The second step was the identification of key terms in the text and the construction of an ontology to make explicit the relationships between the terms. The third step involved the execution of queries to identify records that correspond with each of the categories of incident; this is an automated step performed by software. The final step was a review of the returned results and conse-

quent refinement of the ontology and queries until an acceptable result was achieved. Each step is described in detail below.

3.1 *Data preparation*

The accident reports provided by the FOT were imported into a graph database. Graph databases structure data as nodes and edges, rather than using the structure required by Structured Query Language (SQL), which has been a prevalent structure for databases some decades. As such, graph databases belong to a class of databases known as *NoSQL*.

Data relating to an individual incident was imported as a single node in the database: 5065 record nodes were created in the database. An automatic process was used to analyse the text in the source records and create a new node for each sentence in the text. During this process a simplifying assumption was made that a full-stop followed by a space (.) would always mark the end of a sentence. The sentence nodes were linked to the node that contained the data from the record.

In alphabetic languages, such as the European languages used in Switzerland, the basic unit of text analysis is a word. Fundamentally the process to establish meaning from text is performed by analysing the occurrence, frequency, and colocation of words or groups of words. In this work each sentence was broken into individual words: punctuation marks were separated from words by inserting spaces. Each word was converted to lower-case text and added as a word node in the graph. During this process the frequency of occurrence of each word was stored in the word node. Colocations of pairs of words were shown by the creation of an edge marked *next*; the edge also recorded data on the frequency of the colocation of the pair. This process of creating word nodes and *next* relationships is the same as the process applied by Lyon (2015).

3.2 *Step 2: Ontology learning*

The source data were analysed to identify terms (words and bigrams) for inclusion in an ontology of items. Candidate terms were identified by calculating the TFIDF score for each word in the source text. Subsequently, each bigram was considered to be a single token and a TFIDF score was calculated for the bigram. All terms from all the source records were compiled in a table of descending TFIDF score and presented to an analyst for consideration in the ontology.

The analyst reviewed the list of candidate terms, starting with those with the largest TFIDF score, and selected the terms that appeared to be relevant to each category of incident. Since the TFIDF ranking is intended to list terms in order of relevance, the analyst worked through the list until reaching a point where it was determined the that the terms were generally irrelevant and no further terms would be considered. The analyst in this trial spoke only English and had no fluency in any of the source languages (German, French, nor Italian) and used simple on-line translation tools to understand the candidate terms. Terms were selected based solely on the analyst's understanding of railway operations and safety. After identifying terms, the analyst created an ontology that joined matching or similar concepts. The ontology allowed equivalent terms in different languages to be joined to the same node. For example, in records written in German, the words *ambulanz* and *krankenwagen* were both used to refer to an ambulance and were linked to the *ambulance* ontology node. Similarly the French term *ambulance*, and the Italian term *ambulanza* were linked to the same node. A simplification was made to link plural terms to singular ontology concepts as a simple form of lemmatisation of the text.

The ontology learning process was limited to the creation of only a naïve ontology: only a single type of relationship was defined indicating that each ontological element can be *a type of* another element; for example *a woman is a type of person*. The ontology did not contain relationships such as *a door is a part of a train*; nor *a train can arrive at a station*.

3.3 *Step 3: Execution of queries based on the ontology*

Queries were performed on the data in the graph database to identify records related to each category of incident. The queries were started at the ontology nodes that defined each category of incident and traced via edges in the graph to identify records that contained terms relating to the incident category.

3.4 *Step 4: Iteration and reporting*

As noted above, the process of ontology creation is iterative. After execution of each query, the analyst reviewed the results to determine whether the records correctly corresponded to the category. Since the analyst had no fluency in the languages used to write the records, the TFIDF ranking process was re-applied to only the records returned as a result of each query. The analyst reviewed the terms occurring in the subset of records, using simple translation tools again, to determine whether terms were occurring that did not appear to relate to each query.

4 RESULTS

This section presents the results of each stage of the analysis.

4.1 *Data preparation*

The 5065 records were loaded into the database and a total of 16,419 unique word nodes were created. Relationships were created to show collocations of words. Figure 2 shows an example of the pair of words *dame* and *âgée* with the NEXT edge joining them. The figure shows that the word *dame* occurs 620 times in the source text, the word *âgée* occurs 202 times and, as a colocation, *dame âgée* occurs 150 times.

4.2 *Step 2: Ontology learning*

The process of TFIDF ranking returned 82,726 candidate terms, being 16,419 single words terms (one for each word node in the database) and 66,307 bigrams. From this list the analyst identified 389 terms that appeared to be related to the specified categories of incident. It is notable that, in some cases, the TFIDF calculation produced similar scores for terms with similar meaning in different languages. For example of the 82,726 identified terms, the term *ältere dame* (German for *elderly lady*) was ranked 314th in the list; the term *dame âgée* (French for *elderly lady*) was ranked 316th on the list.

The analyst constructed an ontology based on the identified terms. For ease of analysis the ontology was limited to only objects and actions and structured in two layers. Table 1 shows example the entities included in the ontology.

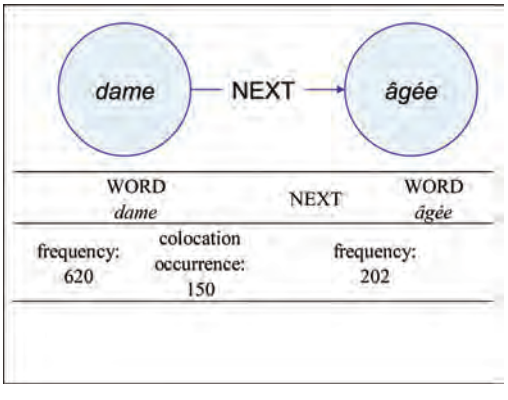

Figure 2. Example of the colocation *dame âgée* and the *next* edge linking the words.

Table 1. Example ontology entries.

Ontology upper layer	Ontology lower layer
person	doctor, self, customer, person, driver, passenger, months old, years old, baby female, old, elderly, young, male, man, lady
places	line, stations, pavement, hospital, ground, platform, stairs
actions	hit, medical, injure, get out, enter, fall, rush
body parts	foot, head, arm, leg
vehicle	carriage, vehicle, ambulance, tram, tain, bus
direction	backwards, direction, in between, in front
items	bag, alcohol, drugs, stairs, footboard, customer information system, ticket, door

4.3 *Step 3: Execution of queries based on the ontology*

Queries were designed and executed for each category of incident based on the terms identified during Step 2. The starting point for each query was the ontological entries that define the key entities being sought in the query. For example to identify records related to injuries caused to passengers by closing doors, the query identified the ontology nodes relating to *passengers*, *closing doors*, and *injury*. The query then identified the terms relating to those concepts, followed by the records that contained those terms. Figure 3 shows an example of records that relate to the ontological concepts of an elderly person and stairs. The query can be thought of executing from the top of the diagram down: firstly the ontology elements for *stairs* and for a *person* – and in particular an old person—are identified. These ontology elements are traced in the query to instances of words that define them, for example the words *Treppe* (being a German word for stairs) and *scale* (Italian for stairs). In turn, these words are traced to instances of accident reports where the words occur. It can be seen that the plural term for men in Italian (*uomini*) has been linked to the singular term in the ontology.

4.4 *Step 4: Iteration and reporting*

The results of the queries were reviewed by the analyst for correctness and the process in Steps 2 and 3 was iterated to refine the terms, ontology and queries to create results that appeared to better align with each category of incident. After iteration of the process, the results of the queries were presented to fluent speakers of each language for review. The reviewers were independent of

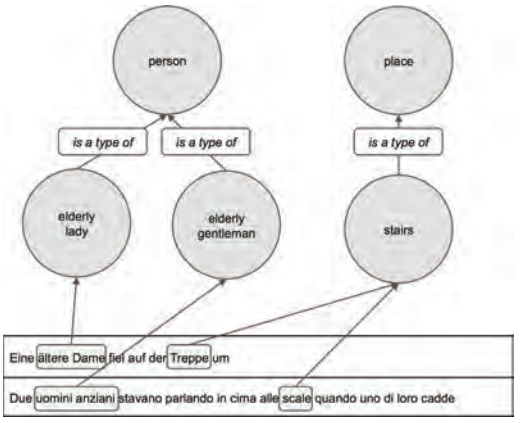

Figure 3. Schematic diagram of an example query.

the process and assessed each record entirely on whether it appeared to correctly describe an event belonging to each category. As such the reviewers' assessed only the rate of true positive matches compared with the overall number of records found to match for each category. The overall results from all reviews indicated that the number of true positives was 98.5% of all positive results returned by the queries.

5 DISCUSSION

The overall finding is that this preliminary study has demonstrated the potential for the technique to be a powerful tool for identifying specific instances of safety-related events from multi-lingual accident reports. The result of 98.5% true positives in all results returned is very strong, especially considering that the analyst did not have fluency in any of the source languages and used only simple translation tools. At this stage, however, it is not clear how many false negatives results occurred as a result of the queries (i.e. records that described one of the categories of incident but were not identified by the queries). Further work would be required to determine the overall accuracy of the process.

The trials of the technique to date have been limited to only a few categories of incident that were specified before the process of ontology creation. Since the process is based on the occurrence of terms in the text, it appears possible that the process could be started by examining the text to determine what categories of incident are being describe, i.e. a *bottom-up* exploration of the text to identify categories rather than starting the analysis with specific categories of incident (a *top-down* analysis). Such a bottom-up approach may be valuable to identify unexpected trends in the data that could not be presupposed; for example unexpected categories of incident caused by emerging technology.

The ontology developed during the process is based on the terms that occur in the text and, as such, it appears that the technique should be applicable to other sources of text that can support safety management such as audit reports, inspection reports; or even to general sources of textual data.

Another limitation of the technique is that it is based on the occurrence of simple concepts being described in the text, but does not consider compounded concepts such as negation. For example when stairs are mentioned in the text, it is presumed that stairs are relevant to the incident, however a record may refer to stairs even though they are not relevant to an incident, (e.g. *an old man, whom I had previously seen on the stairs, fell whilst entering the train*). To address this issue the ontology would need to be updated to include complex ontological concepts. Further work is being carried out to align this study with our previous work (Hughes et al., 2016b) to address these issues in the technique.

Building cyber resilience through a discursive approach to "big cyber" threat landscapes

T.O. Grøtan
SINTEF Technology and Society, Trondheim, Norway

ABSTRACT: Cyber safety, security and resilience of Critical Infrastructures (CI) and critical societal functions is a contemporary challenge. To understand the bigger picture, we may build composite threat landscapes in which vulnerabilities and threats combine and travel across distinct domains between which expertise, competence, experience and knowledge horizon related to safety, security and risk may differ substantially. Additional sensitization towards emerging cyber threats is however needed. Inspired by the post-normal "science of what-if", the "BigCyber" model advance threat landscapes further into sensitivity to hidden, dynamic and emergent vulnerabilities. The approach is exemplified in terms of smart metering of household electricity consumption. The need for discursive support for different stakeholders relating to threat landscapes is identified, and a discursive framework for stepwise nurturing of polycentric governance is outlined. The framework can also be used to elaborate and support the idea of resilience landscapes of autonomous entities, facilitating a polycentric approach to cyber resilience.

1 INTRODUCTION

The potential consequences of failure and disturbance of Critical Infrastructures (CI) and societal functions (e.g., energy, water, transport, and logistics) depending on Information and Communication Technology (ICT) are frightening and potentially devastating. The overall risk picture is increasingly blurred, mixed and constantly evolving. It is difficult to maintain a sharp divide between the stable inside of a critical infrastructure, and a more innovative outside. Presumed motivations of potential adversaries and perpetrators span a wide range, encompassing cyber conflict and hybrid warfare, fake information, political influence, cyber-physical damage, cybercrime, sheer vandalism or teenager tricks. This adds to the existing prospects of the accidents, failures and unfortunate incidents in (already) complex systems. Perrow's (1984) notion of the "normal accident" is persistently hard to escape.

The Internet of Things (IoT) is already on the scene, offering new access (= attack) points, new magnitudes of automation and cyber-physical impact, but also boosting the ability to "informate" (Zuboff 1984); to generate electronic texts about the use of the infrastructure. Moreover, the "Internet of Everything" (IoE) has been coined as the "Big Other" surveillance capitalism (Zuboff, 2015), fueling a logic of accumulation. This is signified by the increasing rate of ICT systems rigged for collecting as much (surplus) data as possible. Vendors collecting extensive information from installations without the customer's consent, could be coined as the "industrial Big Other"

In the 1990's, the prospect of "trusted" computer systems prevailed. Today, few if any ICT systems are delivered with assurances that support this. Practically no ICT system, including CI, may preclude the possibility of intrusion, disturbance and hacking. Big-scale consumer innovations, e.g. autonomous cars and home appliances, are seemingly always lagging in computer security. Some voices even claim that "computer security is broken from top to bottom" (Economist, 2017).

Potential countermeasures are often invasive, e.g. on privacy, often unduly playing on strings of fear and anxiety. Public initiatives, e.g. from the EU (Galbusera and Giannopoulos, 2016) aiming for public, semantic web descriptions of critical infrastructures may also be exploited to enable sophisticated attacks.

We cannot expect of holistic, cross-nation, cross-sector approaches to these challenges. The obstacle is not just the tremendous information coordination challenge, but also the incommensurate and diverse motives and objectives across boundaries of private vs public, classified vs unclassified, national vs international. Information cannot be shared, nor trusted, in one "heap". Motives and objectives are incommensurate, increasingly located in an atmosphere of post-fact attitudes, fake news, and information warfare targeting societal trust, in which even security agencies may find it difficult to navigate.

This fundamental challenge demands an attempt of imagining the inconceivable. Societies, organizations and stakeholders habitually directs their hope and faith for dealing with such challenges to risk management and governance, but these are increasingly acknowledging their limitations. Illustratively, a new Specialty Group (SG) on resilience analysis was approved by the Society of Risk Analysis (SRA) Council on December 10, 2017.

In the following, a diverse portfolio of strategies and approaches that can be utilized at several levels, from the national regulator to the infrastructure owner and stakeholder is proposed. The key issues are about building *threat landscapes* to increase sensitivity to hidden, dynamic and emergent ("*h*/*d*/*e*") vulnerabilities and couplings, and to employ the concept of resilience in a polycentric manner catering for diversity, rather as a system-wide property on uniform terms.

An example is offered: smart household electricity metering as part of smart grids. Energy companies strive to use technology to innovate their customer relations, technical maintenance and grid stability, fearing cyber threats, but also fearing a sudden, technology-driven meltdown of their business models.

2 THREAT LANDSCAPES—AND BEYOND

2.1 *Threat landscapes*

Risk management is traditionally not possible without making demarcations about a system regarding boundaries, threats, vulnerabilities, key events, and other inventories (e.g., acting subjects). In today's complex cyber-inflicted systems, such presumptions become increasingly difficult. *H*/*d*/*e* couplings between parts that we traditionally would prefer to keep apart for analytical clarity, or events and conditions that would be considered as unlikely or even irrelevant in conjunction, challenge organizations' and societies' experiences, capabilities and skills regarding imagination as well as actual resilience towards disturbance and surprise.

A societal perspective will have to address the b*igger picture* by recognizing and combining multiple, distinct domains of expertise, competence, experience and knowledge horizons related to, e.g., safety, security, resilience, threat and risk. In this paper, any such distinct domain is "squared out" as a picture, with a frame representing demarcation of inside vs outside, however with the premise that there *may* always be some relevant knowledge missing.

A key challenge is that due to the diversity and h/d/e ICT-induced couplings of physical as well as logical nature, "pictures" may suddenly turn out to be be flawed, and the new threats may travel across such experience-based boundaries in unprecedented ways. The understanding of such composite threat landscapes require methods beyond the practices used to address single domains. Although it is likely that the (more or less professional) risk management approaches per se do not vary dramatically across such "squared" frames, it is likely that the pragmatic knowledge horizon of each domain, e.g., the sensitivity to different phenomena and the ways information and knowledge is recognized, collected, combined and appreciated, will differ substantially more.

Due to the presumed heterogeneity of the total landscape, it is held unlikely that a joint holistic picture of threats and vulnerabilities can be comprehended from a single knowledge horizon. Hence, it is presumed that the "visible landscape" that can be created and shared between domains is constituted by several "squares", each of which representing a specific horizon of knowledge-gathering ("knowledging") strategies and actual experience. To be able to construct such a landscape, three issues are crucial:

1. Explication of the boundary conditions for each horizon "squared out" (Figure 1) in terms of the frame description, the demarcations of the validity of the inside, and the indicators of its saturation (that is, when it cannot accommodate more issues, without losing its pragmatic meaning)
2. the characteristics of overlap zones and the corresponding h/d/e vulnerabilities and couplings that may enable threats to propagate
3. The joint acknowledgement that single frames, as well as their intersections, are not only uncertain, but also influenced by a background landscape encompassing h/d/e phenomena.

The labyrinth background in Figure 1 signifies the persistent hermeneutical challenge of a "moving horizon" (Gadamer 1992) facing each "squared" horizon, as it encounters new phenomena and contesting horizons through the overlap zones.

The resulting threat landscape metaphoric hence implies a loss of traditional presumptions of clear-cut responsibility and authority traditionally associated with single pictures/frames, but also an increased sensitivity to other horizons of understanding.

For taking advantage of this landscape metaphoric, each knowledging agent or community must acknowledge the need to understand the foundations of its own horizon, and be able as well as willing to take a closer look beyond its prevalent presumptions.

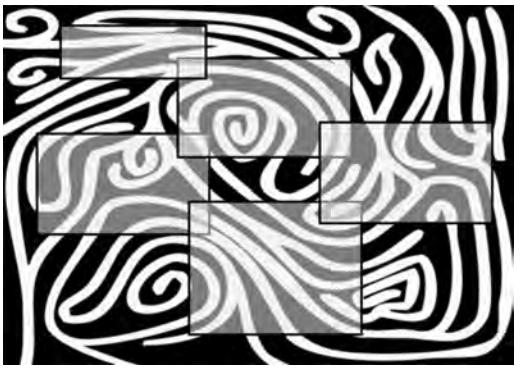

Figure 1. Overlapping threat pictures constituting a threat landscape on a labyrinth background (Grøtan and Antonsen, 2016).

In this way, the threat landscape metaphor may be used to build a "bigger picture" including h/d/e couplings between distinct domains, among which expertise, competence, experience and knowledge horizon related to safety, security, threat and risk are not necessarily commensurate. To establish the grounds for extended understanding of the surrounding landscape, each agent may take advantage of the "take it to the limits" approach (Grøtan and Antonsen 2016) in which a sequence of issues is raised to encircle the boundaries and the saturation points of each frame, and open up for inputs from other domains.

2.2 *"What-if": Sensitization and weak signals*

The threat landscape approach above is primarily useful for utilizing past experience and existing knowledge from professional domains, looking for new combinations, and for revealing or spotting h/d/e vulnerabilities before they have negative impact.

However, many recent events illustrate that cyber (h/d/e) vulnerabilities emerge as a big surprise or a "black swan". A recent example is social media allegedly being used for political communication, tipping elections (Guardian, 2017), indeed exceeding what may be anticipated by means of traditional scientific approaches. The public sphere is very likely to be affected by the consequences, and involved in the key phenomena, e.g., as actually being the product, not the customer, for "Big Others". The threat landscape approach per se may thus not be enough. The residual challenge is thus to be able to raise and pursue the question "what-if" based on hints, weak signals or sheer imagination, and make a serious judgment in time on issues that normally might be discarded as belonging to a risk distribution tail. Also, the "layman" horizon should be included in the process.

To address this residue, inspiration is here gathered from the "post-normal science" (PNS) (also denoted the "science of what-if") introduced by Funtowicz and Ravetz (1993) and Marchi & Ravetz (1999), setting out to resolve a science in crisis (sic!).

Kønig et al. (2017) identify the conditions characterizing a post-normal situation: Irreducible complexity, deep uncertainties, multiple legitimate perspectives, value dissent, high stakes, and urgency of decision-making. The PNS goal is not to attain certain knowledge, but quality, a more robust 'science for policy'. Pointing to how politicization of science renders classical Mertonian scientific norms invalid, they identify an ethos for PNS which they denominate TRUST (Transparency, Robustness, Uncertainty management, Sustainability, and Transdisciplinarity), considering this a nexus for reflexivity practices. They propose that the public trust in science advice can be restored through the PNS ethos.

PNS is also portrayed as "both *descriptive* (describing urgent decision problems – post-normal issues – characterized by incomplete, uncertain or contested knowledge and high decision stakes and how these characteristics change the relationship between science and governance) and *normative* (proposing a style of scientific inquiry and practice that is reflexive, inclusive and transparent in regards to scientific uncertainty and moving into a direction of democratization of expertise)" (Strand 2017).

Here, the PNS challenge is responded to in a more meagre and restricted way; 1) by urging for sensitivity to weak signals, and 2) the proposition of a cyber-vulnerability sensitization model that hopefully make sense to professionals and laymen alike. Hopefully, this is a contribution to the PNS urge to invite "extended peers" into the conversation. Ubiquitous cyber vulnerabilities, and the hope of cyber resilience, should not only be based on a discourse among professionals; ultimately it involves us all.

The turn towards PNS for inspiration, and the return to the less ambitious sensitization model presented below, is thus a natural next step from the idea of the threat landscape as a vehicle for joint comprehension and discourse based on validated of, or even sense-*making* from, weak signals. The notion of "weak signal" is thus not confined to uncertainty within a familiar domain, but include the possibility that something radically outside the normal frames of reference may "travel" trough the landscape, with significant impact at unexpected places.

2.3 *The BigCyber sensitization model*

This sensitization model is intended as a generic tool to support a balanced approach to under-

standing the temptations as well as the possible drawbacks related to utilization of the ever-evolving "cyber space".

2.3.1 *Underlying and formative issues*

2.3.1.1 Potential conflict in cyber space

The actors who own and operate critical infrastructures are usually not directly involved in (military) cyber conflict scenarios, they have traditionally not been seen as military actors. Still, they may be targets for offensive cyber weapons in a potential conflict situation. By making attacks on critical infrastructure from afar technically possible, digital technology also make these types of attacks feasible. It is therefore important that these actors think about the possibility of being targets, and prepare accordingly. An attack of this type could be intended to simply disrupt services, sabotage or even cause physical damage. E.g., Since being coined by CIA Director Leon Panetta in 2016, there has been a persistent concern in the US regarding a potential "Cyber Pearl Harbour" attack.

2.3.1.2 The Internet of Things (IoT)

IoT implies a network of objects able to collect data through embedded sensors and exchanging this information via the internet, but are notoriously hard to secure, and even hard to update when needed.

Both intended, malicious cyber threats and unintended system failures and vulnerabilities of IoT dispersed throughout a CI may lead to severe disruptions in cyber physical systems. In 2016, we also experienced a hint of the future, as the recognized scale of DDoS attacks increased dramatically due to the broad availability of tools for compromising and leveraging the collective, offensive firepower of IoT devices—poorly secured Internet-based security cameras, digital video recorders and Internet routers (Guardian, 2016). The intentions and motives behind may be related to crime and hackers, ranging from teenagers' ploys via organized crime to state actors, but also to cyber conflict and hybrid warfare.

IoT thus sparks the ability to "informate", to generate electronic texts around the use of the infrastructure and technology, boosting the "Big-Other" logic of accumulation.

2.3.1.3 From IoT to Internet of Everything (IoE)

As more and more personal information is being made more or less public, and the possibility for combination increases, a new form of information economy emerges. Zuboff (2015) describes the emergent logic of accumulation in the networked sphere as an "Internet of Everything" (IoE) in which personal information becomes a commodity of high value for a wide range of (unknown) users. This radical new form of surveillance capitalism aims to predict and modify human behavior as a means to produce revenue and market control. Zuboff (2015) launches the need for an 'information civilization' addressing the challenges from "Big Other": "a ubiquitous networked institutional regime that records, modifies, and commodifies everyday experience from toasters to bodies, communication to thought, all with a view to establishing new pathways to monetization and profit" (Zuboff, 2015).

Such an "information civilization" requires a new comprehension of cyber safety and security, including the multifaceted concept of resilience.

2.3.1.4 The lack of assurances

Given the high ambitions related to evaluation criteria for "trusted" computer systems a couple of decades back, there is a striking contemporary silence and numbness related to the lack of assurances about vulnerability of critical computer systems, at least in the non-classified domain. The infamous Stuxnet incident has demonstrated that a widely used industrial control system platform can be used to launch very intricate attacks that are very hard to spot. This is not only about "zero days", it is also about an inherent technological brittleness, and the possibility that industrial plants such as windfarms (Staggs et al. 2017) or smart metering systems (Hansen et al. 2017) demonstrably can be "hacked", with potentially severe consequences. This is also about a flawed marketplace that does not care to ask for such assurances at all, or just to a very minor degree.

2.3.1.5 Privacy

The Norwegian Data Inspectorate have just recently aired their concern regarding the implications of this, and The Norwegian Consumer Council is worried about privacy and consumer rights in a situation where such consumer data has become a "goldmine" for infrastructure operators. The Norwegian telecom operator Telenor is making data from the cellular network to a commodity under the label "mobility analytics". In the US, a new bill is criticized for being a lift of existing legislation that "not only gives cable companies and wireless providers free rein to do what they like with your browsing history, shopping habits, your location and other information gleaned from your online activity, but it would also prevent the Federal Communications Commission from ever again establishing similar consumer privacy protections". It can be doubted whether the individual customer will be able to value his/her privacy sufficiently in relation to the "benefits", or the sheer volume of "user agreements" that are offered.

2.3.1.6 Enter psychology

1. Big Five in Big Data

Psychoinformatics (Montag et al., 2016) is a discipline on the rise. The "Big Five" model has been

a prevalent model for psychological profiling, with alleged predictive power on human behaviour and influence. Recently, the Big Five model has been a driving force in "Big Data" attempts of collecting enough data to reveal patterns from which predictions about human behaviour become quite precise). Some findings seem to suggest strong correlations between Big Five parameters and social media (e.g., facebook) data. E.g., an average of 68 "facebook clicks" seemed to be enough (in 2012) to predict colour of skin, sexual preference, political preference, intelligence, religious belief, use of alcohol/tobacco/drugs, or of having divorced parents, with reasonably high confidence (Grassegger & Krogerus, 2018). With more data, the model predictions beat the assessments of a person from colleagues, friends, parents and spouse. Ultimately, the smart phone is an "enormous psychological questionnaire" feeding us (or someone) with more and more detail. With more information, the prospect is raised that somebody could know "more than the informant think they know about themselves". Inherent in this is the assumed ability to predict an informant's response to a condition/situation.

But it also works the other way around: the user data can also be used as a filter to find and track down users/individuals with specific personality details; providing a method to "profile" people without themselves knowing. It is claimed that this has been used recently in political marketing/communication, by "micro-targeting" through assessments of personalities through Big Five and digital footprints. From which, political messages are organized and based on psychometry rather than demography, by, e.g., designated "messages" as personality-adapted advertisements or "news" (not necessarily "fake"). "Dark posts" are paid fb ads exclusively in the news feeds to users with specific personalities. It can also be about microscopic variations in the same message to accomplish psychological effectiveness, headings, colours, captions, stills or videos, targeting villages, neighbourhoods, or individuals differently. Hence, digital footprints become "real humans" with worries, needs, interests and addresses.

2. Cyber psychology in change

Another issue with possibly unprecedented implications is the potential implications of how digital omnipresence leaks into and potentially changes our psychology as users and operators, e.g. in terms of increased conformity (Størseth 2013).

2.3.2 *The BigCyber sensitization model*

The Big Cyber model summarizes the key issues at large, as illustrated in Figure 2. The model comprises five different "Janus-faces", each of which offering a huge benefit (inside of the dotted pentagon), as well as conducing a severe downside (outside of the dotted pentagon) that can be viewed as an h/d/e threat or vulnerability.

Figure 2. The BigCyber sensitization model.

BigBrother(s) may offer comfort and security in times of crisis and terror, but are giving themselves rather free passes to track down and inflict harm on any instance or person that may be regarded as a present or potentuial adversary. There are no international agreements on ethical conduct of cyber offense.

Personalization and customization of services offers ease of use. But the backside is that we are enrolled into the **BigOther** surveillance capitalism (Zuboff 2015) without being properly asked or informed; "users" are transformed to products and monetized behavioral commodities in a digital economy.

BigData coupled with artificial intelligence and machine learning promise an endless range of new insight and capabilities, but these are not reserved for the "good" purpose. What if the key ideas of "insurance" are jeopardized? Intelligent offense towards CI and ICT systems is as likely as intelligent defense.

The **BigFive** personality model can probably make us even more comfortably numb while effortlessly harvesting the benefits of cyberspace. Will we be able at all to resist the narrowed "alternatives" presented? Will we develop a "cyber psychology" that enables us to recognize and deal with commercially and politically motivated communication?

This is also about an aggregated, unevenly distributed **digital economy and power**. BigOther will have supreme power to utilize BigData as well as BigFive. Evry cyber innovation is aiming for sale, and BigOther is loaded with cash and ready to buy any advantage and "edge" available.

Societies, organizations as well as individuals are always hungry for the **BigInn**(ovation). The lack of basic assurances are hardly noticed, except for the invitation to become an "update junkie", and that the computer industry is not subject to any-

thing near the liability issues that, say, automakers or pharmaceutical industries must consider. Also, outsourcing with fragmented managerial accountabilities is a too easy escape when ambitions of digitalization exceed available competence to deal with the vulnerabilities.

The BigCyber model support understanding of exposure to unfamiliar intentions and motives, and of new attack surfaces and vectors, e.g., cyber-physical impact, small and large, massive profiling, crime and intrusion and an endless stream of "zero days".

3 EXAMPLE: SMART METERING

A smart meter is a physically separate device designed with encrypted communication between the energy supplier and the customer for regular metering at, e.g., an hourly basis. In one way, the Smart Meter is just another Industrial Control System (ICS) or Supervisory Control and Data Acquisition (SCADA) system that is a precondition for even preconceiving the idea of a smart grid, depending on control functions and measurements at an unprecedented scale.

As illustrated in Figure 3, the smart meter also has a "private" physical connector (in Norway denoted a "Home Area Network" (HAN) port) that enable third parties, e.g., providing "smart home" solutions, to read metering data as part of their (innovative) services, connected to the internet. However, do we understand the potential threat landscape of this?

Smart metering is an entry point to the huge challenges of protecting the energy grid as a critical infrastructure. Concerns can be raised, independent on whether the connection is physical or not, on both unauthorised access and to whether the end user oversee the implications of granting additional connections.

The attractiveness of the electricity system for cyber attacks was demonstrated in Ukraine (2015 and 2016). Disruptions may range from massive shutdown (leading to imbalance and potential physical damage) or just poor quality (voltage/frequency). The potential for targeting vast numbers of smart meters simultaneously is demonstrated (Hansen et al. 2017). We have yet to experience the full damage potential, but in the UK, MPs were warned of sabotage threat from smart meter hackers. As experts said rogue programmers could target £11bn system, a massive shutdown will put enormous strain on both the supplier and consumer side (Financial Times, 2016).

Figure 3. The Smart Meter as part of the Smart Grid.

3.1 *The microcosmic threat landscape of ICS*

We start by illustrating the potential of the threat landscape approach at a very small scale. Resting on a similar vocabulary employed by The European Union Agency for Network and Information Security (ENISA), the smart meter seen as an ICS/SCADA system, can be depicted as a "microcosmic" threat landscape in its own respect (Figure 4).

the approach is illustrated in terms of a workshop assessment of an industrial SCADA system in a networked context. The actual "squared" threat pictures (left side of Figure 4) are selected and derived from a similar approach by ENISA. The actual threat landscape composition was conducted as part of the (1st Annual) Workshop on Cyber Safety, Security and Resilience of Critical Energy Infrastructures, Oslo, Norway June 2016. Here, each threat picture was elaborated before combined into the landscape. Both the contents of each "frame" or "horizon", and their overlaps, turned out to be surprisingly complex, and did add weight to the suspicion that the ideal design does not cover every vulnerability in this (microcosmic) threat landscape".

3.2 *The BigCyber-sensitized threat landscape*

Can we conceive a bigger picture, a BigCyber-sensitized smart meter threat landscape?

In addition to necessary functionality for building of smart grids, the smart metering solution is also an excellent example of a connection to "Big

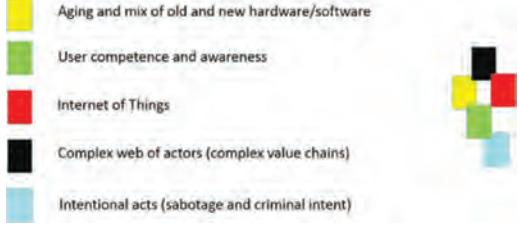

Figure 4. "Microcosmic" ICS/SCADA Threat Landscape.

Other". The joint access to the HAN port it is also a source for building information about "energy behavior" with a huge commercial potential, especially when it is linked to other sources of individual and commercial behavior that can be used to profile targeted individuals or groups. The privacy issues are imminent, but a hostile "BigBrother" may in the ultimate case also weaponize this to trigger collective irregular consumer behavior, and target key personnel, with the intention of disturbing the energy system per se. Another possibility may be conceived through the infamous Stuxnet attack; either by (1) disturbing the crucial grid measurements in order to destabilize trust in grid operation, or (2) initiate (cyber-)physical damage by imposing electrical imbalances.

Hence, we may see the contours of new attack surfaces and vectors of both tangible and intangible kinds, that can be combined and cleverly orchestrated. Vulnerable equipment can be attacked, users and populations can be manipulated and influenced, and key personnel in protection of critical infrastructure services could also be specifically targeted as part of an orchestrated attack, e.g. with a criminal intent. For the defenders, a main vulnerability is the lack of acknowledgement of the coupling.

In Figure 5, a BigCyber-inspired Threat Landscape for smart metering is indicated. The prospects of "clinical" attack vectors, triggering of user behavior as part of attack, optimization of damage and targeting of key personnel on the inside, are simply not refutable one by one. Maybe not even in combination.

3.3 *Weak signals in sight?*

The "metering paranoia" threat landscape (Figure 5) is hypothetical. Are there weak signals that support the likelihood that it may manifest into reality?

- Banks in Asia are already using customers' smartphone data points, like how (often) they drain their battery, to determine whether they're eligible for a loan (CNN, 2016). Can electricity metering derived from smart houses contain behavioral data that could be matched with a personality assessment?
- Will customers care to use the new European privacy legislation to demand insight into smart metering data? Would the trivia of energy consumption draw the necessary attention?
- Energy companies are now increasingly concerned about disruptive competition. Who will take lead in offering homes and companies the dual role of producer and consumer, utilizing solar, wind, (virtual) batteries, e.g. in electrical cars, optimize the energy consumption in a market in which, e.g., consumption based pricing is replaced by capacity-based pricing? Will access to personal energy consumption be part of the "price"? Who will have the data edge in a new market environment? Will we see similar dynamics as when the "Flash Boys" (Lewis 2015) changed the stock markets by means of getting split-second advantages over other actors?
- The grid, however "smart", will still need some supervised electrical stability. Who will be responsible for managing this, with potentially severe consequences in terms of physical damage of electro-mechanical equipment. If for example Google offer an "integrated" energy system to "prosumers", would they care about the grid? If the risk towards the grid level of service is relocated, who will be in charge?

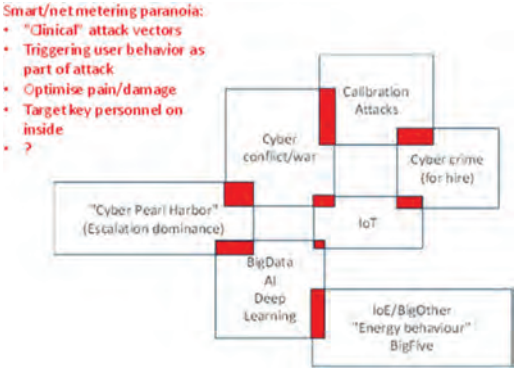

Figure 5. "Smart metering paranoia".

4 DISCURSIVE SUPPORT FOR POLYCENTRIC GOVERNANCE (PCG)

The challenges described above goes beyond the limits of safety and security as traditional disciplines. Petersen (2012) argue that we need an analytical approach "sensitive to conceptual change and diversity" that "enable us to identify innovations in political language" and "provide us with the ability to grasp new developments in the corporate, governmental or organizational conception of risk". There is thus a need for a step change in the way societies and organizations deal with cyber risk, from fragmented to polycentric risk governance (PCB).

The threat landscape metaphoric and the BigCyber sensitization model provide discursive support for PCG. E.g., as in the smart metering example, a regulator can be aware of privacy challenges, but must reach a risk-informed assessment,

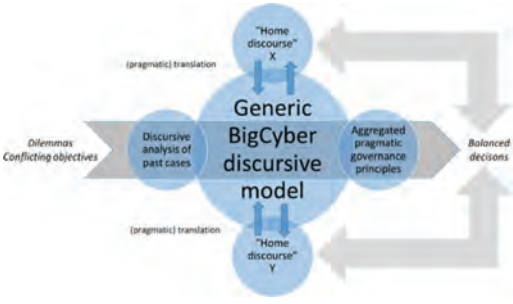

Figure 6. Discursive framework for polycentric governance.

based on current knowledge, without jeopardizing the objective of transforming the grid. We may expect that the regulator take part in a broader, responsible discourse, but we cannot expect them to be voluntarily taken hostage for issues beyond their primary mandate. Hence, we need a discursive framework that sensitizes not only academics and analysts, but also the actual decision makers/processes to the very same issues.

Petersen (2012) claim that "a conceptual discourse does not exist by itself; rather, it will always be defined in interaction with other discourses". Hence, a discursive framework will have to be designed with the following in mind: the users of the framework will come from unique and different "home discourses", and we should enable a sustained resonance between the "home" and the joint discourse, as participants move along their unique trajectories.

As indicated in Figure 6, several stakeholders, each of which bound to a home discourse, e.g., of privacy and consumer rights or of facilitation of smart grid development, can join forces, overlap horizons, share threat landscapes (TL) and challenge themselves and others by using the Generic BigCyber discursive model, which is the simplistic (and recursive) formula of

$$TL \rightarrow BigCyber \rightarrow TL',$$

as exemplified in chapter 3.

Using this discursive framework will contribute to an improved coherence between decisions made by different stakeholders. The "lay" perspective may be voiced through civic participation, NGOs, or proxied through agencies of consumer rights and privacy.

5 FROM PCG TO POLYCENTRIC RESILIENCE

During the past decade, the safety field as well as the societal security and disaster fields, have devoted attention to the concept of "resilience. However, the notion of cyber resilience demands more than a technological fix. Human and organizational issues are more inert than the technological, and also for cyber resilience we must respect the double-hermeneutic scientific principle of understanding *understanding subjects*, rather than explaining them as objects.

It is important that the concept is properly contextualized. Though it sounds normatively good, it carries no guarantee for success. It is an attractive idea that invites fallible practices, and hence it must be brought under managerial supervision, accountability and mandate. If not, we may invite expectations that will victimize those that are not able to thrive from being exposed to risk, or that do not possess the resources or skills in the first place.

We must take the notion of resilience seriously without depriving it from its content and origins through mere re-labelling of traditional risk management practices. Resilience is ultimately a matter of emergent, "bottom-up" and situated solutions to unique and idiosyncratic demands and situations rather that instrumental responses to stereotypical replications of former situations.

By implication of the above, cyber resilience must be translated to a scheme of composite protection comprising a diverse set of (resilient) entities that can be orchestrated to a certain degree. Grøtan and Bergström (2016) propose a theoretical foundation for exploring the concept of resilience landscapes; autonomous but interconnected resilient entities that forms a composite scheme of resilience. Such entities can utilize the same discursive structure as for PCG (Figure 6), and the evolving threat landscape can be a basis for dynamic interfaces and interactive patterns.

6 CONCLUSION

The threat landscape metaphoric and the BigCyber sensitization model is a promising approach that make sense in the smart metering case, and carries a potential for further application for the emerging cyber threat landscapes. The notions of polycentric governance and polycentric resilience landscapes are logical companions to the former, and both can benefit from the discursive support structure presented.

Safety principles for autonomous driving

H. Schäbe
TÜV Rheinland InterTraffic GmbH, Köln, Germany

ABSTRACT: In safety technology, the application of safety principles (e.g. fail-safe or safe-life) is used to design and implement a safe system that eventually fulfils the requirements of the functional safety standards. Safety principles have already been described and applied to guided transport systems, including systems with immaterial guidance principles. The different responsibility of human driver and technical driving system in different automation levels for autonomous driving vehicles require the application of safety principles. We consider, which safety principles have to be applied using general safety principles and analysing the relevant SAE level based on the experience from projects. For the five levels of automated driving as defined by the SAE, safety principles are derived. For the levels 0–2, the driver is fully responsible for driving, whereas starting from level 3, the automated driving equipment monitors the vehicle. To give the driver the possibility to intervene, means that this must be implemented according to the relevant safety integrity level and that the driver must have enough time to take over control. The latter strongly depends on the level of automation and the speed and the environment in which the vehicle moves. Depending on the level of automation, the technical systems are implemented as fail-silent or as safe-life. There are also exclusions, e.g. when the technical systems can be implemented as fail safe. This is possible, when the vehicle always can be brought to a safe stop, e.g. when driving with low speed and on a controlled territory.

1 INTRODUCTION

Autonomous driving has become a very important subject of research and first pilot projects. In safety technology, the application of safety principles as e.g. fail-safe or safe-life is a very important tool to design and implement a safe system that eventually fulfils the requirements of the standards for functional safety. Safety principles have already been described and applied to guided transport systems, including system with immaterial guidance principles.

In earlier papers, safety principles have been described and later applied to guided driving.

In the present paper, we systematically consider which safety principles have to be applied for which SAE level of autonomously driving systems und we show how an autonomous system could be built. This is partially done with the help of general safety principles, partially by analysing the relevant SAE level based on the experience from several projects.

According to UN resolution /UN/ or SAE / SAE/, autonomous driving on the road knows five different levels:

- 0 No automation
- 1 Driver assistance
- 2 Partial automation
- 3 Conditional automation
- 4 High automation
- 5 Full automation

For the levels 0–2, the driver is fully responsible for driving, starting from level 3 the automated driving equipment monitors the vehicle.

This different responsibility of human driver and technical driving system requires the application of safety principles. In the present paper, we systematically consider which safety principles have to be applied for which level und we show how such a system could be built.

This is partially done with the help of general safety principles, partially by analysing the relevant level.

We start with a very simple and abstract model of the system and show that there exist different possibilities to implement autonomous driving. An important result is that an arbiter needs to be installed that gives the human driver the possibility to override the decisions of the autonomous system to fulfil legal requirements.

For the five levels of automated driving as defined by the SAE (2016), safety principles are derived. For the levels 0–2, the driver is fully responsible for driving, whereas starting from level 3, the automated driving equipment monitors the vehicle. To give the driver the possibility to inter-

vene, means that this must be implemented according to the relevant safety integrity level and that the driver must have enough time to take over control. The latter strongly depends on the level of automation and the speed and the environment in which the vehicle moves.

Depending on the level of automation, the technical system are implemented as fail-silent or as safe-life. There are also exclusions, when the technical systems can be implanted as fail safe, when the vehicle always can be brought to a safe stop, e.g. when driving with low speed and on a controlled territory.

We consider the two main functions of guidance and braking / acceleration and their role for autonomous driving. Moreover, detection and reaction with regard to fixed and moving obstacles is discussed.

Two basic requirements for autonomous systems are that they need to be developed according to the relevant standards of functional safety fulfilling an ASIL (or SIL) level and that the capability of the autonomous driving system must at least on the same level as that of a human driver.

We note that Wachenfeld (2016) has proposed a stochastic approach to show that an autonomous system fulfils a certain level of performance or safety. This, however, can only be seen additional evidence, the main evidence for a safe system is an appropriate safety architecture implemented according to the rules of functional safety, see ISO 26262.

2 GENERAL SAFETY PRINCIPLES

In this chapter we will briefly remember the main safety principles, see Gülker & Schäbe (2006) and and Gayen & Schäbe (2008).

Fail safe: If the system has a safe stopping state, i.e. a safe state in which it is not operational and this state is stable which can be reached fast enough, then the fail safe principle can be applied. It means that a system is brought into this sate if a failure occurs which cannot be tolerated. This principle can be implemented as inherent fail-safety, ractive fail-safety or composite fail-safety.

Safe life (fail operational): If the system does not have a safe stopping state which can reached fast enough, then the safety function has to be ensured. This is mainly done by using redundancies.

Fail silent: The fail silent principle is applied to a function the loss of which is tolerable since it is either an assistance function or the function is implemented in several instances. Then, failure of the function must be such that there is no repercussion on the safe functioning of the system. That means, that a fail-silent system must detect its failures and possible dangerous states and switch itself off without influencing other systems in a dangerous way.

3 ABSTRACT MODEL OF THE SYSTEM

Lotz (2017) proposed an architecture consisting of three levels: a navigational level, a manoeuvring level and a controller level. We will try to discuss a model that is as simple as possible.

For systems that drive automatically, partially automatically or autonomously, we will use the following very simple structure for the system. In fact, this system must be equipped not only with a human driver, but also with a technical driving system, that carries out the driving.

The vehicle consists of driving sub-systems as steering, braking, acceleration systems etc. in a very abstract manner. These sub-systems could be even very simple systems as pure mechanical steering system, pneumatic brake systems etc. The driving is carried out by the human driver using these driving sub-systems directly.

The manoeuvring and navigational level according to Lotz (2017) have here been combined in one system (human driver / technical driving system).

If a vehicle shall be operated by a technical system which does the driving in place of the human driver or supports the human driver, then this system must have access to the driving sub-systems. This is possible only using a driving controller and actuator. That means that these types of systems must be present in the vehicle to allow for driving by a technical system.

Then, this allows also the human driver to access the driving sub-systems via the driving controllers.

Hence, there are different possibilities to operate these subsystems.

a. The driver can directly access the driving subsystems, e.g. the steering wheel is mechanically connected to the steered axle.
b. The driver accesses the driving sub-system via a controller and an actuator which operate the sub-system electronically. A typical example for such a system is an electric parking brake.
c. The technical driving system accesses the driving subsystem via a controller and actuator

We will not consider the aspects of how the driver should best access the driving sub-systems yet.

We need to distinguish two situations:

a. driving on an open road and
b. driving on private territory

Without going into details we must be aware of the fact that for driving on an open road, the Convention requires a driver to be always present

which is implemented in the national law of almost all countries. For driving on private territory, the traffic law is not applicable—the car would be a moving machine. Nevertheless, also her, safety requirements have to be obeyed.

4 SAFETY INTEGRITY LEVELS

Whenever a function might lead to harm, i.e. injury of fatalities to persons, material damage, damage to the environment, functional safety has to be applied. That means that the risk arising from a possible functional failure must be reduced to an acceptable level.

For this sake, safety integrity levels are defined. According to ISO 26262 this can be QM, ASIL A to ASIL D with ASIL D being the most severe. This system has to be applied for road vehicles with a gross weight of up to 3.5 t. For heavier vehicles (still) IEC 61508 would be applicable, which knows the safety integrity levels 1 to 4. Also, for moving machines, IEC 61508 is applicable.

In practice this means, that for all driving functions and all driving sub-systems, the necessary safety level (ASIL or SIL) has to be determined using a risk analysis.

5 LEVEL ANALYSIS

In this section we will analyse the levels (SAE (2016)) of automatisation and draw conclusions for the safety architecture of a vehicle.

In levels 0-1 execution of steering and acceleration and deceleration is in the responsibility of the human driver, the driver is responsible for monitoring and the technical system is able to support some driving modes (level 1).

That means, the human driver is doing the driving and the technical driving system can only add some supporting functionality as warn the driver or react in cases, when he is not able to react (emergency brake assistant). This means that the technical driving system must be fail silent, i.e. upon failure of this system the driving behaviour of the vehicle must not be influenced or only influenced in such a manner that safe driving is still possible. The driver should be warned, if such an assistance system fails to work.

In automation level 2, the system takes responsibility in some driving modes. The human driver monitors the technical driving system and he is the fall back solution. That means, that all technical systems are pure assistance systems and that

R1. The driver must have the technical possibility to interfere, i.e. to override the technical systems. That means, that each controller for acceleration, braking and steering that receives signals from the human driver and from the technical driving system must have a voter which always gives priority to the driver. In fact this means that an electronic control system needs to be present for these function that has an ASIL that coincides with the function, mainly this would be ASIL D. This control system then must have a priority input for the driver and another non-priority input for the technical driving system. The relevant driving controller must detect, when the driver wants to override the technical driving system and has to carry out the required reaction.

R2. The driver must have enough time to detect wrong or faulty behaviour of the technical driving system and react and be able to bring the vehicle back to a safe driving state. That means, that the controllers have to limit the influence of the technical driving system, e.g. limit the level of acceleration, deceleration and the steering angles or angular speed and angular acceleration and jerks so that the driver always has the time to react. Moreover, the driver must be trained for this function or the controllers must be designed in such a manner that they give enough time for reaction for any driver.

Level 3 differs from level 2 in just one point. The technical driving system is responsible for monitoring of the driving equipment. That means that the system must diagnose itself and the environment in order to decide whether it can go on with driving or whether the human driver must act as a fall back solution. The following questions are important

R3. A clear handshake must be defined between human driver and technical driving system. Either the technical driving system must go on with functioning until the human driver has accepted to take over control or

R4. A certain time of e.g. one second is foreseen for the human driver to take over control at any time, if the technical driving system asks him to do so.

In the first case, the technical driving must be safe life, in the second case the latency time for the human driver to take over must be ensured by technical systems—either by the safe life property or just by the driving situations and speed. Timing considerations can be found in Vogelpohl et al. (2016).

Levels 4 and 5 are even more advanced. The difference between levels 4 and 5 is relatively small, since the distribution of responsibilities is the same, only in level 4 some driving modes are excluded which allows the technical driving system to have

limited capabilities. However, when this system is active, it must be able to take full responsibility.

As a consequence, the technical driving system must always ensure safe driving and would need to be safe life.

The relevant requirements are derived the so called GAMÈ principle, which can be found e.g. in EN 50126 "All new guided transport systems must offer a level of risk globally at least as good as the one offered by any equivalent existing system". Here we apply the phrase on guided transport system just to an autonomously driving vehicle. We compare the classical vehicle with a human driver with an autonomously driving vehicle. Then, there are two aspects to be considered:

a. Performance and
b. The technical system (vehicle and technical driving system) are sufficiently free from dangerous failures.

Both aspects are considered separately. For performance, the technical driving system must be at last as good as a human driver in the relevant driving situations, see Mazzega et al (2016). If this cannot be ensured for all driving situations, the set of relevant driving situations must be limited and the human driver must handle the most complex ones.

The second, the safety aspect can be handled as for any technical system by defining an appropriate safety level (ASIL or SIL). This leads to

R5. The performance of the technical driving system as reaction time, detection and handling of traffic situations etc. with an un-failed system must be at least as good as that of a human driver.
R6. The technical driving system must be developed according to a reasonable SIL / ASIL.

For level 4, a clear handshake must be defined how to pass over responsibility between technical driving system and human driver. Especially, the driving modes must be defined, where the technical driving system must not be used for reasons of e.g. insufficient performance. Handshake must be carried out either during standstill or the technical driving system must early enough inform the driver that it wants to pass control to the driver and the driver must take responsibility. If the driver does not take over, the technical driving system must still have the possibility to stop the vehicles as long as it is in a driving mode, where automatic driving is allowed and possible.

If the driver passes responsibility to the technical driving system he must have responsibility until the technical driving system informs him that it has taken over responsibility.

When driving on an open road, the driver must be in full responsibility of the driving behaviour of the vehicle, see the Convention. Then, even if the technical driving system is able to perform up to SAE level 5 with the necessary safety integrity, the driver must have the possibility to intervene. So, the requirements under a) and b) mentioned for SAE level 2 hold if driving on an open road.

Autonomous driving, i.e. driving without intervention of a human driver is in fact only realized in SAE level 4 (partially) or 5 (completely). This holds even if the laws require a driver to be present.

6 IMPLEMENTATION

In this section, we will discuss possible implementation schemes and principles.

It is clear that for technical driving systems in levels up to 2 the systems must and can be fail silent and R1 and R2 must be fulfilled to ensure that the driver has the possibility to take over control.

6.1 *Arbitration between human driver and technical driving system*

Comparing this with Figure 1 it becomes clear that arbitration between the commands of the human driver and the technical driving system must take place.

There are different levels on which arbitration can take place:

a. driving subsystems
   In this case the force applied by the driving controller and actuator must be so small that the driver can always overrule without a problem. However, he would be either required to switch off the driving controller an actuator manually, or those system need to have an in-built function to detect the interference of the driver and switch themselves off.
b. driving controller and actuator
   Here, the driving controller has two inputs with different priority. The high priority input is used by the driver, the low priority input by the tech-

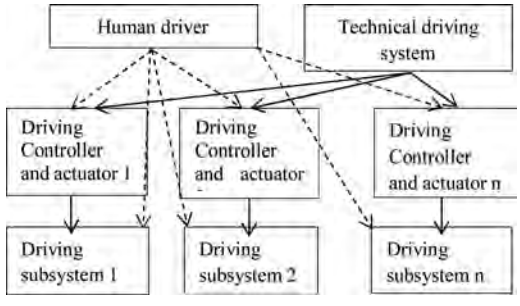

Figure 1. Scheme of a vehicle with automatic driving capabilities.

nical driving system. The arbitration is done by the driving controller which detects overruling by the human driver and switches off the input from the technical driving system. Many controllers in modern cars (brake controller, steering controller etc.) have an additional input for assistance systems which just fulfils this requirement. This approach assumes that the human driver himself controls the vehicle via x-by-wire via the relevant controllers.

c. technical driving system

Arbitration is between the human driver and the technical driving system. If the human driver overrules the technical driving system the latter does not generate its own control signals but simply transfers the signals of the human driver to the driving controllers.

The choice on one of the approaches is a choice of the manufacturer of the vehicle. However, this choice influences the suppliers of the driving controllers and actuators. They need to implement different architectures in their controllers.

In case a) they need to detect intervention of the man driver and deactivate the actuator.

In case b) they need to have two inputs with different priority and need to carry out arbitration

In case c) only one input is necessary and no arbitration is necessary.

We see that x-by-wire is a necessary precondition for solutions b) and c).

We will guide ourselves by the requirements for SAE levels 5 and 2 combined, i.e. for a fully autonomous driving vehicle with a possibility for the human driver to take over responsibility at any time.

6.2 *Technical implementation with safety principles*

For the technical implementation we will discuss the controllers and the technical driving system itself.

Regarding the driving controllers, they need to be developed and implemented according to an adequate SIL. This is for the brake (ABS / ESP) mainly ASIL D, for the steering ASIL B…ASIL D, depending on the function of this controller. With such a choice most of the vehicles can perform with velocities up to 250 km/h.

First of all, we need to determine whether there exists a safe stopping state that can be reached sufficiently quick. Assume the velocity of the vehicle is limited to a value v, the braking deceleration is a and the reaction time t then the vehicle will stop within a distance of

$$s = v \cdot t + v/(2a).$$

Assuming that the steering has no limitation, stopping the vehicle will be a safe action if there is no obstacle within a distance of s from the outer boundaries of the. This area can be made even smaller taking into account that

- actual direction of steering and the (physical) limitations of changes of the steering angle and
- physical limitations for changing the driving direction.

In such case, the technical driving system and the driving controllers could be a complete fail safe system, stopping the vehicle in case that a failure is detected.

Depending on the free space around, the vehicle speed is determined. Obviously, the less free space available, the slower the vehicle must drive.

If the vehicle is intended to move faster, the technical driving system and the driving controllers must be safe life, at least as long as the vehicle is in motion.

The implementation using safety principles differs whether we are talking on a road vehicle or a moving machine. In the first case the environment cannot be assumed to be under control, in the second case this can be ensured since the technical driving system acts on private territory. In this latter case it is much easier to ensure enough free space.

From this consideration it becomes also clear, that not all functions must be always implemented with the highest SIL / ASIL. This depends very much on the speed and the environment. If speed is limited by physical or other means, the also a lower SIL or ASIL can be used. In any case this needs to be shown by the risk analysis that has to be accrued out based on ISO 26262 or IEC 61508.

The following functions are the main functions to be considered:

- Guidance
  How to implement such a function including the steering is described in Bouwman, Schäbe & Vis (2006). Mostly the steering of the axles needs to be safe life and a safe computer has to be used in the technical driving system to determine the steering angles. Another important function is determination of the location, where differential GPS, maps together with ultrasonic sensors, radar or lasers or cameras or different types of marking placed physical on the lane of the vehicle can be used. The safe computer will determine the real location and compare this with the assumed location as a result of its steering activities and correct or stop he vehicle.
- Braking and acceleration
  Assuming that the vehicle moves along the desired trajectory, the vehicle needs to start,

move and stop. So the vehicle needs to react to these commands. It is important to limit the speed e.g. in curves or at narrow places and to be able to perform an emergency stop, if parts of the system fail. In order to perform this function, the system needs to know the location.
Solely with these two functions the vehicle would move without taking into account the environment. Any change in the environment could lead to a collision or the vehicle leaving its track.

- Reaction to unforeseen events (obstacle)
The vehicle must be able to detect obstacles. By an obstacle we denote any object that is in the (planned) or near the (planned) trajectory of the vehicle. We need to distinguish fixed obstacles and moving obstacles. In the beginning we consider as only strategy of the vehicle to stop in front of the obstacle. Moving around the obstacle will be considered later together with moving obstacles
  a. Stationery obstacle: To detect the technical driving system needs to have a blueprint of the environment and needs to compare the real environment with that blueprint and detect differences. This would require certain algorithms for detection and classification of objects. Note that "detection" and "blueprint" does not mean that the technical driving system uses optical means. It can be optical means, but also others or in combination.
  In a first step the obstacle as such needs to be detected. This is possible only at a certain distance and takes a certain time. This performance of the system might limit the speed, since the vehicle must always come to a standstill in front of the object.
  In a second step the technical driving system can classify the obstacles as small. Note that this classification can be present implicitly if the technical driving system will not detect obstacles of small size. Such a classification is always present due to limitations of the system.
  If the obstacle is small enough and not tall, the vehicle might decide to go on with driving.
  b. Moving obstacles: Moving obstacles must be traced and its motion must be predicted using the actual position and speed. It must also be taken into account whether the object can accelerate or decelerate or change its motion direction. The latter factors strongly depend on the nature of the object. E.g. a motorbike can reach other acceleration values as a pedestrian. In order to provide a good prediction, the technical driving system must cluster moving objects according to their capability of motion. Consequently, for each object of the different clusters future positions must be predicted and the technical driving system must define the motion of the vehicle in such a manner that collisions are avoided. This might lead to the decision to stop or to keep the present fixed position.
  Depending on the performance of the clustering and prediction algorithms, the technical driving system would behave more or less conservatively. With better algorithms the technical driving system would stop less frequently. We remind that the performance of these algorithms together with the stopping process in case of doubts about the future trajectory of the obstacle must be as least as good as that of a human driver. This includes of course strategies to drive around an obstacle.
  c. Stationery obstacles that could start moving are in fact a combination of cases a) and b) discussed above. This means, that the technical driving system must not only trace moving obstacles but must also be able to classify stationery obstacles and provide a judgement on whether they might move and with which velocity and in which direction. A most safe strategy would surely be to stop at a safe distance of any unknown object.
  If a proper reaction of the vehicle cannot be ensured for all driving situations, the set of relevant driving situations must be limited and the human driver must handle the more complex ones. This would lead to an SAE level 4 situation. An example would be a strategy, where the technical driving system takes over control on a motorway and the human driver in the city.

7 PROBLEMS

In connection with autonomous driving some problem appear. We will, discuss only some of them and try to describe possible technical solutions.

a. Assume an autonomous vehicle cannot prevent an accident and needs to make a choice, e.g. between material damage, environmental damage and injury or—even worse—injuring or even killing either an older or younger person, another driver, the own passengers etc., see e.g. EK (2017)
This type of discussions automatically comes up when the responsibility for driving is carried over from the human driver to a technical driving system. The ethic problem that is behind this discussion cannot be solved in this paragraph. It is obvious that a technical solution to this problem would require to distinguish between persons and objects or animals, to discriminate between different persons etc.

This would require rather complex algorithms, if it is feasible at all.

The simplest solution to the problem is to apply the principle of driving on sight. That means the rule for the autonomous vehicle would be to drive only with such a velocity that it can stop before each obstacle that appears on the road. This requirement covers:

- Detection of any obstacle above a certain size,
- Prediction of movement of objects (which is the most complicated part),
- Reducing speed if necessary to come to a standstill before such an obstacle.

Based on such a "safety first" approach, later on objects of certain (small) size can be neglected to ensure performance and avoid the vehicle stopping in front of a leaf or a plastic bag.

b. Additional information

A vehicle might optionally use additional information provided by the infrastructure, which might lead to better performance regarding safety.

Let us consider the following example. The vehicle uses information from cameras mounted on the street and has the possibility to "look around the corner". Then, it could e.g. detect a suddenly appearing child running out of the house, what a human driver could not.

c. Safety targets

Since the target of autonomous driving behaviour would always be the performance of a human driver, the technical driving system would have to fulfil this important requirement. However, assume that autonomous systems will set a new target in the future—then the question will arise: Does the driver have the right to switch the automatic system off and decrease the achieved level of safety? It would be somehow equivalent to a train driver switching off automatic train protection, e.g. to use some speed margins. This simple example shows that the way to autonomous driving would be a one-way street, with no return to manual driving at the end.

8 CONCLUSIONS

In this paper we have presented some ideas on possible safety architecture for autonomous driving, deduced from known safety principles and from general requirements. We have analysed the SAE levels and the implication for the safety architecture per level.

Possible implementation principles have been described and specific problems of autonomous driving have been discussed.

Tool for risk reduction at specific component aircraft engine welding

D. Procházková & J. Prochazka
Faculty of Transportation Sciences, Czech Technical University in Prague, Czech Republic

ABSTRACT: The safety is on the first rank in the aero industry. From this reason at the aero components fabrication, the great attention is given on precision and perfection of execution of all production operations. It goes on removing the causes of aircraft accidents caused by errors at production, assembly and maintenance of aero engines. The detail research aimed to improvement of safety was carried out for the GE Aviation Czech company in Praha. It was directed to the aero engine production at which it is necessary to observe the technological procedures and to eliminate the human factor that influences the production process. In the paper there are given results connected with the production of aero engine protective cowling, namely specifically at welding the basic components. It contains special checklist and results of safety audit.

1 INTRODUCTION

In the aero industry, the safety is on the first place. From this reason, at aircraft component production, the great attention is given on precision and perfection of execution of all production operations. It goes on elimination of causes of aircraft traffic accidents caused by faults at production, montage and maintenance of aircraft engine (GE Aviation 2015). The detailed research aimed to safety improvement was performed for the GE Aviation Czech in Praha. It was aimed to domain of aircraft engine production in which it is necessary to respect the technological procedures and to eliminate the human factor troublesome impacts, which influence the production process.

In present paper, the partial results of research are given. These results are connected with the production of protective cowling that is located inside the aircraft engine, and it is attached to the outer aircraft engine shell that fenced the capacity turbine. Its task is to protect the aircraft engine against fragments of blades, discs or of other parts. On the basis of evaluation of information in technical operation notebooks (GE Aviation Czech 2017a) we concentrated the great attention to welding of fundamental components of protective cowling.

For identification and assessment of risks there are used the risk engineering methods, namely the process maps, check lists and safety audits (Procházková 2011a). With regard to the production technological procedure basis (GE Aviation Czech 2016) and the production technical documentation (GE Aviation Czech 2017a), the detailed check list was processed for safety audit that was handed over to experts of the Company Technical Board to the review. After its permission the safety audit was realised with help of checklist under account. The outcomes for individual items of check list at the safety audit were determined as median from results obtained from 3 specialists (company auditor, supervisory department leader, state inspector). By evaluation of audit results the critical spots of welding process were found. Consecutively, the measures for safety improvement of both, the production and the product, were proposed in cooperation with company experts.

2 SAFETY CULTURE, LOSS PREVENTION AND PROCESS SAFETY

The culture denotes the specific material and spiritual values that the humans create by their activities and by which they enhance the life of both, the humans and the whole human society. The society culture is an integral system of substances, values and societal norms, which the members of a given society follow, and which through sharing they transmit to next generation. It is the collection of values, symbols, company heroes, rituals and own histories that act upon exterior, and they have big influence on human behaviour at working positions (Procházková 2011b).

On the basis of just given culture definition, the safety culture means that the human at all his / her roles (control worker, employee, employer, citizen or disaster victim) respects the safety culture, i.e. he / she behaves in a way so he / she may not cause to happen the possible risks realisation, and if risk realisation happens, he / she may contribute to the effective response, the protective interests´

renovation and to start of further development. According to some authors it goes on set of attitudes, surmises, norms and values that exist in a given entity. It is the reflection of way, by which the company is ruled, i.e., they include the general principles of separation of authority and responsibility, principles of management and a certain ration among the accent of working outcomes, authority, care on humans, observance of safety principles and ensuring the given entity functionality (Procházková 2011b).

The effective safety culture is the fundamental element of safety management. It reflects the safety concept and it goes out from values, attitudes and manners of top management workers and from their communication with all involved persons. It is obvious obligation to participate in solving the problems of safety and it promotes so all involved persons perform safely and so they observe the appropriate legal rules, standards and norms. The safety culture rules need to be incorporated into all activities in each entity and in each territory. Their ground is not the concentration to punishment of malefactors / originators of faults, but the lessons learned from the mistakes and the introduction of such corrective measures so mistakes could not repeat, or rather their occurrence frequency might be distinctly reduced.

The safety culture principles with (Česká technologická platforma bezpečnosti průmyslu 2015) are:

1. Outright, open attitude to weak spots, action directed to finding the solution.
2. Diversion from the culture of determination of responsibility for fault and punishment of such person.
3. Employees, employer and top management behave responsibly, separately and with orientation to team. It means that the safety culture is a part of their life.
4. Safety standards are accepted and integrated to everyday company life.
5. Safety and health protection form important value for both, the company workers and the whole company.

The safety culture level is the quantity that cannot be directly and exactly measured, but for all that it has fundamental influence on workers´ behaviours, the management style and the technology level. The definition of weak and strong features in individual parts of safety is important for safety culture level. The comparison of time series of investigations permits to evaluate the effectiveness of corrective measures.

The safety culture for company manufacturing the aircraft engines means that the company undertakes to carry out the manufacturing with the highest safety standards. For reaching such aim, it is crucial and important to have in force the effective and without disincentives the pursued announcement of all accidents, incidents, near misses, random events and cases, experiences, doubts and further information and data that might adversely shaped the element of component of produced aircraft engine. After all, each individual employee is not only kindly encouraged, but also obligated to announce the arbitrary information concerning the safety.

The announcement is not the subject of some imputation and following retributive measure. Its main purpose is the management and govern of risk and preceding the accidents and incidents, i.e. not to impute the blame. They are not made interventions against employee, who reports any data concerning the safety by help of report system, until such announcement without any doubts does not expose that there was commit the criminal act, offensive negligence or intentional and conscious violation of rules or technological procedures. The method of collection, recording and spreading the precaution information secures the protection in the whole width and range according to the law, including the protection of identity of person, who announces the information concerning the safety (Česká technologická platforma bezpečnosti průmyslu 2015). The individual pillars of safety culture are shown in Figure 1.

In link-up with the safety culture there are often in present professional literature connected with technologies used the terms loss prevention

Figure 1. Fundamental pillars of safety culture (DEPOSITPHOTOS 2014). It is necessary to introduce: open communication; accent on prevention; incident analysis; support of safe behaviour; and to provide resources for safety formation.

and process safety. Their definitions we give also for that reason that they are the tools that in connection with technologies serve for protection of persons and property. Loss Prevention is the systematic approach to prevention of accidents, or at least to reduction of their impacts. It includes the means for elimination of sources of risks or for reduction of probability of their realization, and for mitigation of impacts connected with this realization (preventive and consequential measures). Further it includes the identification of suitable supervisory measures, identification and application of suitable remedial measures, by help of which it is ensured the safe entity with appropriate level of security and sustainable development that does not pose unacceptable danger for its vicinity (Procházková 2011c).

The process safety or better the safety of processes is a branch of safety directed to safety in industry, in which there are series of manufacturing and additive processes that are necessary for setting up of final product of a given industry. Together with production it goes on averting the accidents that have special and characteristic features for a given specific industry. It deals e.g. with the prevention of immediate leakage of chemical substances or energies in harmful amount, and in case if such leakages occur with the reduction of their sizes, impacts and consequences. It does not include the questions of classic safety and protection of workers at work, i.e. it deals with purely technical problems, by which it differs from the system safety that is directed to all public assets.

3 AIRCRAFT ENGINE SAFETY

The aircraft is a floating transport vehicle that is heavier than air with the solid wing. It goes on the safe system, which has basic parts: kite (wing, fuselage, tails, flying equipment, landing gear); paraphernalia (life-saving systems, defroster system, air-conditioning, outfit of cockpit, instruments) and propulsive segment (ULT 2014); the schematic technical picture of aircraft is in Figure 2.

So the aircraft might fly, it needs certain flying speed and trend angle, otherwise it might happen the loss of required lift for flight. The required flying speed ensures the tractive component, i.e. the aircraft engine. The aircraft engine consists of generator (engine heart), which is composed from compressor, combustor and generator turbine. The compressor from surrounding atmosphere sucks the air, it compresses it and shift it up to combustor. In combustor it arrives to fuel injection that burns, and developed hot gases drive the generator turbine. Over joint shaft this turbine drives the compressor and by this it obtains the compressed

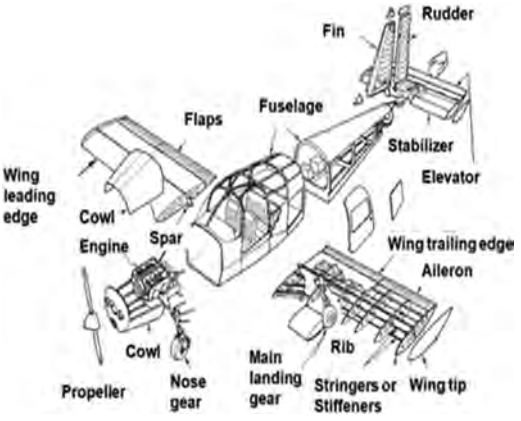

Figure 2. Schematic picture of aircraft (ULT 2014).

air that is necessary for fuel combustion (GE Aviation 2015). For drive of loose turbine that is joined to propeller over the gearbox with constant rate, the aim of which is the reduction of high turns of speed of this loose turbine on the level that is usable for propeller, it is used the remaining energy in hot gases behind the generator turbine (GE Aviation 2015).

The important role at engine protection it fills the protective cowling (GE Aviation 2015). It goes on rigid, i.e. non-rotatory part, the function of which is to catch the prospective fragments of blades, discs or of other parts. It is located inside the aircraft engine, and it is attached to the outer aircraft engine shell that fenced the capacity turbine. Because, it ties to the combustor, from which the hot gases are regulated to the output turbine blades, it is designed by the way, so in addition to absorption of spasmodic performance it would withstand the high temperature and pressure (GE Aviation 2015).

From this reason, the protective cowling needs to have the capability to catch the high kinetic energy. Even if the turbine blade has relatively small mass, so the computation (Marešová 2017) shows that that centrifugal force comes to near 16 000 N, which it is in conversion around 1.6 t.

From the viewpoint of construction of protective cowling, it always goes on compromise. On one side, it is the requirement on sufficiently robust construction, so the safety may be sufficiently ensured. On the other side, it is the requirement, so its mass may be the smallest.

The analysis of faults of rotor (Marešová 2017) shows that on engine failure, they are responsible in 60% fragments of engine parts (56% fragments of blades, 4% fragments of discs, box, gasket etc.), and that the protective cowling does not catch only 15% fragments of blades.

4 DATA FOR PROTECTIVE COWLING

From the technical documentation (GE Aviation 2015), it follows that all parts of hot department of aircraft jet engine, i.e. also the protective cowling need to withstand the impacts of high temperatures and high pressures. From this reason, the only materials´ type, which can be used, is the nickel and cobalt super alloys. To this group, it also belongs the super alloy Nimonic 80 A, which is used for the protective cowling manufacture.

The fabrication of complete protective cowling is time-consuming process. The layout of protective cowling is composed of four parts (Figure 3) that are mutually put together by welding.

The protective cowling composes from 4 parts:

1. Buffer—it is the most important part of protective cowling that comes as the first into contact with blades. Its function is catching the prospective parts of high pressure turbine (blades).
2. Coat—it acts as location of joint (the joint is not part of protective cowling makeup). The joint serves for set up of complete layout of protective cowling with the engine envelope.
3. Whorl—it serves for set up of buffer for tacking to engine envelope.
4. Strut—it serves for set up of coat into proper location compared with buffer.

The manufacturing process of these components includes the great spectrum of manufacturing technologies, as the process map in (Marešová 2017) shows. Among these works, it is possible to find the processing by help of standard lathes or by help of locksmith works, the CNC working as it is use of CNC lathes and CNC milling machines and flection. Further, there are used special working processes as the annealing for remove of internal tension and precipitation case-hardening or the welding by method Tungsten Inert Gas (TIG). The important operations in material processing are inter operational checks for audit of dimensions and correct processing. One of such specific audits, it is special luminescence technology for identification of cracks and surface defects in material. On the basis of analyses of manufacturing procedures in (Marešová 2017) performed on the ground of operation notebooks (GE Aviation Czech 2017a), it was shown that the critical operation is also the TIG welding. From this reason we give below the results of our investigation.

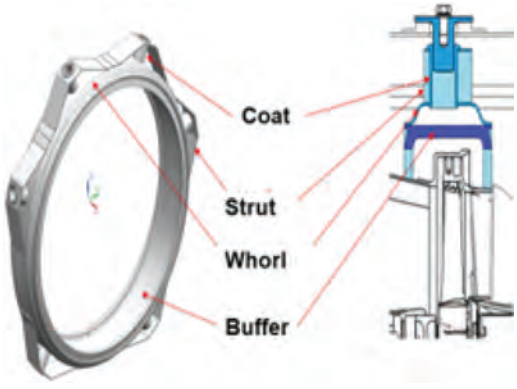

Figure 3. Picture of layout of protective cowling and its components (left) and picture of protective cowling position in aircraft jet engine (right) (GE Aviation Czech 2016).

The TIG welding belongs among the arc welding methods. The electric arc is between the infusible wolfram electrode and molten weld metal in inert protective gas atmosphere. In considered case, there are used argon, helium or their mixtures (Hrivňák 2009).

The TIG welding method was set up at the end of 30 s of twentieth century for welding the magnesium alloys. This welding method partly replaced the fastening with rivets that in that time was the most used method for soldering the components from aluminium and magnesium in aero industry.

The given welding method is the most important at welding the components from stainless steel, aluminium, magnesium, copper and reactive materials (e.g. titanium and tantalum). The thickness of weld materials ranges from several tens of millimetres up to several millimetres (Olson 1993).

The TIG method advantages over against other ways of welding are according (Olson 1993) the following:

1. Manufacture of high quality welds, i.e. low deformation of welded parts, welds with minimum amount of impurities, gasses, respectively pores and cracks by occurrence of which it is reduced the material capacity (resistance to high temperature and high pressure).
2. At welding, the skewness does not origin, and therefore, no need for its removing.
3. Welding is possible to perform with or without additive material.
4. Welding is possible almost for all material kinds and also various materials.
5. Precise audit of weld parameters is possible.

The TIG welding method is used in cases in which there are requirements on high quality of welds. By this method it is possible to weld almost all metal materials. The welder is capable during the welding to perform the precise check of heat taken in weld, because the weld surrounding is not rounded during the welding by vapours and gasses from the process (Olson 1993).

Except of advantages the TIG method has in comparison with other methods also disadvantages, according (Olson 1993) they are:

1. Lower weld output in comparison with other arc welding methods.
2. Higher demands on welder craftsmanship.
3. Higher economic demandingness of production in comparison with welding method by coated electrode.

According to regulation AWS D17.1 (AWS 2013), the welds according to mutual location of welded parts are divided in:

1. Blunt welds—joint of two materials (sheets or pipes), mutually put together by frontal surfaces.
2. Fillet welds—joint of two materials that form an angle and the welding joint is located on edges of these welded parts.

In the next part there are only given results for blunt welds by the TIG method.

5 USED RISK ENGINEERING METHODS

For detection and judgement of risks there were used the following methods: process map, i.e. the scheme picture of production process that shows places in which are possible conflicts in production because of insufficient workplace capacity or bad production planning (ASME 2010); Check list (Procházková 2011a); and safety audit (GE Aviation 2015, Procházková 2011a).

Specific check list was compiled according to manufacturing technique of TIG method (GE Aviation Czech 2016), in which the critical spots were determined on the basis of operating events company book (GE Aviation Czech 2017a). It is given in Table 1.

The judgement of safety audit results was done according the ČSN OHSAS 18001scale, Table 2 (Procházková 2013).

Table 1. Check list used for risks evaluation in welding process; SN—serial number, Y—YES, N—NO, R—remark.

SN	Question	Y	N	R
Preparation before welding				
1	Are connected surfaces of welded parts metallically unalloyed, i.e. are they ridded of tips and rough layers of oxide?			
2	Are connected surfaces of welded parts ridded of smear?			
3	Are connected surfaces of welded parts ridded of other dirt affecting the final weld quality?			
4	Is set up of welded parts, i.e. the size of weld space, in concord with requirements of regulation?			
5	Is set up of welded parts, i.e. the size of overlapped surfaces, in concord with requirements of regulation?			
6	Are the edges of connected materials in place of future weld ridded of splinters?			
7	Are the edges of connected materials in place of future weld without gross shrink?			
8	Are welded parts put down on unpolluted surface of work bench?			
9	Is it manipulated with welded parts in clean cotton gloves that do not release fibres?			
Machines and fittings				
10	Are used for welding only certifiable machines and apparatuses?			
11	Are used for welding only calibrated machines and apparatuses?			
12	Are used for welding only certifiable machines and apparatuses determined in technological procedure (SMC 2004)?			
13	Is the welding source capable to be continuously regulated in the whole range of values of welding parameters given in technological procedure (FLICKER 2012)?			
14	Is the source of protective gas capable to be continuously regulated in the whole range of values of welding parameters given in technological procedure?			
15	Is the source of electric current for welding without symptom of defect?			
16	Is attachment for welding without symptom of defect?			
17	Are cables for welding without symptom of defect?			
18	Is the underlay piece on working table, on which the welded components are located, flat, without sharp roughness and dents?			
19	Is the underlay piece on working table, on which the welded components are located, from the electrically conductive material?			
20	Are the staples of welding apparatus located in close contiguity of welded components?			
21	Is ensured the sufficient conductivity between staple and the underlay piece on working table?			
22	Does the protective gas quality fulfil the minimal demands on pureness according to norms in force and rule (SMC 2004)?			
23	Is used the protective gas according to technological procedure (SMC 2004) with obligatory certificate?			

(*Continued*)

Table 1. (*Continued*).

SN	Question	Y	N	R
24	Is welding burner range for a given electric current load?			
25	Are cable ranges for a given electric current load?			
26	Is the burner spout without noticeable defects?			
27	Is the spout diameter in the range determined in technological procedure (SMC 2004), which enabling the supply of sufficient amount of protective gas for the effective protection of welded metal against influences from surrounding atmosphere?			
28	Does the wolfram electrode type correspond with demands given in technological procedure (SMC 2004)?			
29	Does the wolfram electrode diameter correspond with demands given in technological procedure (SMC 2004)?			
30	Is the wolfram electrode also ranged for maximal electric current load?			
Welding personnel				
31	Does the welding perform the qualified welding personnel?			
32	Is the welding personnel properly trained?			
33	Does welding personnel keep the welding certificate?			
34	Does welding personnel keep the valid medical check?			
Welding process				
35	Are in the case of requirements on tacking, the stitches uniformly arranged?			
36	Are the stitches without cracks and craters?			
37	Is it used as the additive material only certificate weld wire?			
38	Is the additive material degreased?			
39	Is the additive material free from dust and dirt?			
40	Is the additive material properly branded?			
41	Is the additive material stored in original packing?			
42	Does only use the additive material that is properly branded?			
43	Is it suppressed to use the unbranded additive material?			
44	Is used for welding the weld wire with demanded chemical texture?			
45	Is used for welding the weld wire given in technological procedure (SMC 2004)?			
46	Is used for welding the weld wire with diameter in demanded range?			
47	Is the welding current regulated according to the technological procedure or the weld certificate (SMC 2004)?			
48	Is the welding speed set according to technological procedure or the weld certificate (SMC 2004)?			
49	Is the surface of welding formation cleaned after welding by stainless brush?			
50	Is the part influenced by heat cleaned after welding by stainless brush?			
Check after welding				
51	Is the visual check of weld performed in workplace that is determined for such check?			
52	Are accessible the records on minimal demanded value of lighting intensity (300 lx)?			
53	Is the visual check by purely eye performed according to rule for visual weld check?			
54	Is the visual check performed by magnifying glass with demanded enlargement according to rule for visual weld check (SMC 2004)?			
55	Is the personnel pursuing the visual weld check qualified?			
56	Is the personnel pursuing the visual weld check trained?			
57	Are records from weld check get-at-able for next check?			
58	Are in the case of detection of weld defects, these weld defects eliminated?			
59	Are the weld defects eliminated only in range permit by a given rule?			

Table 2. Risk rate according to scale (Procházková 2013).

Risk rate	Number of answers "NO" v%
Extremely high	More than 95%
Very high	70–95%
High	45–70%
Medium	25–45%
Low	5–25%
Negligible	Lower than 5%

6 SAFETY AUDIT RESULTS AND PROPOSALS FOR SAFETY IMPROVEMENTS

The check of welding was performed on workplace "Svarovna" under supervision of technologist and auditor. In case of answer "NO", it was given argument, why this is. The judgement was performed by auditor. Except of judgement by check list, there were drawn up the photo documenta-

tion and taken down the record, that was signed by all participants, i.e. also by welder (GE Aviation Czech 2017c).

From the record (GE Aviation Czech 2017c) it follows that that at answers to 59 questions, six answers were "NO", i.e. 10%. From the risk rate viewpoint, it goes on low rate of criticality.

For removing four problems that affect the weld quality, there were proposed the measures:

1. Problem 1 – the connected spaces of welded parts are not before itself welding ridded of tips, rough layers of oxide, smear and further dirt negatively affecting the quality of final welds (GE Aviation Czech 2016, Hrivňák 2009, Olson 1993). Before the welding, the welded parts are only washed in cleaner bath. On the surface of these parts the residues of cleaner emulsion are evident.
   Proposal for improvement:
   For reach of high quality of weld joint, it is necessary from the surface of parts in place of future weld to remove all grimes. The surface oxides and apposite tips may be removed mechanically by help of stainless brush or SiC abrasive material (abrasive canvas). The part degreasing is suitable to perform chemically, i.e. by acetone or technical ethyl alcohol. This is important, because the smear, especially the sulphur reacts with nickel in welding bath and causes crack in a given weld.
2. The welded parts need to be set up from the reason of reaching the acceptable weld slit (GE Aviation Czech 2016, 2017a).
   Proposal for improvement:
   For reach of high quality of weld joint, it is necessary so weld slit at rim welds was minimal, ideally null-space. The reason is reality that at stiffening the weld metal it arises to its contraction, and by this to origin of tensile stresses. The higher the weld slit is the higher tensile stresses originate. When the size of originated tensile stresses exceeds the material solidity limit, it goes to origin of cracks. From this reason, the quality of performed welds is influenced not only by itself welding process, but also the preparation, i.e. make-up of parts. To reach demanded make-up, the technological procedure (SMC 2004) needs to be kept, i.e. it is necessary to keep the set tolerance, which goes to increase of exactness of dimensions of produced parts.
3. The additive material for welding is used in form of rod with diameter Ø 2.0 mm. In spite of the fact that weld with additive wire Ø 2,0 is certificated as convenient, so for welding the materials from which the protective cowling is produced it would be more suitable to use the additive wire with lower diameter, ideally Ø 1,6 mm. The reason is the lower amount of heat necessary for smelting the welding wire, and so lower amount of heat carried into weld. By this way the part of weld vicinity (TOO) affected by heat is smaller (GE Aviation Czech 2016, SMC 2004). In our case it goes on welding the case-harden material, in which the cracks just originated in the TOO (GE Aviation Czech 2017a), i.e. the smaller TOO, the lower is the probability of defect origin.
   Proposal for improvement:
   On the Czech Republic territory, the supplier of additive material with demanded thickness 1,6 mm is not. The foreign suppliers offer this material in packets with great amount, which leads to wastage. From this reason this proposal has not been realised yet.
4. For execution of welding, it is not positional fittings. By producing such positional fittings with adjustable speed of rotation, it would reach the facilitation of work, increase of comfort, and primary the improvement of work, and by this also the weld (Marešová 2017). The positional fittings can be used for welding the other welded part of aircraft engine.
   Proposal for improvement:
   The purchase of new positional fittings and the judgement of its influence on improvement of weld quality and work ergonomics are in run.

7 CONCLUSION

On the basis of project on co-operation of our faculty with the GE Aviation Czech, there are step by step created the tools for decrease of operational risks with aim to ensure the high safety of aircraft engines. One of such tool connected with welding the protective cowling is described above. The safety audit performed with specific check list revealed four defects. From the safety reasons three defects were fast rectified; the last one is in handling due to the present inaccessibility of economically acceptable product.

Reliability of supplies in a manufacturing enterprise

J. Żurek & M. Zieja
Air Force Institute of Technology, Warsaw, Poland

J. Ziółkowski
Military University of Technology, Warsaw, Poland

ABSTRACT: The article brings closer the methodology of material requirement planning in a manufacturing enterprise. A manufacturing structure consisting of two independent products, A and B, showing modularity of design was assumed. A mathematical description reflecting the dependencies of individual product components used to execute a delivery schedule was used for the calculations. The article describes how to plan the production of products with a module characteristics and determine its supply moment so as to maintain a continuity and rhythmicality of a manufacturing process. It is of utmost importance due to the prompt execution of external orders (independent demand) and thus it has an impact on the dependability of the execution of orders. The suggested methodology of proceedings eliminates errors, reduces the stock level, enables to fully control particular production stages, improves the utilization of the available resources and synchronizes both order and delivery processes of materials with production needs.

1 MATERIAL REQUIREMENT PLANNING IN TERMS OF RELIABILITY OF SUPPLIES

The functional specificity of industrial companies involves processing raw materials into finished products, as a result of a creative process. This process is associated with changing the form, shape or properties of a product defined as a final product.

The aim of the article is to present a methodology for describing products of a modular structure, and then to utilize it to develop a delivery schedule, ensuring reliability of manufacturing orders fulfilment. It can be achieved through timely execution of assembly tasks, precise determination of stock levels, defining the size of manufacturing batches, and synchronizing and control of the manufacturing-assembly process.

Material Requirement Planning (MRP) is defined by the literature in an ambiguous manner. In a book by Cecil Bozarth and Robert B. Handfield, MRP is defined as: "a planning process enabling to translate the superior manufacturing plan onto the planned orders for the parts and components necessary to manufacture products, of which the completion was included in the superior plan" (Bozarth & Handfield 2007). Whereas Donald Waters, in his book, state that: "(…) material requirement planning utilizes the main manufacturing plan in order to schedule the material supply. Expanding the main manufacturing plan allows planning material supplies at the very moment they are needed" (Waters 2007).

B. Śliwczyński has a slightly different perception of the MRP concept, writing: "(…) planning material requirement covers every element of the final product, in each of the manufacturing stages and defines the material requirements, resulting from the product range, volume and lead time of a manufacturing batch. The lead times of deliveries of the materials and elements necessary to manufacture a finished product are calculated as per the MRP method, according to the main manufacturing schedule. As a result of material requirement planning, a delivery schedule is developed, which is the basis for material supply planning" (Śliwczyński 2008). On the other hand, S. Krawczyk positions MRP within the process of handling a manufacturing enterprise, therefore, relates it to, i.a., the level of customer service. Therefore, the author draws attention to the aspect concerning delivery reliability, which should be understood in a slightly narrower sense as timeliness (Krawczyk 2011). The concept of supply reliability, related to a company, may and should be considered on many levels. For example, supply reliability may be shaped by: lack of damage, relevance, timeliness, conformity, completeness, etc. T. Nowakowski indicates that supply reliability is impacted by: its timely execution, completeness of an order and releasing/receiving undamaged goods (Nowakowski 2004 &2011). J. Żurek points to a

direct relationship between reliability and readiness, and relates these terms to operational processes of facilities and technical systems (Niziński & Żurek 2011, Żurek & Jażwiński 2007). With regard to the reliability of systems associated with stock control, the author implies that one of the basic delivery reliability methods is to maintain an excess stock, understood as a safety reserve. Furthermore, the author differentiates between stock levels, depending on the cost criterion (prices). The author states that stock of cheap elements may be maintained at a high sufficiency level, while the stock of expensive elements at a low or zero sufficiency level. Very expensive elements are often purchased only in the event of a demand (Waters 2007). S. Werbińska-Wojciechowska points also to time redundancy in the aspect of evaluating availability of logistics system resources in companies, drawing attention to the issues of temporary stock availability (Werbińska-Wojciechowska 2007, 2013).

An MRP system improves stock management and facilitates the creation of requirement plans for raw materials and materials necessary for manufacturing, for which the demand depends on market needs. They make up the manufacturing schedule, defined by calendar time, which takes into account both the assembly labor consumption, as well as the lead times of component deliveries. Therefore, its correct execution impacts the delivery reliability understood (to a narrow extent) as timeliness of executing manufacturing tasks. Basic information of the Material Requirement Planning system (MRP) form information streams, with their set containing (Bozarth & Handfield 2007, Krawczyk 2011, Skowronek & Sarjusz-Wolski 2012, Śliwczyński 2008):

- main manufacturing schedule;
- product structure;
- stock main set.

MRP system's information streams are presented in Fig. 1.

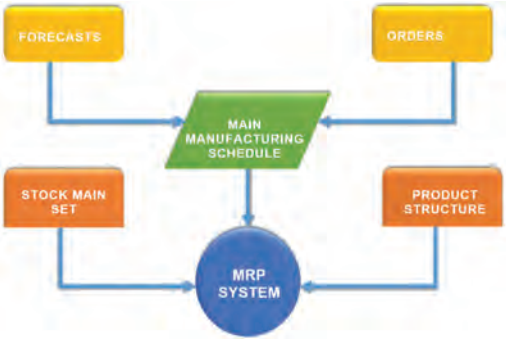

Figure 1. Information streams supplying an MRP system.

As indicated in Fig. 1, information streams making up an MRP system are formed by: the main manufacturing schedule, which is developed in the long term on the basis of sales forecasts, and in the shorter time horizon, it is confirmed by orders coming from the customers. The second stream is a set of stock, expanded by assembly-delivery lead times, while the third one is the modular structure of a product. The components described above shall be used for practical development of a delivery schedule.

2 SCHEDULING DELIVERIES IN PRACTICE

An essential component of an MRP system is the manufacturing schedule, which includes orders from customers, concerning the required number of products and the order lead time. In this context, a correctly drawn up delivery schedule ensures reliability, understood as delivery timeliness. In order to develop such a schedule, we also need the structure of products A and B (Fig. 2 and Fig. 3), and its description method, which shall be utilized for the calculations.

In structural terms, the presented final product consists of products A and B, which include repeating structural fragments, called modules, appearing in at least two locations within a discussed structured.

Two types of functional modules may be distinguished in the structure of product A:

- module of the 1st order C-1 (consists of the mentioned module of the 2nd order D-2 and four elements marked as F);

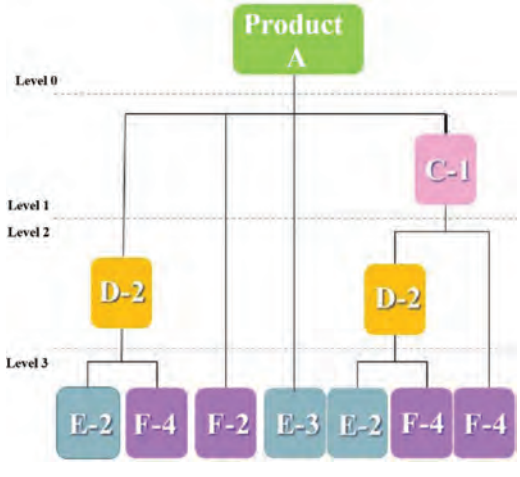

Figure 2. Product A structure.

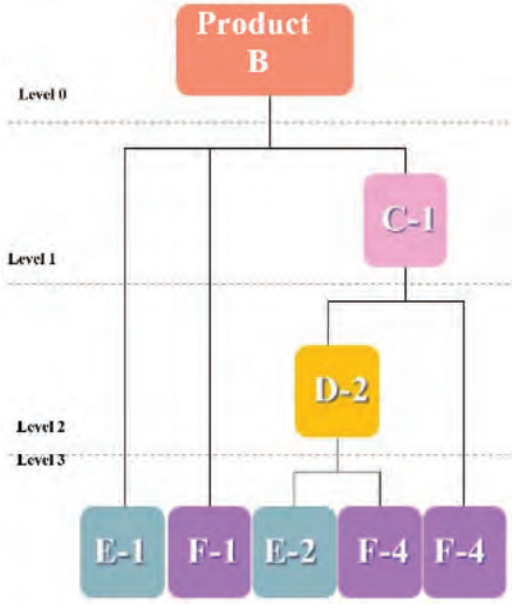

Figure 3. Product B structure.

- module of the 2nd order D-2 (consists of two E type elements and four F type elements).

Furthermore, product A consists of elements located within the structure on three functional levels. The first level contains a C-1 type module, the second one represents the D-2 module, while the third one contains F-2 and E-3 type elements, independent in structural terms, subordinate directly to product A.

The structure of product B should be discussed by analogy (Fig. 3). We should remember that products A and B located in level 0 are structurally independent in relation to each other, but combined form a single final product. The indicated modularity of both products causes a specific description of their structure, used for calculations in the delivery schedule (MRP). Below you can find a presentation of the description methodology, according to which such a schedule is to be executed, starting with level 0, and ending with level 3.

The first structural level of both products making up a finished product, contains one C-1 type module (it is a so-called module of the first order). The second structural level contains a D-2 type module (a so-called module of the second order). The methodology of describing such a structure is as follows:

- products A and B are located at the same level (level 0) and there are no structural links between them, therefore, they are not subject to a description;
- level 1 in both products contains a C type module, the second level contains a D type module, and the third level contains E and F type elements, which are indivisible in terms of structure;
- the fact that module C is present in products A and B is recorded as follows: C(A, B);
- the second product structure level contains a D-2 type module, whereas in relation to the structure of products A and B it has a slightly different location, that is, in the case of product A it is directly subordinate to A (level 0), while in relation to product B, it constitutes a part of a C type module (level 2), and this fact shall be recorded as D(2A, 2C);
- the last level (level 3) contains elements, which should be described according to the principles set out above, therefore: E(3A, B, D) and F(2A, B, 4C, 2D).

Table 1. Main manufacturing schedule.

The above methodology of description shall be used for calculations in a Manufacturing Requirement Plan (MRP).

Table 1 presents the planned manufacturing of products A and B, a D type module and an element marked as E.

Table 2 presents the stock level of a company regarding individual products, modules and elements on week one and seven. They are used to calculate the net demand, which is defined as the difference between the gross demand and available stock.

Table 3 presents the delivery times for products, modules and elements, which enable the determination of an exact moment, so as to ensure manufacturing continuity and an effective utilization of available stock.

Table 4 below, presents a Material Requirement Plan (MRP), for the development of which the data summarized in Tables 1–3 was used. The above description methodology, which is characteristic for the structure of products A and B showing modularity, was used to calculate the gross demand. This methodology applies to the description of modules marked as C-1 and D-2, and the elements defined as E and F, therefore, it relates to the components assigned to levels 1–3 of a product structure (cf. Figs. 1 and 2).

The presented material requirement plan was developed for a time horizon covering a range of 1–10 weeks. The gross demand for products A and B was submitted in weeks 6–10. After taking into account the delivery lead times and assembly times, the generated internal orders actually covered a time period of 1–4 weeks. It is associated with the so-called reverse planning, and a bill of material, related to the structure of the product in each case.

3 CONCLUSIONS

The objective of this paper was to develop a descriptive methodology for products with a modular structure and its application in manufacturing scheduling. The planned objective was achieved, and the article presents the manner, in which to plan manufacturing products of a modular characteristic and how to determine the moment to order them, with the purpose to maintain continuity and rhythm of the manufacturing process. It is extremely important from the point of view of timely processing of external orders (independ-

ent demand), therefore, it impacts the reliability of delivery execution. The presented methodology eliminates mistakes, decreases the level of maintained stock, enables full control over individual manufacturing stages, improves the utilization of available resources and synchronizes the material ordering and delivery processes with manufacturing needs. The methodology was developed in 1957 by APICS (American Production and Inventory Control Society), and its particular development fell on the 1970s and 1980s. It is dedicated to a variable demand, characterized by irregularity, and an enterprise manufacturing products on a mass scale. For this reason, in the first place it should be applied to serial or direct-line manufacturing, and second of all, to unit manufacturing or a combination of the aforementioned types.

Studio Apertura, NTNU Social Research, Norway

ABSTRACT: Growth in the number of certification schemes in the aquaculture industry has been attributed to several factors. The schemes contribute to improved traceability of products, provide healthier stocks, and provide more information to customers' decision-making efforts. There is a wide range of certification schemes and standards available, addressing food safety, environmental impact, animal welfare, and worker conditions, to name a few. The abundance of certification schemes has resulted in concerns about consumers becoming confused with the number of labels and that certification schemes themselves may become a barrier to trade. This paper examines 5 major certification schemes in the aquaculture sector and categorizes them according to their purpose, proprietorship, and process. We investigate what has caused this wave of attention to be given to such a diverse range of issues, exploring how the diversity of these certifications is rooted in their inception and the areas they address.

1 INTRODUCTION

By 2050, the world population is predicted to have increased from 7.6 billion people to 9.8 billion (UN 2017). This implies that the need for fish as a source of nutrition will increase, and with that, there will be increased challenges for wild catch and production.

Capture fisheries have become stagnant since the 1980s, while aquaculture of fish and shellfish has more than doubled its growth in the last quarter of the twentieth century (FAO 2016). Salmon is one of the species that has seen spectacular growth, especially in Norway, Chile, Canada, and the UK (FAO 2003).

The growth of aquaculture production plays an important part in international trade and has helped the economy in many developing countries (Prein and Scholz 2014). However, this growth does not come without negative consequences to people or the environment. The "blue revolution" calls for problems to be addressed, such as water pollution, ecosystem degradation, and poor labor conditions. The rapid growth of the salmon farming industry has in many countries raised public concern and critique from stakeholders and politicians regarding social, economic, and environmental impacts. The concerns are both country-specific and/or global, from the effects of aquaculture on biodiversity and wild fish stocks to socio-economic impacts (e.g. competition for ocean space, land, and property value) (Bush et al. 2013). Asche et al. (1999) categorized salmon farming´s sources of environmental problems into three categories: (1) organic material emission; (2) spread of diseases that may affect wild species; and (3) genetic contamination of wild stocks by escapees.

The critiques of salmon aquaculture, combined with a general increased focus on environmental and social issues, have led to a rise in public awareness and a demand for a more sustainable industry (Prein and Scholz 2014). Despite a unified call for 'sustainability', there lacks a shared consensus as to what that actually entails and how it can be accomplished (Davidson 2010). With little agreement beyond the common notion of the three dimensions of sustainability: *environmental* (ecosystem and biodiversity), *economic* (long-term business viability), and *social* (social responsibility and community well-being) (World Bank 2014), the road to 'a sustainable industry' has become a vague and ambiguous one.

While the main production of salmon aquaculture is found in Norway, Chile, the UK, and Canada, farmed salmon is sold to more than 100 countries worldwide. Stakeholders are therefore not only from the producing countries but from quite a large, global marketplace. With demands for sustainability coming from, and the actual production happening in, very different corners of the

world, there has been an increased need for global consistency in the regulation of the industry (Busch 2011, Stanton 2012).

An effort to achieve this is through the use of global standards, certification schemes, and labeling created by NGOs and retailers (e.g. IKEA, Tesco). These are a form of private governance or 'soft law', which entails that their sanctions do not carry the force of law and are therefore not mandatory (Busch 2011). Certification schemes provide different standards for which the producers can voluntarily choose to comply, and in doing so obtain a certification from the chosen scheme. In Europe, the most prevalent standards in aquaculture are the GLOBALG.A.P. Aquaculture Standard and the Aquaculture Stewardship Council (ASC) standards. In North America, on the other hand, the standards set by Global Aquaculture Alliance, the Best Aquaculture Practice, are widely used (Prein and Scholz 2014).

In recent years, the number of certification schemes for food production and processing has increased significantly, along with a variety of actors involved in the development of these standards. Attempting to cover the many rising challenges in aquaculture, these standards and labels relate to issues such as sustainability, food safety, organic production, etc. As a consequence, the types of schemes, their objectives, and their scope vary considerably (Nadvi and Wältring 2002).

This paper aims to illustrate the multitude of standards existing in the market today. As seen from the literature, there is a wide range of certification schemes and standards available and the arguments for the development of these vary between the need for consumer legitimacy, market demands, quality improvement, etc. This paper explores what has caused this wave of attention given to such a diverse range of issues, which has led to this sea of certifications. By doing a comparison of the *proprietorship*, *process,* and *purpose* (hereafter referred to as the 3 P´s of certification) for 5 major certification schemes in use for salmon aquaculture, we seek to understand how differences in their standards and their focus areas can be related to their origin. What arguments are being used for each certification scheme/standard, and why do they differ in focus and demand for improvement?

2 BACKGROUND

Certification and labeling are one type of signal or attribute giving the consumer the opportunity to evaluate a product before purchase/consumption (Chen et al. 2015). FAO differ between ecolabels, and food safety and quality standards (Washington and Ababouch 2011). Ecolabels, also referred to as 'best practice' labels, focus on responsible aquaculture practices, procurement policies of retailers/brand owners, and support to consumers in their purchasing decisions. The food safety standards are schemes that provide assurance in the quality and safety of products and the processes involved.

Numerous reasons for the emergence of such certification schemes have been identified, seen both from consumers, market actors (e.g. retailers), and producers. One argument focuses on a lack of sufficient regulation, arguing that these certification schemes have emerged where the public regulation is perceived as inefficient or ineffective in their response to food safety, quality, and environmental sustainability (Washington and Ababouch 2011).

For the retailers and companies selling seafood, labels are also viewed as a mechanism to reduce risk related to negative publicity concerning production practices (Boyd and Nevin 2011). Achieving trust from consumers and supporting producer legitimacy are an important part of certification schemes (Bush et al. 2013). Summarized by Morris (1997), the possibility to improve the image and/or sales of a company, in addition to encouraging firms to account for the environmental impact of their production, are important arguments to support certification schemes.

Certification usually provides product traceability, standardization among global suppliers, and transparency of production processes (Washington and Ababouch 2011). Standardization can be seen as a form of risk management that extends a company´s liability to a third-party Certification Body (CB), thus, allowing the company to claim due diligence in the event of a predicament (Busch 2011). In addition to allocation of risk, certification may also deter "real and/or perceived risks along the food chain" (Stanton 2012: 247).

Nevertheless, there are uncertainties about the certification schemes' consequences for sustainability. There is little scientific proof that shows a reduction of negative environmental impacts by certified farms compared to noncertified farms (Boyd and Nevin 2011). Though it might be likely to reduce impact on a farm level, this may not contribute to an overall improvement in sustainability (Tlusty & Thorsen 2017). Questions have also been raised as to whether the increased demand for documentation and record-keeping of the aquaculture companies through these schemes actually are making the production more sustainable (Bush et al. 2013).

Another concern regarding certification schemes is that they may act as a barrier to trade for smaller companies or companies from developing countries who cannot afford the costs and documentation requirements of standards originating in the industrialized countries (Busch 2011).

Although private standards are not legally required, international markets demand that companies comply with supposedly voluntary stand-

Table 1. Various schemes and their characteristics.

Scheme and relevant standard	Origin	Year*	Objectives	S	QS	E	AW	3rd party	Stakeholders	Coverage

We set voluntary standards for the certification of agricultural products around the globe–and more and more producers, suppliers and buyers are harmonizing their certification standards to match.	*	*	*	*	IAF	Board: 5 retailers, 5 producers, NTWG: 41 countries Aqua.TC: 7 retailers, 7 producers (1 Asian) 2 Certification Body (observers) Focus groups: may be non-member, Board-approved Public: 2 public consultation periods	Producers must source compound feed and hatchery level from reliable suppliers. Farm level. (Also offers standards to entire chain of custody, feed manufacturers).
ASC - Salmon Standard	Salmon Aquaculture Dialogues (2004, WWF and IDH)	2012	To transform aquaculture towards environmental sustainability and social responsibility using efficient market mechanisms that create value across the chain.	*	(*)	*	*	ASI	ASC Board: 2 Industry rep (recruit 2 more), 4 non-industry TAG: 3 industry, 4 non-industry, 3 other TWG: 1 industry, 4 non-industry, 1 other SC: 10 industry, 5 non-industry Public: public consultation/complaints	Salmon standard from feed to farm level. (Also offers standards to entire chain of custody).
IFS - Food Standard	Retailer federation and industry companies International Food Standard (2003)	2003	To establish a common standard with a uniform evaluation system, work with accredited certification bodies and qualified auditors for IFS Food, ensure comparability and transparency in the entire supply chain, and reduce costs and time for both manufacturers and retailers.		*			IAF or EA recognized AB	TC: 15 retailers, 4 CBs, 6 Manufacturers, and 1 food services NWG: national retailers (IT, CHL, FR, GER, USA, ES) EWG: retailers and experts RC: retailers, industry, and CB	Only covers processing or handling of products during primary packaging.
BAP - Aquaculture Standard, Salmon Farms	Global Aquaculture Alliance (1997, Farmers)	2004	Achievable, science-based and continuously improved global performance standards for the aquaculture supply chain that assure healthful foods produced through environmentally and socially responsible means.	*	*	*	*	IAF	GAA Board: 20 members SOC: 4 conservation/social NGOs, 4 academia/regulators, 4 industry TC: 4 conservation/social NGOs, 4 academia/regulators, 4 industry Public: 60 days public comment	Salmon standard from feed (BAP-certified feed mills or declares compliance to BAP feed mill standards 3.1. & 3.3.) to farm level.
RSPCA – Welfare standard for farmed Atlantic salmon	RSPCA Animal Welfare and Rescue (1824)	2002	For all farm animals to have a good life and be treated with compassion and respect. To give people a higher welfare choice by ensuring animals are farmed to RSPCA welfare standards.				*	RSPCA Assured assessor, UKAS, ISO17065	STAG: 24 experts for the salmon standards (RSPCA specialist, farms, consultants, veterinarians, RSPCA field staff, and tech/field operations of Freedom Food Ltd). By selection. WCG: retailers, food companies, livestock farmers, farming associated industries, veterinarians, agricultural economists, environmentalists, and relevant individuals/orgs. By selection.	Salmon standard covers all aspects of the fish´s life including health, diet, environment, handling, and slaughter. Feeds produced according to UK & EU legislation.

S = Social, QS = Food Quality and/or Safety, E = Environment, AW = Animal Welfare
*Year refers to the year the specific standard was launched.
(The Food Ethics Council and Pickett 2014, ASC 2017, Freedom Food Ltd 2017, BAP 2017, IFS 2017, RSPCA Assured 2017, GLOBALG.A.P. 2017)

ards (Stanton 2012). Private standards that have become industry norm no longer provide a real choice for suppliers to comply with in order to participate or remain in a specific market. Hence, private schemes become "de facto mandates" as demarcation between mandatory requirements and voluntary standards becomes obscure (Casey 2009, Stanton 2012).

From the perspective of the consumer, the large amount of certification schemes, standards, and labels available may contribute to confuse and complicate the purchase decision, as well as negatively influence their attitude towards the food producers and owners of the label in use. It has also been shown that many consumers do not know the content of each label so that decisions are often made on other characteristics and heuristics (Grunert 2005). Research shows consumers might prefer sustainable seafood; however, they do not pay much attention to this when buying seafood (Alfnes 2017).

3 METHODS

This paper is based on an analysis of documents from a range of certification schemes, the content of their different standards, and literature on certification. The chosen method is aimed to provide a comparison of a selected number of certification schemes and their origin, motivation for establishment, and content of their standard(s). The selected standards are established at different times, some of them are aquaculture and salmon specific, while others are not, and they differ in their focus on sustainability and/or animal welfare. Common for all is their relevance to salmon aquaculture production. The selection of schemes and standards is also based on their prevalence in the major nations of salmon aquaculture production. To illustrate the muddled sea of certifications in which production companies find themselves, the choice of standards in this study is also meant to reflect the diversity of focus areas, motivation, and actors involved. After gathering data and categorizing them according to characteristics (see Table 1), the background for the inception of these schemes was also analyzed (see Figure 1). The following information, unless otherwise specified, comes from the websites of these schemes.

4 STANDARDS AND CERTIFICATION SCHEMES

4.1 *ASC*

Established in 2009, the Aquaculture Stewardship Council (ASC) originated from the Aquaculture Dialogue, a multi-stakeholder roundtable founded

Figure 1. Development of schemes.

by the World Wide Fund for Nature (WWF) in 2004 (WWF Norge 2016). WWF and The Sustainable Trade Initiative (IDH, includes businesses, trade unions, NGOs, and Dutch Ministries for stimulating sustainable trade) from the Netherlands worked together in establishing the Aquaculture Stewardship Council in 2010 (IDH 2017).

ASC is the only aquaculture certification scheme that is recognized as a full member of the ISEAL Alliance Code of Good Practice for Setting Social and Environmental Standards. Also, the organization develops standards that are in line with FAO guidelines. ASC partners with the Global Aquaculture Alliance (GAA) and GLOBALG.A.P., and is supported by various suppliers, producers, retailers, and food brands. Any stakeholder or individual can raise issues regarding a certification of a facility as the certification documents are available online.

There are currently 8 aquaculture standards that cover 12 different species: abalone, bivalves (clams, mussels, oyster, scallop), freshwater trout, pangasius, salmon, shrimp, tilapia, seriola, and cobia. The ASC Salmon Standard was developed in 2012 by over 500 participants (WWF Norge 2016). The scope of the ASC standard for salmon includes: compliance with national and local laws and regulations, habitat, biodiversity and ecosystem, health and genetic integrity of wild populations, responsible use of resources, managing disease and parasites responsibly, socially responsible development and operations, and community involvement. The review of the standards is conducted regularly to ensure that the standards are compatible with new scientific developments and practices. The ASC supervisory board is composed of representatives from academia, NGOs, and the industry while its Technical Advisory Group (TAG) consists of a group of invited technical experts. The Technical Working Groups (TWG) and Steering Committees also meet and guide ASC standard development.

4.2 *GLOBALG.A.P*

EurepGAP was initiated by European retailers in 1997 with the goal of establishing a generic stand-

ard for Good Agricultural Practice (GAP) (Kalfagianni and Pattberg 2013). Prior to its establishment, European supermarket chains started various "Integrated Crop Managements" (ICMs) as an effort to gain consumers that preferred 'sustainable products' (Casey 2009, Kalfagianni and Fuchs 2012). The suppliers struggled with achieving the many ICMs of different supermarkets. As a way of harmonizing these agricultural processes, EurepGAP was born and was renamed to GLOBALGAP in 2007 as the standard became widespread in the international scene (Kalfagianni and Fuchs 2012).

The GLOBALG.A.P. Aquaculture module was included in GLOBALG.A.P. in 2004 and covers the entire production chain of a variety of farmed fishes, crustaceans, and mollusks from suppliers (brood-stock, feeds, seedlings) to the various activities, such as faring, harvesting, processing, and post-harvest handling operations (Prein and Scholz 2014). GLOBALG.A.P. is a business-to-business standard, and is classified by FAO as both a standard and a code (Washington and Ababouch 2011). The scope of the certification for the aquaculture module includes site management, reproduction, chemical compounds, occupational health and safety, fish welfare, management and husbandry, sampling and testing, feed management, pest control, environmental and biodiversity management, water usage and disposal, harvesting and post-harvest operations, holding and crowding facilities, slaughter activities, depuration, post-harvest mass balance and traceability, and social criteria.

In addition to certification, GLOBALG.A.P. also has a consumer label called GGN (GLOBALG.A.P. Number) for certified aquaculture products that are in accordance with GLOBALG.A.P. (GGN 2017). Feed that includes captured fish should come from fisheries that adhere to the FAO Code of Conduct for Responsible Fisheries.

GLOBALG.A.P. members elect the Board (5 producers and 5 retailers), which guides the Secretariat, the Technical Committees (one, out of eleven representatives, is from Asia in the Aquaculture group), and Focus Groups (voluntary members and non-members). The Secretariat gives directions to the Benchmarking Committee, Certification Body Committee, Integrity Surveillance Committees, and the National Technical Working Groups (41 countries). The Technical Committees give direction to the respective Focus Groups. National Technical Working Groups are responsible for translating the national interpretation guidelines and local adaptation of the standard. There are two public consultations or rounds for submitting comments by interested parties within a period of 40 to 60 days.

4.3 *RSPCA*

The Royal Society for the Prevention of Cruelty to Animals (RSPCA) is an animal welfare charity organization in England and Wales. The RSPCA Assured label which replaced the Freedom Food label in 2015, is an ethical food label established by the RSPCA. A report from The Food and Ethics Council and Picket (2014) identified three drivers for farm assurance schemes. Firstly, the 1980s and 1990s in the UK were overcast by a number of highly publicized food scares such as with BSE in cattle and reports uncovering salmonella-infected egg production. In addition to the aim of restoring consumer confidence, the Food Safety Act in 1990 introduced the requirement of retailers' due diligence which assigned food safety responsibility to retailers. A third reason for farm assurance schemes to proliferate during this time was the desire to promote responsible farming and animal welfare (The Food Ethics Council and Pickett 2014).

Priding itself as being the only farm animal welfare scheme in the UK, the RSPCA welfare standards examine all aspects that are vital to an animal´s welfare, such as farm management, husbandry practices, healthcare, living conditions, nutrition, transport, and humane slaughter. The RSPCA welfare standards include beef cattle and calves, chickens, ducks, hatcheries, laying hens, dairy cattle and calves, pigs, pullets, salmon, sheep, trout, and turkey. Meetings with the Standards Technical Advisory Group (STAG) are conducted by RSPCA once a year for each species to ensure effective accumulation of the latest scientific, veterinary, and industry information. STAG members include retailers, food companies, farming associated industries (e.g. manufacturing), veterinarians, environmentalists, or organizations and individuals advising the RSPCA Farm Animals Department on standard development. STAG membership is by invitation only. Membership for the Wider Consultation Group (WCG) is by invitation only by the Farm Animals Department of RSPCA. RSPCA Assured currently covers more than 140 million salmon. Major retailers in the UK offer more than 2,000 RSPCA Assured products.

4.4 *IFS food standard*

The International Featured Standards (IFS), originally called the International Food Standard, was established in 2003. IFS is an association of retailers and industrial companies that aims to set harmonized standards for their producers, logistics companies, brokers, and agents. Since their expansion, they now have 8 standards for food products and services published in five primary languages (English, German, Spanish, French, and Italian). The IFS Food Standard deals with food safety and quality of the product and the processes of food packing and processing companies. The standard is recognized by the Global Food Safety Initiative (GFSI). The scope of the standard includes sen-

ior management responsibility, quality and food safety management system, resource management, planning and production processes, measurements analysis and improvements, and food defense and external inspections.

Retailers that require suppliers to have IFS certification include Aldi, Lidl, and Metro (Bureau Veritas 2017). The IFS certification is also sought after by retailers from their suppliers in the French and German markets (Washington and Ababouch 2011).

The IFS Technical Committee (TC) is composed of representatives from retailers (17, many from Germany, Italy, France, and Spain), industry (6 manufacturers, 1 food service), and certification bodies (4 from Europe). The TC is responsible for content and requirements of the standards. National Working groups (NWG) from Italy, France, Germany, Chile, USA, and Spain are responsible for supporting and providing the TC technical information to the International Working Group. Examination Working Groups (EWGs) are composed of retailers and experts. A Review Committee is represented by retailers, industry, and CBs. They discuss experiences and discuss changes of requirements of the audit report and training.

4.5 *BAP*

The Global Aquaculture Alliance (GAA), a nonprofit organization attending to issues related to advocacy, education, and leadership in responsible aquaculture, is the owner of the BAP certification scheme. GAA was established in 1997 by shrimp farmers as a response to criticisms from Greenpeace in the 1990s and a global moratorium demanded by NGOs and community organizations in Choluteca, Honduras (Lee and Connelly 2006). According to Aguayo and Barriga (2016), BAP standards were led by the industry corporate actors and there was no participation by stakeholders not belonging to the industry (Aguayo and Barriga 2016).

BAP is an aquaculture standard that promotes codes of conduct through best management practices (Lee and Connelly 2006). The standards are continuously improved through efforts from the Technical Committee, Standards Oversight Committee (SOC) comprised of experts in environ-mental conservation, the academia and the industry, and comments from the public, which are available on their website. The BAP consumer eco-label includes a star rating system that shows the level of integration in the food chain, with one star meaning the product is produced by a BAP-certified processing plant while a 5-stars label means that the product has been produced only by BAP-certified facilities (processing plant, farms, hatchery, and feed mill). The standard covers community property rights and regulatory compliance, community relations, worker safety and employee relations, sediment and water quality, fishmeal and fish oil conservation, control of escapees, predator and wildlife interactions, storage and disposal of farm supplies, animal health and welfare, biosecurity and disease management, control of potential food safety hazards, and traceability.

BAP standards are continuously updated. The GAA is responsible for coordinating the development of the standards. The technical details are developed by the Technical Committee (TC) under the guidance of the Standards Coordinator from GAA and subject to the review and approval from the Standards Oversight Committee (SOC). The 12-member SOC should consist of equal numbers of representatives from academia, conservation groups, and industry groups. After the SOC has reviewed the document (and modified, if needed), the changes are published for a 60-day comment period where the public can participate. The SOC carefully considers all the public comments for possible inclusion in the final draft. The draft is then submitted for approval by the SOC and the GAA Board of Directors before the standard is implemented.

5 DISCUSSION

Figure 1 shows a diagram illustrating how standards are established for different purposes and through diverse processes by distinct proprietors. As discombobulating as the figure seems, the reality is far more confounding. This can be explained by the many different stakeholders involved, with their various motives, interests, and desires to tackle the array of challenges that salmon aquaculture is facing. Despite running the risk of confusing the consumers, and at worst, resulting in label indifference, the schemes continue to evolve with a goal of making themselves distinct from the others while aiming to expand their terrain.

To give a more orderly and comprehensive understanding of the differences and similarities that characterize these schemes and their standards, we here provide a summary divided into the 3 Ps of certification: *purpose*, *proprietorship,* and *process*. Purpose refers to the needs and interests that have motivated the development of the different standards. Proprietorship deals with the owner(s) of the scheme. Process involves how the standards were developed and which actors were involved.

5.1 *Purpose*

Each standard was established with a purpose in mind. Some were intended to cover very specific issues, such as the IFS Food Standard and the RSPCA, while others were meant to be more general and all-encompassing. In the latter category, the GLOBALG.A.P. Aquaculture standard and

the BAP Aquaculture standard are similar in that they both cover aspects of food safety and quality, social, environment, and animal welfare. However, GLOBALG.A.P. was initiated to unify several schemes required by suppliers to provide consumers with sustainable products, while the BAP certification was developed as a response to criticisms from environmental groups and NGOs. The ASC Salmon Standard, also in the latter category, differs as it is a species-specific scheme with less focus on food safety, and was developed as a response to increased focus on the environment and social responsibility of the aquaculture industry. As with many of the more general standards, the IFS Food Standard was also aimed at providing a unified standard for suppliers; however, its focus is on general food safety and quality. The RSPCA Assured was established to improve animal welfare and, therefore, focuses more or less only on concerns regarding this issue.

5.2 *Proprietorship*

GLOBALG.A.P. and IFS schemes were both established by retailers while the ASC and RSPCA standards were both initiated by non-governmental organizations. Of the five schemes, only the BAP Aqua-culture Standard was started by producers. Certification is performed by third-party certification bodies, except for RSPCA, which differentiates itself by certifying farms using their own RSPCA Assured assessors. A majority of these private schemes are mostly owned by retailers and NGOs, which means that they are able to exert power over the producers by demanding that these requirements be met if they are to be recognized as suppliers. Moreover, the schemes come from developed countries and Northern markets, tipping the scales in favor of large companies (Belton et al. 2011).

5.3 *Process*

The development of standards for the different schemes is similar in the sense that they are including different stakeholders and expert groups. Some schemes try to balance the number of representatives from the different stakeholder groups, such as BAP and GLOBALG.A.P. Not all the schemes, however, include public consultation. The IFS scheme, for instance, does not mention any public consultation nor does it say anything about NGO participation. Other schemes only include participants by invitation, such as the RSPCA, selecting the experts for consultation and standard development. Furthermore, the documents stating how many of each stakeholder group should be included in a Technical Group does not apply in practice (e.g. GLOBALG.A.P. and ASC).

According to Fuchs et al. (2011), the retailer-dominated private standards, such as IFS, are dominated by the standard owner. The food industry and certification bodies play only a consultative role, while civil society is not provided with a voice. They categorize GLOBALG.A.P. as a standard that provides an equal partnership between the retailers and producers through elections, and certification bodies only act as associate members, while civil society and the NGOs may participate in the annual meetings. Despite the seemingly equal opportunities for stakeholders to take part in representing their group, in reality, not all of the stakeholders afford to take part in the development process as this requires a lot of time and resources.

6 CONCLUDING REMARKS

As has been shown here, there are countless challenges that follow the proliferation of certifications, standards, and labels in the aquaculture industry. Increasing pressure from both public and private regulatory agencies is causing a continuous build-up of demands for production companies. Since standards purposely differ from one another in some ways and overlap in other aspects, there is often a need to comply with more than one standard. This entails that the new standards which emergence do not replace others, but add yet more layers.

Having just one all-encompassing standard could possibly curtail certification-related work for producers and strengthen consumers' trust in labeling; but would this be attainable? Based on our findings in this study, it is unlikely to happen. This can be attributed to numerous explanations. For one, the different certification schemes are in competition with each other, as certifications, standards, and labels have become big business. Furthermore, the standards are created at different times and continue to be adapted and revised, making a potential unification difficult to achieve. Most importantly, the endeavor to improve the aquaculture industry, currently under the banner of sustainability, is pulling in many different directions. The numerous challenges that the industry is facing are subject to trade-offs and political priorities, as many of them run counter to each other. In order for the standard to cover everything, it would necessarily go against itself.

ACKNOWLEDGMENT

An ontological and semantic foundation for safety science

ABSTRACT: This article proposes an ontological and semantic foundation for safety science, based on an etymological and etiological study of the concepts of risk and safety. The awareness regarding the concepts of safety and risk have both evolved in similar ways because of increasingly more demanding situations and events that impact society in an economic way, also linked to the value of human lives. From a purely negative view on risk and safety, this awareness has grown into a more systemic and even holistic perspective on these concepts. The proposed foundation is aligned with the semantics and concepts used in the ISO 31000 risk management standard. Based on this foundation, the article also advocates a theoretical model and a metaphor on how to look at safety and performance in any organization.

1 INTRODUCTION

When one talks about safety, risk or performance, everyone understands what is being talked about. There's no one who doesn't grasp what the words mean in one's own perception and how they can be understood. However, when opening a discussion on what these concepts really are, and how one should study or deal with them, it is most likely to end up in ontological and semantic debates due to different views, perceptions and understanding.

Science is served with clear concepts and well-defined parameters. Because, having these concepts and parameters allows for exact measurement of observations and in its turn, this opens the opportunity of accurate analysis, which then can be used to develop sound theories and practices. When studying in the field of safety science (a relatively young field of science), it is hard to find unambiguous definitions and parameters that clearly link safety, performance and risk.

When reviewing the safety science literature, the question "what is safety" is answered in many ways and it is very hard to find a clear definition of its opposite, which we could also name 'unsafety'. Likewise, there is also a lack of standardization when it comes to defining its opposite. Terms like accident, incident, mishap, disaster, catastrophe, etc. have different meanings depending on the persons or fields of knowledge using these commonly used words.

Because there is no commonly accepted way to define safety and its opposite, it becomes very difficult to measure and compare the level of safety of situations and organizations in an unambiguous or objective manner, certainly amongst different sectors or societies. Also, it is more difficult to think of proactive solutions that generate safety instead of developing reactive methods that prevent unsafety.

Although the field of safety science is relatively novel as a separate and independent domain of study, many theories, models and metaphors have already been proposed, attempting to describe what safety is and how it can be achieved. Often these theories are drawn from the investigation of – and lessons learned from– catastrophes and disasters. As such, these theories are often justified by explaining how these mishaps came about. Therefore, in general, efforts to improve safety of systems have mostly been driven by hindsight, both in research and in practice (Woods and Hollnagel, 2006).

2 EVOLVING PERCEPTIONS REGARDING SAFETY (SCIENCE) AND RISK (MANAGEMENT)

Safety and risk are two concepts that are tightly coupled and have known similar evolutions in their development and in how people understood these

concepts. Also, the evolution on how people have dealt with risk and safety is very much comparable. Safety and risk are often perceived in a similar way and are regularly used as antonyms. Risky often means unsafe and safe often means without or protected from risk (as indicated in many dictionary definitions of safety). And, when looking at the past, one can see that ideas about safety and risk have evolved in a very analogous way and for comparable reasons.

2.1 *A historical perspective on risk management, the etymology of risk and its etiology*

2.1.1 *Ancient times*

For thousands of years, people considered all that happened being the will and acts of the gods (Bernstein, 1996). So, the general idea was that whatever one tried, things finally always happened to the will of the gods and there was nothing to do about it but to accept it.

However, this doesn't mean that concepts as risk and safety were strange to people. In their article "Risk analysis and risk management: an historical perspective", Covello and Mumpower (1985) describe how in the Tigris-Euphrates valley, about 3200 B.C. the Asipu already offered a kind of consultancy services related to risk and safety.

2.1.2 *The Renaissance and modern time period*

The serious study of risk started during the Renaissance and it took until the work of Pascal in the 17th Century to see a sudden progress in the understanding of risk and decision making based on numbers.

In this time period science was on the rise and it was a period of expanding trade of new and scarce products, transported overseas. This created a new reality. Trade oversea to distant regions and countries was a high-risk endeavor. This economic factor made people become more aware of the concept of managing risk. Soon, the insurance industry emerged as an effort to manage risk in commerce. Wealth was no longer the privilege of the happy few, but could be earned by investing in trade and making the right decisions (Bernstein, 1996; Covello & Mumpower, 1985).

2.1.3 *20th century*

Although the etymological roots of the term risk, can be traced back as far as the late Middle Ages, the more modern concepts of risk appeared only gradually, with the transition from a traditional to a modern society. With larger and ever more complex technology systems emerging after the second World War (e.g. nuclear installations), the focus on probability and risk supported a scientific, mathematically-based approach toward risk and risk assessment (Zachmann, 2014).

Later in the twentieth century, with standards of living quickly rising after World War II, other objectives became also important and the concept of managing risk expanded from a mathematically-based approach to include also more qualitative methods. Hence, the origins of operational risk management, which can be traced back to the discipline of safety engineering (Raz & Hillson, 2005).

Continuing losses, injuries and casualties, triggered the US Armed Forces and NASA to develop risk management proposing a more comprehensive approach, called Operational Risk Management (ORM), adapting the world of risk management to the human factor involved in day to day operations. However, by the end of the century further development of the concept of operational risk management expanded the view on risk from a loss and probability perspective to a systemic view, shifting attention from probability to achieving goals.

In the same period of time, due to scandals such as the Barings Bank (1995), the dot.com bubble (1997–2001) and ENRON (2001), people became ever more concerned with the management of risk and the good ethical practices in managing organizations. During this last decade of the twentieth century, there has been a major surge of interest in improving the ability to deal with an uncertain future, and at that time, still with a focus on the negative impact at the organizational level. Operational risk scarcely existed as a category of practitioner thinking at the beginning of the 1990's, however, by the end of that decade, regulators, financial institutions and practitioners could talk of little else (Power, 2005). At that time, the first risk-related standards were published (Raz & Hillson, 2005).

2.1.4 *21st century*

The changes that emerged during the last quarter of the 20th century persisted and ongoing changing ideas concerning risk management generated an increasing understanding of the concept of risk, as modern risk management evolved substantially due to factors such as the rise of knowledge-intensive work, an expanding view on stakeholders, a growing importance of project management, the expanded use of technology, increased competitive pressure, increased complexity, globalization and continuing change (Raz & Hillson, 2005).

This growing concern and increasing awareness regarding risk management at the turn of this century led to the development of a whole range of additional risk management standards. These standards were issued by governments (Canada in 1997, United Kingdom 2000, Japan 2001 and Australia/New Zealand 2004), International insti-

tutions (IEEE-USA 2001, CEI/IEC-CH 2001) or professional organizations (IRM/ALARM/ AIRMIC-UK 2002, APM-UK 2004, PMI-USA 2004). Each of these standards, coming from different perspectives, reflect an increasing understanding of risk and risk management, proposing different definitions of risk and comparable processes to manage risks. At that moment in time, a shift occurs from a purely negative view on risk, still expressed in the definitions of some of those (older) standards (CAN/CSA-Q850-97:1997 and IEEE 1540:2001) to more neutral or even very broad definitions of risk in the other, more modern, standards. Another remarkable aspect of the "newer" definitions is the fact that risk is more explicitly linked to objectives and that the effects of uncertainties on objectives (consequences) can be positive, negative or both (Raz & Hillson, 2005).

2.1.5 *Enterprise Risk Management (ERM)*

Also in the first decade of this century, and due to a number of scandals—similar to ENRON, there is an ever-increasing attention for corporate governance and the role of operational risk management in that regard. This resulted in the first internationally used comprehensive corporate standard on risk management, the COSO Enterprise Risk Management Integrated Framework (2004). (Mestchian et Al, 2005). Enterprise Risk Management (ERM), similar to ORM in the military and aviation sectors, is the more holistic approach that is needed to cope with the complex realities and awareness of risks for the corporate world in the 21st century.

However, the COSO ERM framework, developed as an auditing tool to check compliance, failed during the 2008 financial crisis, because organizations implementing ERM would still follow the reductionist approach these organizations were used to. So, the International Standardisation Organisation (ISO), set out to establish a working group to achieve consistency and reliability in risk management by creating a standard (ISO 31000) that would be applicable to all forms of risk and to all kinds of organizations, creating a foundation for risk management (Purdy, 2010).

Little real progress could be made with the ISO standard until all agreed on a definition of risk that arose from a clear and common understanding of what risk is and how it occurs. The working group arrived at: "*risk is the effect of uncertainty on objectives*". When risk is defined like this, it reveals more clearly that managing risk is, quite simply, a process of optimization that makes the achievement of objectives more likely, objectives being understood in the broadest sense of the word. Successfully detecting and understanding risk, including how it is caused and influenced, allows, if necessary, to change it so that it is more likely to achieve objectives and reach them faster, more efficiently, and with improved results. (Purdy, 2010)

The specific way in which risk is regarded by the ISO 31000 standard also broadens the understanding and attention of risk management towards performance, instead of solely focusing on compliance or the prevention of loss.

2.2 *Evolution of awareness in safety science*

Compared to the other sciences, surprisingly little attention has been given to the history of safety. (Guarnieri, 1992). As such, the following sections only try to give an indication of how and why the perspective of safety changed over time.

2.2.1 *The industrial revolution*

Safety science, similarly to risk management, originated because of a need to cope with uncertain profit, the failure of maintaining possession of valuable assets and the accidental injury or loss of workforce. In the same way expanding views impacted the etymology of the concepts of risk and risk management, ever-increasing awareness and knowledge regarding the concepts of safety and safety management has also impacted the etymology of safety and safety science.

The industrial revolution and the appearance of new technologies provoked reoccurring and severe accidents, damaging valuable assets, causing severe casualties and injuries to workers. In the beginning these accidents are just seen as set-backs, caused by workers behavior and part of the business. However, during the second industrial revolution, starting at the end of the 19th Century, the ongoing mechanization and new technological developments are used to develop new industries. Furthermore, production engineering substantially increased productivity with the advent of mass production. As a result, life was getting better, incomes were rising and mortality was declining. (Mokyr, 1998). These rapid economical, technological and social changes also triggered the dawn of safety as a science.

Accidents have always been a problem. Yet they did not appear as a major economic and health issue until the early 1800s when the declining death rate from infectious diseases shifted attention to other causes of mortality (Guarnieri, 1992). Accidents in a production line are costly, not only due to the casualties and lost workforce, but also the loss in production and production capacity are a burden to the profitability of the new factories. Furthermore, these accidents are responsible for a high mortality in the industrial world, leading to a bad reputation. Due to the rising prosperity, this is no longer acceptable. Accidents are no longer acts of God, but man made and can be prevented. (Swuste et al, 2010).

From the start, the awareness about risk and safety, risk management, safety management and safety science were triggered by the possibility of adverse effects, impacting on the profitability of endeavors and related to new emerging sectors. Both trying to accommodate for losses that impact that profitability. Risk, as such, became the domain of insurers and the start of a whole financial industry to compensate for financial losses. Likewise, safety science started with focusing on accidents, injuries and casualties and their prevention. In both cases, people drifted away from what they really needed, which is safeguarding and achieving objectives, getting what they want and being safe.

One of the first theories on safety is about accident proneness (Farmer, 1925). However, the accident proneness theory only looks at one possible cause of accidents and therefore cannot explain accidents in a general way.

Heinrich observed production facilities to discover trends and patterns in occupational accidents, resulting in Heinrich's pyramid or triangle (Heinrich, 1931). Heinrich also proposed his Domino theory on accident causation when studying the cost of accidents and the impact of safety on efficiency, opening up the perspective to the role of management in accident prevention (Heinrich, 1941). Heinrich's domino theory became a basis for many other studies on accident causation and the role of management in accident prevention, dominating the world of safety practitioners well beyond the Second World War (Hosseinian & Torghabeh, 2012).

2.2.2 *After World War II*

Heinrich's research and work inspired other researchers, also to incorporate the role of management in their models. For instance, Petersen (1971) developed a model based on "unsafe acts" and "unsafe conditions" and Weaver (1971) and Bird (1974) updated the domino model with more emphasis on the role of management. (Hosseinian & Torghabeh, 2012; Swuste et al, 2014).

At the beginning of the second half of the twentieth century, Gibson (1961) and Haddon (1970) focused on the causation of injuries, discovering a formula for injury prevention. This shift in focus, also caused safety science to look at engineering to reduce injuries, leading to safety belts, bumpers and many other devices capable of absorbing or deflecting energy (Guarnieri, 1992). In this period of time, also the introduction of the "hazard" – "barrier" – "target" model and tools, such as Failure Mode and Effect Analysis (FMEA), Hazard and Operability Analysis (HAZOP), the Energy Analysis approach and so on, are to be noted. (Swuste et al, 2014)

Similar to the evolutions in risk management, safety science further evolved as a result of a series of accidents which had a huge impact on society. Flixborough (1 June 1974), Seveso (10 July 1976) and Three Miles Island (28 March 1979) are part of the history of safety science, provoking a broader perspective on safety and increased safety regulations. This enlarged awareness about safety, also reflects in the increasing political attention for safety related issues and the rise in associated regulations, clearly demonstrated by the advent of a number of safety related scientific journals in the last quarter of the twentieth century (Hale, 2014). Investigating these accidents, expands the awareness of safety practitioners from the role of management, to interactions in the entire socio-technical system.

2.2.3 *More major accidents and disasters*

The socio-technical concept arose in 1949 (Trist, 1981). However, at that time in the fifties, the societal climate was negative towards socio-technical innovation. This would only change thirty years later (Walton, 1979). Again, alike the development of risk management and operational risk, safety science took up this wider organizational perspective on safety issues as from in the early eighties. At the same time, advances in technology also make safety engineering an indispensable part of safety science, with the development of safety equipment, for instance safety belts, air bags etcetera.

Another result of analyzing, amongst others, the Three Miles Island accident, is Charles Perrow's book, Normal Accidents (1984), in which the `normal accident theory' (NAT) is proposed. It has been particularly influential among researchers concerned to understand the organizational origins of disasters and the strategies which might be used to make organizations safer (Hopkins 1999).

Safety science further developed in the past thirty year as a result of another series of significant disasters, such as Bohpal (2–3 December 1984), Challenger (January 28, 1986), Tsjernobyl (26 April 1986), and The Herald of Free Enterprise (6 March 1987). Each of these accidents show the complexity of socio-technical systems. As a result, scholars try to model systems in order to predict their behavior. Building on the work of Rasmussen (1983), Reason (1990) proposes the Generic Error Modeling System (GEMS), later to become known as the Swiss Cheese model (of defenses) (Reason, 1997, 2016).

By the end of that disastrous decade, people also look at human factors and behavior, by introducing the notion of safety culture. It is loosely used to describe the corporate atmosphere or culture in which safety is understood to be, and is accepted as, top priority (Cullen, 1990). A more specific approach is the concept of Just Culture (Dekker, 2008, 2017). Furthermore, the concepts of 'High Reliability Organizations (HRO)' (LaPorte & Consolini, 1991; La Porte, 1996; Weick & Sutcliffe, 2001) and 'Resilience Engineering' (Woods & Hollnagel, 2006; Hollnagel, 2013) were introduced, looking at the whole organization.

Recent years have seen a whole range of models that try to model the taxonomy and structure of accidents. Some examples are the Systems-Theoretic Accident Modell and Process (STAMP) (Leveson, 2011) and the Functional Resonance Analysis Method (FRAM) (Hollnagel, 2012). Most remarkable is that FRAM is focused on safety instead of unsafety, going beyond the failure concept and the concepts of barriers and controls, aiming at the day to day performance. (Hollnagel, 2012). The idea is to achieve safety proactively. An idea further developed with the advent of the concepts of Safety-I and Safety-II (Hollnagel, 2014a). In his article, 'Is safety a subject for science', Hollnagel (2014b) indicates the difficulty to change the mindset in the safety science community from what is going wrong to what is going right.

In the new millennium, alike risk management expanded into a systemic/holistic view with the advent of Enterprise risk management, today these approaches come together in concepts such as Resilience Engineering, HRO and Safety-I & Safety-II. Ever more these modern concepts in safety are focusing on what people want and how to achieve it, instead of trying to protect against failure. Likewise, increasingly, scientists are looking for significant leading indicators in order to be more proactive in preventing accidents by achieving what is the aim. Concepts therefore also evolved from a purely negative view on risk and safety towards a more encompassing view, also considering the positive sides of risk and safety. Now the focus is gradually more on safety instead of solely concentrating on unsafety.

3 INCREASING AWARENESS SEEN FROM A SYSTEMIC PERSPECTIVE – THE SYSTEMS THINKING ICEBERG

The above review of risk and risk management, safety models, metaphors and theories is far from complete. A more complete overview is to be found in reading the related references. We only wanted to show the changing etymology of the concepts of risk and safety, and its etiology, over a period of time.

A model that can help in getting a comprehensive view on the evolution of risk and safety is the systems thinking iceberg model (Bryan et al, 2006). The systemic iceberg model, is a way to look at reality from a systems perspective. The visible part of the iceberg, (above the waterline) represents *the events* that result from the system(s) involved. When events are observed over time, patterns and trends can be discovered. It is at this easy to perceive level of awareness of systems that safety science has originated. Still today, safety practitioners are driven by the facts that are directly visible, gathered in statistical data, trying to find and understand trends or delineate recognizable patterns related to the observed events. As such, they try to discover causal relationships and produce better predictions to prevent these negative events from happening.

The common approach to safety is to look at the events such as loss of life, injury, harm, damage, or any other event generating negative effects, trying to understand, predict and prevent accidents. As an example, the accident proneness theory can be seen as a result of that process.

Increasing awareness on accidents allows to become aware of the system of causes and effects that produces the unwanted events and that repeat themselves. It is what every accident investigation tries to achieve, i.e. the understanding how elements act together, in order to find ways to prevent them from happening again. When the system is understood, it is possible to proactively alter the system and prevent the same unwanted events happening. Through history, scholars have been searching for ways to explain why unwanted events happen and how disasters can be predicted, trying to discover the system(s) that is (are) behind their occurrence. One of the first to develop a theory on accident causation is Heinrich and his domino theory, naming the elements of the system that are involved in the creation of accidents and using the metaphor of domino blocks to represent the subsystems and their interaction. Also, NAT and the Brownian movements model (Rasmussen, 1995, 1997) can be seen as such.

To be able to predict or to obtain more understanding and control on the systems involved in accidents, scientists also try to determine the structure of the systems involved, getting a clearer view on the dynamics that are at the genesis of accidents. Recent years have seen a whole range of models that try to model and structure the systems that generate unwanted events. STAMP and FRAM can be seen as examples and there is also the Swiss Cheese model (Reason, 1997, 2016) and the models that build on the same human factor approach.

Finally, scientists and practitioners aim at developing understanding on how mental models generate the system(s) and how they can be controlled and managed. An example of a mental model generating safety is for instance the concept of Just Culture (Dekker, 2008, 2017).

4 A MODERN PERSPECTIVE ON RISK AND SAFETY

Safety is often defined as a dynamic non-event and mostly explained by the events that violated that state of dynamic non-events (Weick, 2011). The problem with this approach is that it only covers the domain of unsafety and leaves any interpretation of safety open. When safety thinking is linked with dynamic non-events it solely focusses on pre-

venting bad things from happening. But is this the right approach in pursuing safety?

Is turning away from unsafety the same as aiming for safety? When one considers a situation of 100% safety, is this a situation where nothing is happening? This seems an impossible assumption. There will always be something happening, events and consequences (positive effects on objectives) one wants and events and consequences (negative effects on objectives) one doesn't want, both are important from a modern safety perspective. So, what is distinctive for safety to emerge, exist and persist? A modern perspective on safety, in the same way as a modern perspective on risk and risk management, looks at the whole picture. It starts with what people want to achieve, what needs to be safe and first make sure this will be achieved. It is making certain that the return on investment is attained when pursuing an opportunity. Hollnagel (2014) talks of Safety I and Safety II, where safety I is the traditional approach of avoiding losses while safety II is making sure the objectives are accomplished. In our view, this is how safety and safety science should evolve. It is about both the absence of unsafety and the presence of achieved and safeguarded objectives.

Nancy Leveson says that Safety is an emergent property of systems, not a component property (Leveson, 2011). It means Safety is something that needs to be achieved by the system, repeatedly. Obviously, a component can also be considered as a system on its own. Every system is made up of sub-systems which have other objectives than the overarching system. The safety of these sub-systems is important to the safety of the overarching system and each of them is subjected to a set of risk sources that can affect those more specific objectives.

4.1 *Total respect management*

The modern perspective on safety, and the mental model to achieve safety in a proactive way we propose, is called Total Respect Management (TR³M). Respect, in the way it is used for this model, is an expression originally derived from the Latin word respectus. Respectus comes from the verb respicere, meaning 'to look again,' 'to look back at,' 'to regard' or 'to consider someone or something.' In other words, the original meaning of the word 'respect' holds the connotation of giving someone or something dedicated attention to have a better view on the matter or give it consideration, particularly to come to a better understanding (Blokland & Reniers, 2017). As much as possible the systems, sub-systems (including the human factor) and their objectives need to be known and understood.

The reason for this 'respect' for systems and their sub-systems is the conviction that there is no common structure to all 'accidents'. This is also a way how we intend to look at the Swiss cheese metaphor. In this metaphor, the whole cheese is a reflection and representation of a socio-technical system and its performance. The cheese itself can be understood as excellent performance, where objectives have been achieved and are safeguarded (Safety-II). On the other hand, the holes in the cheese are the sub-systems of which the objectives are not achieved or safeguarded. As such, these are the different factors contributing to accidents (Safety-I). The model's hypothesis is that one can never know for 100% sure which sub-systems will fail at a given time or why and how they will become connected at a given time to produce a major accident and therefore it is important to give attention to all failed objectives and aim at reducing the number and magnitude of these failed objectives by increasing the level of performance.

Each hole in the cheese is considered being a "failed" objective and therefore unsafe. The Swiss cheese is dynamic. The holes constantly change positions and dimensions in an unpredictable way and could be seen as shifting around, coming and going, shrinking and expanding in response to operator actions and local demands (Reason, 1997).

Although the idea of layers of protection is useful to a certain extent, it only covers for Safety-I. Therefore, the TR³M model also focusses on performance as an element of safety. The aim of performance is to achieve objectives and maintain objectives safeguarded. As such performance stands for the whole cheese, or the whole concerned socio-technical system and the aim of TR³M is excellent performance (excellence) in that regard.

The way TR³M approaches the Swiss cheese metaphor is by stating that each of these latent conditions (failed objectives) can be seen as accidents on their own. It is just the level of importance and number of objectives involved that differentiates 'accidents' worth investigating from 'less important' holes. However, for TR³M each one of the holes is meaningful and needs one's respect. Hence the name 'Total Respect Management'. The holes/accidents result from (sub)systems, created by non-aligned or defective mental models existing in, or surrounding, the system (Blokland & Reniers, 2017).

Risk and the level of risk, in this sense, is nothing more than the possible effects on one's objectives due to the decisions taken and performance reached at a given time, representing a possible future reality. This reality will also determine the level of safety. The better this future reality can be imagined, the more it can be shaped to the desires and needs of the beholders by taking the right decisions at the appropriate time, generating safety proactively.

4.2 *A semantic connection between risk and safety and performance*

Regarding risk, ISO 31000 provides a whole set of definitions, also to be found in the ISO Guide 73. However, for Safety, in its broadest sense, there is no such internationally agreed standard and neither a modern and commonly used definition. A random selection of some definitions (Wikipedia, Merriam Webster, Dictionary.com) gives a traditional view on safety. Safety is a state, a condition, a control, a device, a quality or anything else that keeps us safe. Sure, we all know what safety means, it is being protected from harm, from bad things happening, but what does it really mean to be safe? So, how can safety and security be defined, taking into account the most recent ideas on safety and risk, inspired by the ISO 31000standard and its definition of risk? When are systems or people completely safe? Isn't it when one has attained all of ones objectives, when everything performs well and nothing affects ones objectives in a negative way?

Defining risk being the effect of uncertainty on objectives, means that three aspects define risk, namely; 'Objectives'; 'Effects on objectives' and 'Uncertainty related to the effects and the objectives'.

The proposed semantic foundation can be seen as follows: risk is an uncertain effect on objectives, while the actual performance is the result of that uncertain effect. Performance is Safety I + Safety II. It is why both concepts have evolved over time in similar ways and at a comparable timing.

Risk management, in a way, started closely related with gambling activities. Because professional poker players know that they don't win by chance or as a result of acts from the gods, but through carefully gathering information and analyzing/considering options based on that knowledge. It allows them to increase the probability that they make the right decision to support their aim of winning the game by taking more risk when it is appropriate to do so and limit the risks they take when it is the wiser decision, each time counting on the fact that the risks run are low for the decisions they take. However, they will only be safe when the game is over, all effects of uncertainty have their outcome and the profit has been paid. As such, safety and risk are the same, where risk, and how it is managed, determines the future of one's safety. Therefore, the same semantical foundation can and should be used.

4.3 *What is the usefulness of defining SAFETY in this way?*

This perspective on risk and safety, allows to develop a commonly used terminology for safety science and risk management. It will also allow to build systems that can measure safety instantly and in a much broader range than it is actual the case. Or better said, to measure 'unsafety'. Because measuring safety would require knowing all objectives present in a system and its sub-systems. This is impossible, because most of the time people are not aware of all of their objectives and also organizations are unable to know all the objectives of all their stakeholders. On the other hand, it is much easier to discover unsafety. Because when an objective has failed, it is likely to be seen or trigger a reaction. Human nature is designed to recognize unsafety, because it is necessary for survival. To measure unsafety, it is sufficient to measure all the holes to get an idea of the level of safety in the cheese.

4.4 *Safety first or first in safety*

The adagio "safety first", certainly from a traditional perspective, is fiction. When safety is the prevention of bad things happening, this credo is a real show stopper, as the safest thing to do for avoiding losses is to do nothing and prevent any activity. However, when you look at this motto from a fresh and modern perspective, it becomes a helpful mental model in achieving safety proactively. Safety first then means to achieve and protect objectives as a priority, aiming on excellent performance (safety II) and calling to action instead of inaction. When this is the governing paradigm, it will also become possible to be the first in safety, aiming at excellence. Because also safety performance will be an objective to be achieved and safeguarded.

5 CONCLUSION

In this article, we have expounded the evolutions of the concepts of risk and safety, how the awareness grew due to repetitive adverse effects on objectives and looking for ways to understand and cope with what had happened. We also indicated how the meaning of the concepts changed as a result of this increased awareness. To finally propose a new paradigm regarding safety and performance, linking risk and safety rather as synonyms, instead of treating them as antonyms.

ABSTRACT: Since 2017 Dutch flood protection standards are defined as target flood probabilities that all primary flood defences have to comply with by 2050. Explicitly accounting for uncertainties in probability distributions of load and resistance is an integral part of estimating the actual flood probability. Based on such estimates, many flood defences will be reinforced in the coming years, for design lifetimes that are generally 25–100 years. Therefore it is important that we correctly take into account time-dependence of both load and resistance during the lifetime. Loads are typically uncorrelated from year to year, whereas strength parameters exhibit significant correlation over time. This correlation over time of strength parameters can significantly reduce the failure rate and increase the lifetime reliability of a flood protection structure. In this paper we show the implications of time-dependent reliability for a set of illustrative cases. We consider the effect of different degrees of temporal dependence on reliability, lifetime and relative cost savings. The cases show that for common configurations, the inclusion of time-dependent effects, especially the correlation in time of strength variables, can increase the lifetime of a flood protection structure by up to 50%.

1 INTRODUCTION

Since January 2017 the Dutch primary flood defences have to satisfy new risk-based safety standards. Based on economic risk analysis, analysis of societal risk (risk of large numbers of casualties) and individual risk (risk of dying due to a flood), allowable (i.e. target) probabilities of failure for all major flood defences have been derived (Kok et al. 2017). The failure criterion is herein defined as the loss of flood retention capacity resulting in flood of a (defined) neighborhood with an average depth of > 0.2 meters. Safety standards are generalized into main categories with annual allowable failure probabilities 1/300, 1/1000, 1/3000, 1/10000 etcetera.

These safety standards are based upon a Bayesian interpretation of probability, meaning that the failure probability should be interpreted as a state of belief. A change in the magnitude of uncertainties due to e.g. new knowledge or measurements will then cause a change in the estimated failure probability. Hence, when the safety standard is not met, reducing dominant uncertainties can be a very relevant measure.

The new failure probability requirements for flood defences are formulated as annual probabilities, implicating that for each separate year the failure probability has to satisfy the defined standard. In design this is often interpreted as that the failure probability at the end of the design life has to equal the maximum allowable probability of flooding. This is different from for instance the failure probabilities in the Eurocode, where the design criterion is expressed as both an annual target reliability and a reliability for a lifetime, e.g. 50 years (CEN 2002). Depending on the exact definition of the failure probability, the difference between annual and lifetime reliability, which will be discussed in the next section, can have significant implications.

The actual reliability of a flood protection structure can be assessed by doing probabilistic computations using probability distributions of both load and strength variables. Historically, the tools for design and assessment that were used in the Netherlands are based on a semi-probabilistic approach. Slomp et al. (2016) gives a thorough overview of the current safety assessment tools. The current assessment and design tools allow for both probabilistic and semi-probabilistic assessment and are based on an explicit coupling between (old) semi-probabilistic tools and the new probabilistic safety standards.

The quantitative assessment of failure probabilities also enables accounting for time-dependent reliability effects. Next to time-dependent (uncertain) deterioration and uncertain changes in climate, also correlations between years can be taken into account explicitly. Loads are typically independent from year to year (the maximum water level in year i is typically not conditional on the maximum water level in year $i-1$). However, the strength variables are typically correlated from year to year as these uncertainties are merely caused by spatial variability in combination with limited knowledge. Incorporating this correlation could have significant impact on the assessment of reliability during the lifetime.

Currently there is little attention for the actual source of the uncertainty, which poses a problem when using concepts of time-dependent reliability. For instance for hydraulic load models, model uncertainties are used for water level, wave height and wave period, but the source of these uncertainties is not immediately clear. Also in the distributions for strength parameters, there can be significant uncertainty, especially for geotechnical failure mechanisms. For instance, the failure probability for piping is dominated by uncertainty in permeability and grain size (Jongejan and Maaskant 2015). Strength uncertainties can typically consist of natural variability, measurement uncertainty, transformation uncertainty or model uncertainty (Phoon and Retief 2016). The source of the uncertainty is important for two main reasons:

- It determines the optimal method for uncertainty reduction: some methods might have the same source of uncertainty. These will not (efficiently) increase the quality of available data and hence not reduce uncertainty nor improve the reliability estimate;
- It determines the amount of time dependence of subsequent years as some uncertainties might be (fully) correlated in time and others may not.

In this paper we explore different definitions of reliability that can be used for flood defences. Using illustrative cases with different degrees of uncertainties we illustrate the influence of these definitions and how that translates to the lifetime of flood defences and their life cycle costs.

2 METHODOLOGY

2.1 *Time-dependent reliability*

Flood defences are generally constructed for design periods of 25–100 years which, in the context of annual failure probability, implicates that in any given year in such a period the reliability should be higher than the requirement. In reliability engineering in general, concepts such as the survival time, failure rate and hazard function are used to characterize the temporal reliability (Kottegoda and Rosso 2008). Especially the hazard function is of interest, as this provides the failure rate of the system, this is conceptually shown in Figure 1. Here three phases are distinguished for the hazard rate of a system:

- The inception phase: here the hazard rate decreases as due to first experiences and quality control errors are corrected. One could say that at $t_0 = 0$ the constructed system is accepted.
- The phase where neither initial errors, nor deterioration play a role. In Kottegoda and Rosso (2008) this is denoted the *useful life*.
- The deterioration phase where deterioration of the system causes the hazard rate to increase significantly.

The inception phase for a flood defence has two major aspects: first of all there is the experience from initial performance, mainly during construction, that improves the reliability as instantaneous repairs are carried out. In this paper we consider flood defences that have just been delivered, so this phase is not considered. Secondly there is the dependence of failures on preceding years, meaning that if a dike doesn't fail and there is any kind of correlation between the years it yields some information on its performance. This is an effect that will be relevant during the entire life-cycle.

When also considering the other two phases, the distinction between the three phases doesn't fit that well for flood defences. Most of the deterioration processes are gradual and play a role during the entire life-cycle (see e.g. Buijs et al. (2009),

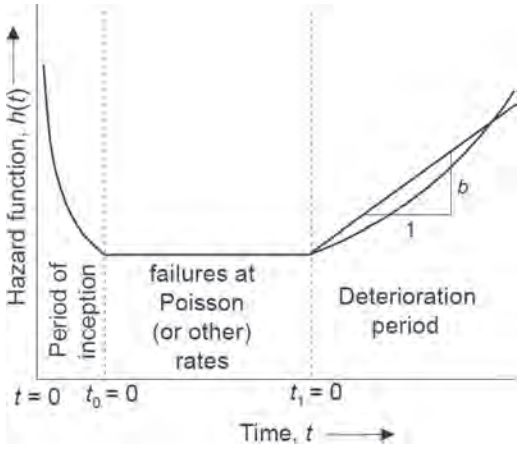

Figure 1. Hazard rate with distinction of three phases (Kottegoda and Rosso 2008).

Speijker et al. (2000)). In practice this means that there is no second phase ("failures at Poisson (or other) rates"), but that after delivery the reliability simultaneously decreases due to deterioration and increases due to information from non-failures. Whether and how these processes are taken into account depends on the definition of the failure probability that is used. For the failure probability in year t $P_f(t)$ the three main ones are:

1. $P_f(t)$ which means that the failure probability in year t is independent from the failure probability in other years.
2. $P(f_t \cap \overline{f}_{1..t-1})$ which denotes the probability of failure in year t and no failures occurred in the previous year.
3. $P(f_t \mid \overline{f}_{1..t-1})$ which denotes the probability of failure in year t given that no failures occurred in the previous year.

where f_t denotes failure at t and $\overline{f}_{1...t-1}$ denotes no failure in the period $1 \ldots t-1$. It has to be noted that most failure rates considered in literature assume a constant failure rate, which is in fact comparable to the first definition. The second and third are best compared to a description of a Decreasing Failure Rate (DFR) as described by Finkelstein (2008). However in order to better connect to current flood defence reliability practice a slightly different description is chosen here.

The choice of definition is dependent on the application and on the specifics of the situation. For cases where either the correlation between $P_f(t)$ and $P_f(t-1)$ is small and/or $P_f(t)$ is small equation 1 holds, and there is little difference in the three definitions.

$$P_f(t) \approx P\left(f_t \cap \overline{f}_{1..t-1}\right) \approx P(f_t \mid \overline{f}_{1..t-1}) \tag{1}$$

For all other cases the first definition is conservative.

Also it has to be noted that dike reinforcements generally do not entail a complete renewal, but rather an improvement of an existing flood defence. This means that part of the flood defence has already passed the inception period (as well as the other periods) and has to some degree proven itself. For this paper we consider a completely new flood defence and do not take that consideration into account although it can be very important if part of the dominant uncertainty is in a part of the dike body that has existed and survived for multiple decades or centuries.

2.2 *Temporal dependence in life-cycle reliability*

We consider a simple reliability problem where the limit state function at time t is given by:

$$Z(t) = R(t) - S(t) \tag{2}$$

with R the resistance and S the strength. In such a case, if we assume the limit state function can be approximated as a linearized hyperplane, the limit state function can be written as:

$$Z(t) = \beta(t) - \alpha_R(t)u_R(t) - \alpha_S(t)u_S(t) \tag{3}$$

where $\beta = \Phi(1 - P_f)$, where $\Phi(\cdot)$ is the inverse standard normal distribution. α_R and α_S are the influence coefficients of the random variables, indicating the respective contribution of their uncertainty towards the failure probability. u_R and u_S are random variables.

If we want to calculate the temporal reliability according to definitions 2 and 3 in the previous section, we need to take into account the correlation between subsequent years. The correlation of a component of the system in equation 2 is defined by:

$$\rho(Z_t, Z_{t-1}) = \alpha_{R,t}\alpha_{R,t-1}\rho_R + \alpha_{S,t}\alpha_{S,t-1}\rho_S \tag{4}$$

where ρ_R and ρ_S is the autocorrelation for the random variables of strength and load. For the strength, provided that there is no deterioration it could be argued that $\rho_R = 1$, the load is independent each year so $\rho_S = 0$.

For combining correlated components one could use numerical integration or probabilistic techniques such as Monte Carlo, but a very fast and efficient method is the Equivalent Planes Method, which is extensively described by Roscoe et al. (2015). In Roscoe et al. (2015) it is shown that this method is accurate for most cases, although some accuracy is lost for very large systems and for very strong correlations. However as the load is uncorrelated and values for α_R^2 are typically at most 0.7, such high values for the correlation will not be encountered when studying temporal reliability of flood defences.

The Dutch flood defense act allows for all three definitions of the previous section to be applied. The Equivalent Planes method therefore provides a fast and reliable method for evaluating the second and third definition of the annual failure probability. For the assessment of existing structures the third definition is most sensible, as in such cases it would be desirable to take into account that the structure didn't fail in the previous years, as has been done in for instance Schweckendiek (2014) and Schweckendiek et al. (2017). The third definition fits best with that. The second definition can be used for design purposes, as it is sensible to not account for the probability of failure in year t when the built structure has already failed in year $t-1$.

It has to be noted that for small probabilities of failure the second and third definition are almost the same as it follows from the definition of conditional probability that the difference between the two definitions for year t equals $1/\left(\prod_{i=1}^{n} 1-P_{f,t}\right)$. This indicates that for small P_f the difference will be negligible.

In order to combine different years, it is important that correlations in time between the limit state function from year $i-1$ to year i are correctly estimated. In many cases the reliability problem will not be so easy as the previously described problem, but will consist of many random variables that are (partially) correlated in time. In order to properly determine the temporal correlation of parameters and uncertainties it is important to classify uncertainties based on their original source, as only then a reliable classification can be made. This is further explained in the following section.

2.3 *Uncertainty in flood defence reliability*

There are various sources of uncertainty in flood defence reliability assessments. These are categorized by Gelder (2000) as inherent (aleatory) in time and space and knowledge (epistemic) uncertainty due to model and statistical uncertainty.Other categories can be used as well, e.g. Walker et al. (2003) distinguishes between different levels of uncertainty, and how these influence a decision problem. In general a distinction is often made between reducible and irreducible uncertainty as these influence the optimal action to deal with unacceptable failure probabilities (see e.g. Slijkhuis et al. (1997) and Schweckendiek (2014)). Inherent uncertainties are typically considered irreducible, where as knowledge uncertainty is considered reducible. This framework works well for typical loads on flood defences (a better model reduces model uncertainty but inherent natural variability in annual maxima of river discharges remains irreducible), but is less trivial for strength uncertainties. The strength uncertainty of flood defences mainly arises due to heterogeneity of the subsoil and dike body combined with limited knowledge of this subsoil, in combination with imperfect models describing the strength of the flood defence. In here, most uncertainty could theoretically be reduced but the question is more whether it is economically feasible to do so than whether it is technically possible (Schweckendiek 2014). It is therefore more applicable to use the classification of Phoon and Retief (2016) where geotechnical strength uncertainties are split into natural variability, measurement uncertainty, transformation uncertainty and model uncertainty. All of these uncertainties can be reduced to some extent, but each requires a different measure. For instance, if the source of uncertainty in Pre-Overburden Pressure (POP) is mainly natural variability, more measurements could be applied. However, if the source is a old and inaccurate measurement method, a more accurate method should be applied as there will also be a lot of measurement uncertainty. Hence it is important to systematically distinguish the main uncertainties based on their original source.

When doing a time-dependent reliability analysis this becomes even more important, as some uncertainties (mainly epistemic strength uncertainties and model uncertainties) will be correlated in time, whereas aleatory uncertainties are not. In order to correctly apply the notion of non-failure in preceding years, these uncertainties should be clearly distinguished. In this paper we will focus on the influence of temporal correlation on time-dependent reliability: it has to be noted that also spatial correlation can be used as information. For instance if the same model is used for different dike sections, and model uncertainty is the dominant parameter, failures and non-failures at location A might provide information on the reliability at location B. However this is out of the scope of this paper.

3 RESULTS

3.1 *Case description*

In order to investigate the effects of different formulations of temporal reliability and the influence of different values of uncertainty and correlation for different values of the reliability index we use fragility curves to describe the strength of a flood defence. This is a broadly used method of aggregating failure probabilities from more complex failure models (see e.g. Bachmann et al. (2013) and Schweckendiek et al. (2017)). The fragility curve expresses the critical height h_c which is an integration of the joint probability of the strength given a certain water level, resulting in the following limit state function

$$Z = h_c - h \tag{5}$$

where h is the water level and h_c the critical height. This approach is sound as long as the water level is (strongly correlated to) the dominant load for the mechanism. In this case we consider flood defence reliability described by the aforementioned limit state function where it holds that h_c and h are normally distributed. The Equivalent Planes method requires information about the influence coefficients (α_{ij}) of all i random variables per year j, reliability indices (β_j) for each year j and, as autocorrelations are constant in time, a correlation matrix with dimensions $i*i$. Using this method we can then combine the non-failure and failure events for subsequent years.

3.2 *Example 1: Life-cycle reliability of a dike without deterioration*

First we investigate the life-cycle reliability of a dike without deterioration, so constant h_c. In this case the value for $P_f(1) = ... = P_f(t-1) = P_f(t)$. For the temporal autocorrelation it holds that the strength is fully correlated $(\rho_{h_c} = 1)$, which is typical for many strength parameters of flood defences. The loads are uncorrelated from year to year $(\rho_h = 0)$, as the maximum water level in year i is typically independent of the maximum in year $i-1$. In the examples we will only consider the second definition for annual reliability index which is $\beta(f_t \cap \bar{f}_{1..t-1})$, as the difference with $\beta(f_t \mid \bar{f}_{1..t-1})$ is very small. For instance, if we assume that $\beta = 3$ and $\alpha_{h_c}^2 = \alpha_h^2 = 0.5$, the relative difference in β after 100 years is only 0.5%.

As h_c is assumed to be fully correlated in time, and h is fully uncorrelated, the influence coefficients will have a significant influence on the difference between $\beta(t)$ and $\beta(f_t \cap \bar{f}_{1..t-1})$.

Figure 2 shows the relative change in reliability index β for different values of α_{h_c} for $\beta = 3$. As expected it is observed that for higher values of α_{h_c} the difference is larger. Typical values for the influence coefficient of the strength for failure due to overflow are very small (order of 0.1 or 0.2), but for geotechnical failures these are often in the order $\alpha_{h_c} = 0.75$, meaning that for a lifetime of 50 years the various definitions of the reliability yield a difference in resulting reliability index of 10%. In terms of failure probability this is approximately a factor 3, which is equal to the difference in safety standard for two subsequent categories as defined in the law (e.g. 1/300 to 1/1000). Another important fact is that the reducing effect diminishes over time, which can be explained from the change in α over time, see Figure 3. The fact that the influence coefficient of the correlated variable reduces in time makes intuitive sense as more of the same information will result in increasingly less new insight.

A last important investigation of this simple case is the level of correlation. As was argued in the preceding sections it is important to distinguish different parameters with different uncertainties and different temporal correlations. However,

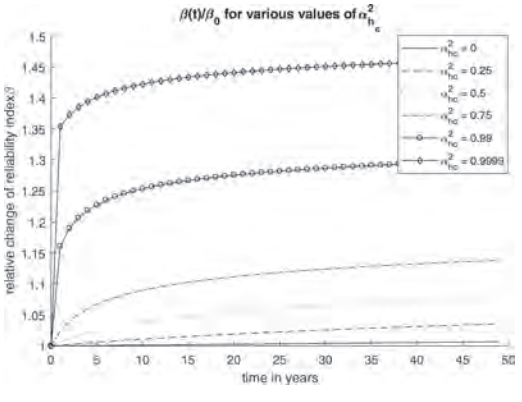

Figure 2. Relative change in $\beta(t)$ for various values of the time correlated α_{h_c} and $\beta(t=0) = 3$.

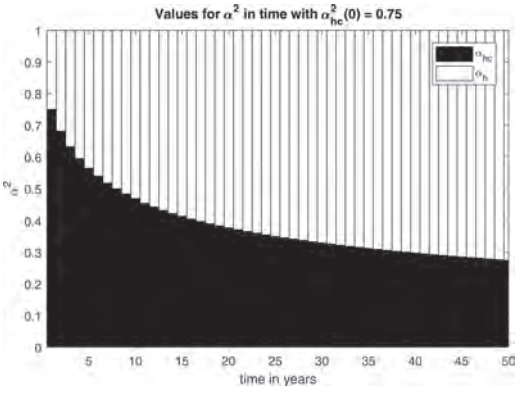

Figure 3. Change in α^2-values over time for a case with $\beta(t=0) = 3$.

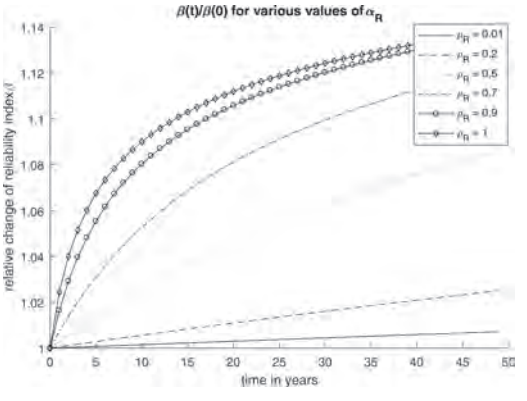

Figure 4. Relative change in $\beta(t)$ for various values of the correlation coefficient ρ_{h_c} and $\beta(t=0) = 3$.

Table 1. Parameters for Example 2.

Variables	Distribution	Parameters	
h_c	$N(\mu, \sigma)$	4.5	1.05
H	$N(\mu, \sigma)$	0	0.6
Δh_c	$\Gamma(\eta, \delta)$	$\frac{1}{var_{\Delta h_c}^2}$	$\frac{1}{\mu_{\Delta h_c} * var_{\Delta h_c}^2}$

Figure 4 shows us that the influence of having a ρ_{h_c} that is slightly smaller than 1 is not that influential on the $\beta(t)$: even for a ρ_{h_c} of 0.7 values close to the ones for full correlation are found. So even if there is a small error due to e.g. combining two (uncertainty) parameters with different time correlations, the influence on the result will often be relatively small.

3.3 *Example 2: Life-cycle reliability of a dike with deterioration*

In practice it will not occur that a dike will remain the same for 50 years. The most common deterioration mechanism for dikes is settlement, which can be described by parametric models (see e.g. Buijs et al. (2009)) or stochastic process models such as the Gamma Process (Pandey and van Noortwijk 2004)). Here we use such a Gamma process. We introduce a new random variable Δh_c which denotes the change in critical height compared to the first year. For the sake of the example we make an important simplification here as we assume that the critical height is fully dominated by the initial crest height and its settlement. For many (geotechnical) failure mechanisms this is not the case, and other types of deterioration will be more dominant. We assume that the average annual settlement is 2 cm with a coefficient of variation of 30%. By splitting the variables we can maintain that $\rho_{h_c} = 1$. We assume $\rho_{\Delta h_c} = 0$ as it is a random process, this leads to the following distributions for the random variables:

The choice of the distributions is such that for the initial situation $\alpha_{h_c} \approx 0.75$, comparable to the first example. The initial $\beta \approx 3.7$. It has to be noted that while we attribute the temporal change to settlement in this case (i.e. decrease in strength), it could also be attributed to an increase in load, for instance due to climate change. The behaviour of such a parameter would be similar: increasing in time with increasing uncertainty.

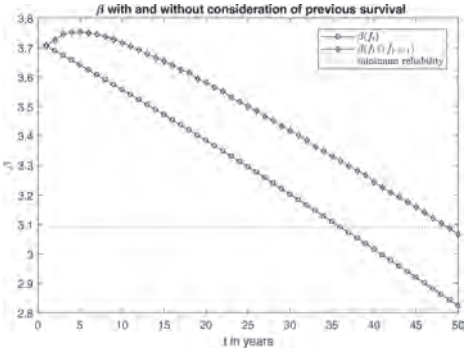

Figure 5. Values for different definitions of β with deterioration

Figure 5 shows the results for the time-dependent reliability. Here it can be seen that for this case the influence of the definition is rather large: when we compare to a minimum required reliability $\beta = 3.09 \left(P_f = 1/1000\ yr^{-1} \right)$, the expected extended life when taking into account survival is approximately 15 years (or: an extension of the lifetime by almost 50%).

This amount of lifetime extension however is dependent on the rate of deterioration, and especially the uncertainty in deterioration. Figure 6 shows the α^2-values for two rates of deterioration, on the left is the same as used in Figure 5, the right is a distribution with higher variation and slightly lower mean, such that $\beta(f_{50})$ is equal for both cases. However for the deterioration with high variation $\beta\left(f_{50} \cap \overline{f}_{1..49}\right)$ is significantly smaller than for the case with smaller variation. This can be explained by a smaller $\alpha^2_{h_c}$ in the design point, meaning that the influence of that uncertainty on the reliability is smaller, resulting in less valuable non-failure information.

3.4 *Economic implications of time dependent reliability*

Generally the goal of flood defence management is to maintain flood defences at a desired level of reliability, against acceptable costs. In many cases Life Cycle Costing (LCC) is used to evaluate costs in time, for which the principles were first reported by Samuelson (1937). In an LCC analysis the Net Present Value, which denotes the value in current day prices, is calculated using the following formula:

$$NPV = \sum_{i=1}^{t} \frac{C_i}{(1+r)^i} \tag{6}$$

where, C_i is the total cost in year i, r is the discount rate and t is the evaluation period. One of the major implications of this economic theory is that postponing an investment yields significant benefits. For instance: if we postpone an investment by 10 years, assuming a discount rate of 3%, the current stand-

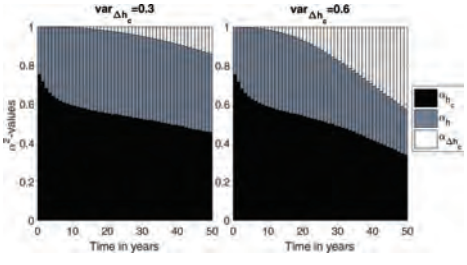

Figure 6. Change of α^2 in time for different rates of deterioration.

ard in the Netherlands (Werkgroep Discontovoet 2015), the cost after ten years is only 75% of the cost, expressed in present day prices. A disadvantage of using LCC is that it is slightly harder to compare investments with different lifetimes. For such comparisons the NPV can be expressed as Equivalent Annual Cost (EAC), which is calculated using the following formulas (Schoemaker et al. 2016):

$$EAC = \frac{NPV}{A_{t,r}} \tag{7}$$

$$A_{t,r} = \frac{1-(1+r)^{-t}}{r} \tag{8}$$

where $A_{t,r}$ is the Annuity factor for year t and discount rate r, which denotes the sum of the discount factors compared to $t = 0$.

In Figure 5 it was shown that the definition of time-dependent reliability can have a significant influence on the lifetime of a structure. To further investigate this we consider 4 situations, and generate distributions for the initial strength h_c corresponding to a wide range of α-values. The 4 cases contain 3 cases (1, 2 and 3) with different reliability requirements and 1 case (case 4) with an adapted uncertainty for the settlement (similar to the comparison of different deterioration rates in the previous section). The different cases are summarized in Table 2. It is expected that the case with low target reliability has the largest life extension, as here a non-failure is more relevant than for the case with a very high reliability. Also, based on the α-plots in Figure 6, where we saw a more rapid decrease in α_{h_c} for a higher variation of the settlement, we would expect the increase in lifetime for the case with small variation in settlement to be larger.

Figure 7 shows the extension of the lifetime in years for the 4 considered cases. Here it can indeed be seen that for a lower reliability larger extensions are gained, and that for lower uncertainty in deterioration the effect of non-failures in preceding years is also larger. It has to be noted that the lines are a bit wobbly, which is due to the fact that the reliability is determined per year, resulting in discrete steps and therefore small wobbles. However the lifetime extension doesn't directly translate into financial benefits. Therefore in Figure 8 the relative savings following from the postponement of a new reinforcement are shown for a discount rate of 3%. Here it follows that in the most extreme case (high $\alpha^2_{h_c}$ for Case 2) the relative savings can amount up to a factor 3. These relative savings are independent of other investments during the life cycle, and also independent of the actual reference year as the relative savings are linear in time (due to the exponential character of the discount rate). For instance for assessments of existing structures this would be a relevant value, as the reference year wouldn't be 0 but somewhere between 0 and the end-of-life. However in design decision making the change in Equivalent Annual Costs is more relevant, as this denotes the economic yearly cost for a design option. If we assume that at t = 0 a reinforcement is made for a lifetime of 50 years, for a discount rate of 3% a reduction in Equivalent Annual Cost of approximately 12.5% is realized for a lifetime extension to 70 years, which is in accordance with Figure 8. Obviously this will not hold for all flood defences in the Netherlands, but mainly in the

Table 2. Cases for analysis of lifetime extension.

Case	$\beta(P_f)$	$\boldsymbol{var}_{\Delta h_c}$
1	$2.326(10^{-2})$	0.3
2	$3.090(10^{-3})$	0.3
3	$3.719(10^{-4})$	0.3
4	$3.090(10^{-3})$	0.05

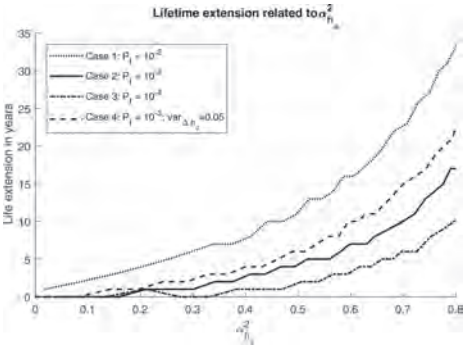

Figure 7. Life extension in years for different α_{h_c}-values for the 4 considered cases.

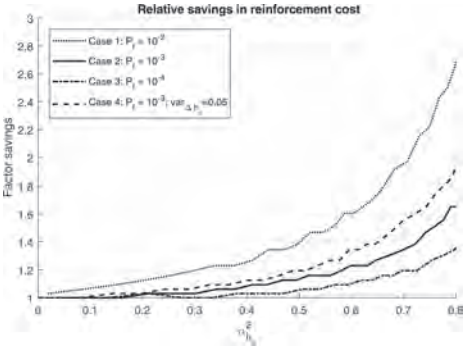

Figure 8. Factor of relative savings for the reinforcement cost for the 4 considered cases

riverine area failure probabilities are dominated by geotechnical failure mechanisms, meaning that such lifetime extensions will not be uncommon.

4 CONCLUSIONS AND RECOMMENDATIONS

In this paper we have explored various aspects of temporal dependence in reliability of flood defences. As flood defence reliability is often determined by highly uncertain but temporally correlated strength parameters, non-failures in previous years constitute information that can improve the estimate of the strength, especially when the estimated reliability is low. In this paper we've explored some parametric cases where it is shown that the savings due to accounting for non-failures rather than the commonly used conservative approach of disregarding temporal dependence in reliability can be significant (up to 20 years in lifetime extension). This is of relevance for many aspects of flood defence management such as design guidelines as well as assessment of existing flood defences where often low reliabilities are found from models. It has to be further investigated for different decision problems in flood defence management what the consequences of accounting for this temporal dependence are, especially by looking in more detail into the sources of uncertainty of actual dike reliability analyses. However, based on the considered cases it is expected that it can significantly improve reliability estimates in assessment and design, especially when there is large uncertainty on strength parameters that are correlated in time. It has to be noted that in such cases it might be necessary to improve the knowledge on strength parameters through obtaining additional information. Due to the high strength uncertainties that are often encountered, the consideration of the value of improved information is one of the major decision problems to be studied for flood defence management.

Impact assessment of road infrastructure: A holistic approach

Y.Z. Ayele
Faculty of Engineering, Østfold University College, Fredrikstad, Norway

ABSTRACT: As construction companies attempt to maximize the value of each road project and optimize their investment portfolio, it has become vital to assess the impact of road transport projects for their cost effectiveness in order to support well-informed decision-making. Proper impact assessment will result in road design that is more advanced, efficient operations, and improved environmental protection. Identifying cost-effective road design, which have a minimal environmental footprint, however, is one of the biggest challenges for road construction industries. The purpose of this paper is thus to propose a holistic methodology for assessing the impacts of the road projects, by taking into account the available natural resources, the environment, and by involving all relevant stakeholders. The paper also outlines steps to assess both monetised and non-monetised impacts. By employing, the proposed steps, the pros and cons of new road networks can be identified in a structured way and hereby highlight factors of success and failure.

1 INTRODUCTION

Across the world, inadequate or poorly designed and performing road infrastructures leads to major financial and social challenges, which governments and businesses need to address (Dobbs et al., 2013, Ayele et al., 2013). Further, in broad sense, road network designs without a proper impact assessment, resulted in a road that is not adequate for meeting the current and future road transport needs of a given society (Systematics, 2012). Hence, in investment decisions, the relevant decision-maker often carry out a cost-effectiveness analysis (CEA) and cost-benefit analysis (CBA) of road network projects. When identifying and categorizing the costs and benefits of road design alternatives, a reasonable effort has to be made to identify those costs that will have the most significant implications on the strategic decision.

To identify cost-effective road network design, which have a minimal environmental footprint, it has been argued that two questions are fundamental (Macias and Gadziński, 2013, Hanley, 2001, Ayele et al., 2016b). Firstly, which road design alternative is estimated to be cost-effective and environmentally sustainable, based on the prevailing evidence? Secondly, should further research be carried out in order to minimise the level of uncertainty related to the decision? To answer these questions and, determine the cost-effectiveness of the road network design, number of studies have been carried out, see e.g. Hanley (2001), Macias and Gadziński (2013), Nagurney et al. (2010), and Welde et al. (2013). For instance, Welde et al. (2013) compared the implementation of CEA and CBA, which are the two common economic evaluation methods, as tools for allocation of national public funds in the transport sector. Moreover, Macias and Gadziński (2013) discussed issues of road transport networks influence on the natural environment. Furthermore, for better understanding of the environmental impacts, Nagurney et al. (2010) proposed environmental impact assessment (EIA) indices for evaluating the environmental effects of link capacity degradation in transportation (road) networks.

However, in most of the available CEA and CBA literature, either cost or environmental impact is the only factor considered; and there is a lack of consideration of the available natural resources, the environment, and all relevant stakeholders when assessing the impacts (monetised and non-monetised) of the road projects. Further, the adequacy of the models used to estimate the various costs and benefits of the road network investment projects is increasingly being called into question (Systematics, 2012).

This is considered as a significant drawback since inadequate or poorly designed infrastructure presents major economic and social challenges. Further, understanding how a specific decision or choice of assessment method affects the intended goals is a key in identifying a cost-effective road network design. Proper CEA and CBA will result in more advanced road network design, more efficient operations, and improved environmental

protection. Moreover, it can be used to identify weaknesses or strengths of existing or new road networks in a structured way and hereby highlight factors of success and failure. It is also a core element in examining the overall quality of the road design alternatives.

Hence, the purpose of this paper is to propose a holistic methodology for assessing the impacts of the road projects, by taking into account the available natural resources, the environment, and by involving all relevant stakeholders. The paper also outlines steps to assess both monetised and non-monetised impacts. The rest of the paper is organised as follows: Sect. 2 presents a problem description. Section 3 discusses the concept of CBA and CEA process. Section 4 introduces the proposed holistic methodology for assessing the impacts of the road networks. Section 5 provides the concluding remarks.

2 PROBLEM DESCRIPTION

The problem considered here is an impact assessment problem of the road networks. Suppose we have a finite number of road network design alternatives, each with a different construction, maintenance and HSE (health, safety, and environmental) costs. The idea is to use the most suitable design alternatives with a minimum environmental footprint. However, considering the available natural resources, the environment, and the involving relevant stakeholders when assessing the CEA and CBA of road design alternatives, a decision-maker will face a time-variant decision making process. In other words, the decision maker is faced with an optimisation problem, since these factors can be considered as covariates. A covariate, in the context of this paper, is a factor that can have an influence on the direct and indirect costs as well as the decisions of the road projects.

To optimise the effectiveness and benefit and, to determine what road design alternative will be used, the proposed holistic methodology constantly assesses the impacts of the road projects, by considering the existing natural resources, the environment, and by involving all relevant stakeholders. The proposed methodology attempt to capture the monetised and non-monetised impacts of new road systems, in a structured way and hereby highlight factors of success and failure.

3 A GENERIC CEA AND CBA PROCESS

Assessment tools are structured procedures or methods which, when used, result in objective and replicable information; either on the technological and design appropriateness of the decision choice or the local allowing or restricting conditions that can influence the attainment or non-attainment of the decision choice (it can be technical or managerial) (Zurbrügg et al., 2014). A range of assessment methods are often developed for assessing a specific aspect of the road networks, such as technical, environmental and health, economic and financial, social and institutional, organizational aspects; and, others attempt to provide a more holistic picture by integrating different assessment methods into the same tool; see e.g. (Welde et al., 2013, Hanley, 2001, Nagurney et al., 2010, Macias and Gadziński, 2013). When assessing environmentally sustainable and cost-effective road project, in general, three main issues govern the final decision. Figure 1 illustrates these three main issues, which needs to be considered while assessing environmentally sustainable and cost-effective road project.

3.1 *CBA and CEA*

3.1.1 *Cost-Benefit Analysis (CBA)*

CBA is an analytical method for assessing the total costs and benefits from the planned project (Finnveden et al., 2007, Skovgaard et al., 2007). It provides a starting point from which to begin evaluation of a project; can provide quantitative data to back up qualitative arguments; it does allow interested parties to clearly define the issues involved; and it allows comparisons to be made between investments or projects (Gerald Shively and Marta Galopin, 2014). However, it requires that the analyst assign monetary values to all benefits and costs, however, there are numerous benefits and costs which are intangible and therefore

Figure 1. An overview of the relationship between the main aspects of road network.

difficult to value; CBA results can be very sensitive to the choice of the discount rate; and some future benefits and costs cannot conceived, much less measured (Gerald Shively and Marta Galopin, 2014).

3.1.2 *Cost-Effectiveness Analysis (CEA)*

A generic CEA process involves: i) determining which cost variables affect the cost-effectiveness of the chosen road design solution. This includes determining and analysing: (a) internal cost factors, which arise because of company decisions and goals; the company largely manages these cost factors and, if necessary, they can be changed and (b) external cost factors, which are not controlled by the company but will influence the overall cost & the decisions. ii) Determining inherent risk factors for the chosen design highway practices and the company tolerance for them. iii) Determining the functional interdependence between the cost and risk variables and the degree to which each of these variables can be controlled. Figure 2 illustrates the key steps in the CEA.

CEA focuses on the costs on achieving the goals of the system and the most efficient way of achieving it (Finnveden et al., 2007, Ayele et al., 2014). The benefits of achieving the goals do not have to be quantified (Finnveden et al., 2007). CEA is most useful when analysts face constraints which prevent them from conducting CBA (Tan-Torres Edejer et al., 2003, Ayele et al., 2014). For instance, the most common constraint is the inability of analysts to monetize benefits. Though the basic cost-effectiveness calculation appears to be simple, choices about units of measurement, scope of costs, and prices to be included not only will alter the numerical results but also will affect the interpretation of the cost-effectiveness ratio (The International Bank for Reconstruction and Development and The World Bank Group, 2006).

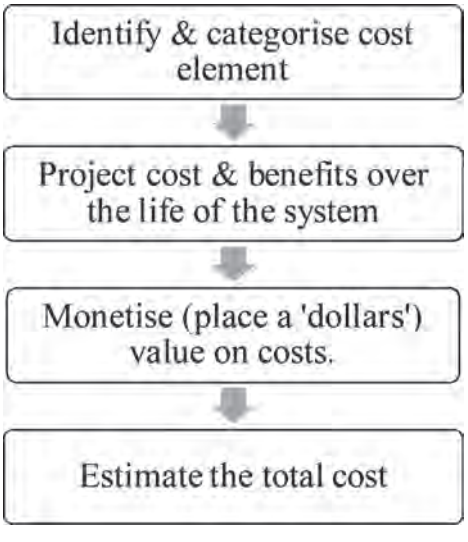

Figure 2. Key steps in the CEA.

3.1.3 *Cost-Effectiveness Ratio (CER)*

The CER is a ratio in which the denominator is the unit of effectiveness and the numerator is the present value of the cost of a particular road infrastructure. Units of effectiveness are a measure of any quantifiable outcome central to the road design objectives. In road construction, the total volume of construction material required would be the most important outcome and, would be an obvious unit of effectiveness. Mathematically, CER for a specific road infrastructure, based on Cellini and Kee (2010), can be described as:

$$CER_{RInf.} = \frac{PVC_{RInf.}}{U_{RInf.}} \tag{1}$$

where:

- $U_{RInf.}$ is the unit of effectiveness of road infrastructure (*RInf.*), and
- *PVCRInf.* is the present value of cost of road infrastructure (*RInf.*), and is given by:

$$PVC_{RInf} = TC_{RInf\cdot 1} + \frac{TC_{RInf\cdot 2}}{(1+r)^1} + \frac{TC_{RInf\cdot 3}}{(1+r)^2} + \ldots + \frac{TC_{RInf\cdot t}}{(1+r)^{t-1}} = \sum_{t-1}^{T} \frac{TC_{RInf\cdot t}}{(1+r)^{t-1}} \tag{2}$$

where:

- $TC_{RInf\cdot 1}$ is the annualised total cost of road infrastructure (RInf.),
- t indicates the year from 1 to T (the last year of the analysis),
- r is discount rate, which is meant to reflect society's impatience or preference for consumption today over consumption in the future.

CER results are very sensitive to the choice of the discount rate, and thus an appropriate choice of the discount rate is critical, and there is ongoing and considerable debate as to the appropriate rate, see e.g. Stern (2006), Lopez (2008) and Cellini and Kee (2010).

3.2 *Environmental Impact Assessment (EIA)*

EIA is a process for assessing environmental consequences (positive and negative) because of the planned project. Conducting an EIA during the project design phase will provide information

about the environmental conditions of the area; early assessment of negative impacts can ensure that appropriate mitigation measures and opportunities are identified and implemented; and it can help to reduce costs in the long term (Jonathan R. and Emma J., 2010). However, some of the reasons given for the non-use of EIA tools are that they are too cumbersome, time consuming, and generalized; another reason is the lack of evidence confirming the actual value and success of EIA's; and in contrast to other assessment methods EIA is generally site-specific (Jonathan R. and Emma J., 2010, Finnveden et al., 2007).

3.3 *Engaging relevant stakeholders*

The impact analysis can only be undertaken when stakeholders agree on a minimum range of prerequisites (points). In addition, during the effectiveness assessment the inclusion of stakeholders, intergenerational equity as well as the satisfaction of the social needs can be assured. That means the involvement of all relevant stakeholders in the decision-making process can be corroborated (Morrissey and Browne, 2004).

4 PROPOSED HOLISTIC METHODOLOGY

The main steps for assessing the impacts of the road project is depicted in Figure 3. The methodology has various key elements; and, it takes into account the available natural resources, the environment, relevant stakeholders. The first stage, in the proposed methodology, is to specify the goals and criteria based on the available standards, regulations, and recommended guidelines. One of the main criteria is that the result from the assessment should support the decision-maker to clearly identify the consequences of the chosen road network design alternative. Moreover, when defining goals for effective and environmentally sustainable road network design, the inclusion of all relevant stakeholders must be ensured.

After defining the objectives, the goals, and the criteria, in the next stage, the road network design options should be specified. In this stage, the aspects of road network design as well as the features of transport network expansion capacity should be outlined. The road network design, in general, deeds with the configuration of network to achieve specified objectives (Tom and Mohan, 2003). Further, there are two variations to the design problem, the continuous network design and the discrete network design. Some of the design problem include, determining the width of the road, setting of road user charges, calculation of signal timings, etc. (Tom and Mohan, 2003).

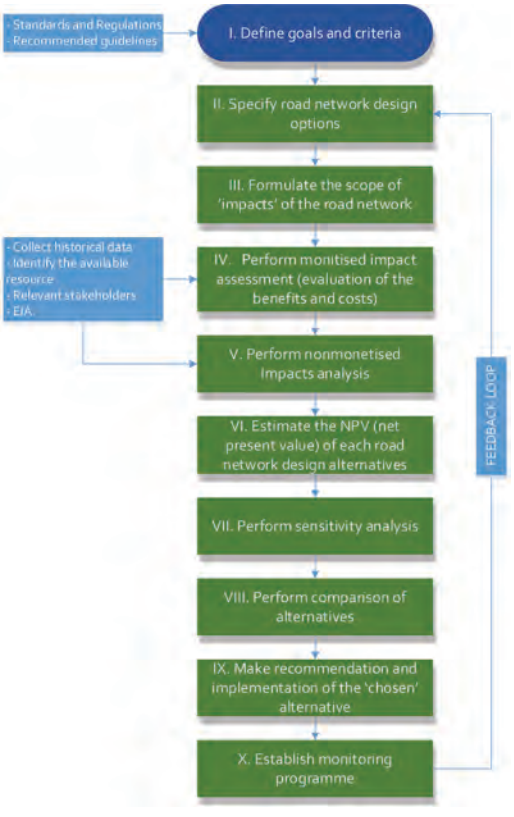

Figure 3. The proposed holistic methodology for assessing the impact of the road infrastructure.

Formulating the scope of the impacts of the road network is the next stage. In this stage, it is essential to identify the scope of the impacts, such as the influence of the road networks in the landscape ecology. In broad sense, with construction of road networks, the range of human activities also expands, which increases the human impact on the natural ecology. Hence, in this stage, the scope should be clearly defined the facet of the impact analysis.

In the next stage, the monetized impact assessment or evaluation of the benefit and cost of the alternatives should be carried out. Figure 4 depicts the key parameters that needs to be quantified. In this stage, the analyst assigns monetary values to all benefits and costs. Since the CBA results can be very sensitive to the choice of the discount rate, the analyst should be vigilant. It is also important to note that some future benefits and costs cannot conceived, much less measured (Gerald Shively and Marta Galopin, 2014).

After assessing and quantifying the impact, thereafter, non-monetised impact assessment

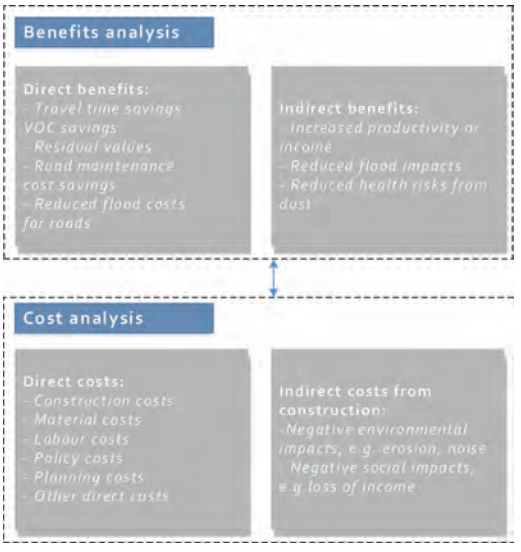

Figure 4. Monitised impact assessment: Benefit and cost analysis, modified from Systematics (2012).

should be performed. In this stage, the main emphases are on assessing the costs on achieving the goals of the network design and the most efficient way of achieving it. Here, the benefits of achieving the goals do not have to be quantified in monetary terms. This stage is most useful when analysts face constraints which prevent them from conducting monetized impact analysis (Tan-Torres Edejer et al., 2003). For instance, the most common constraint is the inability of analysts to monetise benefits.

The next stage, in the proposed methodology, is estimating the net present value (NPV) of each road network design alternatives. Here, by employing the NPV method, the benefit and cost of a given road design alternative over an extended period of time should be calculated and then discounted at a selected discount rate to give the present value (Sinha and Labi, 2011). Benefits are treated as positive and cost as negative and the summation gives the NPV (Sinha and Labi, 2011). In general, any road design with positive NPV is treated as acceptable. In comparing more than one design alternatives, an alternative with higher NPV should be accepted.

After estimating the NPV for each alternative, in the next stage, the sensitivity analysis should be performed. The aim of the sensitivity analysis is to recognize the vital cost variables and their potential impact in terms of changes in the annualised total cost and present value cost. In general, there are two common sensitivity analysis – partial and extreme cases sensitivity analyses. The partial approach varies one assumption (or one parameter or number) at a time, holding all else constant (Cellini and Kee, 2010). On the other hand, extreme case sensitivity analysis varies all of the uncertain parameters simultaneously, picking the values for each parameter that yields either the best- or worst-case scenario (Cellini and Kee, 2010, Ayele et al., 2016a).

Thereafter, the comparison between the alternative design options should be performed. The comparison should consider the strengths and weaknesses of each alternative, check the extent and the validity of the 'results' obtained from the assessment, and investigate whether a given design alternative match the intended plan and outcomes, etc. Further, at this stage, specific effectiveness indicators should be clearly identified; the advantage and disadvantage of the proposed road design alternatives should be assessed; and, the compilation of HSE standards should be ensured, by verifying the consideration and integration of the social aspects.

Thereafter, the recommendation should be made and, afterwards the chosen road design alternative should be implemented. The recommendation should comply with road design standards and guidelines. Afterwards, the approved recommendation should be monitored by establishing the monitoring programme. That means the monitoring programme has to include the follow-up of the implementation of the chosen design alternative, by emphasising what does work, what does not work, and what continues to work. Further, there should be a feedback loop where the recommendations should help to review the impact assessment and, the choice of the alternatives.

5 CONCLUDING REMARKS

To address the challenges related with inadequate or poorly designed and performing road infrastructures, proper impact assessment of road network design alternatives is vital. This consequently helps to ensure cost-effective and environmentally sustainable road infrastructure design. Furthermore, proper impact assessment can have a significant economic, environmental, and social benefit, by reducing the HSE (health, safety, and environmental) impacts, identifying cost-effective and environmentally sustainable road.

This paper proposed a holistic methodology for assessing the impact of the road networks. The proposed methodology is based on the consideration of possible road design alternatives. The first part of the proposed methodology presents the problem description and discuss the concept

of cost-benefit analysis (CBA) and cost-effectiveness analysis (CEA) process. The second part of the paper describes estimation of the net present value (NPV) by categorising the road networks impact into two: monetised and non-monetised. By employing, the proposed methodology the pros and cons of new road systems can be identified in a structured way and hereby highlight factors of success and failure.

Harmonizing normative organizational structures and serification & validation concepts for safety critical generic projects

E.H. Dogruguven
Aselsan Inc., Ankara, Turkey

I. Ustoglu
Department of Control and Automation Engineering, Yildiz Technical University, Istanbul, Turkey

ABSTRACT: Development of a Generic Application or Product (GAP) is always challenging, because it should be designed as much as generic and simply configurable for the final specific applications. If such a development is also safety critical, then the complexity increases dramatically as the resulted system will have impacts on human life, property and environment. The safety management plays a major role to keep this tough development process under control by avoiding systematic faults. Setting up correct organizational structure as well as applying Verification & Validation (V&V) concepts, which are two fundamental elements of safety management, in an accurate way are therefore crucial. This paper discusses railway safety management in terms of organizational structure and V&V with regards to the current normative status with its drawbacks. Proposals are provided for an updated organization and more harmonized V&V concepts including relations with safety management and quality assurance by sharing practical experiences.

1 INTRODUCTION

As Murthy et al. (2008) explain regulatory requirements, customer requirements, and technical requirements shall be fulfilled when producing a safety instrumented system. Independent safety assessment against the international and/or European standards shall be realized for the acceptance and approval of the system. If necessary, national standards, regulations and directives are also to be followed. These are shown in a hierarchical manner in Figure 1.

For railway applications, both On-board and trackside, the European Norms EN 50126, EN 50129, EN 50128, and EN 50159, dealing with RAMS, electronic system, SW and transmission, respectively, are referenced in European countries, and at the same time they are also well accepted and applied in many other non-European countries. These norms are derived from the core norm IEC 61508 like many other European and international norms as depicted below in Figure 2.

Despite the fact that they are very detailed and strict as they are related to complex safety critical electronic systems and subsystems, Hokstad and Corneliussen (2004) draw attention to a couple of ambiguities about safety unavailability from quantitative evaluation perspective diminishing the usefulness of the standards. This paper focuses

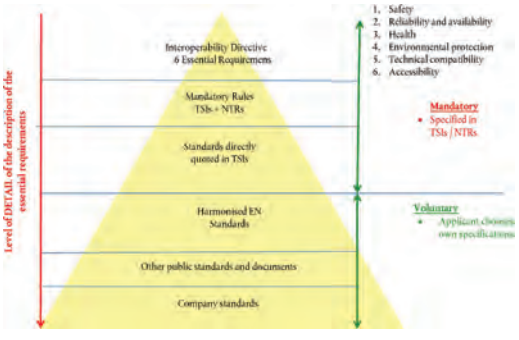

Figure 1. Hierarchy of laws [EU Recommendations commission (2014)].

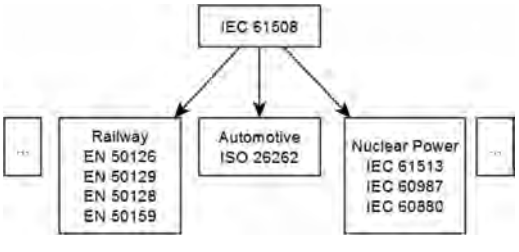

Figure 2. Derivation of standards from IEC 61508.

on two main issues from the qualitative perspective regarding SIL (Safety Integrity Level) 4 development. It is organized as follows. Section I gives a brief information about the standards. In Section II, the organization and responsibilities in the norms are distilled and experiences are highlighted by proposing a new role and responsibilities taking into account the critical duties in a safety critical project. In Section III, Verification & Validation (V&V) concepts confused usually not only on the account of their different understanding in other domains like defense or avionic, but also their different descriptions inside the CENELEC norms themselves are discussed and accordingly the confusing concepts are clarified. Moreover, relations between verification, validation, safety management, quality assurance and assessment are explained. In section II and III, project experiences gained during SIL 4 GAP for mainline On-board signalling part of European Rail Traffic Management System—European Train Control System (ERTMS ETCS) and metro line On-board signalling part of Communication Based Train Control System conjointly with wayside interlocking system assessed independently by a European Notified Body are utilized. Finally, the paper conveys some concluding remarks.

2 ORGANIZATION AND RESPONSIBILITIES

Firstly, the organizational independence for SIL 4 is illustrated as in Figure 3 in EN 50129, the Railway Standard for "Safety related electronic systems for signalling", referred to the System and HW development. In the illustration, same person and same organization arrangements are depicted as solid and dashed lines, respectively. In the figure, PM stands for Project Manager, DI for Designer/ Implementer, VER for Verifier, VAL for Validator. Having provided the illustration and mentioned the independence of roles in Table E.3 in EN 50129, there are no more additional explanations about the independence of roles in this norm.

Secondly, when the norm EN 50128, "Software for railway control and protection systems" is examined, it gives much more detail about the organizational independence (see Figure 4). It defines not only new roles such as Requirements Manager (REQ), Implementer (IMP), Integrator (INT) and Tester (TST), but also new type of vertical lines for the responsibility dependency such that RQM, DES (Designer), IMP shall report to the PM; INT, TST and VER can report to the PM whereas VAL shall not report to PM.

Differently from the norm for electronic systems, this norm elaborates the roles by thirteen

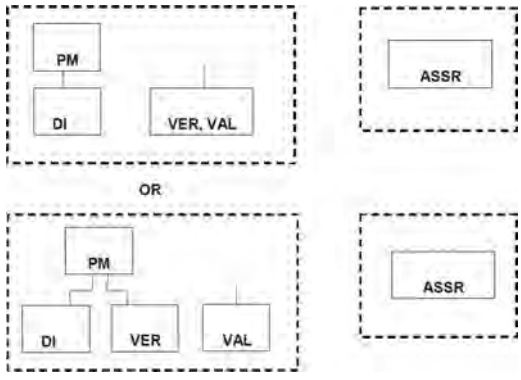

Figure 3. Organizational independence [EN 50129 (2003)].

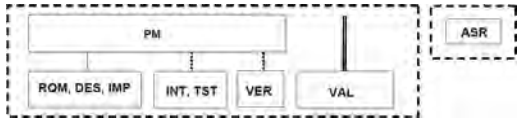

Figure 4. Preferred organizational structure [EN 50128 (2011)].

clauses. In addition, it offers two options for the roles validator and verifier. It allows that the VAL and the VER can be same person guarantying independence from the PM where in this case there shall be a further person who reviews the documents of VER and who does not report to PM. A similar approach is brought to the role of VER in the way that VER and INT/TST can be the same person provided VAL performs verification tasks, too, such that there are double checks.

If considered, the similar tasks are also realized in system and HW development phases. For instance, there will also be HW tests, and a test report and a further verification report, however though the integrity level is the same, the organizational independencies differ from each other which means that the VER can perform test activities and write both test and verification report. We therefore propose at this step that the organizational structures in these norms shall be harmonized and the one stated in EN 50128 can be used for this harmonization purpose, as it declares more roles and therefore more checks which are inevitable in a safety critical system. Another problem for the independency requirements arises from the need of several verifiers in a project, as the verification activities do require specialization in the technique. In this case, a lead verifier can be assigned to the interface and will be responsible for fulfilling all the verification activities. In case there is a limited number of available specialized personnel, this

time there arise personnel availability problems. To overcome this issue, it can be proposed that VER of a work-package can be allocated as DI of another work-package.

Besides, intensive safety analyses (Table 1) shall be performed in safety critical systems to derive safety requirements, both at system and subsystem level. These analyses require broad technical knowledge and long term of experiences, in short special qualification. Therefore it is far more above than the specialization of a designer. Additionally, as Oedewald and Gotcheva (2015) take attention, many safety activities are carried out by subcontractor networks which means that the subcontractors and their deliverables shall be checked for correctness, completeness and consistency by an expert of the main system owner. Hence, we propose a new role, namely the "safety responsible (SR)" to be added to this structure with the tasks provided below:

- Developing the safety plan,
- Performing safety analyses,
- Creating and maintaining the hazard log,
- Ensuring that the entries in the hazard log are successfully closed or further allocated in an appropriate manner,
- Being responsible for ensuring that safety requirements are met successfully,
- Deciding whether a deviation or change is safety relevant or not and ensuring that it is successfully closed,
- Obtaining safety evidence of the third party items including their Safety Related Application Conditions,
- Deriving the Safety Related Application Conditions for the developed item(s) in the project
- Composing the safety case

The addition of the new role "SR" arises from another necessity, as well that in terms of the independence and appropriateness of the tasks of VAL, a considerable number of tasks are usually fulfilled by the VAL which does not coincide with the primary validation tasks. For instance, there is no statement in the norms about the responsible person for the safety plan. It has been observed in the industry that the safety plan is usually written by the VAL. However, the safety plan itself needs both verification and validation. The same is also valid for the safety analyses as well as hazard log and safety case. To make this point clearer, we analyze the V&V concept in the further part of this paper.

Table 1. Failure and hazard analysis [EN 50129 (2003)].

Beside the safety responsible as acting person for safety technical pertinent issues, another work package in a safety critical project is the safety management activities such as planning and coordination of the V&V activities, the internal and external audits and assessments, reviews, management of subcontractors concerning RAMS activities. Both the SR and VAL can perform safety management activities as these activities do not contradict with the validation activities. Below, the proposed organizational structure for all three development processes, system, HW, SW, are depicted. The SR is preferable independent from the PM considering his/her activities explained above such as deciding for the safety relevance of a change request to avoid any stress factor that can be caused by the PM due to time and/or costs pressure. Another issue is that EN 50128 does not allow REQ, DES or IMP to be INT, however, considering the role of INT in the norm, this is not contrary to the independency, and thus we propose to update the organization as in Figure 5.

Furthermore, an important role during safety critical system development is allocated to the customer/operator. However, in GAPs, there is neither customer nor operator, at least during the design phase, which increases the difficulty as the customer has in fact significant tasks in safety relevant projects as explained in Table 2. The customer/operator are incorporated once during the specific application projects on the field. Especially when identifying hazards and assessing risks, the customer is needed, as the standard IEC 61882 clarifies that both the contractor and the client should constitute the HAZOP team. To meet these needs, a person inside the company having experience in the domain and technical knowledge about

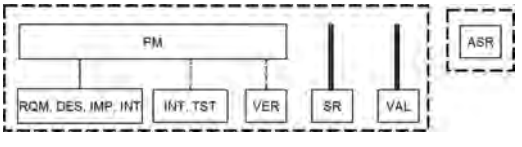

Figure 5. Proposed organizational structure.

the specifications can be assigned as a customer to the project. However, it should be noted that, the customer and the PM have very different responsibilities which shall be performed in an independent manner and it should not be confused that customer and PM can be the same person as there is no limitation in the organizational structure given in the aforementioned norms.

3 V&V CONCEPTS

Although verification and validation definitions should be consistent in the CENELEC Norms, these are defined somehow differently in these norms which causes ambiguity when creating plans and performing activities.

- Verification in EN 50126: confirmation by examination and provision of objective evidence that the specified requirements have been fulfilled.
- Verification in EN 50129: the activity of determination, by analysis and test, at each phase of the life-cycle, that the requirements of the phase under consideration meet the output of the previous phase and that the output of the phase under consideration fulfils its requirements.
- Verification in EN 50128: the process of examination followed by a judgment based on evidence that output items (process, documentation, software or application) of a specific development phase fulfil the requirements of that phase with respect to completeness, correctness and consistency.

As mentioned in the previous section, as TST is not defined in EN 50129, the verification activity here involves test whereas in EN 50128, the verification is based on the review. EN 50129 comments verification as a process, rather than a product. For each phase in EN 50126, there are verification steps of the phase considering the requirements of the phase. EN 50128 makes these more comprehensible and inclusionary, therefore for avoiding misapplication during the project and the harmonization of the verification definition, it is proposed to use the definition in EN 50128 in the whole project.

Coming to the validation, the situation requires the same level of attention. According to the definitions given below, again here, the test is underlined in EN 50129 while EN 50128 uses tests for checking the results. For the harmonization, we propose again that the definition in EN 50128should be used.

- Validation in EN 50126: Confirmation by examination and provision of objective evidence that the particular requirements for a specific intended use have been fulfilled.
- Validation in EN 50129: The activity applied in order to demonstrate, by test and analysis, that the product meets in all respects its specified requirements.
- Validation in EN 50128: Process of analysis followed by a judgment based on evidence to determine whether an item (e.g. process, documentation, software or application) fits the user needs, in particular with respect to safety and quality and with emphasis on the suitability of its operation in accordance with its purpose in its intended environment.

Moreover, validation is depicted (see Figure 6) in all the CENELEC norms in a way that it is realized against system requirements. However, the

validation is to be performed not only at the end against system requirements, but as (Lundteigen et al., 2009) states, verification and validation are important activities in all phases of the project development process. For instance, at the planning phase, the tools shall be validated or if they are already pre-validated, this should be checked against the intended use or the risk analyses are to be validated. Another task can be witnessing the independence during the design and test. Therefore we propose the Figure 7 to represent the V&V activities.

Several management reports are to be created in a safety critical system. The main reports included in the safety case are verification, validation, safety management, quality assurance and assessment reports. An important issue to be tackled is the creation order of these reports, since there must be relations between them. For the order, the following procedure, also approved by an independent assessor, can be applied. After the deliverables are produced, the products of the phase and the process itself shall be verified against EN 50126. Then, the validator can create his/her report considering the deliverables and verification report. Sometimes, the validator can prefer to compile some phases as shown in Figure 8. Following this, the safety management report can be developed using check-list so that every item is closed, or if necessary, transferred to the next phase in an appropriate manner. After this, quality assurance team can verify phase related quality requirements recording the results in their reports. Having applied the illustrated order in Figure 8 during the project, the safety management report to be incorporated in the safety case can only refer to the individual phase relevant safety management reports by summarizing their results.

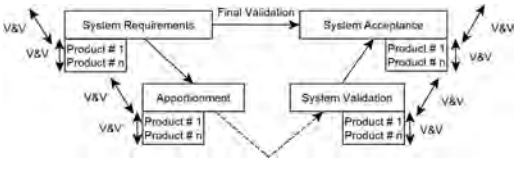

Figure 7. Proposed V&V representation.

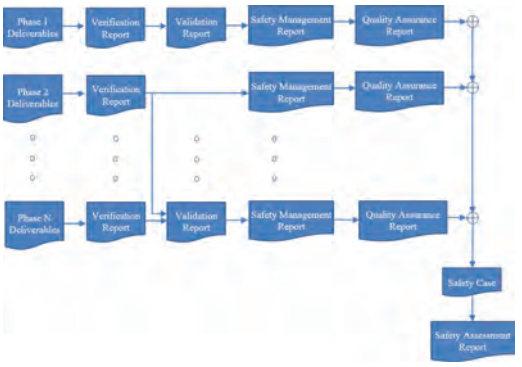

Figure 8. Relations between Verification, Validation, Safety Management, Quality Assurance and Assessment Reports.

4 CONCLUSION

Safety critical systems being developed especially for SIL 4 GAPs require much effort and organizational independences with intensive verification and validation activities. The safety standards are very detailed and evolving continuously. Although the independence and V&V concepts are very crucial and have direct effects on both technical and fiscal success of the project, it has been revealed that these points are neither clearly comprehensible in these reference standards nor discussed in the past studies, but faced once a project is developed. It is therefore very important to place the independency requirements for the roles and set V&V activities at the outset of the project correctly, completely and consistently. Defining a new role as safety responsible is very beneficial as this role fulfills the activities with special qualification and essential independency. The verification covers both process and product. For different workpackage, different verifiers can be assigned in an effective way. Validation is not just performed at the end against system requirements, but mostly at each phase during all system, HW, SW life cycles, hence VAL should play an active role during the whole life cycle with agreements or disagreements affecting the project progress widely. An appropriate relation between verification, validation, qual-

ity and safety management can be constructed in a consecutive way as proposed in this study such that the safety management report is produced step by step resulting in a ready safety management report at the end of the project that could be simply integrated into the safety case to be assessed by the independent assessor.

Manifestation of ontologies in graph databases for big data risk analysis

M. Figueres-Esteban, P. Hughes, R.A.H. El Rashidy & C. van Gulijk
Institute of Railway Research, University of Huddersfield, Huddersfield, UK

ABSTRACT: Big Data Risk Analysis (BDRA) intends to combine the huge volume of information that railway systems produce from a variety of data sources for safety and risk management. One of the most challenging issues is how safety scientists can use big data techniques. This is especially important in the light of data coming from different systems that hold information about critical events, hazards or controls. Yet, the integration of complex safety-related data is not just another IT problem. Fundamentally, it requires the expertise of safety experts in order to make sense of the data. A solution lies in the use of graph databases and ontologies to access this data for safety purposes. This type of database allows for the handling of huge amounts of data whilst it is still accessible to safety experts that are not gifted programmers. This approach opens up big data for safety management and enables a plethora of possibilities for future safety research.

1 INTRODUCTION

A BDRA safety system is defined as an enterprise safety management system that performs the following:

- Extracts information from mixed data sources.
- Processes it quickly to infer and present relevant safety management information.
- Combines applications to collectively provide sensible interpretation.
- Uses online interfaces to connect the right people at the right time.

In order to:

- Provide decision support for safety and risk management.

This definition guides the development of BDRA systems that are of use to companies that work on the GB railways. BDRA aims to use big data analytics techniques for safety (Van Gulijk et al. 2018; Van Gulijk et al. 2017).

One of the key challenges of BDRA is to store and process that massive amount of data and manage the heterogeneous knowledge from different information systems to obtain safety insight. A solution lies in the use of graph databases that are controlled by ontologies to represent a common framework of understanding and integrate data. (Figueres-Esteban et al. 2016; Van Gulijk et al. 2016). The method explained in this paper opens up big data for safety scientists. The method is straightforward but powerful and does not rely on gifted programmers. In theory, the database is infinitely scalable so it is hard to predict the limitations of the approach.

2 DATABASES AND BIG DATA

In the last decades, relational databases (aka SQL databases) have dominate the market of databases until coming up a standard way. They are structured in tables for access and have been very efficient when it comes to rapid and efficient access to data. Nevertheless, in big data environments where huge amounts of information have to be stored and integrated from new unknown sources, relational databases become unwieldy (Sadalage & Fowler 2013).

A solution to bypass this problem is to omit the relational table by simply storing data in a system that, for lack of a better example, finds its analogy in an infinitely scalable library card catalogue (Van Gulijk et al. 2018). Databases that work in that way are called NoSQL databases.

2.1 *Graph databases*

In a relatively novel development these NoSQL databases have been enriched with a sensible visual interface based on graphs. They are simply called graph databases. A graph database is database management system that store data in the form of a property graph (Robinson et al. 2013). Safety scientists will recognise a property graph as a collection of nodes and links; as we often see them in our work.

The organization of the data in graphs is extremely useful in terms of understanding (Figueres-Esteban, Van Gulijk, et al. 2015; Figueres-Esteban, Hughes, et al. 2015). Graph databases allow to represent different types of data models into a common space in order to integrate diverse type of data (EL Rashidy et al. 2017). This issue is a key aspect in order to implement ontologies that represent the knowledge of technical domains such as railways, risk and safety.

3 KNOWLEDGE REPRESENTATION IN RAILWAYS

Railways are a complex systems that represent a rich tapestry of different types of organisational knowledge, created for different purposes and people with different expertise, skills and competences in many different contexts. Bringing together all the data that railways produce means to make sense of heterogeneous knowledge from different information systems.

The most common technique used by computer scientists to represent a common framework of understanding and manage the knowledge is an ontology. A formal, and broadly accepted, definition of an ontology is provided by (Gruber 1995): "*An ontology is an explicit specification of a conceptualization*."

There are different types of ontologies such domain and application ontologies depending on their specificity of the knowledge (Guarino 1997).

In the railway domain, the FP6 European Integrail project (http://www.integrail.eu/) and the RailML community (http://www.railml.org) proved the utility of ontologies in the communication and integration of data through railway information systems (Van Gulijk & Figueres-Esteban 2016).

4 ONTOLOGIES AND GRAPH DATABASES FOR BDRA

Different ontology languages and frameworks have been developed to support the implementation of an ontology (Corcho et al. 2003). The challenge is that a single ontology should be understood by people and machines.

One of the most used frameworks is showed in the left side of Figure 1. Different data structures represented in formats such as XML, JSON and CSV can be integrated through ontologies implemented in RDF/OWL languages. These languages support the application of Artificial Intelligence (AI) in order to reason with the represented knowledge. The approach that this work is taking

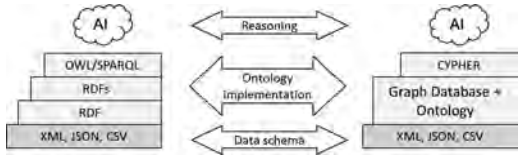

Figure 1. Transformation of the stack of ontology languages for BDRA.

bypasses complicated ontology languages and replaces it with a relatively straightforward visual interface in a graph database. This is where we omit the need for gifted programmers.

This paper demonstrates how to use the framework showed in the right side of Figure 1.

5 METHODOLOGY

The paper describes the implementation of a railway domain ontology by safety experts in order to connect three different data sources to an event related to safety management.

The current BDRA project focuses on understanding SPAD risks (passing red signals) but for the benefit of explaining the method we focus on part of that risk: the "signal obscured" hazard. This means that safety records related to obscured signals and instances of a signal database have to be found and linked to enrich the analysis of these type of events. The methodology has three basic steps:

a. Selection of data sources and storing data in a graph database.
b. Building the signal domain ontology.
c. Implementing the signal ontology for the integration of data.

5.1 *Data sources*

This trial uses four *.csv files extracted from three information systems: three files of text records from the SMIS and IFCS systems of Railway Safety and Standard Board (RSSB) containing around 100,000 incidents and a table of signals from the Ellipse Asset Management tool of Network Rail (NR) containing 40,000 descriptions of signals.

SMIS is a database for recording safety-related events that occur on the rail network in Britain (RSSB 2017). Railway stakeholders such as NR or train/freight operators enter about 75,000 events per year such as derailments and SPADs. In this exercise, we are just using records related to obscured signals. IFCS is a database that focuses on human performance and underlying causes of

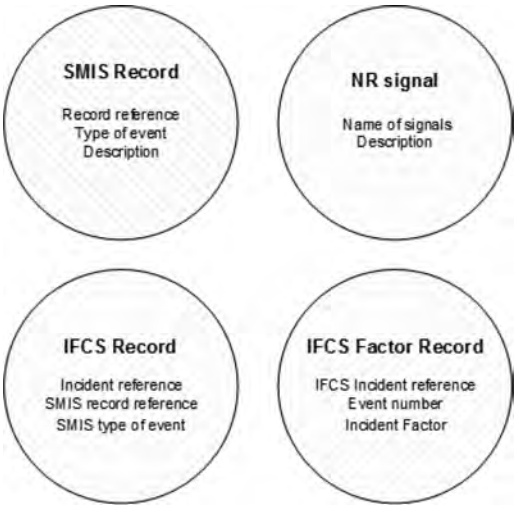

Figure 2. Description of the data sources used to support data integration.

rail incidents. These underlying caused are classified using 10 Incident Factors that are breakdown by different levels of sub-categories (Gibson et al. 2015). The table of signals is a sample of descriptions of signals that is part of the Ellipse Asset Management tool of NR. Figure 2 shows the properties that were used to integrate the data.

5.2 *Signal domain ontology*

The purpose of the signal domain ontology is to align data structures of the information systems with an accepted reference framework by railways. For this exercise, the reference framework for the signal domain has been the railway signal standard in UK (RSSB 2015).

The sources showed below have been used to build the ontology:

- The Signals, handsignals, indicators and signs. Handbook RS/521 Issue 3 (December 2015).
- The data model of the SMIS+ program.
- The schema of the table of signals.

The standard RS/521 provides a classification and description of all railway signals in UK. The data model of the SMIS+ includes a taxonomy of railway signals that is aligned with other reporting systems. The data structure of the table of signals does not provide a signal taxonomy but it can be extracted from the field "Item Name". An example of value of this field is "EZ220 – SIG HEAD – COLOUR LIGHT – LED". Note that programmers don't have the expertise for this exercise, even if they are gifted. The interpretation and consideration of safety-aspects lies within the remit of safety experts.

5.3 *Implementation of the ontology and data integration*

The data from the information systems were stored in a Neo4 j graph database. Each row of the data files represents a node in the graph database and each node has as many properties as columns the data file has. In this first step, the database has no structure and it just stores data under a label (data nodes).

In the same database, the signal domain ontology was implemented in a graph data model (ontology nodes). Using the properties of the ontology nodes and analysing the property of the data nodes that stores the text of the record, the links between each node were created.

The signal obscure event (event node) was connected to data nodes of signals and these ones were connected to the data nodes of SMIS/IFCS records.

6 RESULTS

Table 1 shows an excerpt of the extracted ontology from the table of signals. This ontology was mapped with the explicit ontologies of the standard RS/521 and the SMIS data model. Table 2 shows an excerpt of the mapping table. Figure 3 shows a piece of the final signal ontology.

Figure 4 shows an excerpt of the graph database that contains part of the implementation of the signal ontology and instances of signal and SMIS/IFCS records. The ontology is connected to the

Table 1. Excerpt of the signal taxonomy from the table of signals.

Item name			
First token	Second token	Third token	Fourth token
EZ220	SIG HEAD	COLOUR	LED
EZ101		LIGHT	1 ASPECT
EZ102			2 ASPECT
EZ103			3 ASPECT
EZ104			4 ASPECT

Table 2. Excerpt of the mapping between the signal taxonomies of the RS/521 standard, SMIS and the table of signals.

RS/521	SMIS	Table of signals
SPAD indicator	SPAD indicator	ES100
Limit of shunt signal	Limit of shunt	EZ160
Point indicator	Points indicator	BR100, EZ170

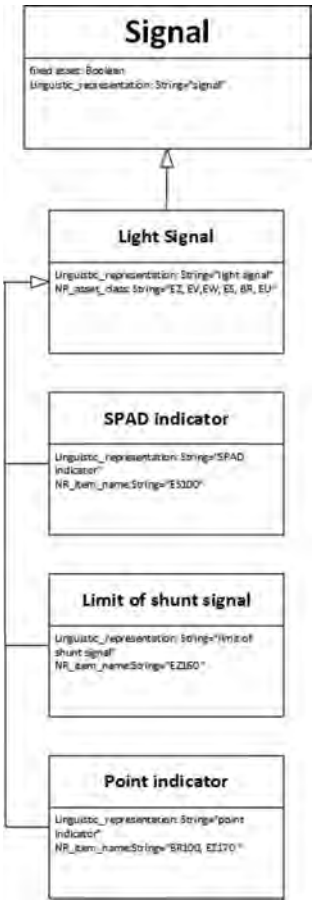

Figure 3. Excerpt of the UML diagram that represents the signal ontology.

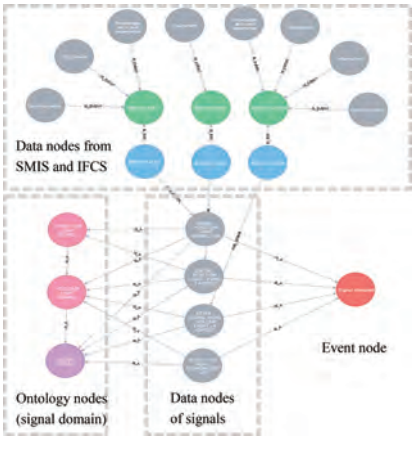

Figure 4. Excerpt of the graph database that integrates different types of instances of data with the event "Signal obscured" by means of the signal domain ontology.

signal nodes that are connected to the SMIS/IFCS records and the signal obscure event.

7 DISCUSSION

This paper shows that NoSQL graph databases guided by ontologies enable safety scientists to work with big data techniques without the intervention of IT experts. Some programming is required but most of it is not much more complicated than excel macros or Matlab. The expertise of safety experts, however, is fundamentally required to build safety and railway domain ontologies to support the integration of data for further safety analysis.

This work demonstrates that graph databases can store complex data structures as single nodes, which helps safety scientists navigate through their data. Figure 4 displays different nodes that represent data from signals and SMIS/IFCS records regardless of the internal structure of the data source.

Domain ontologies can be straightforwardly implemented in the database as a data model to integrate data. These ontologies support the analysis of data nodes that use different semantics about a railway domain. This semantic alignment allows to interconnect data nodes each other or connect them to specific events related to safety management. However, ontologies are far from being populated automatically and require safety expertise and human effort to build them (Figueres-Esteban & Van Gulijk 2016). Table 1 and Table 2 shows the results of this effort in order to align three different data sources with a railway standard in a single ontology that represent the signal domain (Figure 3).

The alignment of different types of data with a domain ontology and events related to safety has important benefits. Firstly, the ontology provides framework in order to query signals. In this case, the standard RS/521 was selected as reference framework. Secondly, the integration of data allows to connect all the information available in the data sources. For example, linking data nodes of signals to the signal obscure event and SMIS/IFCS records allows to filter records by specific types of signals in order to improve the safety understanding related to obscured signals.

8 CONCLUSIONS

This paper demonstrates how safety scientists can enter the realm of big data. It demonstrates that the challenge of storing large amounts of data from diverse railway data sources to extract safety learning requires safety experts that can work with graph databases.

Graph databases allow to store data regardless of the structure of the data. But more fundamentally, it allows the co-location of domain ontologies to integrate different data sources and extract safety learning.

In theory, the database is infinitely scalable so it is hard to predict the limitations of the approach.
