The term "rogue", "freak", "abnormal" or "giant" wave commonly refers to waves that are very steep and large in absolute measures and, at the same time, significantly larger than the surrounding waves in the sea state, and are thus unexpected (Bitner-Gregersen, 2017). They are statistically unlikely to occur in a given sea state (either low, intermediate or high), based on averaged properties of that sea state (Bitner-Gregersen & Gramstad, 2015).

This physical phenomenon is not fully understood, but increasing reliable measurements and records, as well as the significant increase in computational power and numerical modelling capacity, allow to explore these extreme events with greater accuracy.

There are several motivations to reduce the risk of wave-related incidents. First, because they clearly represent a current threat to marine installations. Second, because more severe sea state conditions may be expected in some ocean regions associated with climate change and global warming (IPCC Panel, 2014). Third, because understanding and forecasting waves under various conditions is essential with respect to design and operation of offshore structures.

Based on these initial premises, addressing these extreme events as potential risk and including them in the customary Risk Assessment process of a company that operates physical assets in an offshore environment is entirely justified, despite its complexity and the high number of uncertainties involved.

In the present work a causality-based probabilistic graphical modelling methodology is proposed to assess the risk associated with rogue waves in offshore wind farm projects at the final design stage. The methodology includes the impact of future climate change and provides the structure in which to effectively communicate: a) parameter uncertainty; b) correlation across multiple risk factors (i.e. "Systems of Systems" (SoS) complexity mapping/analyses); c) definition of assessment subjectivity; d) and potential impacts of low probability catastrophic events (i.e. extreme events). The methodology provides a holistic framework that can be integrated into existing decision-making processes currently defined within a large capital project execution process.

In brief, the method studies the probability of a rogue wave impacting an offshore structure situated in a predefined location of the Northern North Sea, between 20 and 60 m depth, and includes 3 main stages: risk understanding, qualitative bow-tie creation; and transformation to a Belief Bayesian Network.

2 RISK UNDERSTANDING

Risk assessment is to a large extent about gaining 'risk understanding' in the sense of knowledge—justified beliefs, by producing a risk description (C_0,Q,K), where C_0 are the specified consequences of the activity studied, Q a measure of uncertainty, and K is the background knowledge on which C_0 and Q are based (Amundrud & Aven, 2015). According to these authors, these justified beliefs are based on data, information (relevant processed data) and models. The uncertainty judgments about C_0 using Q can also be seen as justified beliefs.

K is a limiting aspect in the proposed methodology, due to the lack of understanding of the physical process of creation of rogue waves. For example, describing the wave phenomenon is the result of a set of uncertainties. The random model for ocean waves is constructed by representing the sea surface as a sum of elementary waves with different wavelengths, frequencies, and directions of propagation (Bitner-Gregersen & Gramstad, 2015). However, in reality ocean waves are not described exactly by a linear formulation or second-order theories, and therefore require a set of increasingly accurate formulations. The more accurate, the more mathematically complex and more difficult the model will be. As a result, the logical functions and equations included in the proposed graphical model are based on the linear theory, the most tractable approach for the graphical model under design.

Uncertainty related to environmental phenomena may be divided in aleatory uncertainty (natural randomness) and epistemic (knowledge) uncertainty; and the latest in: data uncertainty, statistical uncertainty, model uncertainty and climatic uncertainty (Bitner-Gregersen et al. 2013).

Assessing data uncertainty is out of the scope of this study, so available data are assumed to be appropriate. To minimize the statistical and climatic uncertainty, a long-term data source was selected. The European Centre for Medium-Range Weather Forecasts' ERA-Interim is a global atmospheric reanalysis from 1979, publicly accessible and continuously updated in real time (European Centre for Medium-Range Weather Forecast, 2017). After establishing a geographical location in the Northern Sea, 4 measurements per day were obtained between 1979 and 2017 (about 55.000 values per variable) for 30 different variables. Only 9 of them were considered relevant for the project: model depth (d), zero-crossing mean period (Tz), wave spectral directional width (σ_θ), significant wave height (Hs), mean wave direction (θ), mean direction of wind waves (θ_1), mean direction of swell (θ_2), and Benjamin-Feir index (BFI).

There are other relevant variables, such as the wave length (λ), that are not independent. In these cases, formulae given by the Recommended Practice DNVGL-RP-C205 have been used (DNV GL, 2017).

Finally, defining and managing the model is the core part of this work and a main responsibility of the risk analyst (designing, building, assigning probability, running simulations, reporting and maintaining). It reflects the limitations of the previous factors and adds new uncertainties, due to failed assumptions in physical process formulations, or choices of probability distribution types for representation of uncertainties. In this regard, the method tries to register and track all the detected uncertainties. To limit this effect, all the variables were fitted to a probability distribution using the software tool, ModelRisk (Vose Software, 2018) only when the best fit was not supported by the Bayesian Network software (OpenBUGS).

3 BOW-TIE CREATION

The bow-tie is a graphical approach frequently used to represent a Risk Event, its Causes (Drivers), Prevention Barriers (Controls), Mitigation Barriers, and its Consequences (Impacts) in a visual and logical manner. Centered on a critical (risk) event, it is composed of a simplified fault tree on the left-hand side and an equally simplified event tree on the right-hand side showing the possible consequences of the critical event based on the failure or success of safety functions (Khakzad et al. 2013). To understand the relations and dependences among factors involved in the creation and impacts of rogue waves and climate change on offshore wind structures, a qualitative bow-tie is proposed. The first step consists of formulating the critical event: impact of a breaking rogue wave on an offshore wind structure (named "IMPACT" in the graphical model). This step seems to be obvious, but in complex or emerging risks it is essential to organize and plan the following phases of the method.

In this case, due to the complexity of the analyzed physical phenomena, the bow-tie focuses on the left-side, or analysis of causes (drivers) and barriers (controls). The event tree of consequences is reduced to one: the failure of the structure (F).

After a deep review of the state-of-the-art related to rogue waves and climate change impacts on the study area, as well as the available data, the drivers and controls are analyzed individually and placed in the bow-tie, establishing the appropriate connections and causal relations. The graphic is continuously updated until it gets its final shape, shown in Figure 1.

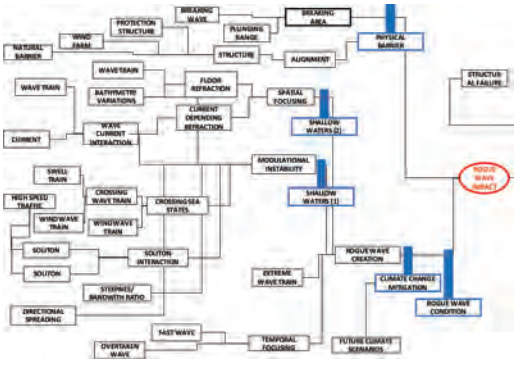

Figure 1. Final bow-tie.

Several different mechanisms may be responsible for generating rogue waves such as linear focusing of energy (spatial and dispersive: K_f, K_c and T_f), wave-current interactions (CI), crossing seas (wind sea and swell or two swell systems, CS), quasi-resonant nonlinear interactions (modulational instability, BFI), shallow water effects (SWC_i), solitons interactions (SO), directional spreading (DS), and wind forcing (W).

Atmospheric forcing has not been considered in the bow-tie as a cause of waves to simplify the visual understanding of the process. The relevant variables obtained from the dataset are included in the bow-tie as primary events. Other relevant variables, as slope (SL), angle between the wave crest and depth contours (α_0), angle between target and protection structure (β), Ursell number (U_R) or maximum height (H_m) are added as primary events, when statistical data are not available but are required for a consistent explanation of an intermediate event. Some of them are calculated in future steps or treated as assumptions. The bow-tie shows two main controls: protective structure (O), as a physical barrier to avoid the impact of a breaking rogue wave against the offshore wind structure (OWS); and climate change (C). C is placed as control, assuming its barrier effect is focused on limiting or preventing the CO_2 emissions caused by humans, where the key assumption is that the accumulation of CO_2 and other greenhouse gases are the primary drivers for climate change and that the human population is largely the driver for the significant increase in the atmospheric concentrations of those gases in the past 200 years. Other controls are related to shallow water restrictions or used for reversing interactions of separated subsystems (current, ship traffic, etc.) over the wave fields or between drivers of different nature, when needed. The other three are natural controls: shallow water conditions and rogue wave conditions.

4 BAYESIAN NETWORK

The bow-tie graphical model is used in this method as a primary tool to understand the risk and locate the critical event in its cause-effect framework. However, it presents a static picture of the problem. Besides, no causal relation can be established between primary events or other events of different branches of the fault or event tree. These problems are solved with its transformation to a Belief Bayesian Network (BBN).

A BBN is an explicit description of the direct dependencies between a set of variables, in the form of a directed graph and a set of nodes linked to a probability. This structure offers the following benefits (Fenton & Neil, 2013): modelling causal factors explicitly, reasoning from effect to cause and vice versa; updating the probability distributions for every unknown variable whenever an observation is entered into any node; reducing the burden of parameter acquisition; overturning previous beliefs in the light of new evidence (explaining away); making predictions with incomplete data; combining diverse types of evidence including both subjective beliefs and objective data; and arriving at decisions based on visible, auditable reasoning.

The conversion of a bow-tie into a BBN is summarized in Figures 2 and 3.

The BBN includes different interacting systems besides the waves system, and includes the current, seabed, wind, climate, ship traffic and artificial structure. Figure 4 shows this graphical model.

The fitted distributions are included as parent nodes, because are the basic parameters of the model. There are 13 "parent distributions", whereas only four of them are not obtained from available data. In these cases, a uniform distribution is assumed. One variable relies on the seabed conditions and would be subject to a better characterization with the consideration of a bathymetry

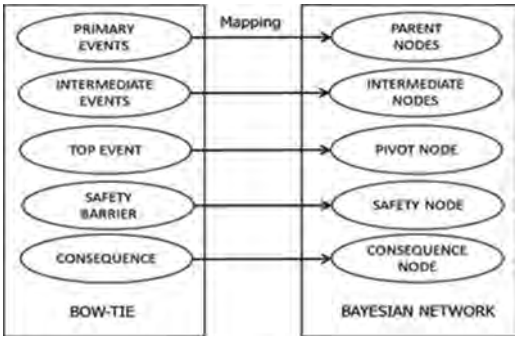

Figure 2. Mapping algorithm from bow-tie to Bayesian Network (Khakzad et al., 2013).

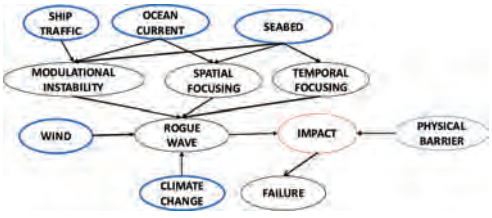

Figure 3. Bayesian Network related to bow-tie elements.

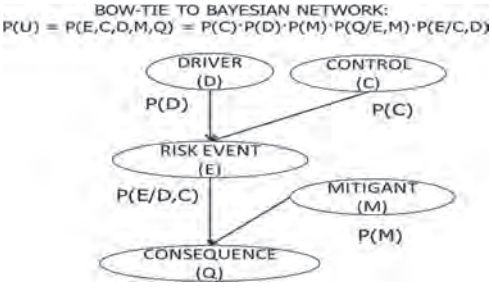

Figure 4. Overall Bayesian Network with interacting systems.

model: the angle between wave crests and depth contours (α_0). Another one (Froude Number Fd) depends on the ship traffic around the offshore wind turbine structure (OWS), but its assessment is out of the scope of this work.

Following the conclusions of the bow-tie analysis, the failure of the OWS occurs when a rogue wave impacts on it. The probability of this impact is "*the probability of a rogue wave breaking in front of the OWS within the plunging range without a protective structure in between*". When the wave breaks just at the location or behind, the plunge distance is not relevant for the targeted OWS. By contrast, when the wave breaks in front of the structure, this distance is relevant, because it defines the area where the wave is dangerous. However, given that the available data are restricted to the selected location, further spatial considerations (i.e. defining a breaking point or a plunge distance in front of the OWS) are out of the scope of this study.

Therefore, for this event to happen or not, it is necessary the presence of a rogue wave that breaks without an opposing protective structure in between.

In the graphical model, an extreme wave is considered a rogue wave R when the height doubles the significant height H_s ($R > 2H_s$) (Bitner-Gregersen & Gramstad, 2015). The wave height is limited by breaking. The maximum wave height H_b condition is based on the Recommended Practice DNVGL-RP-C205 (DNV GL, 2017):

$$H_b = \lambda 0.142 tanh \frac{2\pi d}{\lambda} \quad (1)$$

where λ is the wave length corresponding to water depth d.

The accompanying structure may be natural or artificial. If the structure is artificial, it can be either of floating type with a mooring to the seafloor or a solid anchored structure that is submerged or slightly above the surface. In an offshore wind farm, another OWS may protect the selected structure from the impact of a rogue wave. The condition to be protective is being total or partially aligned with the OWS in the mean wave direction. This condition happens, as shown in Figure 5, when the angle between the wave and the segment that links both structures (β) is between θ+90º and θ+270º (no other physical phenomena, i.e. refraction or diffraction, are included).

The critical assumption of the model is that the extreme wave heights (H_m) calculated from the available data are generated exclusively by the wave focusing under the action of wind. The final wave height (W) is then the result of an increase over the value of H_m due to the causes explained through the bow-tie, as expressed in Eq. (2):

$$W = H_m \cdot (1+C_{5\,m} \cdot SWC_1 \cdot M + C_{6l} \cdot C + step (0.6–U_R) \cdot C_{7t} \cdot TF + C_{3f} \cdot SWC_2 \cdot step (K_f–1) \cdot (K_f –1) + C_{1c} \cdot step (CI) \cdot K_c) \quad (2)$$

where

H_m = extreme value of height;

K_c = height increase proportion due to current refraction;

K_f = height increase proportion due to floor refraction;

M = height increase proportion due to modularity;

C = height increase proportion due to the climate change; and

TF = height increase proportion due to temporal focusing.

It may be argued that the measured heights are already the result of these causes or, at least, the

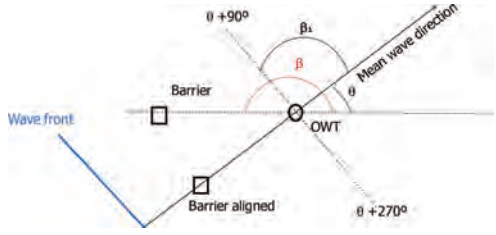

Figure 5. Alignment of the protective structure.

linear causes, i.e. spatial and temporal focusing. To deal with such complications, each driver has one control node (constant), so that the unexpected cause or interacting system can be eliminated from the model: C_{1c} for the current; C_{2s} for the ship traffic; C_{3f} for the seabed refraction; C_{4o} for the protective structure; C_{5m} for the modularity instability; and C_{6t} for the temporal focusing.

There are also natural controls (step(0.6-U_R), step(CI), SWC1, SWC2) that cancel the drivers due to natural conditions. These natural conditions can be modelled.

Only height increases are considered, so the condition to take refraction into account is $K_f > 1$: step ($K_f - 1$).

H_m is calculated following the extreme value theory and fitting the results to a Gumbel distribution.

K_f is calculated based on the Recommended Practice DNVGL-RP-C205 (DNV GL, 2017):

$$K_f = K_s \cdot K_r \tag{3}$$

$$K_r = \left[\frac{1 - sin^2\alpha_0 tanh^2(kd)}{\cos^2\alpha_0} \right]^{-1/4} \tag{4}$$

$$K_s = \sqrt{\frac{c_{g,0}}{c_g}} \tag{5}$$

where

K_s = shoaling coefficient;

K_r = refraction coefficient;

α_0 = the angle between the wave crest and the depth contours at the location;

k = wave number;

d = depth; and

C_g = group velocity.

K_c is a good example of the difficulties found to model some of the drivers involved in the process. The first approach to define the variable K_c was based on the analysis of this phenomenon presented by Sorensen (Sorensen, 2006). Figure 6 shows how a wave propagating with speed C from still water to water having a current velocity U, changes its direction.

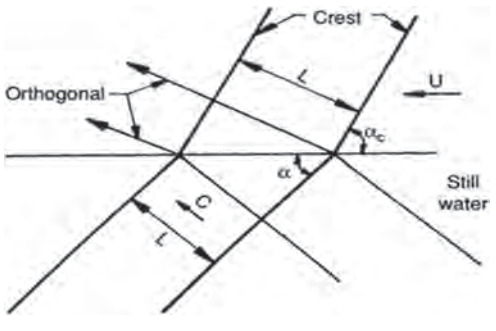

Figure 6. Definition sketch for wave refraction by a current (Sorensen, 2006).

In mathematical terms, these equations are obtained:

$$K_c = \frac{H_c}{H} = \left(\frac{L_c}{L}\right)^2 \frac{cos\alpha}{cos\alpha_c} \left[\frac{\left(1 - \frac{U}{C} sin\alpha\right)^6}{1 + \frac{U}{C} sin\alpha} \right] \tag{6}$$

$$L_c = L \frac{sin\alpha_c}{sin\alpha} \tag{7}$$

$$sin\alpha_c = \frac{sin\alpha}{\left(1 - \frac{U}{C} sin\alpha\right)^2} \tag{8}$$

where

H_c = Height after refraction;

H = Height before refraction;

L_c = Wave length after refraction;

L = wave length before refraction;

U = current velocity;

C = wave velocity;

α = angle between the current and the crest front;

α_c = angle between the current and the crest front after refraction.

Considering $K_c = H_c/H$, an expression of K_c as function of α and α_c can be obtained, but introducing it in the model was impossible and always led to a systematic software error. Other equations were checked, such as those presented by Iwagaki et al. (1977). A different approach was finally selected based on the work by Mathiesen (1987), which is derived from the computer model to measure the refraction of ocean directional wave spectra and applied it to a circular current whirl typical in the Norwegian coastal current. This model found that the relative changes in wave heights were within ±20% as compared with the wave height of the incoming waves.

M is calculated as the average probability of the nonlinear modularity drivers, which are: solitons interactions (SO), variable bathymetry (SL), crossing seas (CS), Benjamin-Feir interaction (BFI), directional spreading (DS) and wave-current interaction (CI). M is limited to a maximum value (M_{max}) of 0.20. This value is defined considering several systematic studies which shows that effects of modulational instability can enhance the crest height for long-crested waves by up to 20%, at lower probability levels, while the troughs become about 20% deeper than second–order troughs (Kharif et al. 2009).

C is calculated based on the CO_2 emissions originating from the socio-economic scenarios (A1B, A2, B1 and B2) proposed by The Intergovernmental

Panel on Climate Change IPCC and the values of emissions currently estimated for the North Sea.

T_f is calculated as a function of the Ursell number U_R, with a maximum value to be established at the moment:

$$U_R = \frac{H\lambda^2}{d^3} \tag{9}$$

Kharif et al. (2009) stated that this number characterizes the ratio of nonlinearity to dispersion. When the Ursell parameter is small, the nonlinearity can be neglected, and the wave is a linear dispersive wave. In real situations of wind waves, the values of U_R parameters are not too large, and the dispersive trains contribute significantly to the statistical wave characteristics. Based on these authors, a value of $U_R < 0.6$ is selected to consider the impact of the temporal focusing as relevant.

There are two restrictions related to the shallow waters which must be considered, and are given the variable names, SWC_1 and SWC_2. Water is considered shallow when the surface waves are noticeably affected by bottom topography (Bitner-Gregersen & Gramstad, 2015). This condition occurs when the depth, d, becomes less than half the wavelength, λ.

Modulational instability becomes weaker with decreasing depth and it is suspected to play a less important role in shallow water (Bitner-Gregersen & Gramstad, 2015). Benney & Roskes (1969) estimated that modulational instability disappears when $2\pi d/l < 1.363$ for unidirectional waves. Under this threshold, the model cancels the driver M. This is the restriction with the variable name, SWC_1

Similarly, the seabed related refraction (K_f) is canceled when the shallow water condition is not accomplished (restriction SWC_2).

4.1 *Modulational instability drivers*

Seven drivers are involved in the creation of nonlinear instability. Their inclusion, conditions and limits are discussed in the following sections.

4.1.1 *Solitons interaction (SO)*

Solitons interaction has been suggested as a source of nonlinearity in shallow water (Kharif et al., 2009). Peterson et al. (2003) linked this mechanism to relatively shallow coastal areas with high ship traffic density, particularly high-speed ships when they sail with critical or supercritical speeds. These speed levels rely on a value of the Froude number, F_d, which is the ratio of the ship speed and the maximum phase speed of gravity waves, equal or higher than 1. Therefore, the model constrains the impact of this driver to this threshold. It is out of scope of this study to analyze the traffic in the vicinity of the location, so a uniform distribution has been used for the variable F_d.

4.1.2 *Variable bathymetry (SL)*

Recent works have shown that the probability of rogue waves may increase on the shallow side of an underwater slope. Sergeeva et al. (2011) linked the probability of rogue waves to the wave steepness, which is characterized in terms of the Ursell parameter. Both variables increase when the depth decreases (water shallowing), and the wave state deviates from the Gaussian. Based on previous research, the condition for nonlinearity due to the interactions with a variable bottom has been fixed when $U_R > 0.6$ (Kharif et al., 2009).

4.1.3 *Crossing seas (CS)*

When two wave systems (wind sea and swell or two swell systems) are separated in direction or frequency and cross, the modularity increases depending on the angle between them. Both wave trains are assumed to be narrow banded and weakly nonlinear (Kharif et al., 2009).

Onorato et al. (2010) suggested that an increased probability of rogue waves was associated with angles between 40° and 60°. This is the condition used in the graphical model. ERA INTERIM database offers separated information about the mean wind waves directions (θ_1) and mean swell direction (θ_2), so the possibility of crossing wind seas is not considered.

4.1.4 *Benjamin-Feir interaction (BFI)*

A key parameter controlling the importance of the nonlinear wave-wave interactions is the Benjamin–Feir Index (BFI) which is the ratio of the wave steepness to the spectral bandwidth (Kharif et al., 2009).

$$BFI = \frac{\varepsilon\sqrt{2}}{\delta_\theta} \tag{10}$$

where:

ε = wave steepness; and

δ_θ = spectral directional width.

Instability condition is given by Eq. (11), and is used as a condition in the graphical model (Bitner-Gregersen, 2017):

$$\sqrt{2}BFI > 1 \tag{11}$$

4.1.5 *Directional spreading (DS)*

Onorato et al. (2002) showed that the probability of occurrence of rogue waves depends not only on BFI, but also on the directional spreading of the waves. Waseda et al. (2011) found evidence that occurrence of rogue waves was associated with sea states with directional spreading of less than about 30°, sug-

gesting that sea states with increased occurrence of rogue waves may occur in realistic ocean conditions. This has been the condition used in the model.

4.1.6 *Nonlinear wave-Current Interaction (CI)*

There are theoretical, experimental, and numerical evidences to support that in some situations the combined effect of wave nonlinearity and currents can lead to an increase in rogue wave occurrence (Nakicenovic et al., 2000). Janssen & Herbers (2009) first discovered that initially stable narrow banded wave fields could become unstable when the nonlinearity was increased due to linear focusing. Toffoli et al. (2015) experimentally showed that realistic random waves propagating in opposing currents could destabilize, with a resulting increase in the occurrence of rogue waves, even for waves with directional spread that normally obey near-Gaussian properties. The probability of a current opposing to a wave field depends then on the angle between wave and current. The opposing condition is addressed by the model as the probability of the mean current direction (θc) between the values of θ + 90º and θ + 270º, with a maximum when θc is equal to θ + 180º, as shown in the Figure 7.

4.2 *Addressing climate change*

For the estimation of the climate change impact on the frequency of occurrence of a breaking rogue wave within the location proposed for an offshore wind farm, several assumptions have been made. It is accepted that there is a stochastic dependence between levels of CO_2 in the atmosphere and the ocean wave climate. On the other hand, only CO_2 is considered as a factor of climate change, although it is just one of the components of the greenhouse gas group (GHG).

The projections of future climate change scenarios are based on the four marker scenarios (A1B, A2, B1 and B2) proposed by The Intergovernmental Panel on Climate Change IPCC, over the twenty-first century (Quante & Colijn, 2016). Each emission scenario reflects different assumptions on future socioeconomic development. Scenario A2 is the worst, followed by A1, B2 and B1.

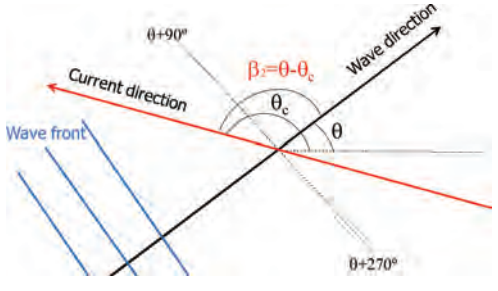

Figure 7. Wave-current interaction.

Regarding the study area, Grabemann et al (2015) analyzed a set of ten wave climate to estimate the possible impact of anthropogenic climate change on mean and extreme wave conditions in the North Sea. The projections were based on different IPCC emission scenarios, included different global and regional models starting from different initial conditions.

They found a solid pattern for the increase in median and severe significant wave height in the eastern North Sea (parts of the southeastern North Sea and large parts of the Dutch, German, and Danish coasts up to the Skagerrak) towards the end of the twenty-first century, while a decreasing trend in the western North Sea was detected. However, the magnitude of this increase was much more uncertain and oscillates between about −10 and 15% relative to the reference Hs. These numbers are consistent with other relevant studies in the area, which establish the increase between 6–8%, or up to 10% (Kharif et al., 2009).

Therefore, in the model the increase on the wave height has been defined as:

$$C = c_0 \cdot \sum_j^{10} x_{ij} \cdot s_i \tag{12}$$

where c_0 = maximum emission factor in decimal fraction; x_{ij} = reduction factor for the emission scenario i during the decade j in decimal fraction; and s_j = emission scenario.

Based on the abovementioned data, a value of 0.10 has been assigned to c_o. It corresponds to the value for the worst scenario (A2). The values of s_{ij} have been calculated based on the projections of the IPCC simulated with model AIM in the OCDE region, as stated in Table 1.

Table 1. Emission Reduction factors based on IPCC scenarios (x_{ij}).

Decade	Scenario s_i			
	A2	A1	B2	B1
1990	1	1	1	1
2000	1	1	1	1
2010	1	0.97	0.93	0.89
2020	1	0.91	0.86	0.81
2030	1	0.83	0.78	0.71
2040	1	0.77	0.73	0.64
2050	1	0.72	0.68	0.58
2060	1	0.64	0.58	0.48
2070	1	0.57	0.49	0.4
2080	1	0.49	0.41	0.31
2090	1	0.4	0.33	0.23
2100	1	0.32	0.26	0.16

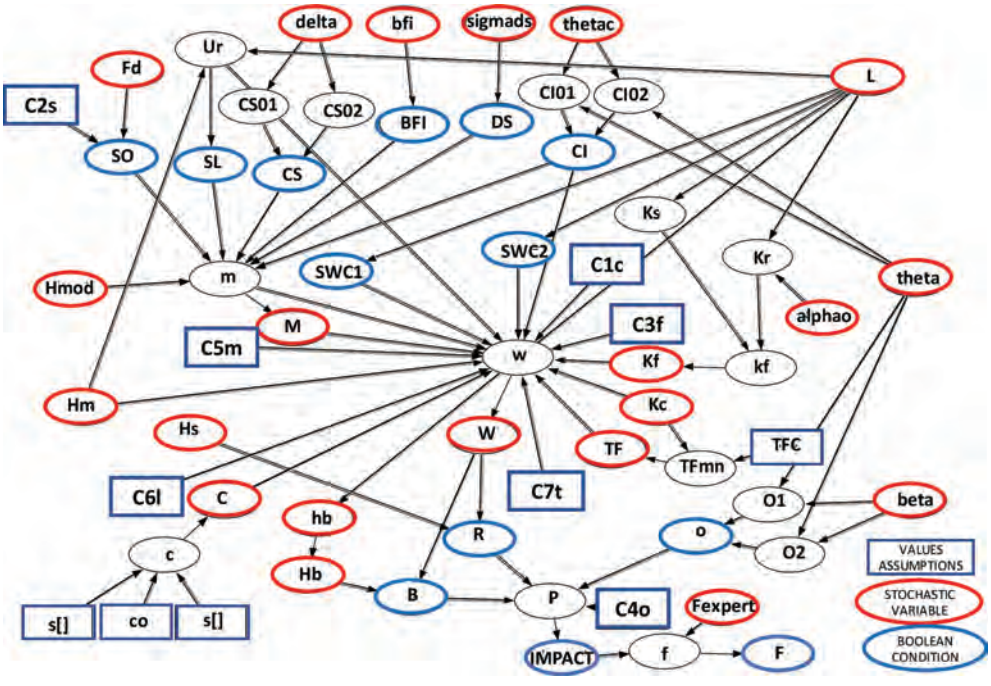

Figure 8. Final version of the Bayesian Network.

The final structure of the proposed Bayesian Network is presented in Figure 8.

5 DISCUSSION AND CONCLUSIONS

In the current study, a method for assessing a complex risk associated to physical phenomena not fully understood has been presented. The high level of complexity results in a high number of uncertainties which necessarily must be faced by the risk analyst. The focus of this study has been on understanding the physics behind the rogue wave phenomenon and determining the conditions under which such waves can be expected to occur more frequently when considering specific temporal and spatial ranges. Without the right outcome from this stage, the aim at creating a Bayesian Network would have been impossible. The role of the analyst in a decision-making process is to create a model as efficient as possible. This requirement includes its running speed, computational calculation and memory requirements, maintenance effort, file size, the least amount of assumptions, and finally, the ability to communicate the risk and the utility for the decision makers.

Due to the complexity of the risk analyzed, the number of assumptions in the model is remarkable, but a considerable effort has been made to manage those assumptions via: tracking for awareness and future improvement; and defining the model with multiple options for isolating and simulating only a partial number of individual drivers.

Currently, the BNN is being tested under different scenarios and limitations. Further conclusions will arise with the coming analysis of the results. In the worst scenario, the method will serve as a learning tool to understand the risk and its consequences in a deeper way. It will also be used to perform sensitivity analysis of the different drivers involved in the critical event. The optimal implementation would be reached when the model is used as a part of the strategic decision-making process. However, several limitations have been already detected. The output interface of the BBN software (OpenBUGS) complicates the presentation of results. There are other products in the market that seem to be more prepared for sharing results with the management in a visual way. On the other hand, spatial considerations cannot be addressed by the graphical model, i.e., the analysis of the plunging distance and the location of a potential breaking point of the wave in front of the structure.

ABSTRACT: Predicting the occurrence of failures in power grids through specific outage risk predictors is a primary concern for utilities nowadays. Wooden poles represent core items to focus on in this process. Millions of them are used worldwide and they are all subject to the risk of crack formation. Analyzing the evolution of pole cracks is particularly relevant in reliability analyses of power grids for two main reasons. First: the cracks might highlight previously unconsidered or changing factors, such as unusual local weather conditions (e.g. overload of ice and/or wind). Second: as cracks provide an access for external threats (e.g. humidity, fungi, insects) to potentially non-treated internal parts of the poles, they might in turn accelerate the occurrence of further failures. Evaluating the role of crack formation is thus essential for estimating the risk of outages in power grids. As climatic variations are known to be among the most influencing factors in the initiation and propagation of cracks in wooden poles, we address this topic by suggesting a method combining open-access weather-data sources with information provided by new technologies, such as drones. We first highlight the influence of climatic factors on the reliability of wooden poles by reviewing studies describing the physical properties of wood. We then focus our research on a Norwegian case study and show how we can combine up to 60 years of meteorological information with the information provided by 17,352 geo-localized aerial pictures of cracked and non-cracked wooden utility poles. We finally discuss the way an indicator constructed on this combination can be used to predict the formation of cracks and optimize the allocation of decision-maker resources for inspection procedures.

1 INTRODUCTION

The modernization of the society has led to a global increase of power consumption over the last 50 years (Refsnæs, Rolfseng, Solvang, & Heggset, 2006; Shiu & Lam, 2004; Yoo & Kwak, 2010). As numerous businesses, public infrastructures and private households rely on the provision of power for their daily tasks, there is a need for companies in charge of the power supply to maximize their capacity and reliability in delivering power.

Predicting outage risks and avoiding downtime is crucial to ensure customer satisfaction. Moreover, anticipating unwanted events directly enables power utilities to significantly reduce losses and costs. Finally, it also enables them to optimize resource allocations for the inspection of their infrastructures after natural disasters (e.g. storms, flooding) or during scheduled maintenance procedures.

Ensuring this quality of service requires utilities to use reliable components, from the power source, through the transmission lines and to the consumption nodes. Wooden poles are widely used for the distribution part of the power grid (from regional substations to local substations and from local substations to end-users) (Eurelectric, 2010).

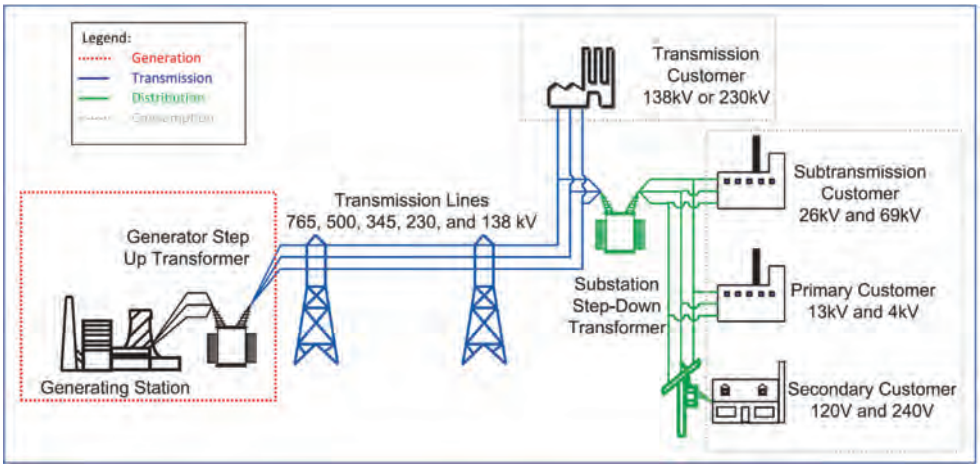

Figure 1. Outline of the transmission and distribution of power in a power grid, going from the production sites to the consumption nodes. Adapted from (U.S.-Canada Power System Outage Task Force, 2004).

Identifying the principal factors responsible for the apparition of cracks in wooden poles represents thus a main objective for predicting their failures. For this purpose, we suggest a method enabling to evaluate the effects of potential predictors. The contribution identifies the way forward for this research topic and presents preliminary findings, representing the basis for future research.

The rest of the paper is constructed as follows. Section 2 provides an overview on wooden poles characteristics and failures. Section 3 mentions various studies summarizing the main properties of wood on microscopic level. On this basis, it highlights the influence climatic variations can have on the physical structure of wooden poles. It furthermore shows how the variations can affect the reliability of the pole and thus of the transmission line. Section 4 describes the strategy applied to provide values of a crack-apparition likelihood using a Norwegian case study. It explains the choices made in the selection of the different datasets and the methods used to acquire them. Section 5 discusses the pros and the cons of the method used and shortly describes plans for future research. The last section finally concludes our work by summarizing and suggesting additional research possibilities.

2 WOODEN POLES CHARACTERISTICS AND FAILURES

Figure 1 shows schematically how power is delivered from a generating station, through transmission and distribution lines (respectively maintained by Transmission System Operators (TSO) and Distribution System Operators (DSO)), to different categories of end customers. Wooden utility poles used in the power grid exist in different shapes and configurations, depending on the physical requirements of the power lines, on the geographical conformation of their location, and on their position in the transmission or distribution line (see Figures 2–4 as illustrations).

Figure 2. First example of the shape of a wooden utility pole.

Despite the variety of the existing shapes and configurations, the number of elements basically composing an electrical pole is relatively limited. A wooden utility pole is generally composed of one or more wooden poles, one or more crossarms and multiple insulators responsible for the junction between the electrical cables and the pole. Figure 5 schematizes this assembling.

Using wooden utility poles has multiple advantages in comparison to concrete or steel utility poles (Bolin & Smith, 2011; SEMCO, 1992; Stewart, 1996)

Figure 3. Second example of the shape of a wooden utility pole.

Figure 4. Third example of the shape of a wooden utility pole.

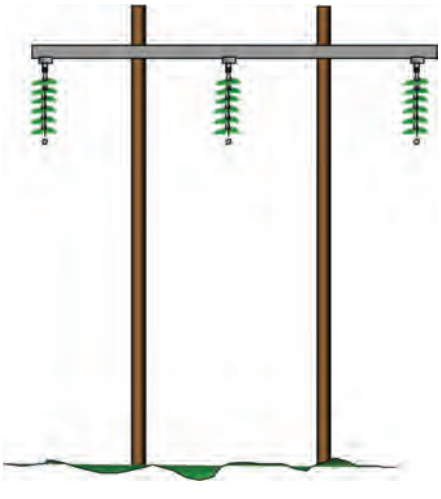

Figure 5. Basic components of a wooden utility pole: poles (brown), cross-arm (grey) and insulators (green) (Refsnæs, 2008).

– They are lighter and easier to transport on mountainous fields.
– They do not require earthing, which makes them interesting when lightning occur.
– They are easy to produce in wooded areas (e.g. Canada, Norway).
– They generally have a reduced environmental impact.
– They have interesting lifetimes, possibly going up to 75 years in favorable conditions.

Identifying the main threats for wooden utility poles enables to look for root causes of failures. This gives the possibility to estimate their effective remaining lifetime and optimize their replacement before any outage.

In their review on power line inspection procedures, Nguyen et al. (Nguyen, Jenssen, & Roverso, 2018) summarize some of the main common faults of power line components. They identify the apparition of cracks in the wooden poles as being one of the main failure to identify during visual inspection procedures. An additional review of the literature shows that there is need for inspection protocols enabling to recognize and assess cracks in timber structures in general (Dubois, Chazal, & Petit, 2002; Riahi, Moutou Pitti, Dubois, & Chateauneuf, 2016) and in wooden poles in particular (Morrell, 2012).

Identifying cracks is fundamental for two main reasons:

– First, as "stresses perpendicular to grain induce cracks which propagate longitudinally" (Coureau & Morel, 2005), we can consider multiple apparitions of significant cracks as being indicators of the presence of stress factors. This can for example suggest the existence of a localized area subject to harsher weather conditions (e.g. overload of ice and/or wind) (Wong & Miller, 2010) and prompt deepened analysis of the concerned region.
– Second, as cracks provide an access for external threats (e.g. fungi, insects, humidity) to potentially non-treated internal parts of the poles, their existence might accelerate the apparition of decay (Morrell, 2012; Refsnæs et al., 2006; SEMCO, 1992). This permanently alters the structural resistance of the pole and considerably increases its probability of failure.

3 WOOD PROPERTIES AND POTENTIAL INFLUENCE OF CLIMATIC VARIATIONS ON CRACK APPARITION

The theory of fracture mechanics has mainly been developed since the first half of the 20th century. Initiated by A.A. Griffith in 1920 (Griffith, 1921), it has then been popularized by G.R. Irwin in

1958 (Irwin, 1958) and is since being widely used to analyze the origins and consequences of crack apparition in physical objects. Focusing on the microscopic level, it enables to provide models describing the "mechanical behavior of cracked materials subjected to applied load" (Perez, 2017).

Multiple studies use this theory as a basis for the evaluation of crack growth in wooden structures (Barrett, Haigh, & Lovegrove, 1981; Coureau & Morel, 2005; Dubois et al., 2002; Riahi et al., 2016). A characterization of the structure is initially made on microscopic level to understand how wood behaves when it is subject to a modification of its external environment (load variation, climatic variation, etc.). Figure 6 shows the structure on microscopic level of a typical softwood. It highlights the anisotropic characteristic of wood and intuitively shows that cracks are more probable to occur parallel to the direction of growth of a three (longitudinal direction).

Wood being furthermore a viscoelastic material, its physical properties (e.g. modulus of elasticity, volume) are directly influenced by their environment. This is due to the hygroscopic behavior of wood (i.e. tendency to absorb humidity) and implies that physical properties of wood are highly sensitive to the meteorological properties of its surrounding (especially temperature and humidity) (Chaplain & Valentin, 2010; Hamdi, Moutou Pitti, & Saifouni, 2017; Lamy, 2016; Morrell, 2012; Refsnæs et al., 2006; Saifouni, 2014; Thybring, Lindegaard, & Morsing, 2009).

Because of the former functionalities of their cells during their living period and because of the variations in their environment during their growth, mechanical properties of timber-based structures can furthermore be locally modified. This includes structure modifications due to natural defects such as knots, rotten knots holes or cracks due to freezing lifeblood. Combined with the application of external loads (e.g. wind, ice on the wires in the case of wooden poles) and the modification of its internal structure due to temperature and humidity variations, there is a fertile ground for the apparition of cracks.

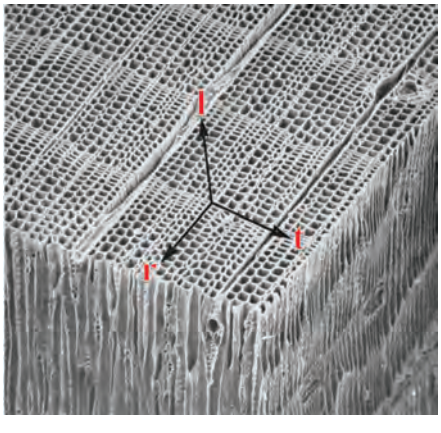

Figure 6. Typical softwood structure showing orientation of longitudinal (l), radial (r) and tangential (t) directions (Barrett et al., 1981).

4 DATA ACQUISITION AND PREDICTION METHODS

Utility companies in Norway use over 3.5 million wooden poles in their power grids to support over 25,400 km of electrical overhead lines (Eurelectric, 2010; Refsnæs et al., 2006). The Norwegian IT company eSmart Systems[1] is specialized in digital intelligence and uses artificial intelligence to support Statnett, Norway's TSO, as well as some of the main Norwegian DSOs (e.g., Lyse Elnett, Ringeriks-Kraft Nett, Troms Kraft Nett, Hafslund Nett). In particular, the algorithms used by eSmart Systems automatically identify specific objects and recognize pre-defined faults, such as cracks on wooden poles (see Figure 7 as an illustration). This enabled us to access a database of 17,352 geo-localized aerial pictures of wooden utility poles, from which 5383 are classified as cracked.

In most of the cases, two to three pictures of a unique utility pole were taken from different angles. This was done to ensure having accurate information for each of the observed poles without suffering from hidden information. We merged this information with the exact geographical coordinates of the electric poles, made available by the Norwegian Water Resources and Energy Directorate (NVE)[2]. We could thus analyze a dataset of 7653 geo-localized wooden utility poles, either classified as cracked or not.

Figure 7. Wooden pole where a crack has been localized on the mast (see rectangle).

2. NVE: www.nve.no.

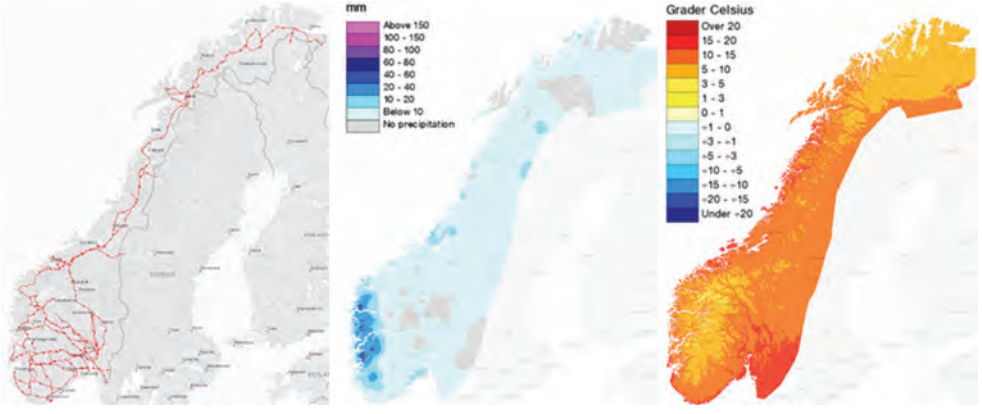

Figure 8. From left to right: main axes of the Norwegian electrical grid[6]; map of the precipitation in Norway on the 1st of August 2017[7]; map of the temperatures in Norway on the 1st of August 2017[7].

In parallel, seNorge[3] (created in collaboration between the NVE, the Norwegian Meteorological Institute[4] and the Norwegian Mapping Authority[5]) enables us to access daily observed (or interpolated) records of the climatic conditions in Norway. Especially, it enables us to access temperature and precipitation measures going as far back as 1957.

Figure 8 illustrates the type of information made available by NVE and seNorge. Using a scroll up/down feature of the websites, it is possible to move from a global and national overview up to a specific geo-localized point (in our case, the localization of the wooden utility poles).

Different approaches are considered in our work. The purpose is to create an indicator for the likelihood of crack apparition on wooden poles.

In order to benefit from the high granularity offered by the webservices used, we plan to use daily records of temperature and precipitation as potential predictors for a binary classification problem (labeling as cracked or not-cracked). Predictive features can be designed, that summarize at different granularities the daily weather data and extract relevant indicators that correlate with crack appearance. Considering an extreme reduction, we can for example summarize the intensity of the meteorological variation on a localized point into, e.g. a temperature coefficient and a precipitation coefficient. This would lead to a method using only two predictors when focusing on this classification problem.

Equation (1) provides an example of the type of coefficient c that can be used when focusing on a specific pole.

$$c = \sum_{i=2}^{n} \frac{|X_i - X_{i-1}|}{X_{max} - X_{min}} \quad (1)$$

Where n is the number of daily records since the installation of the wooden pole observed; i the enumeration index; X_i the value of the meteorological phenomenon observed on the specified location on day i (here in millimeters or in degrees Celsius); X_{i-1} the record of the same phenomenon on the same location on the previous day; X_{max} (resp. X_{min}) the maximum (resp. minimum) value of the observed phenomenon that has been recorded over the entire timestamp of observation on the specified location.

Alternatively, predictive features can be automatically learned from the raw temperature and precipitation time series using deep learning techniques. Such techniques, belonging to the class of artificial intelligence methods (and more especially, to the class of machine learning methods) are based on recursive analyses of data over time and/or over space, from which they identify and highlight step by step the most relevant characteristics.

High temperatures favor the proliferation of fungus, which weakens the structure of the wood. Furthermore, high humidity levels on extended periods might soften the wood and make it more sensitive to sudden external loads (e.g. wind or ice rain). Finally, the intrinsic properties of wood

3. seNorge: www.senorge.no.
4. Norwegian Meteorological Institute: www.met.no.
5. Norwegian Mapping Authority: www.kartverket.no.
6. https://temakart.nve.no/link/?link=nettanlegg.
7. http://www.senorge.no/index.html?p=senorgeny&st=weather.

lead it to easily accept slow variation of external loads and environmental conditions but make it particularly sensitive to sudden variations. These approaches will thus enable us to identify meteorological patterns favoring the apparition of cracks, as well as located regions where the likelihood of crack apparition will be higher.

An increase in the period of exposition to external factors leads to a rise of the probability of crack apparition. This implies that the age of the poles plays a big role in the suggested methods. However, part of this information might be missing. In such a case, we could consider a generic day of installation depending on the period of installation of the power line in the observed region.

5 DISCUSSION

The suggested methods enable to evaluate the role that temperature variations and precipitations have on the formation of cracks on wooden poles. These methods have the advantage to be flexible and easily integrated when accessing additional data sources, such as daily records of wind intensity and direction, humidity variations, clouds presence, etc. They are nevertheless highly dependent on two main facts:

- First, the initial classification of the poles as cracked or not. This is an important topic as the size of the cracks directly affects its detection by the algorithm used to classify the poles. There is thus a need for utility companies to define what should be considered as a problematic crack or not.
- Second, the information initially available on the poles themselves (e.g. age, maintenance tasks carried out). This information might be difficult to access because not necessarily well reported in the first phases of the grid installation.

Despite using relatively simple techniques and being highly dependent on initial parameters, the proposed methods represent a first approach in the analysis and handling of cracks in wooden poles. This information may in turn be useful for decision makers in the prioritization of additional inspection procedures and future maintenance tasks.

It is to mention that our paper only highlights preliminary results of an ongoing research, as the described methods have not yet been fully applied. Further work will thus focus on the extensive application and validation of these approaches and provide an in-depth analysis of the phenomenon of crack apparition on wooden poles by using additional real data from the Norwegian network.

6 CONCLUSION

Our paper highlighted the importance for utilities of early detection and analysis of cracks on wooden poles. We summarized how environmental conditions can directly affect the physical properties of wood and thus favor or limit the apparition of cracks on wooden poles. In order to better understand and predict their occurrence, we then suggested two approaches using pre-classified and geo-localized aerial pictures of cracked and non-cracked poles in combination with up to 60 years of meteorological measurements. Further, we saw that, despite being highly dependent on initial information, our approach might provide useful information for the generation of maintenance policies. This approach might finally be a good starting point for researchers wanting to combine fields of expertise such as structural study of wood on microscopic level and crack detection methods using image analysis.

ABSTRACT: A risk-based approach has been demonstrated to be capable of evaluating the quality of permanently plugged and abandoned petroleum wells. The quality measure in this context is the leakage risk, expressed in terms of probability of barrier failure and the leakage rate (consequence), where associated uncertainties are dealt with by means of probability distributions. In complex engineered systems, such as a barrier system in a permanently plugged and abandoned oil or gas well, it is reasonable to question whether the probability distributions provide adequate representations of the uncertainties. To improve the risk-based approach for plug and abandonment, and to contribute to more informed decisions by better reflecting the uncertainties upon evaluation of the leakage risk, in this paper, we propose an approach to assess the assumptions made and reflect the strength of knowledge, to complement the probability distributions. An example is included to illustrate the approach.

1 INTRODUCTION

The final phase in the life cycle of a petroleum well is permanent plug and abandonment, in order to e.g. prevent hydrocarbon leakage to the surface and pressure breakdown of the formations (Liversidge et al., 2006). On the Norwegian continental shelf (NCS), a significant number of offshore oil and gas wells will be entering their final phase in the coming decades and need to be permanently plugged and abandoned. Plug and abandonment (P&A) designs on the NCS are governed by the requirements and guidelines in NORSOK Standard D-010 (Standards Norway, 2013). In line with these requirements, P&A operations are considered prescriptive "one-size-fits-all" approaches (Arild et al., 2017). A criticism of the prescriptive approach is that it neglects the well-specific characteristics, which can differ from well to well, such as geological formations, reservoir qualities, wellbore schematics and surrounding marine environments, and is thus not cost-effective.

A quantitative risk-based approach for evaluating the containment performance of permanently plugged and abandoned oil and gas wells has been established as an alternative to the prescriptive approach (Arild et al., 2017). The risk-based approach is considered a "fit-for-purpose" alternative, which incorporates the well-specific characteristics. Here, the quality of the plugged and abandoned wells is measured by the leakage risk, which is expressed in terms of the probability of barrier failure within a given time period and the associated leakage rate at the seabed. The risk-based approach, demonstrated by Arild et al. (2017), builds on the leakage calculator presented by Ford et al. (2017) and can be seen as a risk assessment tool applicable in the recommended practice of "fit-for-purpose" well abandonment assessment proposed by Buchmiller et al. (2016).

In order to evaluate and assess the leakage risk for a permanently plugged and abandoned well, the risk-based approach identifies potential failure modes of each barrier element in the well, and assesses the failure probabilities and consequences. Thus, leakage risk can be considered as the two-dimensional combination of probability and consequence, which is widely criticized in the literature as being too narrow (see e.g. Aven (2014), pp. 28).

The workflow is described in detail by Arild et al. (2017). Simply stated, the assessment of failure probability is performed by means of

Bayesian analysis, to create a lifetime distribution of the well. Assessment of the consequences is done by calculating the leakage rates through identified leakage pathways, to provide a distribution of overall leakage rates at the seabed. For both assessments, uncertainties are dealt with by means of probability distributions (propagated through the use of Monte Carlo simulations).

A risk-based approach for evaluating the P&A of oil and gas wells should provide a broad, informative and balanced description of the leakage risk, as a means to support decision-making. To achieve this, proper treatment and communication of uncertainties are necessities (Flage & Aven, 2009). Looking at the current practice in the risk-based approach for evaluation of P&A, where uncertainties are treated by probability distributions, it is reasonable to ask whether all relevant uncertainties are fully reflected. Probability distributions are based on assumptions which may be more or less reasonable, and knowledge which may be strong or weak (or in-between). These two aspects are somewhat ignored, or not adequately reflected, by the probability distributions.

The present paper intends to improve the risk-based approach by implementing a semi-quantitative assessment of the uncertainties, in addition to the probability distributions, to incorporate the aspects mentioned above. The improved approach goes beyond probabilities to assess and express uncertainties, by focusing on the knowledge, which forms the basis for the assessment. A strength-of-knowledge categorization, in line with the scoring used by Flage & Aven (2009), will be the starting point of the semi-quantitative analysis to reveal uncertainties hidden in the background knowledge. In addition, the concept of assumption deviation risk, introduced by Aven (2013), will be applied as a tool to reveal the effect of potential deviations in the assumptions. Assumption deviation risk assessment has been demonstrated in recent time to be a useful tool in the context of highlighting critical assumptions (see e.g., Berner & Flage (2016), Khorsandi & Aven (2017)). The improved approach for risk-based P&A intends to provide a more complete risk description, such that the decision-makers have greater decision support when reasoning and deliberating upon the decisions to be made (Aven & Zio, 2011).

The remainder of this paper is organized as follows: In Section 2, we briefly introduce the probability and consequence assessments in the risk-based approach, respectively. In Section 3, we discuss the weaknesses associated with the current practice in the risk-based approach. Section 4 presents the suggested improvements. Section 5 illustrates the improved approach through an example, while Section 6 discusses and evaluates the improved approach. Section 7 concludes.

2 INTRODUCING THE CURRENT RISK-BASED APPROACH

The current risk-based approach for evaluating the containment performance of plugged and abandoned oil or gas wells is based on the assessments of probability of failures and consequences. Here, we briefly introduce the two assessments. See Arild et al. (2017) and the references therein for further details.

2.1 *Probability assessment*

A key quantity of interest when evaluating the quality of a P&A design is the lifetime of the well, i.e. reflecting how long it will take before the barrier system starts to leak (Arild et al., 2017). Commonly used lifetime distributions are the exponential and Weibull distributions (Singpurwalla, 2006). In order to establish a lifetime distribution, historical data are often used as a basis to perform statistical inference, such as maximum likelihood estimation (MLE), to obtain estimates of the parameters which best explain the distribution of the observed data.

To be applicable in estimating the parameters of a lifetime distribution, traditional methods such as MLE require that some failures have occurred (Singpurwalla, 2006). On the NCS, however, none of the 334 wells which are assumed plugged and abandoned are said to have failed since they were abandoned; they are considered censored observations (Arild et al., 2017). One approach which is deemed feasible when working with completely censored data is Bayesian analysis (Singpurwalla, 2006).

In Bayesian analysis, the objective is to use known quantities along with a specified parametric expression to make inferences about the unknown quantities or parameters (Singpurwalla, 2006). Since the parameters are unknown, we assign prior distributions for the parameters to reflect our lack of knowledge about the parameter values a priori any evidence. After some data are observed, Bayes' formula, expressed in terms of probability distributions, is used to update the prior beliefs into posterior distributions of the parameters. The quantity of interest in the probability assessment is the lifetime of the well and not the parameters estimated by Bayes' formula. By drawing parameters of interest from the posterior distribution, a posterior predictive distribution of the lifetimes can be generated, which is a distribution of unobserved observations (predictions), conditional on the observed data.

2.2 *Assessing the consequences of a failure*

If a well barrier fails, leakage of hydrocarbons to the seabed can occur. Ford et al. (2017) have developed a simple leakage calculator to assess the leakage potential from a well barrier system. This

calculator estimates the cumulative leakage rate through potential leakage pathways for each well barrier. We refer to Ford et al. (2017) for detailed explanations of the leakage calculations. The leakage pathways considered in this paper are: leakage through bulk cement given by Darcy's law (e.g. Godøy et al. (2015)); leakage through fractures or cracks in the cement (e.g. Sarkar et al. (2004)); and, leakage through the micro-annuli (e.g. Aas et al. (2016)). These pathways are represented by the following equations, respectively:

$$Q_1 = \left(\frac{kA}{\mu L}\right)\left(\Delta P - \rho g L \cos\theta\right) \quad (1)$$

$$Q_2 = \left(\frac{h^3 \cos\alpha}{12\mu}\right)\left(\frac{\Delta P}{L}\right)W \quad (2)$$

$$Q_3 = \left(\frac{\pi R_c \Delta P}{6\mu L}\right)\delta R^3 \quad (3)$$

where Q = flow rate; k = cement permeability; A = cross-section of the cement plug and/or annulus; μ = reservoir fluid viscosity; L = length of the plug or annular cement; ΔP = pressure difference over the cement plug and/or annuli; ρ = density of the reservoir fluid; g = gravitational acceleration; θ = inclination of the well at the depth of the plug; h = fracture aperture; α = orientation of the fracture; W = fracture width; R_c = casing diameter; and δR = micro-annuli gap.

3 ISSUES WITH THE CURRENT RISK-BASED APPROACH

In the risk-based approach, as in any risk assessment, we make a number of assumptions that are more or less explicitly stated. A single assumption may be formulated as $X = x_0$, where the value x_0 is fixed, such as an increasing failure rate ($X = x_0 = \beta = 1.5$, in a Weibull function). Since the result of the leakage risk assessment is conditional on the assumptions made being true, it is important to understand the uncertainties related to these assumptions. We can classify the assumptions as either probability-influencing assumptions or consequence-influencing assumptions (which is a broad interpretation of the three areas of assumptions listed by Khorsandi & Aven (2017)).

3.1 *Weaknesses with the probability assessment*

By virtue of Bayes' theorem, the posterior predictive distribution is based on the posterior distribution of some parameters θ. The true values of such parameters are unknown. By using an alternative prior distribution, or probability distribution, a different posterior predictive distribution would be generated. Paramount for the assessment is to understand the basis for the resulting predictive distribution. Other technical difficulties with Bayesian analysis are summarized by e.g. Ferson (2005).

The historical data extracted from the Norwegian Petroleum Directorate (2017) database can be questioned, regarding the validity and value of information with respect to when an abandoned well will fail. Censored data, as we have here, imply that we have not detected any failures (leakages) since the wells were abandoned. For a leakage to be detected, a failure must have taken place. In that sense, it is reasonable to assume that no detected leakages imply zero failures. A failure, on the contrary, does not automatically imply a detectable leakage. So the true survival times of the data are actually unknown.

The data contain survival times of abandoned wells, designed according to NORSOK Standard D-010. As the risk-based approach intends to incorporate well-specific characteristics, such as flow potential, it is contradictory to use all available data as a basis for the probability assessment. Further investigation of the data shows that observations differ with respect to well-specific properties, such as geology and flow potential. It is reasonable to question whether a survival time from a well in a reservoir with, say, limited flow potential is relevant when evaluating a P&A design for a well in a reservoir with high flow potential. The risk-based approach aims to justify alternative P&A designs, which are "fit-for-purpose". Utilizing the whole sample when evaluating the leakage risk is therefore a radical assumption, as it takes into account censored lifetimes from, most likely, stricter P&A designs.

3.2 *Weaknesses with the consequence assessment*

Challenges with the leakage rate assessment relate to uncertain input values, as the models (Equations 1–3) are established on strong knowledge, according to criteria in e.g. Aven (2014), pp. 139.

There are two categories of inputs in the consequence approach: (1) uncertain inputs that can be described by probability distributions, and (2) known inputs related to design variables, scenarios or low importance inputs (Arild et al., 2017). The former is the focus of the present paper. With respect to Equations 1–3, Table 1 summarizes the uncertain inputs of interest. Both the values and distributions (here, a triangular distribution) given in the second column are assumed. These values are difficult to measure exactly, and they impose uncertainties. The degree of uncertainty is case-specific

Table 1. Uncertain parameters (Arild et al., 2017).

Uncertain parameters	Values (min, most likely, max)
Cement permeability	0.1, 0.5, 5.0 μD
Micro-annuli gap	3, 20, 70 μm
Fracture aperture	10, 50, 200 μm
Inclination of fracture	0, 30, 70°
Fracture width	1, 2, 3 mm

and subject to judgment by the assessor (Flage et al., 2013).

4 DISCUSSION OF SOME POSSIBLE IMPROVEMENTS FOR THE RISK-BASED APPROACH

The common denominator for the aspects discussed in the previous section is lack of knowledge when quantitatively assessing the leakage risk. A limited amount of information is available on the subject matter, and determining whether the parametric functions and input parameters are appropriate is challenging. Decision-making under such conditions is also challenging. Not all uncertainties can be fully expressed or transferred into quantitative formats. The background knowledge, on which the probabilities of failure and leakage rates are based, can hide uncertainty. The assumptions made are known to potentially deviate in reality, and any deviation that could affect the risk picture needs to be highlighted and assessed. We believe the following approaches can improve the treatment of uncertainty in the risk-based approach: (1) crude strength-of-knowledge assessment (SoK) and (2) assumption deviation risk assessment.

4.1 *Crude strength of knowledge assessment*

In the probability and consequence assessments, uncertain inputs are used as the basis for the assessments. Subjective probabilities (distributions) are assigned to these inputs, expressing our degree of belief about the values of these parameters, conditional on our background knowledge. To reflect the strength of this background knowledge, a crude SoK assessment is recommended. A categorization in line with the scoring by Flage & Aven (2009) is used as a basis for an assessment of the SoK. Here, the background knowledge is categorized as strong if all the following criteria are met (Flage & Aven, 2009):

- The assumptions made are seen as very reasonable (s1)
- A large amount of reliable data is available (s2)
- There is broad consensus among experts (s3)
- The phenomena involved are well understood (s4).

If, on the other hand, at least one of the following criteria is true, the background knowledge is classified as weak (Flage & Aven, 2009):

- The assumptions made are strong simplifications (w1)
- Data are non-existent or unreliable (w2)
- There is a lack of consensus among experts (w3)
- The phenomena involved are not well understood (w4).

An in-between background knowledge is classified as moderate. The SoK assessment intends to capture uncertainties which are not easily transformed or expressed quantitatively, e.g. by probabilities.

4.2 *Assumption deviation risk assessment*

The concept of assumption deviation risk, introduced by Aven (2013), highlights the risk with respect to the (main) assumptions on which the quantitative risk assessment is based. In general, Aven (2013) suggests focusing on the magnitude of the deviation, the degree of belief in this magnitude occurring, how this deviation will influence the risk, and the SoK related to the phenomena affecting the assumption (as described above).

Thus, the concept of assumption deviation risk goes beyond traditional sensitivity and uncertainty analysis. Sensitivity analysis, such as asking "what if" questions, is informative, as it produces a range of outcomes based on different input values. Assumption deviation risk extends this type of analysis, as it assesses the risk of deviations, covering an assessment of the consequences of the deviations, uncertainties related to the outcomes and a crude SoK assessment. The concept of assumption deviation risk aims to better communicate the uncertainties related to the leakage risk to the decision-maker, by explicitly assessing and identifying the influence of any deviation in the assumptions. The assessment is systematic, as it intends to identify critical assumptions, analysing the risk of deviations in those assumptions, and is a means to understanding assumptions which may deviate far ahead in the future (Khorsandi & Aven, 2017). Requirements, such that the well barrier should perform its purpose for eternity, make it important to understand how the leakage risk may change over the lifetime of an abandoned well. This is better understood when we understand how deviations in the assumed states can occur. The main concerns in the leakage rate assessment are the negative consequences; hence, we can restrict our focus to deviations that worsen the outcomes.

Often, as the decision-making problem becomes more complex, the number of assumptions has a tendency to increase and the assumption deviation risk assessment becomes tedious and time-consuming. To make the improved approach practical, we suggest handling each assumption systematically, in line with guidance suggested by Berner & Flage (2016), who focus on six so-called settings that the decision-maker faces when making assumptions in a risk assessment. These settings are classified by the degree of belief in deviation from the initial assumption, the effect of such deviation and the SoK related to the assumption. When we know what setting we are facing, a general approach to handle the assumption is suggested. We must emphasize that the guideline should not to be used as a mechanistic framework and must be adapted to the case of interest.

In addition, the assumption deviation risk assessment will increase the likelihood of detecting surprises. Two categorizes are of particular concern with respect to surprises: a moderate/high belief in deviation, and when the SoK is moderate/weak. Assessment of the assumptions will highlight such potential surprises. This is a way of revealing black swans (Aven, 2014).

5 A CASE STUDY

A synthetic vertical gas well is considered to be plugged and abandoned. The well, well barrier and reservoir characteristics are based on Arild et al. (2017) (except the inclination of the well). For simplicity, we refer to the values in Table 1 for the uncertain parameters and to Arild et al. (2017) for an overview of the known parameters of interest. The secondary barrier, which functions as a backup to the primary, is placed right on top of the primary barrier, and the combination of the two is treated as one barrier (plug 1+2). In addition, there is a surface barrier (plug 3) located at 300 m TVD (true vertical depth).

Let us say that the well appears to have a low leakage risk (before any assessment is conducted). Negligible issues, such as scaling and cross flows, were observed during the production phase. The only concern is an unconsolidated sandstone formation around the plug 1+2, indicated by an acoustic log. However, the overall impression is that the NORSOK Standard D-010 requirement of having 100 m thick barriers is too strict. In other words, the requirement is questioned in terms of its cost-effectiveness. A more cost-effective design, with shorter cement plug lengths, is considered as an alternative.

Reducing the cement plug lengths intuitively increases leakage risk and needs to be justified before implementation. A deviation in some of the assumptions, which form the basis for the assessment, can be critical, as the consequence threshold will be further reduced. The aim of the analysis is to illustrate how assumptions can be assessed according to the methods presented in this paper, to achieve better decision support. The case study is divided into three parts. First, the current risk-based approach is applied to assess the leakage risk. Then, the suggested improvements discussed in this paper are applied to the same case. Finally, we compare the current risk-based approach with the improved approach, in terms of decision support.

5.1 *The current risk-based approach*

The alternative P&A design, with shorter cement plug lengths needs to be justified before implementation. This is done by the leakage risk, which depends on the probability of failure and the associated leakage rates. These are estimated by the procedures introduced in Section 2.

5.1.1 *Probability assessment*

Following the approach described in Section 2.1 and the example of Arild et al. (2017), we establish a Weibull distribution to reflect the probability of failure within a given time for this well. We assume that the shape parameter is 1.5, indicating that the failure rates increase with time. The scale parameter is assumed to have a uniform distribution, between 0 and 1000 years. Basically, this means that whether failures are likely to occur in 10 years or 1000 years is unknown. The data used to update our prior belief about the scale parameter are the 334 censored observations of wells assumed to be permanently abandoned. Probability of failure within a certain time period is then predicted from the posterior predictive distribution in Figure 1. The probability of failure within the first 100 years is approximately 5%, if the assumptions hold true.

5.1.2 *Consequence assessment*

If a failure occurs, the quantity of interest is the leakage rate. Here, we follow the calculations from

Figure 1. Posterior predictive probability of failure times given the initial assumptions.

Equations 1–3 for both the surface barrier and the combined primary and secondary barrier. Leakage to the seabed is determined by the minimum leakage rate through the surface barrier or the combined plug. The combined plug has a significantly lower flow rate, due to having twice the thickness of the surface barrier, presented with sensitivity to different plug lengths in Figure 2, where the solid lines represent our 90% certainty that the flow rate is below these flow rates, the dashed lines are the most likely rates, and the stippled lines reflect our 90% certainty that the flow rates are above these flow rates.

When the plug lengths are above the prescriptive length of 100 m, there is a negligible increase in the flow rates from reducing the plug lengths. However, a reduction in plug lengths which are shorter than 100 m, imposes a relatively significant increase in flow rate.

5.1.3 *Results from the current risk-based approach*
The probability and consequence assessments resulted in low leakage risk. The probability of failure within the next 100 years is predicted to be 5%. With plug lengths of 50 m, there is 80% probability that the leakage rate will be in the range of 1.303×10^{-6} m^3/s to 5.087×10^{-5} m^3/s, with a most likely leakage rate of 1.829×10^{-5} m^3/s. If we assume that the reservoir fluid composition is mostly methane, these flow rates correspond to a yearly release in the range of 0.021 to 0.831 ton, with a most likely yearly release of 0.298 ton. With the prescriptive plug lengths of 100 m, there is an 80% probability that the flow rate is in the range of 7.667×10^{-7} to 2.780×10^{-5} m^3/s (0.012 to 0.454 ton/year), with a mean flow rate of 1.021×10^{-5} m^3/s. (0.457 ton/year). The leakage rate is almost doubled by reducing the plug lengths from 100 to 50 m. These results represent the base case of this analysis. As the assumptions made in the probability and consequence assessment may deviate, we need to assess their influence on the leakage risk, in order to justify a plug length of 50 m.

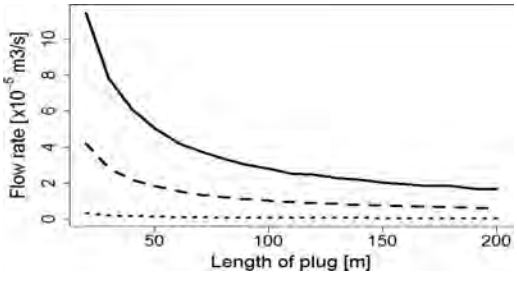

Figure 2. Flow rates through the primary and secondary plug for different cement plug lengths.

5.2 *The improved risk-based approach*
Following the approach described in Section 4, we intend to provide a more detailed understanding of the assumptions, and therefore the leakage risk, before making a decision. For simplicity, we have only considered a few assumptions in this paper. The assumption deviation risk assessment is summarized in Table 2, and complements the results presented in Section 5.1. All the assumptions are assessed in terms of degree of belief in deviation, effect of such deviation on the leakage risk and the SoK regarding the assumption. Some of the assumptions show significant influence on the leakage risk.

Assumptions classified by a moderate or high belief in deviation from the initial assumption and moderate or high influence on the leakage risk, based on weak background knowledge, are the most critical in the leakage risk assessment (assumption Nos. 1, 2 and 3). For assumption No. 1, the SoK is weak. This is controversial, as weak knowledge discourages the establishment of probability distributions and raises questions regarding the final result. A uniform prior distribution is the most appropriate option, since it intends to reflect the epistemic uncertainty to some degree. The goodness of this distribution is, however, open for debate, as we do not know with certainty which prior distribution or interval to choose. A deviation in the range of the uniform prior distribution greatly affects the probability of failure.

Assumption No. 2, regarding the validity of the historical data, is also critical. As the historical data are based on P&A designs in line with NORSOK Standard D-010, the data are poor representations of this well. There is a trade-off between large sample and relevant data, which the assessors need to consider and reflect. Based on sound engineering thinking, it is likely that this well, with shorter plug lengths, will have a higher probability of failure within the first 100 years, compared to the values in Figure 1.

The assumption deviation risk assessment revealed that most of the assumptions are believed to deviate to some degree (Nos. 4, 6, 7 and 8), in addition to having moderate influence on the leakage risk. As the SoK is not weak for these assumptions, probability distributions may be established. These assumptions may deviate, reflected by not being based on strong background knowledge or by the fact that we believe in a deviation; and the number of such assumptions is of great concern. If deviations from more than one of the assumptions take place simultaneously, the cumulative influence on the leakage risk can be significant, despite a deviation in each assumption, separately, showing little influence. This is highly relevant for the

Table 2. Summary of the simplified assumption deviation risk assessment for the case study in Section 5.

No.	Assumption influence	Assumption ($X = x_0$)	SoK	Belief in deviation	Deviation	Effect of deviation	SoK evaluation
1	P	Scale parameter has a uniform prior distribution on the interval [$x_{min} = 0$, $x_{max} = 1000$], resulting in: $P(T < 100) = 5\%$, $P(T < 1000) = 76\%$.	Weak	Moderate	$x_{max,1} = x_{max} + 1000$ $x_{max,2} = x_{max,1} + 1000$	$P(T < 100 \mid x_{max,1}) = 2\%$ $P(T < 1000 \mid x_{max,1}) = 49\%$ $P(T < 100 \mid x_{max,2}) = 1\%$ $P(T < 1000 \mid x_{max,2}) = 35\%$	w1, w2, w3, w4, Critical
2	P	Historical data are representative for this well. $X = x_0$ = survival times.	Weak	Moderate/ high	Failure times could increase, $X > x_0$.	Moderate/high	w1, w2, w4 Critical
3	C	Triangular distribution for all uncertain parameters, $X = x_0 = T$ (min, mode, max).	Weak	Moderate/ high	High	High	w1, w2, w4 Critical
4	P	Failure rate (shape parameter) is constant, $X = x_0 = 1.5$.	Moderate	Moderate/ high	$X \in [1.0, 2.0]$	High $\Delta P(T100\mid X) \in [121\%, -36\%]$	S1, w2, w4 Critical
5	P	Failure rate is increasing, $X = x_0 = \beta > 1.0$ (see No. 4).	Moderate	Low	Low	High, but not likely to have a decreasing failure rate.	s1, s3, w4
6	C	Cement permeability has a max value of $X = x_0 = 5.0$ μD.	Moderate	Moderate/ high	$X \in [0.5, 2.0]$ μD	Low, flow through bulk cement is negligible.	s2, s4, w1, w3
7	C	All three leakage pathways occur at the same time (with probability of 1) if a failure occurs.	Moderate	Strong	Moderate/high. (i.e. only one of the three can occur)	Moderate	Conservative assumption
8	C	All the barriers have the same properties.	Strong	Low	Low	Moderate	s1, s2, s4
9	C	Maximum pressure difference over the plug or annulus.	Moderate	Low	Low	Low (not likely to be worse)	Conservative assumption
10	C	Micro-annuli gap is given as a triangular distribution, T(3, 20, 70) μm.	Weak/ moderate	Moderate	Mode and max can deviate with + 20-70 μm (due to cement shrinkage potential).	Moderate/high	w2, w4

P: Probability assessment; C: Consequence assessment; SoK: Strength-of-knowledge. Sok Evaluations: see Section 4.1; $\Delta P(T) = [P(T|xi) - P(T|x0)]/P(T|x0)$.

evaluation of P&A designs but beyond the scope of the present paper.

5.3 *Evaluating the results*

Based on the assumption deviation risk summarized in Table 2, it is now possible to argue that a reduction in the plug length from 100 to 50 m is not justified. If a decision were made exclusively on the probability and consequence assessment, the conclusion would most likely be different. The two-dimensional leakage risk of probabilities and consequences is low. Seeing beyond such a narrow perspective on risk, we see that there are some uncertainties which should not be ignored. An incorrect choice of the prior distribution can greatly affect the probability of failure, for example. In addition, the data may provide too optimistic information about expected survival times if the prior distribution's ability to support longer lifetimes is poor. The leakage rate can also be significantly increased if the assumed value of the micro-annuli gap is slightly too low, compared to the true future value. The latter can take place if the annuli cement has expanding properties, such that the cement, over time, may expand radially towards the formation and cause a greater inner micro-annuli gap (Baumgarte et al., 1999).

Ideally, the justification should be made with reference to some risk acceptance criteria. This has not been established at the time being. The final decision should be made after a managerial review and judgment process, according to the idea of risk-informative decision-making (e.g. Aven & Zio (2011)).

6 DISCUSSION

The main aim of this paper was to illustrate how the risk-based approach for evaluating of the containment performance of a plugged and abandoned well can be improved by assessing uncertainties beyond probabilities. The methodology is systematic in its treatment of the assumptions. It should be mentioned that no effort was conducted to quantify what a high degree of sensitivity actually corresponds to, although this would affect the number of critical assumptions. Does a deviation in an assumption, resulting in a 20% change in the leakage rate indicate high sensitivity? The challenge is related to how to justify what increase in the leakage risk is acceptable, which is beyond the scope of this paper.

The quantitative approach for assessing the leakage risk is attractive. This type of approach in plug and abandonment evaluation is new to the industry and has seen little practical experience. One of the main challenges that remains to further develop the approach is to establish criterion which can be used in the justification of a specific design. Then the lifetime distribution and calculated leakage rates complemented by an assumption deviation risk assessment would provide a powerful tool for making risk-informed decisions.

Many of the assumptions made are based on relevant literature on the subject matter. The key point is that these values may be more or less relevant for the specific case. Assessing the assumptions helps to declare whether the assumptions are appropriate or not. However, it requires the assessor to have a sound understanding of what it takes for an assumption to occur. If the knowledge is weak, we cannot say something with certainty about the deviation in an assumption and the effect of such a deviation. We should communicate this fact to the decision-maker. The assumption deviation risk assessment provides a deeper understanding of the phenomena involved in a P&A operation, thus revealing uncertainties beyond the capability of the current risk-based approach. The fact that barriers should perform their functions to eternity requires that assumption deviations are taken into consideration when justifying an alternative P&A design.

A deviation in an assumption which increases the leakage risk is undesirable. To avoid such negative outcomes, it is common to apply conservative assumptions, which are often strong simplifications. In the current risk-based approach conservative assumptions are often made, such as assumption Nos. 7 and 9 in Table 2. One reason why we often resort to conservative assumptions is lack of knowledge. Rather than searching for increased knowledge, it is less time- and resource-consuming to make a conservative assumption. A danger of such a practice is that a too high risk picture is presented to the decision-maker (Aven, 2016). Basic safety management principles would then imply an implementation of costly risk-reducing measures. Thus, the careless use of conservative assumption works against the purpose of the risk-based approach to provide decision support regarding an alternative, more cost-effective P&A design.

7 CONCLUSION

In this paper, we have shown how assumption deviation risk assessment can improve the treatment and reflection of uncertainties. The assumptions are assessed separately with respect to the analyst's degree of belief in deviation, the sensitivity of the leakage risk to such deviation and the SoK related to the assumption. The fact that assumptions are

known to potentially deviate more or less should not be ignored. Not all uncertainties are easily transformed and expressed quantitatively, and they require a more semi-quantitative approach to be fully reflected, to ensure appropriate decision support. By complementing the leakage risk with an assumption deviation risk assessment, more informed decisions can be made.

A case study was performed to illustrate how the improved risk-based approach provides more informed decision support than the current approach. In this case, an alternative P&A design was evaluated. The assumption deviation risk assessment highlighted some critical assumptions, which led to a decision that differed from what we would decide upon if it were made exclusively on the leakage risk.

The use of bond graph modelling in polymer electrolyte membrane fuel cell fault diagnosis

A. Vasilyev & J. Andrews
Department of Mechanical, Electrical and Manufacturing Engineering, Loughborough University, UK

L. Mao & L.M. Jackson
Department of Aeronautical and Automotive Engineering, Loughborough University, UK

ABSTRACT: As a possible alternative energy source, hydrogen fuel cells, especially Polymer Electrolyte Membrane (PEM) fuel cells, have received much more attention in the last few decades, which have already been equipped in many applications. A series of studies have been devoted to PEM fuel cell fault diagnosis to ensure its reliability during its lifetime, but due to the complexity of PEM fuel cell systems and incomplete PEM fuel cell test protocols, it is difficult to test various PEM fuel cell failure modes, thus the performance of fault diagnostic techniques cannot be fully investigated. On this basis, it is necessary to develop a reliable PEM fuel cell model with capability of simulating various PEM fuel cell faults. In this study, a hybrid model is developed to represent the behavior of PEM fuel cells in both continuous and discrete-time domains. With a continuous-time domain sub-model, various aspects of PEM fuel cell behavior can be simulated, including fluid, thermal, and electro-chemical dynamics. Moreover, the PEM fuel cell failure modes are implemented with stochastic Petri nets in the discrete-time domain. Based on the developed hybrid model, various PEM fuel cell failure modes can be simulated and their effects on the system performance can be observed. With the simulated data under different conditions, the performance of fault diagnostic techniques can be better evaluated by studying their performance in different failure mode scenarios.

1 INTRODUCTION

Due to the characteristics such as zero-emission and high efficiency, the PEM fuel cell has attracted more attention as an alternative energy source. In the last few decades, PEM fuel cells have been equipped in several systems, including automotive, consumer devices, and stationary power systems.

However, the reliability of PEM fuel cell during its lifetime is still a main barrier for further commercialization. To address this, several studies have been devoted to PEM fuel cell fault diagnosis, which could detect and isolate PEM fuel cell abnormal performance, thus mitigation strategies can be taken to recover and extend the fuel cell performance. Based on the methods adopted, these studies can be loosely divided into two categories, model-based techniques and data-driven approaches [Petrone et al. 2013, Zheng et al. 2013].

In model-based techniques, a PEM fuel cell model should be developed to express the system behavior, and the fault can be identified by calculating the residual between the model outputs and actual measurements [Kamal and Yu 2011, Ohs et al. 2011, Zeller et al. 2010]. With data-driven approaches, the features indicating the fuel cell condition would be extracted from the measurements, and the fuel cell state can be determined by applying pattern recognition algorithms to the extracted features [Mao et al. 2017, Placca et al. 2010, Rubio et al. 2010, Steiner et al. 2011, Zhongliang et al. 2015].

From the previous studies, data-driven approaches are more widely used in PEM fuel cell fault diagnosis [Zheng et al. 2013]. The main reason is that the PEM fuel cell contains physical interactions consisting phenomena from fluidic, thermal and electrical domains, making it difficult to develop an accurate model, where data-driven approach can perform fault diagnosis using only measurements from PEM fuel cell system.

However, due to the incomplete protocol of the PEM fuel cell failure tests, only limited PEM fuel cell failure mode conditions can be tested in the lab, [Yuan et al. 2011, Miller and Bazylak 2011], which cannot fully investigate the effectiveness of data-based fault diagnostic techniques. Therefore, further studies for the performance of these approaches indiagnosing more PEM fuel cell failure modes are still required.

In this study, a PEM fuel cell model is developed based on the bond graph technique, which

can represent multiple physical phenomena in a unified graphical notation. With the developed model, various PEM fuel cell failure modes can be simulated, and simulated data can be used in data-based fault diagnostic techniques to investigate their effectiveness. In section 2, the knowledge of the PEM fuel cell and development of its bond graph model will be presented. The performance of the developed model in representing PEM fuel cell performance will be validated in section 3. In section 4, the model will be used to simulate the fuel cell dehydration phenomenon, and the performance of data-based fault diagnostic techniques will be studied using the simulated data. From the results, some conclusions are given in section 5.

2 PEM FUEL CELL BOND GRAPH MODEL

2.1 *Introduction of PEM fuel cell*

A typical PEM fuel cell includes several components, i.e. anode and cathode electrodes, gas diffusion layer, catalyst layer, and polymer electrolyte membrane, which are depicted in Figure 1.

During operation, hydrogen and air/oxygen are injected into the anode and cathode sides, respectively. Hydrogen is divided into protons and ions with Eq. (1), protons can pass through the membrane, while ions can only arrive at the cathode via the external circuit, where current is generated. At the cathode side, protons, ions, and oxygen will react to produce heat and water (Eq. 2), which can be removed from the cathode side.

$$H_2 \rightarrow 2H^+ + 2e^- \tag{1}$$

$$\frac{1}{2}O_2 + 2H^+ + 2e^- \rightarrow H_2O \tag{2}$$

2.2 *Bond Graph method*

The core principle of the bond graph (BG) method is energy conservation, i.e. the total energy in a closed system is never destroyed or lost, but converted from one form to another. With this method, systems involving multiple physical domains can be unified.

In a BG the rate at which energy is transferred between components is power, which is denoted as a half arrow as shown in Figure 2. It can be seen that power flow is characterized by two power variables: effort (e) and flow (f), where

$$e \cdot f = \text{power} \tag{3}$$

Table 1 depicts some commonly used analogies for the meanings of effort and flow.

Elements in the BG are located at the BG nodes, and represent different energy manipulation mechanisms. Sources of effort (Se) and flow (Sf) are active elements and provide inputs to the system. Such elements, controlled by an external signal, are called 'modulated' and denoted by a prefix 'm', e.g. mSe. Energy dissipation and storage phenomena are implemented via resistive (R), capacitive (C) or inductive (I) elements. Detectors of effort (De) and flow (Df) are shown with a full arrow to emphasize that they do not participate in energy exchange, but rather simply act as sensors and measure corresponding power variables.

Multiple power bonds can meet at one of two junction types, 0- and 1- type, which enforce the laws of energy conservation within the system. Another junction structure called Transformers (TF) act as energy transducers converting the transferred power from one physical domain to another. TF elements can only have two bonds connected. Figure 3 shows the different junction types, and corresponding equations are written in Eqs. (4)–(6).

$$\text{1-junction} \quad f_1 = f_2 = \ldots = f_N \sum e_N = 0 \tag{4}$$

0-junction $e_1 = e_2 = \ldots = e_N \sum f_N = 0$ (5)

Transformer $e_1 = me_2 f_2 = mf_1$ (6)

2.3 *EM fuel cell BG*

The hierarchy of the PEM fuel cell BG includes basic bond graphic elements describing energy storage and transfer mechanisms, which are at the base. A set of BG elements describing pneumatic and heat transfer phenomena are constructed for the two bipolar plates and for the anode and cathode sides, and BG elements describing electrochemical, transport and thermal phenomena representing the membrane electrode assembly [Saisset et al. 2006]. Additionally, cooling channels and the end plates are implemented as separate components [Vasilyev et al. 2017].

Figure 4 depicts the blocks resembling physical components of the PEM fuel cell and bonds connecting them representing power flows between components. Anode/cathode inlet and outlet blocks correspond to mass flow controllers or valves and regulate the flow of matter in or out of the cell. This is shown by bond labelled with P, T as efforts and $\dot{m}, \dot{H}$ as flows. The source of electric current (mSf) represents the load demanded from the fuel cell. Electrochemical phenomena within the membrane electrode assembly components calculate the rates of reactants and product consumption $\dot{m}_{H_2}, m_{O_2}$ and $\dot{m}_{H_2O}$. Transport phenomena determine the diffusion flows through the membrane electrode assembly, while thermal effects evaluate heat flows $\dot{Q}$ between the bipolar plates and the membrane.

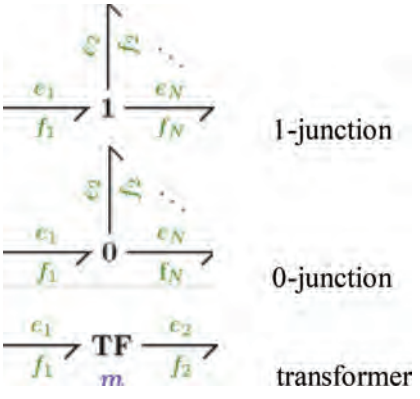

Figure 3. Bond graph junctions.

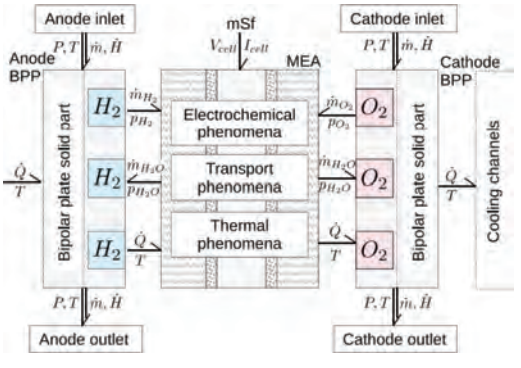

Figure 4. PEM fuel cell BG [Vasilyev et al. 2017].

A set of equations are used to develop the PEM fuel cell BG, including the computation of mass flow rates of gasses in and out of the cell, and thermal and pneumatic activities within bipolar plates. More details about the modelling procedures for the PEM fuel cell BG can be found in previous studies [Gawthrop and Bevan 2007, Vasilyev et al. 2017].

With results from different PEM fuel cell components, the single cell voltage can be calculated using Eq. (7).

$$V_{cell} = E_{Nernst} - \eta_{act} - \eta_{ohm} - \eta_{con} \quad (7)$$

where E_{Nernst} is the reversible potential, η_{act}, η_{ohm} and η_{con} are the activation loss, ohmic loss, and concentration loss, respectively.

Figure 5 depicts the single PEM fuel cell BG by putting the developed individual components together. Figure 6 shows the PEM fuel cell system BG including single cell BG and cooling loops, where inlet mass flows are regulated by Rth1 and Rth2. Each cooling loop is comprised of a single

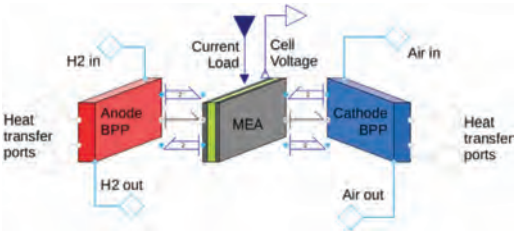

Figure 5. Single PEM fuel cell BG [Vasilyev et al. 2017].

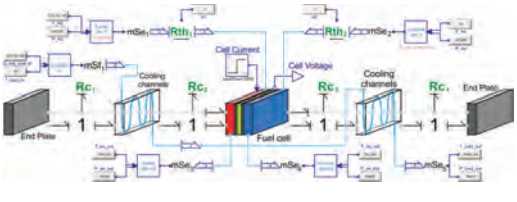

Figure 6. PEM fuel cell system BG [Vasilyev et al. 2017].

Cth-element and elements RC1-4 calculating the heat transfer rate.

3 VALIDATION OF PEM FUEL CELL BG

Before using the developed PEM fuel cell BG in fault diagnosis, the performance of the developed BG should be validated.

In this study, the Electrochemical Impedance Spectroscopy (EIS) is obtained from the test to determine the model parameters including electrical resistance and double layer capacitance. With the determined model parameters, the polarization cure is obtained from the model and compared with those from the test, the comparison results are depicted in Figure 7.

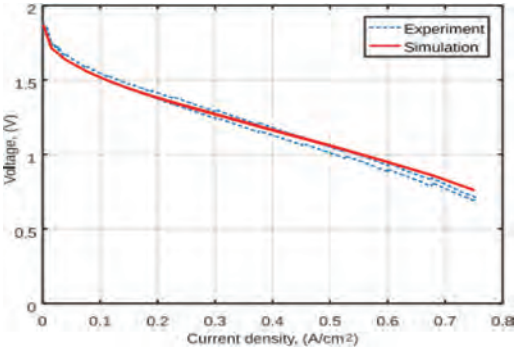

Figure 7. Comparison results of polarization curves between the model and test [Vasilyev et al. 2017].

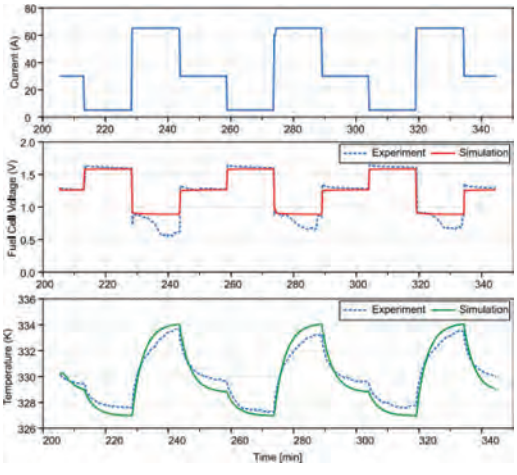

Figure 8. Comparison results of cell voltage and temperature curves between the model and test [Vasilyev et al. 2017].

It can be seen from Figure 7 that the overall polarization from the model can match the tested data with good accuracy, and the deviation becomes slightly larger in the region of concentration loss with current density higher than 0.55 A/cm^2. The reason is that the model doesn't fully consider the electrode porosity and effects of liquid water formation within the cell.

Furthermore, a test with varying current densities is performed, and the cell voltage and temperature are obtained and compared with those from the developed model. Results are shown in Figure 8. It can be seen that the developed model can capture the PEM fuel cell behavior with good quality, which paves the way for using the developed model for the following analysis.

4 USE OF FUEL CELL BG MODEL FOR FAULT DIAGNOSIS

4.1 *Simultion of PEM fuel cell failure mode*

In this study, dehydration is simulated and the simulated data is used to test the performance of data-driven fault diagnostic approaches. The reason for selecting dehydration is that it is a commonly experienced failure mode in PEM fuel cell systems due to unbalanced water management. Moreover, dehydration is not usually performed in testing as it will cause permanent damage of the membrane. Therefore, with the developed PEM fuel cell BG model, the performance of data-driven approaches can be investigated more efficiently in terms of both computational time and financial cost.

In the simulation, the constant current (70 A herein) is applied to the developed model, and after normal operation of a certain time, the relative humidity at the anode side is reduced from 100% to 50% at 500h, which can cause decreased water contents within the cell and thus dehydration. Figure 9 depicts the variation of anode relative humidity, voltage, and stack temperature.

It can be seen from Figure 9 that when operated at the constant condition, PEM fuel cell voltage will decay linearly, representing the degradation phenomena due to fuel cell aging. Moreover, with decrease of anode relative humidity, stack voltage shows a more steep decrease, and the increased stack temperature can be observed more clearly, this is due to the reduced water content within the cell from the reduced relative humidity of inlet gas.

4.2 *Data-driven fault diagnostic approaches*

In this study, several fault diagnostic approaches have been applied to the simulated data for both normal and dehydration conditions. As data from

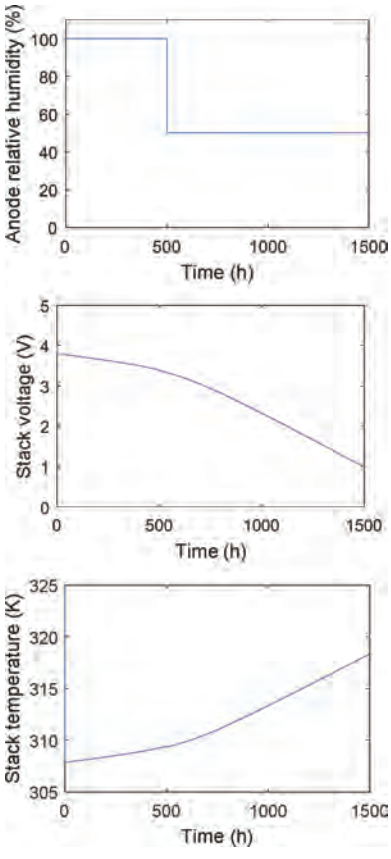

Figure 9. Simulation results of anode relative humidity, fuel cell stack voltage, and stack temperature.

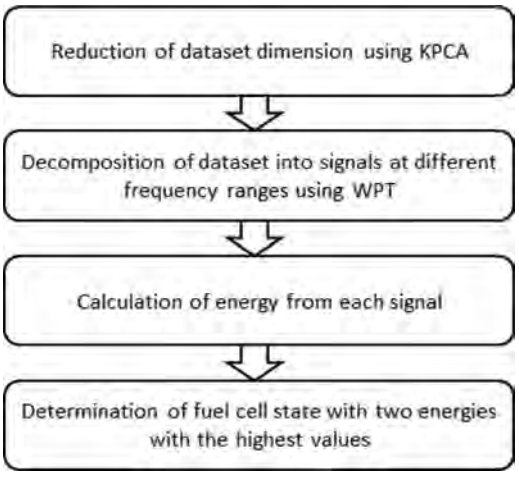

Figure 10. Flowchart of PEM fuel cell fault diagnosis using data-driven approaches.

Table 2. Sensor measurements used in the analysis.

Sensor	Unit	Sensor	Unit
Voltage	*V*	Air inlet flow	*l/min*
H2 inlet flow	*l/min*	Air inlet pressure	*bar*
H2 inlet pressure	*bar*	Air outlet pressure	*bar*
H2 outlet pressure	*bar*	Air inlet temperature	*K*
H2 inlet temp	*K*	Stack temperature	*K*

multiple sensors are simulated, the approaches reducing the size of dataset is applied, Kernel Principal Component Analysis (KPCA) is selected herein due to its better performance in non-linear systems. After that, wavelet packet transform (WPT) is applied to decompose the original signal into different frequency ranges, from which the features are constructed. The features with the highest values are used in this case to discriminate the PEM fuel cell states. This flowchart is illustrated in Figure 10. It should be noted that the selected diagnostic framework is effective in identifying various failure modes in PEM fuel cell systems [Mao et al. 2017]. More details about these approaches can be found in previous studies [Mao et al. 2017, Placca et al. 2010].

4.3 *Diagnostic results*

In the analysis, simulation data from multiple sensors are used, which are listed in Table 2. The reason of using multiple sensors is that multiple sensors can provide complementary information about the PEM fuel cell performance, which should be included in order not to lose useful information, without further interpretation of the sensor measurements.

KPCA is applied to the dataset including measurements from sensors (listed in Table 2) to project the dataset into the two principal directions. It should be noted that the simulated data shown in Figure 9 is divided into 2 parts representing different states (normal and dehydration), and each part is further divided into several segments for the following analysis.

WPT is then applied to each segment data from KPCA over 3 levels, the extracted wavelet coefficients are used to re-construct the signals at different frequency ranges, from which the signal energies are calculated. Figure 11 depicts the energy distribution at both normal and dehydration states.

It can be seen from Figure 11 that the energy shows similar distribution at different PEM fuel cell states, and the first few highest energies are

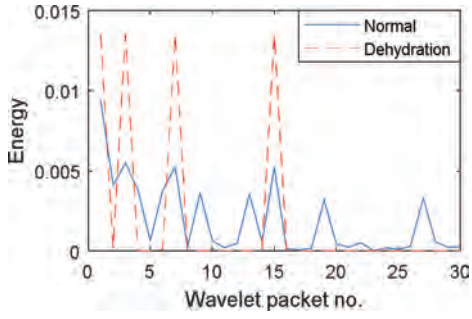

Figure 11. Distribution of energy from signals at different frequency ranges.

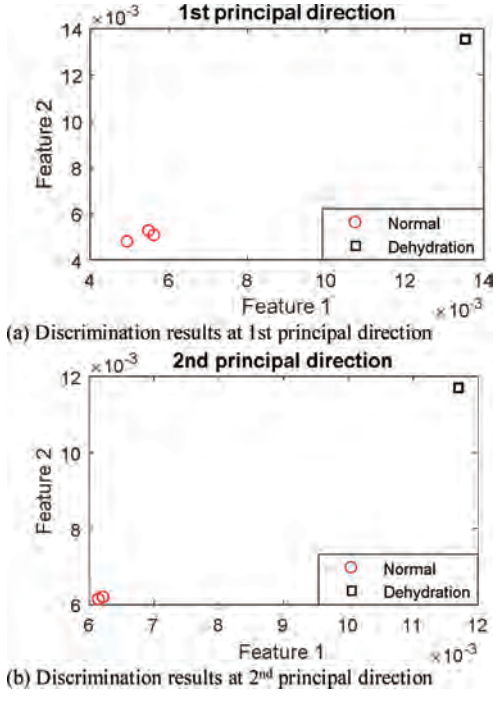

Figure 12. Discrimination results using selected features.

located at the same wavelet packet. Therefore, the first two highest energies are used as features herein for the discrimination. The results are shown in Figure 12. Since KPCA is used to project the original dataset into the two principal directions, the discrimination results at these two directions are depicted. It can be observed that the dehydration state can be discriminated with good quality from the normal state, indicating the applied data-driven approaches can identify the PEM fuel cell dehydration accurately.

5 CONCLUSIONS

In this paper, the PEM fuel cell model is developed using the bond graph technique, which can represent the various behaviours in PEM fuel cell system. The model parameters are determined using the collected EIS from the PEM fuel cell, and the performance of developed model is validated using the fuel cell test data at different conditions.

With the developed PEM fuel cell bond graph model, the data from different fuel cell failure scenarios can be simulated. In this study the fuel cell dehydration is simulated, and the simulated data is used in the data-driven fault diagnostic approaches. Results demonstrate that the used approaches can discriminate the dehydration state with good quality. In the future study, more fuel cell failure modes will be simulated using the developed model, and the capability of various fault diagnostic approaches in identifying these fuel cell faults can be fully investigated.

Risk assessment and the influence of new information

Tor Stålhane
Norwegian University of Science and Technology, Trondheim, Norway

Stig Ole Johnsen
Norwegian University of Science and Technology, Trondheim, Norway
SINTEF Safety and Reliability, Norway

ABSTRACT: We have run experiments with 17 groups with three participants—to see how they assess hazards, probability and possibility to avoid dangers. We considered two scenarios taken from ISO 15998-2. We used a three-step process—each participant read the scenario and assesses consequence, probability of the event and the possibility of avoiding the hazard. Then they wrote down their rational for the assessments and adjusted. They then presented their rationales to the other two members and made final assessments.

We discuss the results: what rationale made participants change their assessments, and which parameters were changed? As in earlier experiments, risks are overestimated. We need to improve the way we describe hazardous scenarios so that we can get more realistic risk assessments.

There exist several guidelines for writing scenarios, and they are followed by ISO 15998-2 but this did not seem to help. We suggest some new guidelines for scenario description.

1 INTRODUCTION

Risk assessment is usually done by one or more persons, based on a scenario description. No feedback or rational is needed. We would like to examine how the assessment process will work if the participants need to write rationales for their decisions and how the assessments process will be affected by hearing other persons' rationales.

By studying how the assessment process is influenced by other peoples' rationales and studying which parameter's value is influenced, we can get a better understanding of the involved persons' assessment process and come up with a better way to construct scenarios and procedures for risk assessment.

2 RELATED WORK

There is a lot published around problems pertaining to risk assessment. A large part of these papers appears in the field of psychology. The papers cited below is just a small sample of the published material.

Kahneman (2011) has done research on human reasoning. One result is of special interest here—the strong tendency always to assume the worst consequences. His observation is worth quoting in full: "*The danger is increasingly exaggerated as the media compete for attention-grabbing headlines. Scientists and others who try to dampen the increasing fear and revulsion attract little attention, most of it hostile: anyone who claims that the danger is overstated is suspected of association with a 'heinous cover-up*'".

Sandeman et al. (1998) have done research on risk communication and found that you get a better assessment of risks by enabling the respondent to relate it to a "normal" situation—a situation that the respondents already were comfortable with.

Li and Wang (2010) report valuable experience with using the Delphi process in a risk analysis process. A more complete evaluation of the Delphi method used in risk assessment is given by Zaloom and Subhedar (2009) who report an experiment using the method to assess the likelihood of 10 identified risk scenarios. Unfortunately, after the second round of the process, there was still only one risk scenario where the participants agreed and they ended up using the score averages as the result.

Scenario construction is an important part of risk assessment. One way of writing and analysing scenarios is presented by Whitney and Thompson (2009). They argue that a useful scenario should contain information related to who, what, why, when, where and how. In addition, it is not enough to assess consequences, probability and how easy it is to avoid the danger. It is also necessary to assess the probability of the scenario.

Last, but not least, it is important to remember that all experiments and case studies into the

domain of hazard assessment have shown that there is no significant difference between laypersons and experts. See e.g. Rowe and Wright (2001) for an extensive discussion of this topic.

3 THE EXPERIMENT

3.1 *The experiment layout*

Input to the experiment was two scenarios for earth-moving machinery. These scenarios, and seven others, have earlier also been used in a set of experiments reported by Stålhane and Malm (2016). The scenarios are taken from ISO 15998-2:2012. According to the standard, the two chosen scenarios—later referred to as case 4 and case 5—should be assessed as needing performance level (PL) c and e respectively. Average probability of dangerous failure per hour (1/h) for PL c is $> 10^{-6}$ to $< 3 \times 10^{-6}$; for PL e $> 10^{-8}$ to $< 10^{-7}$.

The scenarios are described as follows:

- Case 4: Articulated Wheeled Loader. Machine boom moves without command. Operator is not compelled to be in the operator station. Operator may be greasing machine or otherwise near moving parts. Operator typically in harm's way much less than 10% of time. If operator is near moving part, it may be very difficult to get away quickly enough to prevent injury.
- Case 5: Articulated Wheeled Loaders < 40 km/h. Complete loss of Primary Steering and Emergency Steering (Either steers un-commanded or not at all while propelling). Operator has braking to stop the machine. Operator is not warned prior to loss of steering. Potential to hit higher speed vehicle with multiple passengers' Multi-passenger vehicles in the path of machine is much less than 10% of time. Operator can stop the machine. Vehicle may be able to avoid the loader.

To check the quality of the two scenario descriptions, we run a set of readability checks—Adobe (2007). Most of the readability scores—e.g., the Gunning Fog index and the Flesch Kincaid Grade level gave approximately the same results for both scenarios. The main difference was observed in the Flesch Reading Ease index where 70 to 60 indicates that the text is easy to read while 50 to 40 is difficult. Case 4 scored 41 and case 5 scored 59 indicating the case 4 is more difficult to understand.

The experiments were performed with 51 participants in 17 groups with three persons in each group. Each group did the experiment under the supervision of the researcher. The participants were given the scenario descriptions shown above and went through a three-phase process which was a simplified version of the Delphi process—see Linestone and Turoff (1975). The process used was as follows

1. Phase 1: Read the scenario and the scoring rules for the following three parameters: event consequence (S), event probability (F) and the possibility of avoiding the danger caused by the event (P). Descriptions for scoring of the parameters were taken from ISO 13849-1:2015. Based on the scenario description, they decided which value to assign to each of the three parameters.
2. Phase 2: Write down the rational for the three values assigned. During this process, they were free to change their assessment if they felt that the rational did not fit their previous assessments.
3. Phase 3: Read the rationales aloud to the rest of the group. Each participant was then free to change his scores. At last, they wrote their new assessments on the form and returned it to the researcher. There was no pressure or incentives for the group to reach a final agreement.

The process described above gave us total of 51 answers, which were registered in an Excel sheet. Each answer contained the participant's assessment of S, F and P for each phase—a total of 153 values. The response set for each participant contains three sets of assessed S, F and P values plus the rationales for each choice.

3.2 *The assessment model*

The assessment model—from risk parameters (S, F and P) to performance level (PL) or safety integrity level (SIL) are defined by a decision tree. For each of the risk assessment parameters S, F and P, an assessor (e.g., the participants in our experiment) can choose between two values as shown below:

- *Severity of injury*. S1 Slight injury – bruise. S2 Severe injury – amputation or death.
- *Frequency of exposure to injury*. F1 Seldom. F2 Frequent to continuous.
- *Possibility of avoiding the hazard*. P1 Possible. P2 Less possible. Based on the speed of approach of the hazard and the ability of the operator to avoid the hazard. (If the operator can avoid the hazard you would choose P1).

4 DATA ANALYSIS

We will need to discuss whether differences are statistically significant when discussing differences between persons or groups. We have approached this by using a simple approximation to the standard uncertainty for probability differences. The equation that we start with is

$$d^2 = u_{\alpha/2}^2 p(1-p)/N \quad (1)$$

Here p is the probability of the event under consideration and N is the size of the sample. Since p(1-p) is always less than or equal to ¼ and $u_{\alpha/2}$ for 5% significance is approximately 2, we get the simple approximation

$$d^2 = 1/N \quad (2)$$

Thus, for differences between the 17 groups, the uncertainty is 0.24 (4 groups) and for differences between the participants, it is 0.14 (7 participants).

4.1 *An exploratory case*

The experiments where not done to accept or reject one or more predefined hypotheses. Neither did we start with a set of research questions. What we did was to run the experiments to collect data and then perform an explorative data analysis—looking for what the data might tell us. For this reason, the results are not final. However, they will serve as a starting point for hypothesis and subsequent experiments. Throughout this paper, when we say, "the data shows that…" we mean "the data indicates that…"

We got the following data from the experiment (1) the participants' scores for S, F and P, (2) their rational for choosing the values, and (3) how these values changed when they write down a rational for their decisions and share this information with the other persons in their group when assessing the three parameters. Since we have the rationales we connect them to the information provided by the scenario descriptions—e.g., which parts did they use and what was used in addition.

4.2 *Different processes—different results*

Earlier, a total of nine cases—including case 4 and case 5 used in this experiment—have been assessed earlier, see Stålhane and Malm (2016). Most of assessments for all cases, irrespective of the results required by the standard, were S = 2, F = 1 and P = 1.

For case 4 we get S = 2 and F = 1, while the split between P = 1 and P = 2 is 67% versus 33%.

When we introduced the need to write a rational and use it as feedback to the other participants in the group, most of assessments, both for case 4 and case 5 changed to S = 2, F = 1 and P = 1 or P = 2. As we see, the split between P = 1 and P = 2 is 44% versus 56%. The results for case 5 is almost identical.

The feedback cannot be the only cause of this change since the decision tree structure is almost the same for phase 1 and phase 3. The only case 4 change between phase 1 and phase 3 are that we in phase 1 has 45% 2, 1, 2 and 55% 2, 1, 1, while we in phase 3 have 57% 2, 1, 2 and 43% 2, 1, 1. These differences are not significant at the 5% level. Thus, the main reason for the changes is the requirement that the participants must write rationales. In addition, we should note that this change only affects the P-parameter.

4.3 *Documentation of the rationales used*

Different participants used various parts of the scenario description when writing their rationales. If they found the scenarios to lack information, they used the information in the scenarios plus their own experience to make their own rationales. Tables 1 and 2 show the used information from the scenarios while Tables 3, 4 and 5 show information used but not found in the scenario descriptions.

For case 5, we see that two thirds of the participants used one or more terms from the

Table 1. Part of scenario information used in case 4.

Case 4				
Scenario info used	S	F	P	Sum
Machine boom moves without command	4	1	2	7
Operator may be near moving parts	17	9	15	31
Operator in harm's way less than 10% of time	2	14		16
Near moving parts = > difficult to get away quickly	3	1	21	25
Persons (#)	24	23	26	
Persons (%)	48	48	52	

Table 2. Part of scenario information used in case 5.

Case 5				
Scenario info used	S	F	P	Sum
Speed less than 40 km/h	27	2	9	38
Complete loss of primary and secondary steering		11	5	16
Breaks are working OK	2	3	22	27
No warning prior to loss of steering	1			1
May hit high speed vehicles with multiple passengers	10	1	1	12
Multi-passenger vehicle in path less than 10% of time	1	10		11
Operator can stop machine	4	3	4	11
Vehicle may be able to avoid the loader		3	15	18
Persons (#)	38	31	39	
Persons (%)	73	61	75	

Table 3. General information used to assess S in cases 4 and 5.

S – event consequences		
Rationales	Case 4	Case 5
Safety instructions	1	
Crushed limbs	14	4
Machine turned off	1	
Strong hydraulics	2	
Heavy parts or machine	8	6
Person run over	3	
Hit someone		3
Persons (#)	29	13
Persons (%)	57	25

Table 4. General information used to assess F in cases 4 and 5.

F – event probability		
Rationales	Case 4	Case 5
Happens seldom	8	11
Operator mindful of danger	10	1
Regular maintenance	2	2
Safety mechanisms	4	
Harm other vehicles		3

Easy to avoid	5	2
Severe injuries	2	4
Cannot stop the machine		3
Persons (#)	24	13
Persons (%)	48	26

scenario descriptions when writing a rational for their choice of scores for S, F and P. As for case 4, there are no statistically significant differences between the three parameters at the 5% level. The differences between the two cases are, however, statistically significant at the 5% level. The only part of the case 5 scenario that is not used is "*Either steers un-commanded or not at all while propelling*".

For case 4, we see that half the participants used one or more terms from the scenario descriptions when writing a rational for their choice of scores for S, F and P. There are no statistically significant differences between the three parameters at the 5% level. The only part of the scenario that is not used is "*Operator is not compelled to be in the operator station*".

Several parts of the scenario descriptions are used for several parameters—see Tables 1 and 2. For case 4 the statement "*Operator may be near moving parts*" is used for all three parameters.

The Tables 3 to 5 show the rationales which are not taken from the scenario descriptions. The terms used have been extracted from the rationales and grouped under a set of generic terms—e.g., all rationales related to safety instructions and safety procedures have been grouped under the term "Safety instructions".

That three participants used "Cannot stop the machine" as a problem for case 5 is strange, since the scenario explicitly states that "The operator can stop the machine".

We went through all rationales to look for rationales used for the wrong parameter—i.e., the whole or a part the rational indicates one parameter while it is used for another. Examples of wrong / misplaced rationales:

- **S** (P): If the operator is in the danger zone, he may be seriously injured if he is crushed by the machine
- **S** (F): If an accident occurs with a big and heavy machine—e.g. get caught in moving parts—the probability for severe damages is large
- **F** (P): The operator is not close to dangerous parts of the machine very often
- **P** (F): Daily inspection of hydraulics will enable us to discover problems before an accident. Routines

When we went through all the rationales, we found the following:

From the table, we see that the most frequent wrong or mixed rationales are related to F and P, while the next most frequent is between S and P.

4.4 *Parameter changes*

The last piece of information that we need is the changes—when and where. This is shown in the two tables below.

There are 41 changed assessments from phase 1 to phase 2 and 32 changers in assessment from phase 2 to phase 3. The difference between the two cases is statistically significant at the 5% level.

The agreement for all parameter assessments improved from phase 1 to phase 3. However, the only statistically significant differences are between

Table 6. Wrong/mixed parameter rationales for cases 3 and 5.

Case 4		Case 5	
S	P = 3 SP = 7	S	P = 4 SP = 7
F	P = 20 FP = 13	F	P = 9 FP = 14
P	S = 1	P	F = 1
Sum	44	Sum	35
%	28	%	22

Table 7. Parameter assessment changes in case 4.

Case 4			
Phase 1 to Phase 2		Phase 2 to Phase 3	
S	5	S	0
F	3	F	3

S	2	S	0
F	18	F	18
P	6	P	2
Sum	26	Sum	20
Percentage of total	52	Percentage of total	40

phase 1 and 3 for S and P in case 4. For case 5, there are no statistically significant differences.

4.5 *Summary of the data analysis*

Based on the tables above, we formulate the following exploratory research questions—ERQ:

1. Which parts of the scenario descriptions are used for the risk assessment?
2. From where do the participants who do not use the scenarios take their information?
3. Which assessments are stable and which do change?
4. How often do the participants assess two or more factors using the same rational?
5. Based on the findings from these ERQ, how can we improve the assessment process and the standard's scenario descriptions so that they are used in a more efficient way?

ERQ1: Roughly 50% of the case 4 assessments and 75% of the case 5 assessments used only terms from the scenario descriptions—see Tables 1 and 2. The most commonly used terms are:

- Case 4, S: "Operator may be near moving parts", F: "Operator in harm's way less than 10% of time" and P: "Near moving parts = > difficult to get away quickly"
- Case 5, S: "Speed less than 40 km/h", F: "Speed less than 40 km/h" and "Multi-passenger vehicle in path less than 10% of time" and for P: "Breaks are working OK".

One possible reason why the case 5 assessments used more scenario description terms that the case 4 may be that this description is longer – 76 words—while case 4 has only 58 words.

ERQ2: Those who also used other terms than those used in the scenario, used terms related to the machine, the environment and the machine's behaviour. The same terms are considered important for both cases e.g., "Crushed limbs" or "Heavy parts or machine" for consequences.

ERQ3: For case 4, approximately a third of the assessments have been changed. For case 5 approximately half of the participants changed their mind one or more times during the three phases. There are significant differences between the two cases. For case 4, P is changed most often while for case 5, F is changed most often. The differences between case 4 and case 5 are statistically significant at the 5% level.

ERQ4: We see from the data that more than half of all assessment rationales for S, F or P mixed two parameters—most commonly, they mixed F and P. However, a considerable amount of the participants also mixed S and P. The participants' logic is clear and can be split into the following:

- For S: since it is easy to avoid the hazard, the consequences are not severe
- For F: since it is easy to avoid the hazard, it cannot happen so often

ERQ5: Based on this summary we suggest three temporary conclusions:

- Differentiating between P and the two other parameters is difficult for the participants. The possibility to avoid the danger is used to influence the assessment of the event frequency and the seriousness of the consequences.
- A considerable part of the participants did not think the information given in the scenarios is sufficient or relevant for risk assessment.
- Most participants always consider the worst consequences.

These temporary conclusions lead us to the next conclusion, namely that standards should use a

different scenario description and a different decision tree to help the participants to arrive at more consistent hazard assessments.

The terms used in the assessment rationales but not present in the case descriptions, are the following:

- Case 4 and 5: crushed limbs (S), heavy parts (S), heavy machinery(S), happen seldom (F), safety instructions (P), easy to avoid (P)
- Case 4: operator mindful of danger (P)
- Case 5: cannot stop the machine (P)

Some of these rationales are just derived from the information found in the case description—e.g., crushed limbs, heavy parts and heavy machinery. These words are warning signal words—Hellier (2000)—to add emphasis to the case description. Others are contradicting the case description—e.g., cannot stop the machine.

5 ASSESSMENT CHANGES

The most important observation related to the assessments done in this experiment is the misplaced assessment rationales, especially for F and P. The discussions in chapter 4.2 and 4.3 lead us to the conclusion that people are not good at separating dangerous event probability and the possibility of avoiding dangers.

Thus, instead of the current three-level decision tree used in the standard we suggest that the standard should use a two-level decision tree. As before, S is the consequences of the dangerous event while P should be defined as the probability that a person is harmed. This will include both the event probability and the escape opportunities. Based on this, we suggest the following ratings:

- P = 1: we will almost surely avoid the consequences
- P = 2: we might avoid the consequences
- P = 3: we will most likely suffer the consequences

As noted earlier, there are more changes to assessment between phase 1 and phase 2 than between phase 2 and phase 3. The significant difference between the two transitions is that in the first phase, each participant first writes down his assessment and then wrote down the rational.

There are presumably two mechanisms at work when a participant changes one or more parameter assessments: (1) one or two of the other participants use a negative term when describing their parameter choice rational or (2) he sees that the rational he wrote does not support his assessment. In many cases, both for laypersons and for experts, the assessment is done based on intuition—see Freeman et al. (2012). The rational is written after the decision and is thus an attempt to justify this decision—see e.g., Pigozzi et al. (2009).

26 of the changes caused a parameter to be changed from 1 to 2 (a parameter was changed from 2 to 1 in only six cases). In these six cases, the changes occurred after phase-2 and in all cases the parameters were changed back to 2 again in phase-3. Thus, in no case did any participant in the final case move any parameter assessment from 2 to 1. This agrees with the general observation that one negative statement wins over several positive ones—see e.g., Baumeister et al. (2001). The research of e.g., Shang et al. (2015) show that "people are likely to direct more attentional resources toward high-hazard stimuli compared to low-hazard ones", thus supporting Baumeister's conclusions.

The P parameter (probability of avoiding the hazard) is the one changed most frequently – 11 times for case 4 and seven times for case 5. This fits well with our observation that P is the parameter that the participants had the most problem with. The mixing of F and P assessment gets even more problematic if we consider it together with the effect of a negative assessment. This may cause a negative P assessment to change a positive F assessment to a negative assessment and vice versa.

6 ANOTHER WAY TO DESCRIBE SCENARIOS

6.1 *The scenarios revisited*

If a scenario shall be useful in risk assessment, it must include information on the event– what went wrong– possible consequences– and how can we avoid or reduce these consequences? To check this against the scenarios used here and the rationales used by the participants we will first restructure the scenarios so that each argument is separated and tagged with the relevant part of the risk assessment – S: event consequences, F: event probability or P: avoidance possibility. The result is shown in the two lists shown below.

Case 4: Articulated Wheeled Loader.

- Machine boom moves without command – S, F
- Operator is not compelled to be in the operator station – P
- Operator may be greasing machine or otherwise near moving parts – P
- Operator typically in harm's way much less than 10% of time – P
- If operator is near moving part, it may be very difficult to get away quickly enough to prevent injury – P

Case 5: Articulated Wheeled Loader

- Speed < 40 km/h – S, P

– Complete loss of Primary Steering and Emergency Steering (Either steers un-commanded or not at all while propelling) – F
– Operator has braking to stop the machine – P
– Operator is not warned prior to loss of steering – P
– Potential to hit higher speed vehicle with multiple passengers – S
– Multi-passenger vehicles in the path of machine much less than 10% of time – P
– Operator can stop the machine – P
– Vehicle may be able to avoid the loader – P

The most important thing to note is that most statements/sentences are about getting away or preventing harm—four out of five for case 4 and five out of eight for case 5. Thus, there is little focus on the event probability (F) and much focus on the possibility for getting out of harm's way (P). This is another factor that can explain the large portion of P-related rationales for assessment of the F parameter.

6.2 *How were the scenarios used in the standard?*

The scenarios used in the standard can be used in two ways. They can be considered as reference scenarios – if your case is like this, then the PL should be the same as the PL for this scenario in the standard. The other way is to use it to indicate which factors are important in the risk assessment process – see Tables 1 and 2. Thus, the information listed in Tables 3–5 is indicators that the participants found the information in the scenarios to be wanting. Our experiments have shown that the participants in many cases need more or different information than what the scenarios provide. The most used pieces of information not in the scenario descriptions and not derived from this are

– Consequences: person run over – used three times
– Equipment descriptions: safety mechanisms – used four times
– Operator description: mindful operator, safety instructions – used 20 times

The escape or avoid part (P) of the risk assessment process will be greatly improved if the scenarios were accompanied by a preamble giving information about operator courses, protective gear and safety instructions.

6.3 *A better way to construct scenarios*

A good method for construction scenarios is the GMA approach. However, using GMA may lead to many possible scenarios and it is not always clear how we can reduce this to a practical volume. Another, event-driven method for constructing scenarios is the STEP process—Hendrick (1987). However, this method is difficult to use with the scenarios used in the relevant standard – e.g., it is difficult to model statements such as "*Operator typically in harm's way much less than 10% of time*".

A doable alternative is to use the work of Whitney and Thompson (2009). They have suggested a checklist for scenarios, which runs as follows:

– Who: groups, individuals and organizations involved
– What: activity, objectives and targets
– Why: motivation of person or organizational
– When: triggering events, time requirements, opportunity
– Where: city, building, institutions or road
– How: approaches required related to technology, funding or know-how

We might think that the quality of the scenarios increases with the amount of available information. However, Oskamp (1965) has published both own results and meta-studies that seem to confirm that "*Beyond some early point in the information-gathering process, predictive accuracy reaches a ceiling*". Oskamp's studies are related to psychological diagnoses but the results are general enough to apply also to our case. Thus, we need to keep the amount of information low so that we do not water down the few, important pieces of information.

Since we need to assess three parameters, we need to provide sufficient information for the assessment of each of them. Sticking to the schema of Whitney and Thompson (2009), we must decide which three of the checklist items that are most important for each parameter. We suggest the following

S: Event consequence:

– **Who** is or could be involved?
– **What** may happen or is happening?

F: Event probability:

– **What** may happen or is happening?
– **Where** is the event happening?
– **How** – which approach is taken or required to initiate the event?

P: Possibility to escape consequences:

– **Who** is or could be involved?
– **How** – which approach is taken or required?
– **Where** is the event happening?

When we go through the two scenarios used in our experiments, we see that both scenarios lack information needed to assess probability – i.e., how probable this scenario is.

If we apply the checklist of Whitney and Thompson to the two cases we have considered in this experiment, we get the following results:

Case 4: Articulated Wheeled Loader.

- Machine boom moves without command – S, F **What.**
- Operator is not compelled to be in the operator station. Not used during assessment.
- Operator may be greasing machine (implicates "near moving parts") or otherwise near moving parts – P **What, Who**
- Operator typically in harm's way much less than 10% of time – P **Who, When**
- If operator is near moving part, it may be very difficult to get away quickly enough to prevent injury – P **Who, Where, When**

Case 5: Articulated Wheeled Loader

- Speed < 40 km/h – S, P **What**
- Complete loss of Primary Steering and Emergency Steering (Either steers un-commanded or not at all while propelling – not used during assessment) – F **What**
- Operator has braking to stop the machine—P **Who, What**
- Operator is not warned prior to loss of steering – P **Who, What, When**
- Potential to hit higher speed vehicle with multiple passengers – S **What, Who**
- Multi-passenger vehicles in the path of machine much less than 10% of time – P **What, Where, When**
- Operator can stop the machine – P **Who, What**
- Vehicle may be able to avoid the loader – P **What**

Note that F and P share the keywords "where" and "how". In addition, S lacks "who"-information, which is important to understand the consequences. F does in both cases lack information on "where" and "how", which are important to understand the failure mechanism and thus assess the event probability. P lacks information on "what" and "how", which makes it difficult to assess the escape probability.

Tables 3, 4 and 5 shows information added by the participants during their assessment. The information added are the same for both cases. If we apply Whitney and Thompson's key words to the information in the Tables 3, 4 and 5 we find that for S we can add "what" and "who", while we for F and P can add "when", "who" and "what". Thus, for both cases we still miss "how" for F and P and "where" for P.

Suggested additions to take care of the "where" aspects for the two cases are e.g., "on a construction site" for case 4 and "on a public road" for case 5.

An additional challenge when writing scenarios is the choice of words. Our will have an important influence on how much and what kind of attention each part of a scenario description will get. In the end, it will also decide the assessment of PL or SIL.

7 THREATS TO VALIDITY

The main threats to validity are the small sample and participant motivations. We will give a brief discussion on how these two threats may influence our temporary conclusions.

We chose the two cases 4 and 5 for the experiment to get a large distance in protection levels. Case 4 should have PL c while case 5 should have PL e—both according to ISO 13849-1:2015. However, just two cases are way too small a sample for making a statistically significant statement about the Delphi method when it comes to PL assessment. On the other hand, 51 participants assessing two cases is still enough to say something about the general trends, such as mixing P and F, and the influence of the general observation that "bad is stronger than good".

The questions related to participants' motivation is more serious. People who do this for real have a strong incentive to get it right while the students are just motivated to get the job done because that is what they promised the researcher. Thus, we cannot be sure that they "really put their soul into it".

Even so, it is our opinion that the data are sufficient for doing some exploratory data analysis and to come up with some issues that should be considered more seriously in future research.

8 CONCLUSIONS

Based on the results of this small experiment, we have tentatively identified the following potential problems with the way hazard analyses are performed:

- Whatever the scenario description, people mostly goes for the worst case because "***it just might happen***" and "Bad is stronger than good". Thus, we should ***not*** use the Delphi process to assess risks. Relevant empirical data might improve this situation.
- Many persons have problems with keeping separate the dangerous event probability and the probability of avoiding harm.
- Those who write scenarios for risk assessment – e.g., for standards – should consider available rules for writing efficient scenarios – e.g., considering the rules of Whitney and Thompson (2009) and readability checks, Adobe (2007).

These problem areas need to be addressed when writing a scenario intended for risk assessment. The first problem is the most serious and difficult one because it is related to psychology and not to any technical problem. The two other ones can be solved by providing relevant information to the assessors.

Risk assessment in construction projects with the use of neural networks

L. Giannakos
School of Science and Technology, Hellenic Open University, Patra, Greece

Y. Xenidis
Department of Civil Engineering, Aristotle University of Thessaloniki, Thessaloniki, Greece

ABSTRACT: The inherently complex nature of risks interdependencies in construction projects coupled with incomplete data records during projects development often results to inaccurate assessments. This paper showcases the use of neural networks for risk assessment in construction projects. A detailed literature review identifies the different types and training methods of neural networks as well as the respective tools applicable to construction projects risk management. Based on these findings, the paper presents the development of a specific neural network that partially assesses occupational risk in a construction engineering project. The proposed neural network is trained with metadata from previous risks assessments. The modeling of the network is realized through two software tools, in order to identify potential difficulties in the modeling process as well as potential deviations in the assessments' outputs. The main conclusion is that neural networks are reliable for conducting risks assessments that realistically integrate risks interdependencies in complex problems.

1 INTRODUCTION

Neural Networks (NNs) are inspired by the biological neural network of human brain (Haykin, 2008). According to Haykin (2008): "*A Neural Network is a massively parallel distributed processor made up of simple processing units that has a natural propensity for storing experimental knowledge and making it available for use. It resembles the brain in two respects: 1) Knowledge is acquired by the network from its environment through a learning process. 2) Interneuron connection strengths, known as synaptic weights, are used to store the acquired knowledge*."

Three basic types of NNs' architecture are recognized (Haykin, 2008): 1) single-layer NN, 2) Multi-Layer NN (MLNN) and 3) recurrent NN. The learning processes through which NNs function can be categorized are (Haykin, 2008): 1) supervised learning, 2) reinforcement learning and 3) unsupervised learning. Usual basic problems that NNs are capable of dealing with are fitting (or function approximation), pattern recognition and association, and clustering and prediction, all applicable to many scientific fields such as automotive, financial, medical, robotics, telecommunications and management (Prieto et al., 2016).

The ability to use NNs either individually or in combination with other Artificial Intelligence (AI) techniques, such as Expert Systems, in construction industry and construction project management has been recognized since the beginning of 1990 (Moselhi, 1991). Currently, alternative tools of traditional methods based on AI techniques, such as NNs, are widely applied in engineering and construction industry (Paliwal & Kumar, 2009) and with a variety of ways in construction project management such as assessing project success and identifying critical success factors of the project, planning, estimating time and cost and managing risks (Magaña Martínez & Fernandez-Rodriguez, 2015).

Construction projects are featured by complexity and incomplete data records during development, thus affecting the capacity of a construction organization to conduct a credible risk assessment for every new project in hand. Furthermore, the inherently complex issue of risks interdependencies has led so far to approximate assessment approaches or to assessments based on simplistic assumptions that only remotely represent reality. This paper proposes the use of NNs for risk assessment in construction projects through the presentation of a specific application of a NN that partially assesses occupational risk in a construction engineering project.

2 METHODOLOGY

The paper, first, presents very briefly the basic characteristics of NNs to demonstrate the advantages of using them for risk assessment. Then, it investigates the existing applications of NNs in construction project risk management, in order to document their appropriateness for use in complex nonlinear problems such as construction projects. To this end, a detailed literature review identifies the different types and training methods of NNs that are applicable in construction projects risk management as well as of the respective tools that are available for real applications.

Based on the findings from the literature review, the paper, then, presents a specific application of a neural network that partially assesses occupational risk in a construction engineering project. The training of the proposed NN is based on metadata retrieved from a compilation of available data from previous risks assessments. The modeling of the network is realized with the help of two different software tools, namely Palisade's NeuralTools (Palisade Corporation, 2015) and Mathwork's Neural Network Toolbox, in order to identify potential difficulties in the modeling process as well as potential deviations in the assessments' outputs.

3 REVIEW OF NEURAL NETWORK APPLICATIONS IN CONSTRUCTION PROJECT RISK MANAGEMENT

As mentioned in Section 1, the ability to use NNs in the construction industry and construction project management has been recognized since the beginning of 1990. One of the first NN applications in construction project management is authored by Boussabaine (1996) who recognized the usefulness of NNs in construction project management and in risk analysis specifically. Especially in construction project risk management, previous NN applications focus on various topics as presented in Table 1. It is noted that even more applications than those presented in Table 1 were identified on the analysis of claims from legal disputes as well as of contractor's performance.

Especially for construction project risk management, the first application of NN was, probably, carried out by Sanchez (2005) with the aim of quantifying total risk in economic terms. Wen (2010) developed a total risk assessment model, embedded with NN, Genetic Algorithm (GA) and Rough Set Theory (RST) techniques, for construction projects. Zhu et al. (2011) implemented NN to perform analysis and evaluation of project cost risk and identification of critical factors. Chenyun & Zichun (2012) developed a Back-Propagation (BP) NN to assess risks in the construction phase of an expressway.

Concerning claim causing assessment, Al-Sobiei et al. (2005) developed two models for predicting the risk of contractor default in construction projects utilizing NN and GA techniques. Chau (2007) predicted the outcome of construction claims through the adaptation of a Particle Swarm Optimization (PSO) NN, trained with data from cases and past court decisions. Hosny et al. (2015) developed a NN-based predictive and decision-awareness framework for construction claims using backward optimization. Gholhaki et al. (2016) used Radial Basis Function (RBF) NN to predict claims' causes and control and minimize claims.

Manik et al. (2008) investigated the use of NNs to predict pavement construction payment-risk based on the quality of the construction. El-Sawalhi et al. (2008) developed a hybrid BP NN and GA model for predicting contractor's performance in terms of cost, time and quality in a process of contractor's prequalification. Jin & Zhang (2011) used NNs to model risk allocation decision-making process in PPP projects, mainly drawing upon transaction cost economics. Goh & Chua (2013) performed NN analysis in quantified occupational safety and health management system audit with accident data obtained from the Singaporean construction industry to predict accidents and identify critical factors.

Gajzler (2013) developed a method for supporting the decision-making process for the selection of materials and technology for repairing industrial building floors using Knowledge-based NN, Hybrid model of BP NN, RBF NN and Fuzzy Logic (FL). Gajzler & Konczak (2015) investigated the possibility of applying NN in the analysis of observational data on the issue of simulation concrete supplies in the construction industry. Patel & Jha (2016) developed an application of BP NN for the prediction and evaluation of employees' work behavior in construction projects using the constructs of the safety climate. Shahrara et al. (2016) used NNs to model the relationship between important project parameters and risk variables in the process of negotiating the financial parameters and uncertainties of a Build-Operate-Transfer project with the use of NN.

Regarding the software programs used in the abovementioned studies, Neural Network Toolbox of Mathwork's Matlab was used by Manik et al. (2008), Wen (2010), Jin & Zhang (2011), Li et al. (2012), Chenyun & Zichun (2012), Shahrara et al. (2015), and Gholhaki et al. (2016). Haykin (2008) also used it for the example applications of his work. Al-Sobiei et al (2005) and Goh & Chua (2013) deployed NeuroShell Predictor and Neu-

roShell2 respectively. El-Sawalhi et al. (2005) used Neuro Genetic Optimizer for their research. Gajzler & Konczak (2015) used STATISTICA Data Miner.

Other software programs that were used in the general field of construction project management are NeuralWorks Professional II/Plus, Neurosolutions, SPSS and FANN Library.

A research concerning software use in NNs showed that Matlab is the most widely used software for NN implementation accumulating 28% users' choice (Baptista et al., 2013). The reasons for this preference are that it is a complete, flexible and easy to program software, has strong and fast computational power and several types of NNs available (Baptista et al., 2013). In the same research, "self-created code" (24%) and "other software" (36%) including NeuroSolution (1%), also accrue large percentages. Additionally, Matlab responds better to the needs of the NN research community with 29%, while SPSS collects 1% of the question "what other software are you using" (Baptista et al., 2013).

It is obvious that NNs can find application in a variety of ways in construction project risk management. Applications primarily introduce qualitative and quantitative risk analysis and risk response analysis addressing the problem with different approaches either as function approximation or as pattern recognition. In most of the cases, the use of NNs reproduces credible results, which is the reason behind suggesting the use of NNs in construction project risk management. BP algorithm has a prominent place in supervised learning and the development of robust and credible models. Furthermore, the combination of NNs with other techniques seems to present even more potential in the development of such models. Research into the implementation of NNs in construction project risk management is still a dynamic scientific field given the small number of scientific studies of the last decade in the field.

4 DEVELOPMENT OF A NEURAL NETWORK MODEL FOR RISK ASSESSMENT IN CONSTRUCTION PROJECTS

4.1 *General context*

A common and acceptable formula of risk assessment is shown in Equation (1):

$$R = P \times S \tag{1}$$

where R = risk; P = probability index; and S = severity of harm index or importance of effect index.

For several risk factors i with different probability of occurrence and consequences, equation (1) is extended to the forms shown in Equations (2) and (3):

$$R_i = P_i \times S_i \; i = 1, 2, \ldots, n \tag{2}$$

$$R = [R_1, R_2 \ldots, R_n] = [P_1 \times S_1, P_2 \times S_2, \ldots, P_i \times S_n] \tag{3}$$

Assuming that each risk R_i is independent of other risks, the total risk R can be assessed according to Equation (4):

$$R = \Sigma R_i = P_1 \times S_1 + P_2 \times S_2 + \ldots + P_n \times S_n \tag{4}$$

Nevertheless, considering individual risks as independent and using their algebraic sum to assess total risk is considered to be an extremely simplistic approach as well as mathematical modeling of risk. The complex and often unpredictable nature of construction projects and their risks inevitably contribute to complex nonlinear risks interdependencies.

NNs can approximate every function for the assessment of total risk in construction projects given that a sufficient volume of valid and reliable historical data is available (Haykin, 2008); however, as already mentioned, such a historical record is lacking in most of construction projects as former research efforts for applications of NNs in construction projects risk management evidently show.

A NN trained with data of similar projects to a project in hand can capture the inherent relation between individual risks and total risk of the projects. This is possible through the appropriate modeling of the project's development parameters in combination with accurate historical data on previous risks occurrences and their impact. The rightly designed NN can approximate the value of the total risk in an indirect, yet practical manner since the historical record used to train the network while it does not analytically present the interdependencies between risks, it inherently contains them; therefore, the trained NN possesses the respective knowledge on this aspect (i.e. total risk) and its assessment can be considered reliable and credible. The historical data can also serve for: a) deriving distributions of the probability of occurrence of each risk, and b) quantifying each risk's severity index. Both are useful in assessing the total risk of construction projects using modern computational tools such as NNs.

4.2 *Data compilation for training the neural network*

Occupational safety and health is a key factor towards a successful delivery of construction projects. Proper assessment of occupational risk in project's design stage can significantly contribute to avoiding accidents (Pinto et al., 2011). The importance of occupational risk assessment is evidenced by the increasing rate of published safety and health studies in the construction sector and the development of relevant risk assessment models (Zhou et al., 2015).

The training of the proposed NN is based on metadata retrieved from a compilation of available data from previous risk assessments. Available data concern the possible risk sources that may occur during the execution of construction projects, as well as the ranges of their probability of occurrence (P) and their severity of harm (S) (Argyriou, 2016). Risk sources are categorized into general risk categories based on the grouping of risk sources according to the Labor Inspection Body of Greece. In Table 2, the risk range $R_i = [R_{imin}, R_{imax}] = [P_{imin} * S_{imin}, P_{imax} * S_{imax}]$ for each source of one category and the total risk range $R_t = [\Sigma R_{imin}, \Sigma R_{imax}]$ of the category are evaluated, using Equations (2) and (4) and the minimum and maximum values of P and S, and presented. Totally, 300 scenarios of construction projects risks in the ranges described above were randomly generated. Each scenario was assigned 100 random values of three overlapping ranges. Values were generated from a uniform distribution for both individual risks and total risk. The use of the overlapping ranges was performed towards a more credible reflection of reality considering that they introduce more interdependencies to the modeling of a NN that assesses total risk. Two similar scenarios of data sets as described above and depicted in Figure 1 were used for training the NN. The difference between them lies in the extent of the overlap between risks ranges, as the second data set introduces a more extensive overlap. The reasoning behind this differentiation was to address more individual risks in the scenarios reflecting in this way the complex and nonlinear relationships which are met between risks in construction projects.

Table 2. An example of a risk category, risk sources and risk ranges.

Category	Risk source	Risk range
Fall of person	Fall from height—moving ladder	0,182–3,171
	Fall from height—steady ladder	0,182–3,171
	Fall from height—stairs or steps	0,061–3,171
	Fall from height—moving scaffolding or staging	0,091–3,171
	Fall from height—steady scaffolding or staging	0,091–3,171
	Fall from height—assembly/disassembly of scaffolding	0,091–3,171
	Fall from height—roof	0,151–3,171
	Fall from height—floor	0,061–3,171
	Fall from height—platform	0,151–3,171
	Fall from height—through floor openings	0,182–3,171
	Fall from height—mobile platform	0,182–3,171
	Fall from height—moving vehicle	0,182–1,269
	Fall from height—work at height without protection	0,091–2,230
	Fall at the same height—sliding / obstacle impact	0,061–2,262
	Fall down by stairs or ramp	0,242–2,262
Total risk range		2,001–42,904

4.3 *Neural network tools selection*

Several software products were investigated for modeling the developed NN. In order to identify potential difficulties in the modeling process as well as potential deviations in the assessments' outputs, a decision was made to test with two different software tools. The first choice was to use the Neural Network Toolbox of Mathwork's Matlab, which is considered as the most widely used software in NN modeling (Baptista et al., 2013).

The second choice was Palisade's NeuralTools because of its ease of use as an extension of Microsoft's widely used MS Excel and the ability to combine it with other management-oriented software programs of Palisade (e.g. @Risk). A final reason for selecting NeuralTools was that the conducted literature review revealed its limited use in research studies contrary to its wide application in practice.

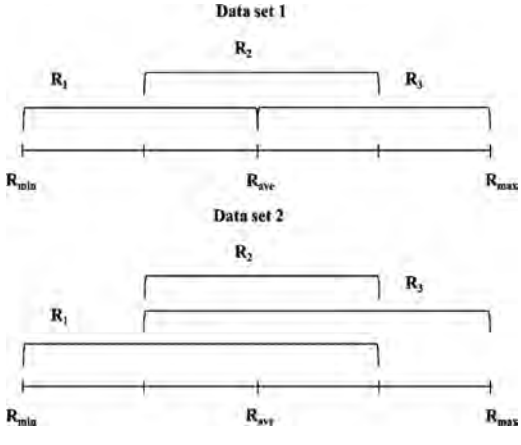

Figure 1. Data sets for training the NN.

This finding urged for application of NeuralTools to allow an insight and useful conclusions regarding to its appropriateness in NN modeling.

4.4 *Neural network training and results*

Supervised learning is the learning process used to train MLNNs developed both in NeuralTools and Neural Network Toolbox. MLNNs were chosen due to their ability to approximate any function satisfactorily thanks to the speed of learning and the plethora of options for their training as long as sufficient and reliable data is available. It is noted that the conjugate-gradient back-propagation algorithm is exclusively used in NeuralTools, while the Levenberg-Marquardt back-propagation algorithm is the default option in Neural Network Toolbox with the possibility of modification. In this research the default option was selected.

The first data set was randomly separated in 85% for training and 15% for testing the MLNN in NeuralTools. A 15-4-1 MLNN was finally chosen as the one with the best achieved performance. It is noted that available stopping criteria for the training can be a) training time, b) number of trials and c) training error decrease below a user-defined limit for a period of time, while there is also possibility of combining the above criteria. In this case, the training time was set to two hours; the number of trials was 10.000.000 and the error decrease less than 1% for five minutes. The third criterion was the one to cause training stop. The performance measures were: a) Root Mean Square Error (RMSE) equal to 3,873 and 5,046, b) Mean Absolute Error (MAE) equal to 3,019 and 4,261 and c) Standard Deviation of Absolute Error (SDAE) equal to 2,426 and 2,703 for the training and testing samples, respectively. Then, a regression analysis between the results of the network and the desired output was used to evaluate the reliability of the data. For that purpose, StatTools of Palisade was used and the results are depicted in Figure 2. The values of R (0,8920) and R^2 (0,7957) suggest a good relationship between results and desired outputs. The accumulation of extreme prediction values of the testing sample in one value, as seen in Figure 2, possibly indicates that the test data fall outside the range of the training and validation data and the network may be extrapolating. A better separation of the data set could lead to more accurate and reliable results.

The same 15-4-1 MLNN was then developed with Neural Network Toolbox. The data set was randomly divided into three samples; the training sample (70%), the validation sample (15%) and the test sample (15%). Training stopping criterion used in this case was the increase of the validation sample error for six iterations. The increase of the validation

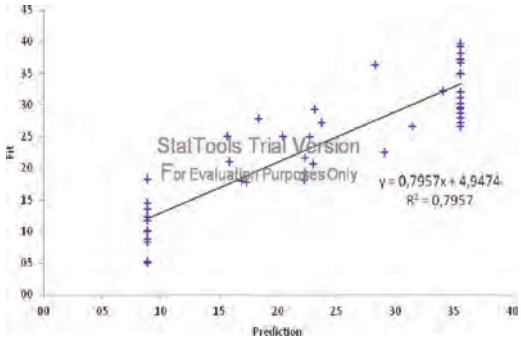

Figure 2. Regression analysis for the testing sample of 15-4-1 NN (NeuralTools).

sample error indicates the NN's inability to "explain" the data and in conjunction with the simultaneous reduction of the training sample error is a sign of memorization of the training sample. As a result, generalization, which is the NN's ability to deal with new data adequately, cannot be achieved. NN was trained for 11 epochs, while the best performance was achieved in the fifth epoch. Performance measure was RMSE equal to 4,362, 5,483 and 4,968 for training, validation and testing, respectively. Regression analysis between results and desired outputs suggests a good relationship between them for all three samples as depicted in Figure 3. Results with both software tools seem to be relatively close. Finally, a multiple regression analysis was carried out with the use of StatTools in order to compare NNs' results with those of a common and widely used traditional method. Aggregate results are presented in Table 3. Results are close enough to come to an exclusive conclusion. Furthermore, all models probably accommodate improvement.

The use of wider overlapping ranges used in the second data set, as mentioned in Section 4.2, is expected to match values of independent and dependent variables with more randomness resulting in even more complex relationship between individual risks and total risk.

In this case, the development of MLNN was performed with Neural Network Toolbox because regression analysis, which is a performance measure of the reliability of data division, is automatically generated, while using NeuralTools requires the processing of the results using another MS Excel extension, such as StatTools. Best performance was achieved with a 15-12-1 MLNN. The Levenberg-Marquardt BP algorithm was used for training the NN, while training stopping criterion was also the increase of the validation sample error for six iterations. Performance measure was RMSE and best value (5,645) was achieved at the third epoch for the validation sample. For the

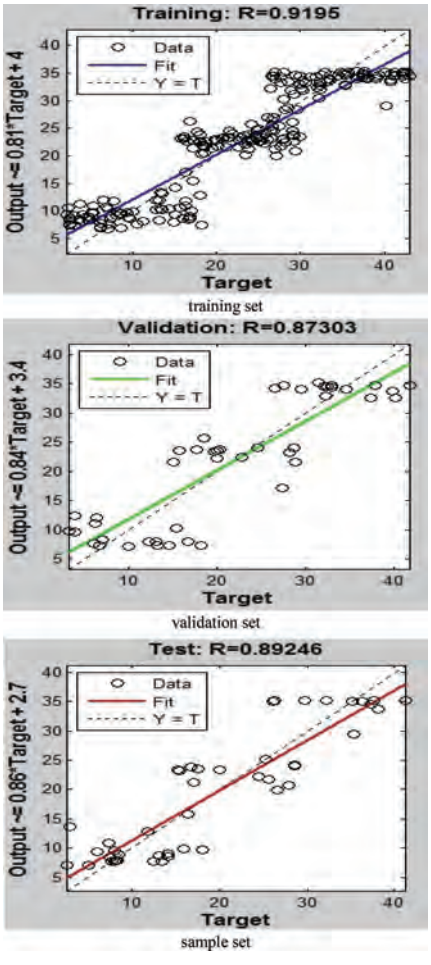

Figure 3. Regression analysis for training, validation and testing sample of 15-4-1 NN (Neural Network Toolbox).

Table 3. Regression analysis' R values for the testing sets of the models developed.

Model	R
NN 15-4-1 (Neural Tools)	0,8920
NN 15-4-1 (Neural Network Toolbox)	0,89246
Multiple regression analysis	0,8922
NN 15-12-1 (Neural Network Toolbox)	0,85649
Multiple regression analysis	0,837

training and testing sample, RMSE was equal to 5,676 and 6,451, respectively. Regression analysis between results and desired outputs delivered values of R equal to 0,861, 0,879 and 0,856 for training, validation and testing respectively, as depicted in Figure 4. Multiple regression analysis was also conducted and delivered R equal to 0,837. The relationship between variables is better depicted with the NN in relation to the regression model, as R values suggest. Aggregate results concerning training set R values of all the models developed are presented in Table 3.

Similarly, NNs can be developed to assess the risk of all risk categories, as well as the total risk of a construction project by combining those NNs. Generally, the results of this research demonstrate the computational power of NNs as a function approximation tool and confirm their usefulness in construction projects risk management and particularly in quantitative risk analysis, provided that reliable and sufficient historical data is available.

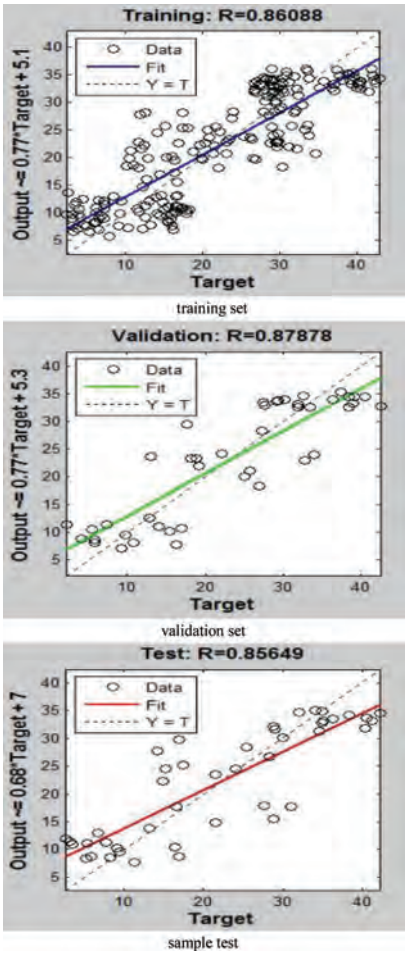

Figure 4. Regression analysis for training, validation and testing sample of 15-12-1 NN (Neural Network Toolbox).

5 CONCLUSIONS

NN applications in construction project risk management primarily concern qualitative and quantitative risk analysis and risk response analysis addressing the problem with different approaches either as function approximation or as pattern recognition. In most of the cases, the use of NNs reproduces credible results, as evaluated in the studies suggesting the use of NNs in construction project risk management. Similarly, results of the present research work demonstrate the computational power of NNs as function approximation tools and confirm their usefulness in construction projects risk management and particularly in assessing total risk. Neural networks are reliable for conducting risks assessments that realistically integrate risks interdependencies and complexities stemming from non-linearity in problems modeling. The availability of training data constitutes a prerequisite towards this goal. In this context, it is necessary to collect historical data concerning construction projects features and risks. Further research into the field can be addressed in improving the models developed, deploying other techniques and incorporating them in NN models for construction project total risk assessment.

ABSTRACT: In the framework of chemical and process industry, accidental fires may lead to damages to equipment with severe consequences and possible domino effects. The availability and effectiveness of safety measures, aimed at reducing the risk associated with this type of events, may be strongly affected and decreased if the facility is located in harsh environment, due to complicating meteorological factors and extreme temperatures. The present work is aimed at defining a structured approach to the quantitative assessment of fired domino events accounting for the influence of harsh environment conditions on safety barriers performance. A specific metric is defined in order to consider the external factors related to harsh environments on the determination of hardware and emergency safety barriers availability and effectiveness, with a specific focus on the evaluation of the time-scale of emergency response. A dedicated event tree analysis is then applied implementing the obtained performance values of the safety barriers, in order to support the quantitative assessment of accident frequency associated with domino scenarios. The present method is applied to the analysis of a chemical facility located in harsh environmental conditions.

1 INTRODUCTION

In the last decades, interest has been increasing for cascading events and the assessment of their possible risks. The chemical process industry has been hit by major accidents worldwide, some of which were completely disregarded by hazard identification techniques (Paltrinieri et al., 2010; Paltrinieri and Reniers, 2017). Among them, several domino events have been documented (Abdolhamidzadeh et al., 2011; Darbra et al., 2010; Delvosalle, 1996; Kourniotis et al., 2000; Lees, 1996; Rasmussen, 1996).

One of the most destructive cascading event disasters is the one that happened in Mexico City in 1984 (Pietersen, 1988). Europe recognized the hazard posed by domino events and specific requirements are stated in the article 9 of the latest Seveso Directive (European Commission, 2012). According to these, the risk of propagation of primary hazardous scenarios to nearby units is required to be assessed.

Different safety barriers are used and monitored in chemical process plants (Paltrinieri and Khan, 2016), such barriers defined to prevent escalation scenarios. These include active, passive and procedural protections. Examples include the water deluge system (WDS), fireproofing coating, pressure safety valves (PSVs) and the site emergency response plan. Different performance parameters in terms of availability (expressed as probability of failure on demand) and effectiveness are associated to every safety barrier.

However, barriers are subject to deterioration and depletion of their performance. Meteorological and climatological conditions are factors that can

enhance these phenomena. For instance, cold temperatures, extreme wind and snowfall may either cause deterioration of hardware plant components or lead to difficulties for operators performing routine tasks and/or in emergency contingency situations (Bercha et al., 2003; Gao et al., 2010). The Arctic and sub-Arctic regions experience extremely unique weather conditions that may be challenging for technical barrier components as well as human intervention. However, a dedicated framework for the analysis of safety barriers performance degradation in harsh environment is still missing.

This work is aimed at investigating the safety barrier performance of chemical and process facilities operating in harsh environmental conditions, in order to evaluate the frequency and probability of escalation scenarios triggered by fire.

The paper is organized as follows: Section 2 provides a detailed overview of the methodology applied to assess the frequency of cascading events addressing the effect of severe environment on protection devices; Section 3 describes the reference case considered for the present analysis; the results of the application of the methodology to the reference case are shown in Section 4, while Section 5 provides room for their discussion. The paper ends with conclusions in Section 6.

2 METHODOLOGY

2.1 *Overview*

Figure 1 shows the flowchart of the methodology adopted in the present study. The methodology was developed for the oil and gas sector (Landucci et al., 2017) and it is hereby extended to chemical process industry. A detailed description of the methodology is provided in sections 2.2–2.5.

2.2 *Identification of reference safety barriers*

The first step of the methodology consists of a preliminary characterization of the safety barriers performance, with particular reference to the prevention and mitigation of cascading events triggered by fire. According to CCPS—Center of Chemical Process Safety (2000), barriers are classified as:

- Passive, which are in place and do not require external activation;
- Active, which require automatic and/or external activation;
- Procedural and emergency measures, which involve the intervention of operators and emergency teams.

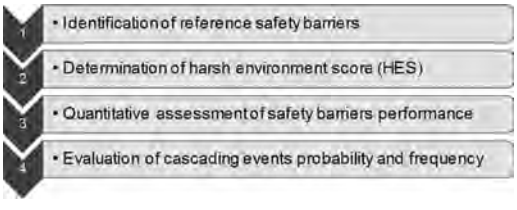

Figure 1. Flowchart of the methodology.

This step is based on the application of a previously developed methodology (Landucci et al., 2016) in which the evaluation of safety barriers performance in the framework of escalation is aimed at quantifying:

- availability, defined as the probability of failure on demand (*PFD*) of the safety barriers;
- effectiveness (η), defined as the probability that the safety barrier, once successfully activated, will be able to prevent the escalation.

Once the parameters needed to support the quantitative evaluation of safety barriers are defined, the influence of harsh environmental conditions on their performance is inferred in the following steps.

2.3 *Definition of Harsh Environment Score (HES)*

The Harsh Environment Score (*HES*) is a preliminary metric aimed at describing the harshness of the environment and it is used to assess the influence of weather conditions on safety devices performance. *HES* consists of a combination of different site-specific environmental parameters, such as, for instance, temperature and wind velocity.

The approach for the *HES* evaluation is based on the identification of stressors. They are factors that mostly affect the human performance during operations in extreme weather conditions (Section 2.4.1) but are adopted in the present study also to address the influence of extreme weather conditions on hardware barriers performance (Section 2.4.2).

Musharraf et al. (2013) identify the significant stressors for harsh environment as coldness, ice slippery, difficulty in breathing, combined weather effect, low visibility and remoteness. The present approach associates one or more external factors (EFs) to each stressor. EFs are climate or environmental conditions that can be measured and/or quantified. To each EF, a non-dimensional penalty, namely a score S_i, is assigned. Scores represent the distance from favorable conditions. They vary from 0 to 1, where 0 represents good favorable conditions and 1 the worst ones. Table 1 lists the EFs and relative scoring system applied in the present study.

Table 1. Summary of external factors and scores adopted for HES evaluation (adapted from Landucci et al., 2017).

External factor	ID	Range	S_i
Temperature (°C)	1	>45	0.4

More detailed information about the scores assignment process and the EFs may be retrieved in a previous study (Landucci et al., 2017). The scores are assigned according to extensive literature surveys about the effects of different physical factors on technical and human behavior (American Petroleum Institute, 2000; DOA—Department of Army, 1982; Kunkel et al., 2007; Landsberg and Pinna, 1978; Musharraf et al., 2013; Shaw and Austin, 1919).

Finally, *HES* is obtained as a weighted summation of the assessed scores, as follows:

$$HES = \sum_{i=1}^{N} w_i S_i \tag{1}$$

where S_i and w_i are respectively the score and the weight associated to the *i*-th EF. In the present analysis, a preliminary set of weights is assigned by using the Zipf's law (Zipf, 1949).

2.4 *Barrier performance assessment*

2.4.1 *Hardware barriers*

According to Gao et al. (2010), extreme environmental conditions may affect hardware barrier availability but they have no significant effect on their effectiveness. The depletion of barrier performance is strictly related to environmental temperature. Recommended Practices 581 by American Petroleum Institute (2000) identify a threshold value of –6.7°C for considerable effect on protection performance. This value corresponds to a penalty $S_1 = 0.6$ or higher according to Table 1. This framework addresses the depletion in barrier availability using the proportional hazard model (Cox, 1972) as suggested by Gao et al. (2010). The failure rate of a generic component, λ, increases in harsh environment according to the following relationship:

$$\lambda(z) = \lambda_0 \, e^{-1.409 z_1 - 1.013 z_2} \tag{2}$$

where λ_0 is the failure rate in normal environment (namely, the baseline value), assumed hereby as constant during the entire lifecycle of the facility. The factors z_1 and z_2 are the named covariates; z_1 describes the protection conditions and z_2 the equipment quality, respectively. Covariates are considered as binary and they can assume the value +1 or –1. The positive value is associated with good quality of protections and equipment. The base relationship for the estimation of tested component unavailability (Lees, 1996) is applied to obtain the barrier *PFD* describing, from this analysis perspective, the barrier availability.

The present work considers that the effectiveness of the barriers is not affected by environmental conditions. Once activated, hardware barriers perform as in the case of normal environment (Landucci et al., 2016).

The reference active safety barriers analyzed in the present study are water deluge systems (WDS) aimed at attenuating heat radiation from fires affecting process units. According to different experimental studies (Hankinson and Lowesmith, 2004; Roberts, 2004a, 2004b; Shirvill, 2004), the heat-load reduction on a target due to presence of WDS is about 50% compared to the unmitigated case. Hence, Q_{WDS} (the heat load received by a fired target in case of available WDS) is expressed as follows:

$$Q_{WDS} = 0.5 \, Q_{HL} \tag{3}$$

where Q_{HL} represents the heat-load affecting the target due to the primary fire scenario.

Passive safety protections include the PSV and the fireproofing coating. Birk (2006) proved that the presence of the PSV alone does not delay significantly the time to failure (*TTF*) of the target equipment. In that case, the PSV effectiveness is considered as unitary but the TTF is evaluated assuming that the vessel is unprotected (Landucci et al., 2009). Fireproofing coatings are instead able to delay the vessel failure. Their effectiveness is set as 1. The *TTF* of the target vessel in case of presence of protective coatings is evaluated by adding a further term, TTF_C, as shown in Eq. (4), which represents the delay action of the coating:

$$TTF = TTF_{unprotected} + TTF_C \tag{4}$$

The TTF_C is evaluated according to a simplified approach considering the quality of the materials used as coating. For high performance materials (intumescent, vermiculite spray, fibrous mineral wool) the TTF_C is set conservatively as 70 minutes. TTF_C is equal to 0 minutes in case of use as coatings of common insulating materials (glass wool, rock wool).

2.4.2 *Procedural barriers*

Human reliability may be significantly affected by extreme weather (Musharraf et al., 2013).

A customized version of the Success Likelihood Index Methodology (SLIM) (Embrey, 1986) is adopted in the present framework to evaluate the deterioration of emergency response availability (e.g. in terms of *PFD*). *HES* is considered as a simplified ranking of performance shaping factors affecting the emergency response in harsh environment (Landucci et al., 2017). The higher the *HES* the lower the probability of success of the emergency team intervention. The *PFD* is then evaluated as:

$$\log_{10} PFD = a(1 - HES) + b \tag{5}$$

where *a* and *b* are –0.954 and –0.046 respectively. They have been determined by setting the *PFD* equal to 0.1 in case of favorable environmental conditions (*HES* = 0) and by setting the *PFD* as 0.9 in worst case environmental conditions (*HES* = 1) (Landucci et al., 2016).

The evaluation of the emergency response effectiveness is carried out by following the approach suggested by Landucci et al. (2017). The evaluation is based on the comparison between the *TTF* of the target equipment and the Time for Final Mitigation (*TFM*) required to the emergency team to extinguish the primary fire. The *TFM* is defined as the sum of different times for emergency operations as follows:

$$TFM = \sum_{j=1, j\neq 2}^{6} \tau_j \tag{6}$$

The times are defined according to Table 2 (Landucci et al., 2017), where also the different relationships applied to account for the delay due to harsh environment are shown. The effectiveness of the emergency response is set equal to 1 or 0 by comparison between *TFM* and *TTF* of the target equipment. When *TFM* is lower than *TTF* of the target equipment, the emergency response effectiveness is set as unitary, otherwise it is zero.

2.5 *Evaluation of escalation probability*

A customized Event Tree Analysis (ETA) is adopted in order to evaluate the frequency (and probability) of domino escalation triggered by fire. The availability and effectiveness of barriers evaluated as described in Section 2.4 are addressed in the ETA by using dedicated logic gates, as shown in Table 3.

Further detailed information about gate definitions may be retrieved elsewhere (Landucci et al., 2016).

Gate A represents a simple composite probability. In this case, the availability (expressed in terms of PFD) is multiplied by a single probability value expressing the probability of barrier success in the prevention of the escalation.

Gate B represents a composite probability distribution. In this case, the PFD is multiplied by a

Table 2. Time scale for emergency operations and simplified relationship for the estimation of time increment due to harsh environment (adapted from Landucci et al., 2017). The baseline is the time required in normal environment (HES = 0).

ID	Name	Baseline (min)	Simplified relationship (τ in min)
τ_1	Time to alert	5	$\log_{10}\tau_1 = -0.3(I - HES) + 1$
τ_2	Time to onsite mitigation	20	$\log_{10}\tau_2 = -0.3(I - HES) + 1.6$
τ_3	Time for external team intervention	12	$\log_{10}\tau_3 = -0.3(I - HES) + 1.38$
τ_4	Time for equipment deployment	7	$\log_{10}\tau_4 = -0.3(I - HES) + 1.15$
τ_5	Time for extra set-up operations	8	$\log_{10}\tau_5 = -0.3(I - HES) + 1.2$
τ_6	Additional time in case of need of interregional assistance	30–60[a]	$\log_{10}\tau_1 = -0.3(I - HES) + 2.08$

[a]Depending on the type of location.

Table 3. Summary of gates introduced in the ETA to account of barrier performance (adapted from (Landucci et al., 2016)).

Gate type	Graphical representation
A	IN → A → $OUT_1 = IN \cdot [PFD + (1-\eta) \cdot (1-PFD)]$; $OUT_2 = IN \cdot (1-PFD) \cdot \eta$
B	IN → B → $OUT_1 = IN \cdot [PFD + (1-\eta) \cdot (1-PFD)]$; $OUT_2 = IN \cdot (1-PFD) \cdot \eta$
C	IN → C → $OUT_1 = IN \cdot PFD$; $OUT_2 = IN \cdot (1-\eta) \cdot (1-PFD)$; $OUT_3 = IN \cdot (1-PFD) \cdot \eta$
D	IN → P_D → $OUT_1 = IN \cdot P_D$; $OUT_2 = IN \cdot (1-P_D)$

probability distribution expressing the probability of barrier success in the prevention of escalation, thus obtaining a composite probability of barrier failure on demand. In this work, the integrated probability is adopted, obtaining the rule for gate quantification reported in Table 3.

Gate C is associated with a discrete probability distribution.

Finally, Gate D incorporates equipment vulnerability models based on probit approaches for the estimation of P_D (the probability of vessel failure). The effect of harsh environmental conditions has been addressed in the probit models in describing the vessel resistance behaviour. More details on vessel fragility models are extensively described in previous works (Landucci et al., 2009).

3 CASE STUDY

3.1 *Overview*

The reference case study refers to a production plant for the production of personal and home hygiene products. The plant uses as main raw materials ethanol and propane and, for the quantities stored, it is subject to fulfill the Seveso Directive requirements concerning hazardous materials (European Commission, 2012). The field is located in harsh environment (see Section 3.2). The methodology described in Section 2 is applied to estimate the frequency of domino events triggered by fire and thus providing a more complete risk picture of the facility.

Figure 2 shows the layout considered in the analysis of the case study. Ethanol is stored in three underground tanks (T1, T2, T3) with an overall volume of 90 m^3 and kept at 15°C. Ethanol is transferred to the processing area (see Fig. 2)

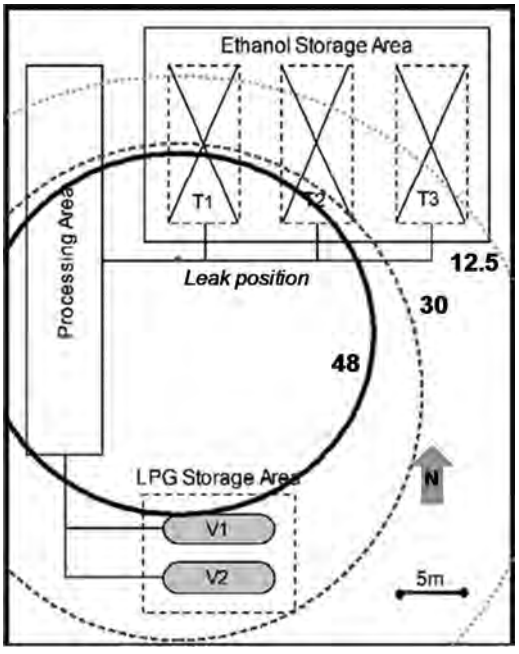

Figure 2. Layout defined for the case study associated with a non-confined pool-fire following the rupture of the process ethanol pipeline.

through a pipeline featuring 20 m length and a nominal diameter of 100 mm. Full-bore rupture of the pipeline is considered to derive the features of the primary scenario potentially triggering the domino escalation. In particular, a non-confined pool fire following immediate ignition of the spilled ethanol is taken into account. A standard frequency of $3.9 \cdot 10^{-7}$ y^{-1} has been assumed from literature analysis for pool-fire. The physical effects associated with the pool fire have been analyzed applying the conventional literature integral models implemented in the DNV GL Phast 7.11 commercial software. According to consequence assessment results, the pool fire affects the target propane storage tank (V1, see Fig. 2), which is exposed to about 48 kW/m^2.

The safety barriers in place to protect V1 are listed in Table 4. They are defined on the basis of different regulations for fire protection of liquefied petroleum gas storage units (American Petroleum Institute, 1996; National Fire Protection Agency (NFPA), 2018, 2017). The results of their performance assessment (in normal and harsh environments) are shown in Section 4. The quality of both the target equipment V1 and its protection devices is assumed as low following a conservative approach.

Table 4. Summary of fire protection devices for horizontal LPG storage tank (American Petroleum Institute, 1996; National Fire Protection Agency (NFPA), 2018, 2017).

Target	Active barriers	Passive barriers	Procedural barriers
V1	Water deluge system (WDS-V1)	Pressure safety valve (PSV-V1) Fireproofing coating (PFP-V1) (2 h rating)	Emergency response (ER-01)

3.2 *Environmental and meteorological conditions*

The reference production plant is located in an industrial site close to Bodø just North of the Arctic Circle, in Norway. The climatic conditions in the reference area can be characterized as severe. Table 5 summarizes the meteorological and climatological conditions experienced in that area and adopted for the determination of *HES* and, thus, to derive performance data in harsh environment.

4 RESULTS

4.1 *Performance assessment of safety barriers*

Adverse meteorological conditions significantly affect the protection effect of safety devices. In order to account for this effect, the methodology described in Section 2 has been applied to the reference chemical processing plant described in Section 3.

According to the meteorological and climatological data summarized in Table 5 and to the scoring system described in Section 2.3, the estimated *HES* is 0.43 for the considered case. This value is implemented to evaluate the performance of the safety barrier protecting the target tank V1. Since the score associated with the external temperature $S_1 = 0.6$, a degradation of hardware barrier availability must also be considered (see Section 2.4.1).

Data were also calculated for normal environmental conditions for sake of comparison (thus, featuring *HES* = 0). The time for external emergency response is calculated according to the guidelines described in Section 2.4. It increases from 77 minutes (normal environmental conditions, HES = 0) to 124 minutes (harsh environmental conditions, HES = 0.43).

Table 6 summarizes the results of performance assessment in normal and harsh environment and it shows the gates associated with each barrier.

4.2 *Evaluation of escalation probability*

The customized ETA approach for the evaluation of the escalation probability and frequency has been carried out starting from the frequency and consequence assessment of the primary scenario (ethanol non-confined pool-fire).

Figure 3 shows an extract of the ETA developed for harsh environmental conditions (*HES* = 0.43). Each branch in the event tree is quantified according to the rules described in Section 2. A similar event tree is derived for the normal environment case.

Three different scenarios arising from unconfined pool fire are analyzed in both normal and harsh environment. These scenarios are:

Table 5. Summary of meteorological and climatological conditions experienced in Bodø.

Factor	Meteorological data	Reference
Temperature	Coldest month: January Minimum average temperature: –11.8°C Typical value: –2.2°C	(Norwegian Meteorological Institute, 2017)
Wind speed	Harsh month: January Maximum wind speed: 24.4 m/s (10 m above sea level) Annual range: 8.9 m/s	(Norwegian Meteorological Institute, 2017)
Snow	Duration: 6 months (October-April) Average snowfall per day: 2.54 cm	(weatherspark.com, 2017)
Fog/snow effect	Visibility lower than 2000 m	(ISO-International standardization organization, 2010)
Sunlight hours	1200–1600 h/year	(Landsberg and Pinna, 1978)
Remoteness	The plant is located in an industrial site close to cities and amenities. The remoteness is considered to be low.	(Suedfeld and Steel, 2000)

Table 6. Summary of data adopted for the quantification of the ETA in the present case study. HES = 0: normal environment; HES = 0.43: harsh environment.

Barrier	Gate type	PFD		Effectiveness	
		HES = 0	HES = 0.43	HES = 0	HES = 0.43
WDS-V1	A	$4.33\ 10^{-2}$	$5.57\ 10^{-1}$	1	1
PSV-V1	A	$1\ 10^{-2}$	$1.29\ 10^{-1}$	1	1
PFP-V1	A	$1\ 10^{-3}$	$1.29\ 10^{-2}$	1	1
ER-01	C	$1\ 10^{-1}$	$2.57\ 10^{-1}$	0; 1[a]	0; 1[a]

[a]Depending on the comparison between TFM and TTF.

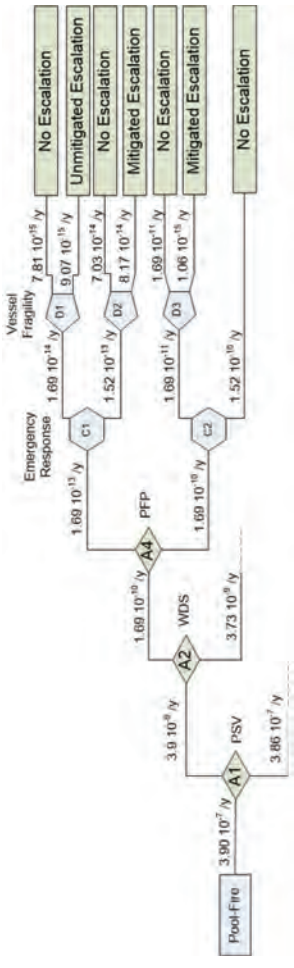

Figure 3. Extract of the ETA for the evaluation of cascading event probability/frequency for the target tank V1. It refers to the case of harsh environment, with $HES = 0.43$.

1. Unmitigated domino (not effective activation of safety barriers);
2. Mitigated domino (partial or ineffective activation of one or more safety barriers);
3. No domino scenario (barriers effectively mitigate/suppress the primary fire and avoid escalation).

The target equipment V1 may withstand the fire even in the absence of barrier activation. Also in these cases, escalation is excluded.

Figure 4 shows the result of the analysis in terms of frequency and probability of the three examined scenarios. The "No safety barrier" scenario has been considered for sake of comparison, e.g. based on the method developed in a previous work (Landucci et al., 2009).

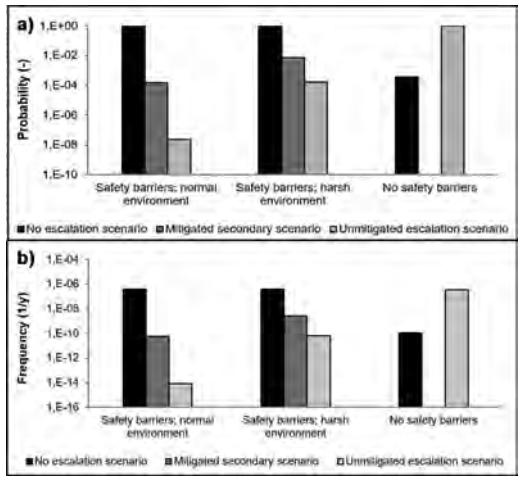

Figure 4. a) Probability and b) frequency of secondary scenarios.

5 DISCUSSION

The analysis of the case study demonstrates the potentialities of the methodology in the assessment of domino scenarios for chemical facilities located in harsh environments. As shown in Figure 4, a significant increase in escalation probability and frequency is predicted in harsh environment operation with respect to normal environment. When safety barriers are considered, unmitigated domino scenario is the less credible, both in normal and harsh environments. Anyway, the degradation of barrier performance in harsh environment leads to higher frequency values. In particular, reduction of four orders of magnitude with respect to the case without protection is obtained for harsh environment. In normal environment, the reduction is of eight orders of magnitude.

This is due to the depletion in the barrier performance in harsh environment, as documented in the analysis shown Section 4.1. In particular, procedural and emergency measures are significantly affected by cold environmental conditions. In fact, the time for external emergency response increases about 60% compared to the value in normal environment. This is due to delays and difficulties in carrying out emergency actions.

The escalation frequency results obtained from the ETA analysis shown in Section 4.2 may be implemented in detailed quantitative risk assessment studies. In this way, a more detailed risk picture of the facility may be evaluated, thus including escalation scenarios. The necessary input to apply the method, as exemplified in Sections 3 and 4, is normally available from conventional risk analysis

studies and therefore no additional work needs to be carried out for collecting input data. The meteorological and climatological data for the HES assessment are site-specific, but easily retrievable from national institutes (see the example dataset gathered in Table 5).

It is worth mentioning that the methodology addresses human factor and deterioration of barrier phenomena in a very simplified way, despite these issues featuring relevant complexity. For that reason, the so evaluated escalation probabilities and frequencies should be considered on the safe side.

The methodology allows room for further refinement of data and for using different available methods. In particular, for human reliability, more advanced techniques may be implemented supporting the evaluation of operators' performance and error probability given the environmental stressors; on the same time, emergency response analysis may be improved with site specific response time data for a more accurate effectiveness estimation.

Finally, for hardware barriers, further review of the methodology should be considered when site-specific performance data will be available from facilities operating in harsh cold environments.

6 CONCLUSIONS

The present contribution shows a systematic approach for the quantification of domino event frequency and probability for chemical facilities operating in harsh environmental conditions. The approach accounts for the deterioration of safety barriers performance due to extreme climate conditions. A dedicated metric is used as preliminary index to assess the influence of environmental conditions on barrier performance, thus allowing for a modification of barriers availability and effectiveness. The modified values of barrier performance data allow for a more detailed probability and frequency assessment of cascading scenarios triggered by fire.

The outcomes of the methodology may drive the design of hardware barrier components and improvement of emergency procedures in order to decrement the risk of severe accidental scenarios in chemical facilities operating in harsh environments.

ABSTRACT: Major part of the nuclear power sites house more than one reactor unit and other nuclear facilities such as spent fuel pool storage. Currently, multi-unit risks have not typically been adequately accounted for in risk assessments, since the licensing is based on unit-specific PSA with focus on a reactor accident. This paper presents an approach to site risk analysis, taking into account various dependences between the units. The dependences can be caused by external hazards, which can affect multiple units at the same time; shared operational and safety systems at the site; common staff who should manage the situations. The site risk assessment approach has been developed with aid of two pilot studies made for two Swedish sites. Preliminary results from the pilot studies are presented in the paper.

1 INTRODUCTION

After the Fukushima Daiichi accident in March 2011 general interest in site level Probabilistic Safety Assessment (PSA) has increased. Major part of the nuclear power sites house more than one reactor unit and other nuclear facilities such as spent fuel pool storage. Currently, multi-unit risks have not typically been adequately accounted for in risk assessments, since the licensing is based on unit-specific PSA with focus on a reactor accident.

The methodology for a site level risk analysis needs to consider the dependences between the units. By "unit" we mean here not only reactors but also other relevant sources for radioactive release such as spent fuel pools and storages. The dependences can be caused by external hazards, which can affect multiple units at the same time; shared operational and safety systems at the site; common staff who should manage the situations. Site risk analysis is not only a matter of extending current risk analyses to properly cover inter-unit dependences in the risk assessment, but it should also provide risk insights for the site level safety management, e.g., w.r.t., severe accident management, emergency preparedness, design, operation and maintenance of shared systems.

In 2017, the Swedish nuclear utilities Forsmark Kraftgrupp and Ringhals Ab and the Swedish Radiation Safety Authority financed together with the Finnish Nuclear Safety Research Programme SAFIR2018 a project, called SITRON (SITe Risk of Nuclear installations). The objective with SITRON is to develop methods and requirements for a nuclear power plant site risk analysis, driven by a performance of pilot studies. The paper will summarise the developed method for the site risk analysis and preliminary results from the pilot studies.

2 OVERALL APPROACH

2.1 *Definitions*

This section introduces main concepts and definitions used in this paper. They are adopted from the SITRON project reports (Holmberg 2017; Bäckström et al. 2018).

A "single-unit PSA" means a PSA made for a nuclear facility such as the reactor facility and the interim storage for spent fuel. A single-unit PSA is assumed to cover all fuel locations within the facility. For a reactor facility, the reactor and the fuel pool are the relevant locations from the risk assessment point of view. Single-unit PSA can be

also understood to refer the types of risk analyses that currently have been prepared for licensing of nuclear facilities.

A "multi-unit PSA" means a PSA or a set of PSAs made to cover accident scenarios related to all fuel locations at the site, including spent fuel transportations. Multi-unit PSA can be also understood to be an extension of a single-unit PSA which can be used to quantify multi-unit risk metrics. The aim of this paper is to discuss one approach towards this direction.

The SITRON project is limited to level 1 and level 2 PSA reflecting the current state-of-the-practice for nuclear power plant applications and licensing requirements in most countries. Level 1 PSA assesses the risk of a reactor core damage or more generally the risk of a fuel damage. The main risk metric of level 1 PSA is the Core Damage Frequency (*CDF*) or generally the Fuel Damage Frequency (*FDF*).

Level 2 PSA assesses the risk of radioactive release to the environment as a consequence of a fuel damage. In level 2 PSA, it is typical to use several risk metrics following the categorisation of releases. Internationally commonly used risk metrics are the large release frequency (*LRF*) and the large early release frequency (*LERF*) (OECD 2009). Meaning of "large" may vary depending on the regulatory framework, e.g., in Finland it is a release larger than 100 TBq of Cs-137 (STUK 2013). "Early" release means an accident where the release occur before sufficient time for offsite protective measures. As a general term for level 2 PSA risk metrics, "release category frequency" (*RCF*) is used in this paper.

The structure of PSA model can be defined to consist of a number of initiating events (IE) and plant response models that are used to quantify in level 1 the conditional probabilities of core damage (*CCDP*) with respect to each IE and in level 2 the conditional probability of certain release given the Plant Damage State (PDS). Plant damage states are interface states between level 1 and 2 PSA to facilitate more compact modelling of level 2 PSA.

When analysing and modelling multi-unit scenarios, it is necessary to extend the above concepts into those involving a single-unit impacts and those involving multi-unit impacts. For instance, initiating events are grouped into single-unit initiating events (SUIE) and multi-unit initiating events (MUIE).

Risk metrics for level 1 PSA can include the following *CDF* metrics:

- Single-Unit Core Damage Frequency (SUCDF) – frequency of a reactor accident involving core damage on one and only one reactor unit per site calendar-year.
- Multi-Unit Core Damage Frequency (MUCDF) – frequency of an accident involving core damage on two or more reactor units concurrently per site calendar-year
- Site Core Damage Frequency (SCDF) – frequency of a reactor accident involving core damage on one or more reactor units concurrently per site calendar-year.

For a level 2 PSA, the significance of the release can be characterised by two components: magnitude of released radionuclides (Cs-137 is typically used as a representative isotope) and the timing of the release. Unlike to level 1, in level 2 there is no need to count the number of units or sources that contributes to the release. Therefore, the release categorisation in multi-unit scenarios can be based on the following metrics:

- Release magnitude = sum of release magnitudes from the units having fuel accidents
- Release timing = time point when the magnitude criterion for the release category is exceeded.

The Site-level Release Category Frequency (*SRCF*) is the sum of frequencies of the single-unit and multi-unit scenarios leading to a certain release category.

It should be noted that the SITRON project has not proposed numerical criteria for release categorisation due to national differences in the risk criteria for level 2 PSA. It is, however, recommended that release magnitudes are counted in absolute units (e.g. TBq of Cs-137) rather than in relative units (e.g., x% of core inventory is released).

2.2 *Basic assumptions for site risk analysis*

A key assumption for the SITRON project is that the site risk analysis does not need to start from scratch. It is assumed that the nuclear power plants have rather complete and well-developed PSAs for the units at the site. The site risk analysis is expected to complement the existing PSA-studies by addressing multi-unit scenarios and unit dependences.

The impact of site risk analysis is two-fold. Firstly, it should lead to improved single-unit PSAs, by ensuring that multi-unit scenarios and unit dependences are properly accounted for. Secondly, site risk analysis should provide a representation of risk at the site-level, i.e., it enables the quantification of site-level risk metrics.

One important principle in the method development of the SITRON project is that it should be possible to quantify the site-level risk metrics with the single-unit PSAs, without a development of dedicated multi-unit risk models. This idea follows the assumption that approximative quantifications are sufficient for site-level PSA application purposes.

Another important principle of the site risk analysis is that effective screening will be applied to

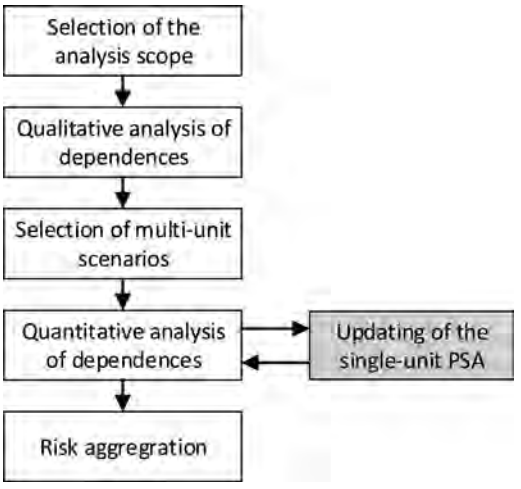

Figure 1. Site risk analysis procedure.

identify relevant multi-unit scenarios. In principle, one could postulate a huge number of multi-unit scenarios, but most of them can be shown to have an insignificant risk contribution and could be thus screened out from further analysis. For instance, it can be shown that a combination of two simultaneous independent initiating events (events occurring within a certain short time window) has an insignificant risk importance and therefore can be screened out (Bäckström et al. 2018).

2.3 *Analysis steps*

Figure 1 depicts a general procedure for a site-level PSA. As the first step, the scope of the analysis is determined, including a selection of sources of radioactive releases considered in the study and which level of PSA is considered. Section 3 of the paper will describe the elements of the qualitative analysis of dependences, which results in the selection of multi-unit scenarios for the quantitative analysis and finally the risk aggregation. These topics are discussed in Section 4.

Figure 1 also includes a grey box, "updating of the single-unit PSA", which can be seen an excursion in the procedure. This analysis step is needed to cope with identified deficiencies in the single-unit PSA. It also facilitates the quantification approach that is based on an effective utilization of single-unit PSAs.

3 QUALITATIVE ANALYSIS OF INTER-UNIT DEPENDENCES

Qualitative analysis of inter-unit dependences should be a systematic and comprehensive assessment of possible inter-unit-dependences to identify important factors in multi-unit scenarios. The purpose is to ensure that the dependences that are considered likely to be relevant are captured correctly in the quantitative analysis, but also to screen out dependences that do not require further analysis.

The analysis should cover various dependences topic by topic, as will be discussed in the following sub-sections. The identification of relevant initiating events is the basis for further analysis. The analysis of dependences due to shared systems and structures is a step that can be performed in a general manner without postulating any particular multi-unit scenario (by a multi-unit scenario we practically mean a scenario initiated by a multi-unit initiating event). The other topics (identical components, human and organisational dependences, and plant operating states) are more practical to assess when the relevant multi-unit scenarios have been selected.

3.1 *Identification of initiating events*

The primary way of identifying important multi-unit scenarios is based on the analysis of initiating events which can have multi-unit impacts. There are two types of such events: 1) a multi-unit initiating event that has more or less simultaneous impact on multiple units, and 2) a propagating initiating event, which has first impact on a single unit and then it propagates to other units.

The identification of multi-unit initiating events should be a straight-forward task since practically all external hazards form this group of events. Screening can be carried on the frequency basis, but this could have been done already in the single-unit PSAs.

The identification of relevant propagating initiating events may require further analysis compared to the analysis made in the context of the single-unit PSA. An initiating event that causes a disturbance on one unit could potentially propagate to another unit, either by creating an initiating event during the accident progression, for example loss of offsite power, or through an accident scenario (core damage) that ultimately affects the other unit. Another example of an initiating event that propagates would be a fire in one unit that spreads to another unit. An assessment of propagating hazards (fire and floodings) may require plant walk-downs to judge the likelihood for a hazard propagation.

3.2 *Common systems, buildings and structures*

There are different types of shared connections in a nuclear power plant. These connections can be categorized according to the approach used in (Muhlheim & Wood 2007), where the two main

categories "structures and facilities" and "systems and equipment" are used.

Examples of shared structures and facilities include for example service water intake structures and different types of storage tanks. There are also plant designs where, for example, turbine or auxiliary buildings are shared.

Shared of systems and equipment can be grouped into three categories

- Systems that can support several units simultaneously. Systems in this sub-category include for example station blackout gas turbines and common fire protection systems.
- Independent systems at each unit that can be cross-connected to support another unit or single systems able to fully support only one single unit at a time. Systems in this sub-category could for example include demineralized water distribution. Emergency diesel generators may also be configured to support only one unit at a time.
- Independent systems at each unit sharing standby or spare equipment. Systems in this sub-category include for example portable pumps for independent cooling.

Which connections that are shared differ widely between plants, even between plants with the same vendor. Many of the shared connections are, however, not important from a PSA point of view, e.g. shared office buildings and shared communication systems.

3.3 *Identical components*

Identical components at different units form a potential group of components which can fail due to Common Cause Failures (CCF). In (Schroer & Modarres 2013) strong evidence is presented that dependent failures occur with a relatively high frequency involving multiple units. The OECD/NEA CCF data project ICDE has also made a study on multi-unit CCF events, which indicate that such events happen (Håkansson 2017), and therefore they cannot be categorically ruled out from a multi-unit PSA. The CCF candidates are selected by studying the scenarios for the relevant multi-unit initiators.

3.4 *Human and organisational dependences*

Human and organizational dependences related to the multi-unit scenarios should be identified and covered in the human reliability analysis (HRA). In general, multi-unit HRA will need to put more emphasis on organizational and management aspects in the analysis. These factors need to be included in not only quantification, but also task analysis and modelling.

Multi-unit accidents pose additional challenges on operators which are not modelled in a single-unit PSA. These challenges may arise from constrained human resources, additional complexity in managing multiple scenarios from a common location, shared system prioritization, prioritizing the deployment of portable equipment, etc. A radioactive release from one unit in case of a multi-unit accident might affect critical operator actions that have to take place outside the main control room of another unit.

The degree of added complexity for multi-unit accidents will depend greatly upon the amount of interdependence between the individual units. This interdependence may come from the nature of the initiating event, the amount of shared systems/equipment or the amount of shared resources.

3.5 *Plant operating states*

PSA models for nuclear power plants shall take into account various Plant Operating States (POS) of the facility, since list of relevant initiating events, status of safety systems and system success criteria can vary strongly between POSs. Usual POS categorisation includes states full-power operation, reactor shutdown (from full-power to outage), reactor up-rate (from outage to full-power) and a number of POSs during the maintenance outage period.

A realistic multi-unit scenario assessment has to account for the units' various combinations of POSs. However, a complete consideration of all possible combinations of POSs between several units could lead to a large number of "site level" POSs. For instance, in a Hungarian pilot study (Bareith et al. 2016), 123 distinct site level POSs were identified for a site with four reactors and four spent fuel pools.

In SITRON, it is assumed that the need to consider various POS combinations can be considerably reduced by screening of irrelevant combinations and by merging together similar POSs. This should be true at least for various outage period POSs which have short time windows or for which the time to fuel damage is very long due to the high capacity of water pool to keep the fuel cooled even without active cooling system. In any case, the final screening of relevant POS combinations must be carried out specifically for each multi-unit initiating event.

4 QUANTIFICATION OF MULTI-UNIT SCENARIOS

4.1 *Basic approach*

The modelling and quantification approach followed in SITRON assumes that the single-unit PSA

is properly addressing the multi-unit scenarios, i.e., the impacts of dependences are modelled in such manner that the quantification of the model provides "correct" risk metrics from the single-unit point of view.

4.2 *Generation of scenarios*

Generation of scenarios means studying the Minimal Cut Set (MCS) lists for the identified multi-unit initiating events. Minimal cut set (MCS) lists are generated from the single-unit PSA. Basic events that can be associated with multi-unit dependences are identified for further quantification of dependences (see Section 4.3).

At this stage, unimportant dependences can be quantitatively screened out. One approach is to study the maximum contribution from potential multi-unit sequences for each relevant dependence (represented by selected basic events). If the sequence has a frequency below a screening criterion (e.g. 1E-8/yr) – even if full dependence is assumed—then the dependence can be screened out. Another approach is to select MCSs which are above a screening criterion and to restrict the examination of basic event dependences into that MCS list.

4.3 *Quantification of dependences*

For those dependences and associated basic events that are not screened out, a quantification of the degree of dependence must be performed. Basically, it means the evaluation of the conditional probability of an event at another unit given that a dependent event has occurred at one unit.

For multi-unit initiating events, a full dependence is assumed. For propagating events and for partial multi-unit events, case specific assessment needs to be made.

For shared systems that are common a full dependence is assumed. For shared systems, which have partly common sections and partly unit-specific sections, an assumption needs to be made which unit takes credit for the common section.

The assessment of inter-unit CCFs is crucial issue from the quantification point of view. When the units are identical, there are several important CCF groups that dominates the risk. Since typically full CCF dominates the results, a conservative approach is to assume that the components of two units form a joint CCF group. The event of interest will be a complete CCF of the full group given that a specific half of the components have failed. In SITRON, several approaches to assess the conditional CCF probabilities have been tested, e.g., using the CCF parameters of the single-unit model, ICDE operating experience data (Håkanson 2017) and generic U.S. CCF data (U.S.NRC 2016).

Post-initiating event operator actions can be divided into three groups from the dependence assessment point of view. Firstly, there are actions that can be considered unit-specific without dependences. This group mostly includes actions required in the short time window when the units need to manage the disturbance individually. Secondly, there are actions in longer term, for which partial dependence could be assumed due to shared resources. Thirdly, there are actions for which full dependence should be assumed.

4.4 *Computation of multi-unit CDF*

The general formula for two-unit CDF for a multi-unit initiating event i is

$$MUCDF_i = f_i \cdot \sum_j p(d_j) \cdot P(CD1 \mid IE_i, d_j) \cdot P(CD2 \mid IE_i, d_j), \quad (1)$$

where f_i is the initiating event frequency; $p(d_j)$ is the probability of the dependence event(s) j; and $P(CD1|\cdot)$ and $P(CD2|\cdot)$ are the conditional core damage probabilities given an initiating event i and dependence event(s) j.

There are several possibilities how to handle the dependent events. One approach used in the pilot studies was to re-quantify the joint MCS list generated from the MCS-lists of single-unit models. In this approach, a basic event, A, associated with a dependence is partitioned into a "common basic event", cA, and a "unit-specific event", iA,

$$A = cA * iA. \quad (2)$$

When the joint MCS list is created as a Boolean product of MCS lists, the dependences will be explicitly taken into account by the common basic events. The probabilities for the common respectively unit-specific basic events are obtained from the previous analysis step (Section 4.3).

5 PILOT STUDIES

5.1 *Pilot study scope*

In the SITRON project, two Swedish pilot studies are made, one for the Forsmark nuclear power station (Cederhorn et al. 2018) and second for the Ringhals nuclear power station (Bäckström et al. 2018). Forsmark pilot study is limited to reactor units 1 and 2, and the Ringhals pilot study to reactor units 3 and 4. Forsmark 1 and 2 are boiling water reactors (BWR) of Asea-Atom design and

Ringhals 3 and 4 are Pressurised Water Reactors (PWR) of Westinghouse design.

In both cases, the two units are practically identical reactors located close to each other and have several common systems and structures such as sea water intake. For both cases, there exist complete level 1 and 2 PSAs covering all initiating event categories (internal events, internal hazards, external hazards) and plant operating states (power operation, shutdown, outage, power up-rate).

In 2017, the pilot studies have included a qualitative analysis of unit dependences and a quantitative analysis of the multi-unit initiating event Loss-Of-Offsite Power (LOOP). The pilot studies were limited to level 1 PSA.

5.2 *Findings from the qualitative analyses*

In this section, a summary of findings from the qualitative analysis of the two pilot studies are presented. It can be noted that the identified dependences are very similar even though the other study concerns with two BWRs and the other with two PWRs. Therefore, the discussion given below is valid for both studies.

For initiating events, both PSA-studies include a comprehensive analysis of external hazards. The list of external hazards can be directly taken as a list of potential multi-unit initiating events, including events like loss of offsite power and organic material in sea water. Assessment of propagating initiating events was left out-of-the-scope of the pilot studies, since this task would require plant visits and walk-downs. It was however identified that there are few common buildings for which fire and flooding hazards may be considered as propagating events. Later when the pilot studies will be extended to level 2 PSA, propagating effects of severe accident situations, e.g. increased radiation level at the site, may need to be considered, too.

Both pilot cases have almost same important system and building dependences. Examples of important common systems are the offsite grid connections and sea water intake. There are also several less important common systems such as the fire water system, and the demineralized water system.

Since in both pilot studies the units at the site are identical, practically all common cause failure groups could be considered potential inter-unit CCF groups. Assessment of relevant CCF groups was limited to the example scenario, LOOP.

Both pilot studies consider a full scope of plant operating states. The average time share that the twin-units are simultaneously at-power is about 90%. Since maintenance outages are not carried out in parallel, it can be assumed that the other possible POS-combinations include one unit being at-power and the second unit being at some shutdown state.

5.3 *Results of the quantitative analyses*

In both PSAs, LOOP initiating events are divided into several sub-cases. In the pilot study, the multi-unit LOOP, leading to simultaneous loss of external grid for twin-units is considered. This initiating event has rather high risk importance in both PSA studies.

LOOP event has been considered for all POSs. When quantifying the time shares of POSs and risk importances of LOOP during various POSs, the result was that only both units being at-power is a significant POS combination. The reason for this is that other POSs are very short except one longer POS during maintenance outage during which the core/fuel damage risk is very low due to long time window to recover the situation. Also, the POSs immediately after and before at-power POS are from the PSA-modelling point of view very similar to the at-power scenarios. Same inter-unit dependences are important for those POSs as for at-power POS.

Most important minimal cuts sets for the multi-unit LOOP have been analysed qualitatively to group similar minimal cuts sets together and to characterize the cut sets from the time window and system failures point of view. There are about ten groups of minimal cut sets that dominate the result.

In almost all cases, the core damage happens due to loss of power supply to systems required for core cooling. A common feature is that house turbine operation fails after which the safety functions are dependent on Emergency Diesel Generator (EDG), Gas Turbines (GT) or mobile diesel generators (MDG). Recovery of external grid is also a possibility.

From the timing point of view, there are two main categories for the loss of 500 V AC power supply:

- Immediate loss of power supply. This is caused by various combinations of failures to start EDGs, GTs or to connect them to supply the bus bars.
- Later loss of power supply. This is caused by various combinations of failures where EDG start succeeds but stops later. From the battery capacity point of view, these minimal cut sets could be further divided into those occurring before or after the battery depletion time.

In the assessment of twin-unit CDF, the following events have large importance

- Failure of house turbine operation. House turbine operation is rather unreliable and a high probability is assumed that it is failed in both units (2×2 turbines). This event is included in all dominating MCSs
- Inter-unit CCF of batteries (two systems), which are vital for successful power supply from

EDGs. Over 80% of *MUCDF* can be eliminated if both CCFs can be eliminated. Inter-unit CCF for batteries have been assessed conservatively assuming that they form a joint CCF-group. The conditional probability for a full CCF given that half of the batteries have failed is high due to the assumed CCF-model parameters.
- Failure to recover 400 kV grid which is a common event for both units. *MUCDF* is decreased by almost 50% if LOOP is only a short-term event.
- Unavailability of gas turbine, which is a common system for both units. Gas turbine events contribute about 50% to *MUCDF*.

Regarding operator actions, multi-unit dependent actions are important only in later phase of scenarios and they do not have large risk importance.

The *MUCDF* assessment has been very simplified, and includes several uncertainties. Conditional probability of a double-unit core damage given one core damage is 0,1–0,2. The most important uncertainty is the assessment of the probability of the inter-unit CCF. If no inter-unit CCF is assumed, *MUCDF* decreases by a factor more than 100.

6 CONCLUSIONS

Qualitative analysis of multi-unit dependences is a rather straight-forward task and should be included already in the single-unit PSA. For instance, multi-unit IEs can be rather easily identified since they are practically equal to the list of external hazards.

In the first hand, it can be assumed that external hazards are complete multi-unit IEs. To judge whether hazards should be considered partial multi-unit IEs may require considerable more effort, plant visits and statistical analyses or expert judgements. The same applies for the identification of propagating IEs for whose relevance from multi-unit risk point of view cannot be judged without plant visits.

Identification of common systems and structures is also a straight-forward task and should have been already considered in the single-unit PSA. Relevant operator action dependences can be assumed to exist mainly in long term action since in the beginning of scenarios, the units are designed to manage the emergency situations independently.

Relevant multi-unit dependences and scenarios are related to events impacting safety functions core cooling and residual heat removal. From the initiating event point of view, the common disturbances can be classified in the general groups 1) loss of power supply or 2) loss of ultimate heat sink. Some external hazards can cause both plant impacts.

From the POS combinations point of view, it is likely that the only POS combination which needs to be considered is both units being at-power. The other combinations can be screened out either by their very short time duration or by the very long recovery times for which reasons such events have negligible contribution to the multi-unit risk. This conclusion is based on the assessment of the multi-unit LOOP initiating event.

The assessment of inter-unit CCF is crucial issue from the quantification point of view. When the units are identical, there are several important CCF groups that dominates the risk. The applied quantification principle in the pilot study is presumably very conservative, which can lead to high conditional probability for a multi-unit core damage given a single-unit core damage.

The pilot study case, loss of offsite power (both 400 kV and 70 kV) did not reveal any such dependences that would suggest revisions in the single-unit PSA. There are few dependent operator actions which have some importance, but they are treated in the current PSA quite simplified manner. The functional role of gas turbine in the multi-unit scenario might also require some more detailed analysis.

From the *MUCDF* assessment point, a rather simple quantification can be performed using dominating minimal cut sets and basic events. Two quantification approaches have been tried out in pilot studies, both providing practical approaches to assess the multi-unit risk metrics and risk importances of various items of the model.

It should be noted that the conclusions made here are based on a single scenario and on level 1 PSA. It could be expected that some weather-related hazards impacting the sea water intake and the extension of the analysis to level 2 may bring up further issues, e.g., the role of dependent operator actions may be more important.

Risk-informed safety classification of components of auxiliary systems for emergency diesel generators in nuclear power plants

J.-E. Holmberg
Risk Pilot AB, Espoo, Finland

ABSTRACT: Safety classification of structures, systems and components of nuclear power plants shall be based on the functional importance of the items. One challenge with the nuclear safety classification is that different classification systems are used in different countries and standards. Even if certain classification scheme can be agreed upon, it is not straight-forward how the classification should be carried out for various components, e.g., in electric and automation systems. At higher plant and system level, the safety importance of functions can be defined directly, but the classification of smaller components requires further assessments. In principle, a component's safety class follows its functional importance. Downgrading is possible if mitigative factors and reliability arguments can be shown. The importance of finding correct safety class is that it determines the QA requirements for the component. The paper will outline a risk-informed safety classification approach for the components, based on both probabilistic and deterministic assessments. Emergency diesel generator system will be used as an example.

1 INTRODUCTION

Safety classification of Structures, Systems and Components (SSC) of nuclear power plants (NPP) shall be based on the functional importance of the items. One challenge with nuclear safety classification is that different classifications are used in different countries and standards. International standards and guidelines give some common guidance to the classification, but in practice the licensees and vendors need to adapt the classification into the national system (WNA 2015). Even if certain classification scheme can be agreed upon, it is not straight-forward how the classification should be carried out for various components.

At higher plant and system level, the safety importance of functions can be defined directly, but the classification of smaller components requires further assessments. In principle, a component inherits its safety class from its functional role based on the functional impact of its failure. This principle can be considered a deterministic approach to safety classification since the functional importance is determined by the deterministic safety analysis and the defence-in-depth concept of the design.

The strength with the deterministic approach for the safety classification is the link with the strong safety design principles such as defence-in-depth, safety margin, redundancy, diversity and independence (Ahn et al. 2010). This approach has limitations since it does not systematically and explicitly consider the risk importance of items, which could be assessed by Probabilistic Safety Assessment (PSA). Deterministic approach generally only considers worst case scenarios (Kirschsteiger 1999).

The importance of finding correct safety class is that it determines the Quality Assurance (QA) requirements for the component. Too low safety class may imply a system reliability concern; too high safety class can be a significant cost factor, and it can be even a problem of finding a component supplier for nuclear market, which has specific QA requirements.

Since the development of PSA methods and applications for NPP safety management, there have been attempts to implement risk-informed approach to safety classification. A well-known and applied approach is the U.S.NRC (2011) guide to risk-informed decision making. Shortly, the PSA is used to determine the risk importance of a component and the risk importances are compared to the deterministic safety class. Risk importance measures such as Fussell-Vesely and Risk Achievement Worth are used for this purpose. Such studies and discussions can be found, e.g., in (Jänkälä 2002; Holmberg & Männistö 2008).

Safety Integrity Levels (SIL) introduced in IEC-61508 (IEC 2010) and related branch-specific standards are also examples of risk-informed safety classification. The reasoning behind SIL is, however, quite different from the nuclear safety classification principles for which reason it would

be difficult to apply it as such in nuclear context, though associations can be made between SIL and nuclear safety classes, see e.g. Annex D of IEC 61513 (IEC 2011).

This paper discusses an approach to the risk-informed safety classification. The primary role of the deterministic safety classification is acknowledged, especially the assessment of the functional importance of items. The issue to be resolved is how the safety classification of components can be reassessed based on their risk importance. Electric and automation systems are the main intended application area since these systems consist of large number of components with different functional role, failure modes and risk importance. Section 2 describes the safety classification system. Section 3 presents the emergency diesel generator (EDG) system used as an example. Section 4 outlines the safety classification approach, and Section 5 concludes the paper.

2 SAFETY CLASSIFICATION SCHEME

2.1 *Defence-in-depth and plant condition categories*

The safety philosophy of NPPs builds on the Defence-in-Depth (DiD) principle. Here, we consider DiD as successive levels of protection, which rely on the application of safety principles of multiple barriers, physical separation, redundancy and diversity. The standard nuclear five level classification is taken as the basis (IAEA 1996). DiD levels can be mapped one-to-one with "plant condition categories" or "design basis categories", which are fundamental elements of deterministic safety analyses, see Table 1.

The relationship between defence-in-depth and safety classification is immediate in the sense that each DiD level is assigned to certain safety class, and all items belonging to one level have the same safety class. It follows that all items within one level have the same requirements for design, qualification, regulatory review and QA procedures during all life cycle phases. Different DiD levels can belong to different safety class, and this is considered beneficial both from the diversity point of view and from the optimal resource allocation point of view.

2.2 *Safety classification systems in nuclear field*

In nuclear field, there is both national and international variations in the safety classification systems, though all systems have a link to the DiD principle. For example, the International Electrotechnical Commission categorization (IEC 2009) defines three safety categories A, B and C, whereas the American standards of Institute of Electrical and Electronics Engineers uses a classification that only distinguishes between safety and non-safety systems (IEEE 2003).

Table 1. Defence-in-depth levels and plant condition categories.

DiD level	Objective	Plant condition category
1	Prevention of abnormal operation and failures	Normal operation
2	Control of abnormal operation and failures	Anticipated operational occurrences (AOO)
3a	Control of accident to limit radiological releases and prevent escalation to core melt conditions	Design basis accidents (DBA)
3b*		Design extension conditions (DEC)**
4	Control of accidents with core melt to limit off-site releases	Postulated core melt accidents or severe accidents (SA)
5	Mitigation of radiological consequences of significant releases of radioactive material	—

*3b controls postulated common cause failures in level 3a; **DEC has three subcategories (STUK 2013a): a) AOO/DBA & common cause failure in level 3a, b) significant events identified in PSA and c) rare external events.

The International Atomic Energy Agency (IAEA) has adopted the following three-level safety category system (IAEA 2016):

- Safety category 1: Any function that is required to reach the controlled state after AOO or DBA and whose failure, when challenged, would result in consequences of 'high' severity.
- Safety category 2: Any function that is required to reach a controlled state after AOO or DBA and whose failure, when challenged, would result in consequences of 'medium' severity.
- Safety category 3: Any function that is actuated in the event of AOO or DBA and whose failure, when challenged, would result in consequences of 'low' severity. Any function that is designed to reduce the actuation frequency of the reactor trip or engineered safety features in the event of a deviation from normal operation, including those designed to maintain the main plant parameters within the normal range of operation of the plant.

In addition to the overall safety classification systems, there are more technically-oriented clas-

sification standards, such as IEC 60709 for the physical separation of I&C equipment (IEC 2004) and IEEE 384 for independence requirements of electric circuits and equipment (IEEE 2008). In this respect, the treatment of electric and I&C equipment is quite straight-forward. With regard to mechanical equipment in electric and I&C systems, there are not so strict requirements, which leaves room for an interpretation.

2.3 *Risk-informed safety classification system*

In this paper, a risk-informed safety classification system is outlined, in which the system functions and associated components are first classified based on their functional importance. Refined assessment of the component safety classes is made based on the assessment of mitigative factors and reliability considerations. The procedure is illustrated in Figure 1.

In the first step, the functions, sub-function, sub-sub-functions, etc. of the system are defined down to a sufficient level of details so that the functional importance of each component can be defined. Here "component" is associated with the spare parts level itemization of a system, which is the level of details that needs to be achieved in the safety classification from the QA requirements point of view.

Functional importance of components can be analysed, e.g., using Failure Modes, and Effects Analysis (FMEA). The functional impact of the component's failure mode determines the preliminary safety class.

In the final step, the component's safety class can be reassessed based on two more criteria: the reliability of the component and the existence of mitigative factors. Low failure probability and mitigative factors can be used as arguments to downgrade the safety class (see Section 4 for details).

A three-level safety class system is proposed. Three classes are considered practical for the categorisation of components and yet sufficient to be acceptable in various national regulatory frameworks.

Safety Class 1 (SC1) represents the highest safety category. It is assigned to functions, which are required to cope with DBAs, i.e., they belong to DiD-level 3, which is the most important from safety point of view and has thus highest QA requirements.

Safety Class 2 (SC2) is assigned to other safety related functions than those critical in DBA scenarios. This includes, e.g., functions related to DiD levels 2, 3b and 4. In addition, SC2 can be assigned to manual back-up of SC1 functions, monitoring and surveillance of SC1 functions and functions whose failure can impact the long-term reliability of SC1 functions.

Safety Class 3 (SC3) is assigned to non-safety related functions. This includes, e.g., functions related to DiD level 1.

Compared to the safety classification systems of IEC and IAEA, the proposed classification system has one class less. Practically, SC1 corresponds with the highest safety category of the nuclear classification systems, SC2 corresponds with other safety related classes (e.g. Cat. B and C in IEC 61226). The reason to merge the other safety related classes into a single class is that it is not practical to have too many safety classes for the categorisation of components.

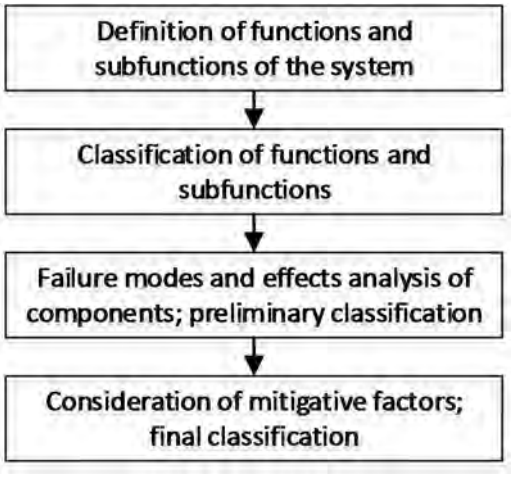

Figure 1. Procedure for risk-informed safety classification.

3 FUNCTIONAL DESCRIPTION OF EMERGENCY DIESEL GENERATORS

3.1 *Main functions and subsystems*

In this paper, Emergency Diesel Generators (EDG) will be used as an example. The main safety function of EDGs for nuclear power plants is to provide power supply to safety-critical electric bus bars in case of Loss Of Offsite Power (LOOP) initiating event. Typically, there is one EDG per one safety train or per two safety trains, i.e., there are two to four EDGs per reactor providing emergency power supply. In this paper, "EDG system" refers to the complete set of redundant EDGs (2 to 4 EDGs), and "EDG" refers to a single-train EDG.

For new designs, the requirement is to have a diverse back-up for the EDGs to cope with the DEC scenario where LOOP occurs in combination with a CCF of EDGs. For this purpose,

the plants may have diverse DGs, called Station Black-Out (SBO) DGs, gas turbine or/and mobile DGs. Even cross-connections between reactor units may be a solution, though this is not allowed in all countries.

To analyse EDG from the safety and reliability point of view, it needs to be broken down into subsystems and functions as well as a system boundary must be defined. In practical EDG applications, system boundaries vary, but here we divide the whole system into three major parts. The EDG generates the electric power from diesel fuel, and include subsystems, such as generator, diesel engine, fuel oil system, cooling system, lubrication system, starting air system, combustion air system, exhaust system, and I&C system. Important auxiliary or support systems of EDG include systems such as fuel oil storage and supply, cooling water system, cooling air and ventilation system for the engine room, and electric power system for the control and protection system. In addition, the EDG function needs electric power transmission lines and control logic to the bus bars dependent on the EDG.

3.2 *Functional classification*

For the sake of simplicity, we consider two types of LOOP events:

- Design Basis Accident (DBA) LOOP for which case the fuel stored in the day tank is sufficient. This is called short-term LOOP and the corresponding EDG function belongs to the DiD level 3a, receiving SC1.
- Design extension condition (DEC) LOOP for which cases the fuel oil from the storage tank is also needed. This is called long-term LOOP and the corresponding EDG function belongs to the DiD level 3b, receiving SC2.

Sub-functions of EDG can be classified depending on their criticality to the above main safety functions. As an example, the sub-functions of the fuel oil subsystem are provided in Table 2. Figure 2 depicts a simplified flow diagram. The fuel oil subsystem is responsible for the feeding of the diesel engine with fuel oil. Feeding is arranged from the day tank, which can be loaded from a larger storage.

The fuel oil subsystem has a functional safety class 1 since it is necessary for the DBA safety function. Most subsubsystems of the fuel oil subsystem have the same safety class. Oil storage and transfer is not needed during the DBA case but is needed in the DEC case. Therefore, it belongs to SC2. Fuel unloading from the oil storage belongs to SC3 since it is a maintenance action with no safety relevance.

In the functional analysis, the sub-functions are broken down into a level that facilitates the classification of components. In Table 2, the sub-function 4 "Fuel oil feeding and circulation" has been broken down into seven sub-sub-functions. The next step is to perform an FMEA to assign preliminary safety classes for the components. Table 3 shows an example for some components contained in the

Table 2. Functional classification of the fuel oil system.

Sub-function	Class
Fuel oil system	1
1. Fuel unloading	3
2. Oil storage and transfer	2
3. Fuel oil day tank	1
4. Fuel oil feeding and circulation	1
4.1 Fuel feeding	1
4.2 Fuel oil impurity removal (filters)	2
4.3 Fuel injection to engine	1
4.4 Leak fuel handling	1
4.5 Emergency cut-off	2
4.6 Overpressure protection	2
4.7 Drain	3
5. Fuel oil cooling	1
6. Leak fuel handling	1

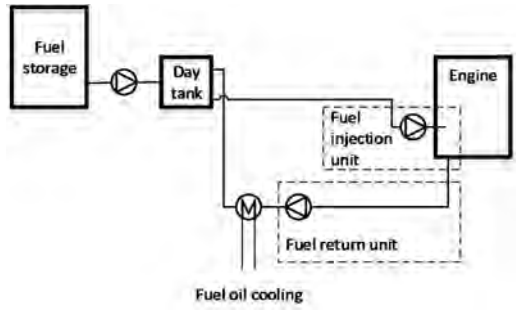

Figure 2. Simplified flow diagram of the fuel oil system for EDG.

Table 3. Failure modes and effects analysis example. Columns F = Function, C = Failure cause and D = Failure detection are left undeveloped in the example.

Component	F	Failure mode	C	D	Impacted function	Prel. class
Pipe x	.	Rupture	.	.	4.1	1
		Leakage	.	.	4.1	1
		Blocking	.	.	4.1	1
Manual shut-off valve y	.	Wrong position	.	.	4.1	1
Pump z	.	Failure to start	.	.	4.1	1
		Spurious stop	.	.	4.1	1
Strainer s	.	Clogging	.	.	4.1	1
		Rupture	.	.	4.1	1

subsubsystem "Fuel oil feeding and circulation". The primary classification is derived from the safety class of the impacted function.

4 RISK-INFORMED SAFETY CLASSIFICATION

The risk-informed safety classification account for two criteria in addition to the functional importance of the component. These are the reliability of the components and the existence of mitigative factors.

Reliability of a component is principally measured by the frequency or probability of the critical failure modes. The role of the component reliability assessment is two-fold: 1) to demonstrate the fulfilment of the system reliability target, 2) to justify down-grading for components whose unavailability can be demonstrated to be insignificant.

Mitigative factor is a feature of the system or component design which can eliminate or mitigate the impact of the component failure. Mitigative factor can be also seen means to improve the system reliability. Effectiveness of mitigative factors can be thus measured probabilistically.

Figure 3 depicts a principal scheme for the reclassification. It should be noted that this scheme is only applied to SC1 and SC2 components. For SC3 components, there is no need to consider reclassification from safety point of view. In the following subsections, a further interpretation for the boxes of the scheme will be provided.

4.1 *Safety goal based reliability targets*

4.1.1 *System reliability target*

In the risk-informed safety classification, the functionally derived classification of components can be revised based on the risk importance of the component. The idea is *not* to exactly quantify the risk importances, but to use probabilistic reasoning in an indicative manner to define reliability levels that can be used to define rules for the reassessment. Further, the derived reliability targets for equipment can be used in the argumentation on reasonable level of required reliability. In addition, the discussion can be used to support the assessment of effectiveness of possible mitigative factors and to derive an interpretation for negligible risk contributors.

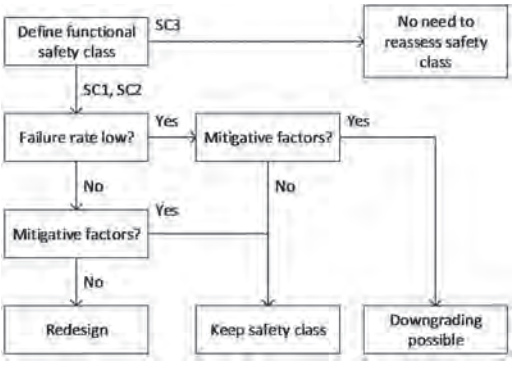

Figure 3. Principal scheme for final classification of components.

We assume certain generic risk criteria and design features of a nuclear power plant to obtain system reliability targets. In a specific project, these assessments need to be re-evaluated. Typical risk criteria for are (OECD/NEA 2009) 1E-5/yr for the Core Damage Frequency (CDF) and 1E-6/yr for the Large Release Frequency (LRF).

EDG-failure related accident sequences may not contribute more than 1% to the CDF criterion (1E-7/yr). This is a hard requirement, but station black-out sequences have also a high potential to a large release (LRF criterion).

The frequency of LOOP is typically of order 1E-1/yr (Johnson & Schroeder 2016) but most LOOP events are very short. The frequency for LOOP when recovery of offsite power cannot be credited is assumed to be about 1E-2/yr.

The plant has a diverse back-up for EDGs in case of station black-out. The unavailability of the diverse back-up is 0.1. This is a conservative value. The above probability numbers yield a failure probability target for the EDG-system

$$U_1(\text{system}) = \frac{CDF_{\text{target}}}{f(\text{LOOP}) \cdot p(\text{EDG back-up})} = \frac{1\text{E-}7/\text{yr}}{1\text{E-}2/\text{yr} \cdot 0.1} = 1\text{E-}4. \quad (1)$$

This target is for a set of redundant EDGs. Typically, an NPP has 2 to 4 EDGs. To derive a target for one EDG, the probability of Common Cause Failure (CCF) must be estimated. Probability of CCF is dependent on many factors, e.g., number of EDGs and the testing scheme of EDGs. Using CCF-parameters of EDGs estimated from data from US NPPs (U.S.NRC 2016), it can be estimated that the fraction of total CCF for two-redundant respectively four-redundant systems is about (order of magnitude)

$$\text{CCF2/2} \approx 5\% \quad (2)$$

$$\text{CCF4/4} \approx 0.5\% \quad (3)$$

Assuming a four-redundant system, an unavailability target for one EDG (out-of-four components) can be defined as follows

$$U_1(1\text{oo}4\ \text{EDG}) = \frac{U_1(\text{system})}{\text{CCF4/4}} = \frac{1\text{E-4}}{0.005} = 2\text{E-2}. \quad (4)$$

This is a first estimate for a single-train EDG reliability target, and it will be compared to experience based values for EDGs in the next subsection to define final choices for a reasonable reliability target.

4.1.2 *Experience based reliability of EDG*

As a reference for the reliability targets for EDGs, experience based reliability of EDGs is examined. The estimates will be made using T-book (TUD Office 2015) and U.S. NPP EDG reliability data (U.S.NRC 2015). Repair and maintenance time unavailabilities are omitted in the estimation.

Using the parametrization of T-book, the unavailability of EDG can be expressed as follows

$$U \approx q + \tfrac{1}{2}\lambda_s \cdot TI + \lambda_d \cdot TM, \quad (5)$$

where q = constant unavailability (failure to start); λ_s = standby failure rate (failure to start); λ_d = mission time failure rate (spurious stop); TI = test interval; and TM = mission time.

In T-book version 8, the generic parameters for the failure rates and probabilities are q = 3.9E-4; λ_s = 4.0E-3/h and λ_d = 3.9E-2/h. Assuming a test interval TI = 672 h and a mission time TM = 8 h, the mean unavailability is

$$U_{\text{T-book}}(1\text{EDG 8 h}) = 1.8\text{E-2}. \quad (6)$$

In the U.S. NPP reliability database, the parametrization is slightly different, as follows

$$U \approx q + \lambda_1 \cdot 1\text{ h} + \lambda_2 \cdot (TM - 1\text{ h}), \quad (7)$$

where q = probability of failure to start; λ_1, = first hour (load run) failure rate; and λ_2 = mission time failure rate after first hour. The parameter values for EDG are q = 2.88E-3 (table EDG-FTS); λ_1 = 3.72E-3/h (table EDG-FTLR); λ_2 = 1.52E-3/h (table EDG-FTR). These parameter values yield

$$U_{\text{US}}(1\text{EDG 8 h}) = 1.7\text{E-2}, \quad (8)$$

which is remarkably close to the T-book's estimate.

One should note that the EDG system boundaries used in T-book and US data may vary. In addition, the EDG system boundary applied by the above references do not include all support systems and connected systems, which are also critical to the overall EDG function. The conclusion is thus that the experience based unavailability figure of EDG is higher than the target derived in Section 4.1.1 (formula (4)). A difference is that the reliability based values reflects old systems while the target value derived in Section 4.1.1. is suited for new systems. Therefore, this target value is chosen for further development of the component reliability targets, i.e.,

$$U_1(\ 1\text{EDG}) = 2\text{E-2}. \quad (9)$$

If this value can be demonstrated for a single-train EDG including auxiliaries, the system should be at least as good as current EDGs.

In case of the DEC target (SC2 function), the mission time is longer and the fuel storage and transfer to day tank are included in the consideration. If the mission time is changed to 72 h (as an example), the following experience based unavailabilities are obtained (excluding auxiliaries)

$$U_{\text{T-book}}(1\text{EDG 72 h}) = 1.2\text{E-1}, \quad (10)$$

$$U_{US}(1\text{EDG 72 h}) = 1.1\text{E-1}. \quad (11)$$

Considering possible trending and missing auxiliaries in the above estimates, one could nevertheless define the following design extension condition reference value for the EDG

$$U_2(1\text{EDG}) = 1\text{E-1}. \quad (12)$$

The above unavailability targets may seem to be rather high, but it should be noted that EDGs are backed-up by diverse power supply in all new NPPs and in all modernised NPPs, e.g., by SBO DGs, mobile DG, unit cross-connections or by gas turbine. Therefore, from risk point of view, there is usually no need to demonstrate better reliability for EDGs.

4.1.3 *Derivation of reliability targets for EDG items*

The next step is to derive reliability targets for the items of the EDG. This cannot be done straightforwardly, since it depends on the way EDG is decomposed into items and the way reliability targets should be distributed between the items. For some items, a higher unavailability can be allowed if, at the same time, others can be shown to be very reliable. In any case, a fault tree analysis should be used to demonstrate that the overall system reliability target is achieved.

It is assumed that the items form a serial system so that the EDG unreliability is sum of items' unavailabilities. The impact of redundancy and other mitigative factors will be considered separately.

Using a kind of ALARP-approach (As Low As Reasonably Practicable), a limit and a target value

is defined for the reliability. The limit value must be achieved, and the target value is a reference for the interpretation of a negligible contribution.

We assume that there are, from the reliability point of view, three groups of components: a) unavailability is close to limit value, u^a, b) unavailability is clearly below the limit value but not negligible, u^b, and c) unavailability is negligible, u^c. The relationship between the unavailability values u^a, u^b, and u^c can be defined as follows

$$u^a = 10u^b = 100u^c. \tag{13}$$

The total unavailability will be then

$$U \approx n_a u^a + n_b u^b + n_c u^c \approx n_a u^a + n_b u^b, \tag{14}$$

where n_a = number of components having unavailability close to the limit u^a; n_b = number of components having unavailability well below the limit; and n_c = number of components having negligible unavailability, i.e., the term $n_c u^c$ is insignificant.

Next, we assume that the number of components that have unavailability close to the limit value, n_a, is much smaller than the number of component that have lower unavailability, n_b. We can thus allocate the system unavailability target about evenly between these two groups, i.e., 50% of the target value to a-components and 50% for b-components. Further, as an order of magnitude estimate, we may say that there are about 100 components per single EDG (in the spare parts level of itemization) in each safety-critical class, SC1 and SC2. n_a could be about 10 and n_b about 100. This reasoning leads to a relative item-level unavailability limit 5%, which corresponds with the following absolute unavailability limits

$$u_1^*(\text{EDG-item}) = 1\text{E-}3, \tag{15}$$

$$u_2^*(\text{EDG-item}) = 5\text{E-}3. \tag{16}$$

Consistently, the target value based on formula (13) should be a factor 100 lower,

$$u_1^0(\text{EDG-item}) = 1\text{E-}5, \tag{17}$$

$$u_2^0(\text{EDG-item}) = 5\text{E-}5. \tag{18}$$

The unavailability limits/targets include the following unavailability contributions of an item,

- latent failures occurring during the standby period or in connection to the previous test, maintenance or operation moment. This can be split into a time-independent part and a time-dependent part, c.f., formula (5),
- mission time failures.

The maintenance and repair related unavailability contribution can be omitted in this context since it is stipulated by Safety Technical Specifications.

Since for almost all items, the failure modes can be related either to the system standby time or to the operational time, there is no need to further split the item-specific reliability limits/targets into latent respectively mission time reliability targets.

Table 4 provides item-specific limits and targets. These numbers have been derived using specific

Table 4. Indicative unavailability limits and targets for items of a serial system with reliability targets 2E?2 (SC1) and 1E-1 (SC2). Assumed number of items per function ~100.

Failure mode time dependency	SC1 function		SC2 function	
	Limit	Target	Limit	Target
Latent, time-independent failure probability, q	1E-3	1E-5	5E-3	5E-5
Latent, time-dependent failure rate, λ_s*	1E-6/h	1E-8/h	5E-6/h	5E-8/h
Mission time failure rate, λ_d**	1E-4/h	1E-6/h	1E-4/h	1E-6/h

*1-month test interval assumed;
**8 h/72h mission time assumed for SC1/SC2 functions.

Table 5. Classification of mitigative measures.

Mitigative measure	Description, examples	Mitigation factor
Practical elimination of the failure mode	Inherent feature that eliminates the failure mode	~10^{-4}
Reliable elimination of the failure mode	Fail-safe behaviour, e.g., instrumentation failure causes an actuation or it does not stop the function if already actuated	~10^{-3}
	Diverse back-up, automated function, very reliable switch function, negligible possibility for CCF	
Redundancy	Duplication with an identical item, automatic reliable switch function, small (but non-negligible) possibility for CCF	~10^{-2}
Manual back-up, manual recovery	Back-up function exists, but it is not automated. Success conditions for the action exist. Human reliability analysis is needed to verify this.	~10^{-1}

Table 6. Reconsideration of component's safety class accounting for reliability and mitigative factors.

Mitigative measure	Component unavailability u_i		
	$u_i >$ limit	limit $> u_i >$ target	target $> u_i$
Practical elimination of the failure mode	safety class can be reduced		
Reliable elimination of the failure mode	keep safety class*	safety class can be reduced	
Redundancy	keep safety class	keep safety class*	safety class can be reduced
Manual back-up, manual recovery	keep safety class		keep safety class *
None	redesign	keep safety class	

* For SC2 components, the option is "safety class can be reduced".

assumptions about the system reliability target and numbers of items between which the reliability target must be allocated. Proposed numbers should be considered indicative values to support qualitative argumentation in the reassessment of the classification.

4.2 *Assessment of mitigative measures*

The reliability of equipment can be improved by various mitigative measures. These are classified in Table 5 regarding their effectiveness. The mitigation factors given in the last column of the table should be regarded as indicative probability numbers, with some correspondence with typical failure probability numbers used in risk and reliability studies for technical systems.

Combining the original component's unavailability with additional mitigative factors, the functional safety class of an item can be reconsidered. A proposal for such an approach is outlined in Table 6.

5 CONCLUSIONS

Safety classification of structures, systems and components has an important governing role for the definition of QA requirements for various items. Safety classification is fundamentally based on deterministic safety analysis thinking where an item's functional importance determines the safety class. At higher plant and system level, the safety importance of functions can be defined straightforwardly, but the classification of components requires further assessments. This is especially true for electric and automation systems, which consist of a large range of components whose importance can vary a lot.

The paper presents a risk-informed approach to safety classification where the safety classification is carried out in two phases: 1) deterministic, functional classification, 2) re-assessment considering of mitigative and reliability factors of the item. In the functional classification, the system functions are broken down into sub-functions and sub-sub-function until a level of details is reached so that the component's functional importance can be determined. FMEA is considered a practical tool to assess the functional importance which is determined by the functional impact of the component failure.

A challenge with the nuclear safety classification is that different classifications are used in different countries and standards. Besides the international standards organizations, almost every nuclear safety authority has local requirements. Thus, there can be inconsistencies between international and national codes and standards, which is problematic when local regulation must be combined with standards and applicable in vendor home countries.

The paper suggests a three-level safety classification system, which is considered sufficient for component level classification and yet applicable with respect to various national and international systems. Highest safety class, SC1, is applied functions belonging to DiD level 3. Other safety-related functions not critical to DiD level 3 functions are assigned to the second safety class, SC2. Non-safety-related functions are assigned to SC3.

Reassessment of component safety classes can be based on argumentation on the reliability of the components and existence of mitigative factors. The paper outlines an approach to judge which levels of reliability together with mitigative factors can justify downgrading. The basic idea is to control that the overall reliability target for the system will be reached, which also provides a reference for the judgment of unavailability contributions that are negligible. In any case, a fault tree analysis or equivalent quantitative system reliability assessment need to be performed to verify the fulfilment of the system reliability targets.

Development of a qualitative framework for analysing high-impact low-probability events in power systems

I.B. Sperstad
SINTEF Energy Research, Trondheim, Norway

E.S. Kiel
Norwegian University of Science and Technology, Trondheim, Norway

ABSTRACT: High-Impact Low-Probability (HILP) events in power systems historically involve a multitude of aspects, including diverse and disparate threats, failures and sequences of events. Each of these aspects are associated with different types of uncertainties. In practice, the analyst has to make trade-offs between computational efficiency and accuracy in the different aspects that are included in the analysis. Without a clear understanding of the specific problem to be solved and which aspects that are important to capture, elaborate quantitative analysis may be of limited value. This paper presents the development of a *qualitative* framework for analysing HILP events in power systems. By mapping aspects of power system HILP events to a bow-tie model, it provides a framework for defining, decomposing and delimitating decision problems related to such events. The framework may guide the analyst in the development and application of methods for quantitative analysis and for considering different types of uncertainties.

1 INTRODUCTION

A High-Impact Low-Probability (HILP) event, also referred to as an extraordinary event, is an event with a high societal impact and a low probability to occur. In power systems, such events are often understood as blackouts, i.e. wide-area power interruptions. A number of such major blackout events have occurred in the last few decades (Bompard et al. 2013, Hillberg 2016), each resulting in critical consequences to society. Such events therefore receive great attention both by power system operators and other stakeholders, such as researchers and the general public, despite their low probability of occurrence. Partly due to this low probability, these events typically are not captured in conventional reliability and risk analyses, which calls for analysis approaches specific to HILP events.

HILP events historically involve a multitude of diverse and disparate threats and complex sequences of events, which present the analysts and researchers studying them with numerous uncertainties. Relevant aspects that can be taken into account in quantitative modelling of HILP events include: failure bunching due extreme weather (Panteli and Mancarella 2015), other natural hazards, cascading outages (Vaiman et al. 2012, Dobson and Newman 2017), dynamic phenomena, system protection schemes (Hillberg et al. 2012), corrective actions (Vadlamudi et al. 2016), and valuation of the societal impact. Different approaches and methodologies exist for quantitatively analysing these events (Gjerde et al. 2011), including methods of identifying unwanted events, causal analysis, consequence analysis, and risk and vulnerability evaluation. Such methods typically focus on one or a subset of all potentially relevant aspects. The realization is that there is no single methodology covering all these aspects that is suitable for analyzing HILP events in power systems (Kjølle et al. 2013), and the full set of aspects is too comprehensive to analyse quantitatively. Without a clear understanding of what specifically is the problem to be solved or decision to be supported, and consequently which aspects are important to capture, elaborate quantitative analysis may be of limited value.

In this paper, we take a broader view on HILP events and present the development of a qualitative framework for analysing HILP events in power systems. A qualitative framework provides the analyst with a more complete overview of the set of problems and a starting point for detailed analysis. Previous work on HILP events largely focus on methods of detailed, quantitative analysis (Vaiman et al. 2012), but some work on the more conceptual level also exists. For instance, (Watson et al. 2014) developed a framework for resilience metrics for energy infrastructures. In (Veeramany et al. 2016),

an overarching modelling framework is formulated under which different models can be integrated for an multi-hazard risk assessment of power system HILP events. The cascading aspect of some HILP events is discussed conceptually in (Vaiman et al. 2012, Dobson and Newman 2017).

The qualitative framework presented in this paper is based on an existing framework for power system vulnerability analysis (Kjølle et al. 2013, Kjølle and Gjerde 2015). The present paper advance previous work and attempts to consolidate relevant aspects of HILP events in a consistent and all-encompassing mapping. This framework explicitly discusses and structures uncertainties related to different decision problems. The framework is presented in Section 2, which forms the bulk of this paper. Subsection 2.1 shows how mapping relevant aspects and their relationships to a bow tie model provides a more complete overview of HILP events. Subsection 2.2 to Subsection 2.4 presents an approach to defining, delimitating and decomposing decision problems related to HILP events. This provides a starting point for quantitative analysis, as discussed in Section 2.4, and a basis for taking into account uncertainties, which is discussed in Section 2.5. Throughout these subsections, concrete examples of problems are discussed to illustrate the application of the framework. Finally, Subsection 3 concludes the paper and indicates future work in refining and applying the framework.

2 QUALITATIVE FRAMEWORK FOR HILP EVENTS

The qualitative framework presented in this paper is based on the conceptual bow tie model and a previously developed framework for power system vulnerability analysis (Kjølle et al. 2013, Kjølle and Gjerde 2015). The bow tie model describes the relationship between causes and consequences of unwanted events, which are here defined as power system failures. Note that the unwanted event in the centre of the bow-tie is not by itself a HILP event, but it could be the initiating event of a sequence of events with critical consequences that constitutes the HILP event.

2.1 *Getting a better overview of relevant aspects*

The bow tie model can be used as a visual aid in structuring the causes and consequences of unwanted events as illustrated in Figure 1. This figure gives a comprehensive overview of aspects relevant to HILP events in power systems and how these relate to each other. Such an overview is useful when structuring an analysis of HILP events.

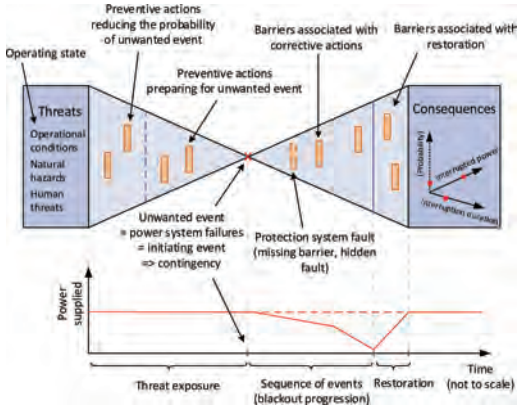

Figure 1. Overview of relevant aspects of HILP events in power systems mapped to a bow-tie model.

The left-hand part of the figure shows schematically how the exposure of the power system to different threats can cause power system failures, and the right-hand part shows how power system failures can result in consequences external to the power system, i.e. societal impact. The criticality of the consequences can be measured along different dimensions, but for the illustrations in this paper we will consider total end-user power interruption (MW) and interruption duration (hours) as the two principal dimensions. Each HILP event could, in principle, also be associated with a probability. Other relevant factors include the types of end-users affected and the dependence of the society on electricity supply; for further discussion of the definition of "critical", we refer to (Kjølle et al. 2013, Kjølle and Gjerde 2015).

Relevant threats on the left-hand side include conditions related to the operating state of the power system (e.g. challenges related to the power import/export situation, prior outages, etc.), natural hazards such as major storms and human threats. Barriers on the left-hand side of the bow tie reduce the susceptibility of the power system to threats. These barriers reduce the probability of unwanted events through preventive actions such as condition monitoring, preventive maintenance and vegetation management. Some barriers also preemptively increase the coping capacity of the system to reduce the probability of critical consequences in case an unwanted event does occur. This category of barriers includes preventive scheduling, grid reconfiguration and islanding in preparation for a major storm.

Barriers on the right-hand side of the bow-tie are intended to reduce the consequence of power system failures and correspond to the coping capacity of the power system with respect to these

unwanted events. Examples of such barriers are corrective actions such as emergency generation rescheduling, controlled load shedding, controlled islanding, and various system protection schemes. Other barriers are associated with the restoration of system operation after power has been interrupted, for instance the black-start capability of generators and the availability of spare parts, equipment and competent personnel.

To illustrate the distinction between these two types of barriers, we have in Figure 1 superimposed a timeline with an example of how the interrupted power could develop as a function of time throughout the course of the HILP event. The sequence of events after the occurrence of the initiating event can be broadly separated in a blackout progression phase and a restoration phase. Corrective action barriers are associated with the blackout progression phase and primarily intended to reduce the amount of interrupted power, whereas barriers associated with the restoration phase generally intended to reduce the restoration time and thus the interruption duration.

2.2 *Defining and framing the problem*

The analysis of HILP events in power systems is a broad problem area involving different decision problems as well as more fundamental research problems. The question one needs to ask is why one is interested in analyzing HILP events the first place. It is necessary with a clear definition the problem and a clear understanding of the motivation and purpose of solving the problem.

Figure 2 shows two dimensions that can be used to frame problems related to HILP events: The time scales for power system-related decisions and relevant stakeholders or decision makers. The figure also indicates the motivation of the stakeholders with regards to HILP events. The two dimensions in Figure 2 determine what information is available to the analyst and thus what uncertainties must be taken into account. This will be discussed in more detail in Section 2.5.

Here we will distinguish between operational, tactical and strategic decisions by the time scale of the planning horizon that is considered. Following the classification in (GARPUR Consortium 2016), these three time scales correspond to system operation (including both real-time operation and day-ahead operational planning), asset management, and system development or planning, respectively. Note that other references may use other terms and definitions for the time scales. For instance, (Watson *et al.* 2014) distinguishes between system planning decisions and policy decisions, and (Yang and Haugen 2015) defines both strategic and operational decisions as planning decision, which are in turn distinguished from instantaneous or emergency decisions.

Stakeholders can be differentiated in terms of their influence over power system related decisions, and since system operators have the most direct influence, we will in the following take the perspective of the system operator as a decision maker. Furthermore, we will focus on transmission system operators (TSOs) since distribution system operators (DSOs) have less influence over decisions relevant for wide-area power interruptions. In practice, decisions will be taken by different departments and at different levels in the organisation, but in the following we simply refer to the decision maker as "the system operator".

To put the more general problem of analysing HILP events in a decision-making context, Figure 3 shows some examples of relevant decision problems for system operators, sorted by time scale. These decision problems will be defined in broad terms below and be used in the following sections to illustrate the qualitative framework. Although we do not define the decision problems formally in terms of their objective function etc. as done e.g. in (GARPUR Consortium 2016), it

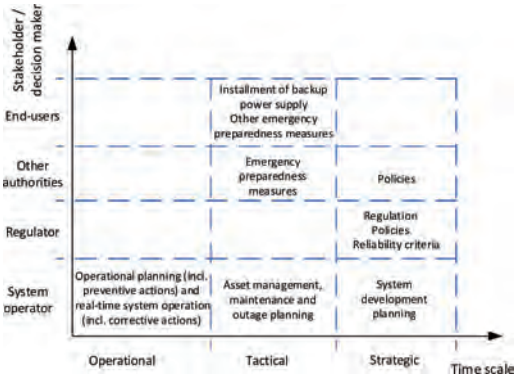

Figure 2. Two dimensions relevant for framing problems related to HILP events: The stakeholder or decision maker, and the time scale of relevant decision problems.

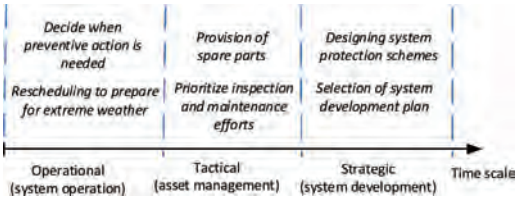

Figure 3. Examples of decision problems for transmission system operators with relevance for the analysis of HILP events.

is important to keep in mind that these reliability management decisions typically involve some form of trade-off between costs and reliability of supply. The value of reliability of supply is sometimes monetized in the form of expected interruption costs, i.e. the cost of energy not supplied.

Selection of system development plan: An example of a strategic decision problem is the evaluation of candidate system development plans (e.g. for new transmission lines) and selection of the best candidate. Regulation may dictate that a socio-economic cost-benefit analysis of the candidates is performed. Ideally, the cost of energy not supplied associated with possible HILP events should be included in such an analysis.

Designing system protection schemes: System protection schemes (SPSs) are important examples of barriers on the right-hand side of the bow-tie, and the system operator has to plan which SPSs to implement. The motivation of implementing an SPS could be to increase the transmission capacity of the system as well as to increase the coping capacity of the system with respect to the occurrence of contingencies that would otherwise result in critical consequences (Hillberg *et al.* 2012).

Prioritize inspection and maintenance efforts: The system operator has to decide how to best allocate limited resources for preventive actions such as intensified inspection and maintenance and improved condition monitoring of power system components. Mitigating certain susceptibilities could help reduce the risk of HILP events as well as more ordinary events.

Spare parts etc. for critical components: If the power system is vulnerable to the loss of certain component, e.g. a transformer, the decision can be made to provide for spare parts to reduce the duration of potential power interruptions.

Decide when preventive action is needed: During operation, preventive actions such as generation rescheduling may be needed e.g. due to the development of threat exposure and/or the operating state. The first step for the system operator is to correctly assess the situation and decide whether or not to effectuate preventive actions.

Rescheduling generation e.g. to prepare for extreme weather: During an extreme weather event the near-simultaneous failure of multiple transmission lines (failure bunching) is more likely. In this case, one relevant preventive action is to reschedule generation in a way that makes the power system better able to cope with failures on one or several transmission lines.

2.3 *Defining and delimiting the analysis*

Decision making for problems as exemplified above can be supported by the analysis of HILP events. One way of defining and delimitating "analysis of HILP events" is to consider sub-problems distinguished by the objective of the analysis. One possible classification is:

1. identifying critical contingencies
2. identifying critical operating states
3. identifying critical barriers
4. assessing the contributions to the overall reliability of supply

Each of these sub-problems can be associated with different parts of the bow-tie model as illustrated in Figure 4. In practice, the objectives may be overlapping and the sub-problems may be combined in one of the same analysis. The classification may nevertheless be useful in discussing specific decision problems and the underlying motivation.

2.3.1 *Identify critical contingencies*

A critical contingency is here understood as a failure or unplanned outage of a power system component that may potentially result in critical consequences. One purpose of identifying critical contingencies is to identify critical power system components with the motivation to strengthen or introduce appropriate barriers, cf. Section 2.3.3.

One example of a system operation decision involving the identification of critical contingencies is the (optimal) preventive rescheduling of generation in preparation for an extreme weather event. In this case, the system operator should ideally know which (critical) higher-order contingencies to take into account when rescheduling. In the context of system development, one would like to identify critical contingencies in the candidate development plans to reduce the vulnerabilities of the development plan that is selected. Another purpose of identifying critical contingencies can be to screen contingencies to be considered as input to more detailed (e.g. dynamic) analysis.

2.3.2 *Identify critical operating states*

We here understand a critical operating state as an operating state which in combination with a

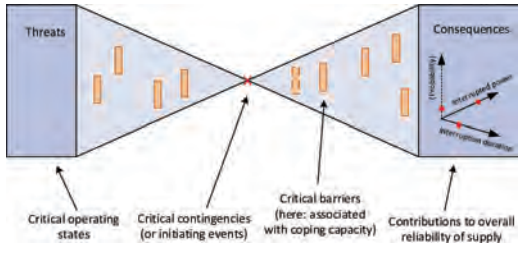

Figure 4. The placement in the bow tie model of different criticalities and sub-problems relevant in the analysis of HILP events.

critical contingency potentially result in critical consequences. The motivation for identifying these could be to increase the situational awareness of the system operators, which has previously been identified as being crucial to avoid HILP events (Johansson, E. *et al.* 2010). Situational awareness is relevant for operational decisions on which corrective actions to carry out after a contingency has occurred. Identifying critical operating states prior to contingencies may also be important to be able to decide when preventive action is needed.

2.3.3 *Identify critical barriers*

The identification of critical barriers may be used in selecting barriers to strengthen, and the identification of critical barriers that are missing may be used in proposing new barriers to put in place. This involves corrective barriers such as well-designed system protection schemes, or preventive barriers such as inspection and maintenance. For the latter example, the decision of which components to prioritize also depends on the identification of critical contingencies.

2.3.4 *Assessing the contributions to the overall reliability of supply*

An underlying premise of this work is that conventional power system reliability analysis methods do not fully capture HILP events. The reliability of a power system can be defined as "the probability of its satisfactory operation over the long run. It denotes the ability to supply adequate electric service on a nearly continuous basis, with few interruptions over an extended time period" (Kundur *et al.* 2004). The overall reliability of supply may be quantified by reliability indices such as the expected annual energy not supplied. Over the long run, HILP events do contribute to these reliability indices, but their contribution may be underestimated by conventional reliability analysis methods. For instance, this may happen when the methods do not capture failure bunching, protection system failures, or any of the other aspects and dependencies that may conspire to result in a HILP event. Furthermore, the short-term impact of a HILP event may be disproportional to their long-run visibility in expected values of reliability indices and therefore warrant separate treatment (Vaiman *et al.* 2012). These are some of the reasons why methods of vulnerability analysis focusing on HILP events have been advocated to complement traditional risk and reliability analysis methods (Johansson *et al.* 2013, Kjølle and Gjerde 2015).

Nevertheless, estimates of reliability indices are used by system operators as part of their reliability management processes also for decisions relating to HILP events. An example is the selection of system development plans for a given region, supported by a socio-economic cost-benefit analysis including expected interruption costs. If the region is exposed to strong winds, this could motivate capturing the contribution of HILP events due to failure bunching effects in the estimated interruption costs.

2.4 *Decomposition in quantitative analysis*

After defining the purpose of the analysis, one needs to consider which quantities the analysis method needs to estimate and which of them is most important to estimate accurately. Here we will consider three primary output parameters: 1) The probability of an event and its consequence in terms of 2) power interrupted and 3) interruption duration. As illustrated in Figure 5, these output parameters are broadly speaking associated with different parts of the bow-tie model. To assess the consequences of an unwanted event, it is sufficient to consider the right-hand side of the bow-tie: The interrupted power is primarily determined by the sequence of events within the phase labelled "blackout progression", and the interruption duration is primarily determined by the events in the restoration phase. On the other hand, to determine the probability of a HILP event, characterized by a given consequence, one has to consider both the left-hand side (with the label "threat exposure" in Figure 5) and the right-hand side of the bow-tie.

To approach more quantitative analysis and consideration of different uncertainties, we overlay the bow tie model with a schematic data flow diagram for the analysis in Figure 6. A cause analysis is depicted on the left-hand side of the bow tie that gives as output the failure rate (or the probability of failure during a certain time interval) for a given unwanted event (i.e. a given power system failure). Such a module could for instance be based on a fault tree. Failure bunching effects, for example due to major storms, could be incorporated in this step using existing tools for estimation of wind-dependent failure rates, as done in (Solheim *et al.* 2016).

The consequence analysis on the right-hand side of Figure 6 is divided in two modules representing

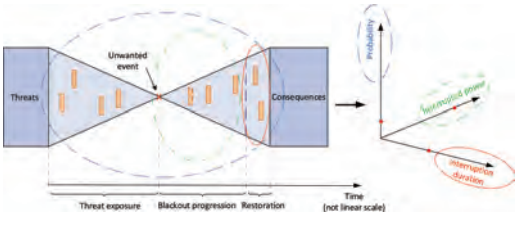

Figure 5. Illustration of how the problem of analysing extraordinary events can be decomposed and delimitated based on what quantity one is focusing on estimating.

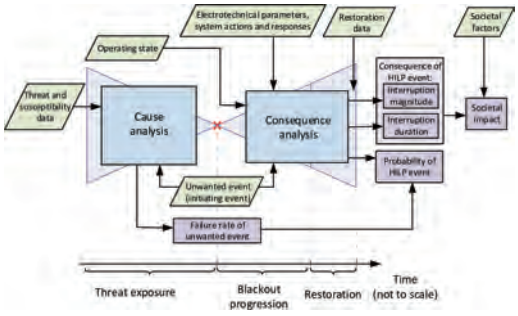

Figure 6. Schematic of quantitative analysis (blue, within the bow-tie) with input data (green parallelograms) and output data (purple).

the blackout progression phase and the restoration phase, respectively. The module for the blackout progression phase models system responses and resulting power interruptions. It could be based on an event tree model, power flow analysis, dynamic analysis, etc. This module can take as input electrotechnical parameters describing the power system and its operational limits as well as parameters describing the actions and responses in the system. For instance, if the analysis method is based on an event tree accounting for corrective action failures (Vadlamudi *et al.* 2016), input parameters can be conditional probabilities determining the probability of different sequences of events. The restoration phase module represents the restoration process. For instance, the restoration time could be modelled by average outage times of the components involved, in which case such outage times are needed as input. Alternatively, the restoration process could be modelled in more detail, which would require additional input parameters.

When analyzing system protection schemes to identify critical barriers for certain unwanted events, it may not be important for the purpose of the analysis to consider what caused these unwanted events. For such an analysis, one could omit the left-hand side of Figure 6 and focus on the first part of the consequence analysis, e.g. using dynamic analysis to estimate the power interrupted. On the other hand, if the objective is to assess the contribution to the overall reliability of supply, one would typically also have to represent power system restoration in the analysis.

In the determination of the consequences illustrated in Figure 6, the consequence analysis stops after finding the interruption magnitude and duration. However, as mentioned in Section 2.1, the societal impact of an HILP event is not determined by these two parameters alone. The box labeled societal factors in Figure 6 represent other factors determining the societal impact, such as the type of customers (end-users) and the criticality of the loads that are interrupted. Consequences of power interruptions are typically monetized using interruption cost functions determined by customer surveys, but these interruption costs give only a lower bound for the total socio-economic costs of the power interruption (GARPUR Consortium, 2016). Estimating quantitatively the impact on society more widely might involve modelling of the interactions between the power system and other infrastructures (Johansson et al. 2015).

2.5 *Taking into account uncertainties*

HILP events can be argued to be inherently associated with uncertainties (Taleb 2010, p. xxviii). Factors such as the operating state, the technical condition of components and failure bunching effects due to adverse weather all have their own individual uncertainties. HILP events are often the results of multiple, interacting factors and circumstances. As such, their combined uncertainty is larger than the uncertainty of the individual factors.

First, it is common to classify uncertainties as either aleatory, i.e. associated with random variability, or epistemic, i.e. associated with a lack of knowledge. Given that HILP events are characterized by a scarce experience base and severe lack of knowledge, epistemic uncertainties are especially important to consider. Next, following a similar classification as in (Rausand 2013), we will broadly distinguish between three types of uncertainties:

- Input data uncertainties
- Modelling uncertainties
- Completeness uncertainties

For the analysis of HILP events in power systems, these types of uncertainties can be related to Figure 6 as follows. Input data uncertainties and modelling uncertainties are related to green and blue boxes, respectively. The additional category that we have here chosen to label "completeness uncertainty" represents uncertainty associated with the completeness of the models of the system. Although there are different ways to understand this term (Rausand 2013, Aven 2016), and "completeness uncertainty" may not be unambiguously distinguished from "modelling uncertainty", we find the term useful to describe uncertainty associated with aspects omitted and/or outside the scope of the analysis. As an example, a consequence analysis starting from a given set of contingencies (i.e. covering only the right-hand side of Figure 6) does not explicitly consider what might have caused the contingencies. If the problem was to identify effective system protection schemes, for instance,

threat and susceptibility aspects may not have been within the scope of the analysis.

Sources of incompleteness in the analysis can be either known or unknown to the analyst (Aven 2016). If the analyst is unaware that an aspect is not considered in the analysis, this uncertainty can be labelled an "unknown unknown" (Feduzi and Runde 2014). Here, we use this term in a wider sense to refer to lack of knowledge that is implicit, i.e. a form of epistemic uncertainty associated with "what we don't know we don't know". Furthermore, we focus on "unknown unknowns" that are "knowable", i.e. that can in principle be transformed into "known unknowns" (Feduzi and Runde 2014).

Another way to classify uncertainties related to an analysis of HILP events that is more specific to the domain of power systems is to consider uncertainties related to the aspects discussed in Section 2.1. An example of such a classification is illustrated in Figure 7. Here, each of the categories along the vertical axis corresponds to one of the components of quantitative analysis that were illustrated in Figure 6. This shows how a domain-specific classification can be combined with the generic uncertainty classification discussed above: For each category, a given analysis is associated with uncertainty (indicated along the horizontal axis) related to the accuracy of modelling assumptions and the input data.

This multi-dimensional classification of uncertainties can be used to structure a qualitative assessment of the strength of background knowledge (Aven *et al.* 2014, p. 87) underlying a given analysis: If an aspect is modelled in a simplified or inaccurate manner, the knowledge of this aspect that is represented in the analysis is weak and the uncertainty is correspondingly high. Even if the modelling of an aspect is accurate, the uncertainty is still high if the associated input data represented in the analysis is inaccurate.

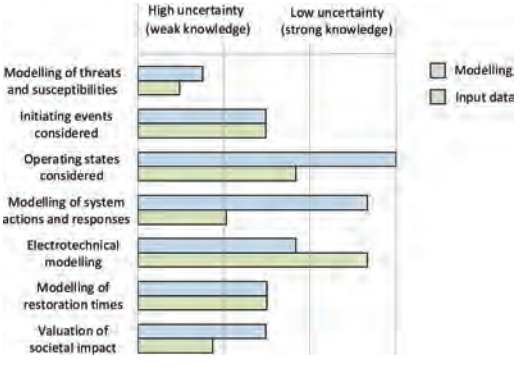

Figure 7. Example of classification and assessment of uncertainties associated with analyses of HILP events.

Such a structured assessment of the uncertainties of a HILP event analysis can be used by the analyst to rank which uncertainties are most important (Aven *et al.* 2014) to improve the overall accuracy and suitability of the analysis. More accurate modelling of an aspect often implies longer computation times. In practice, a trade-off must therefore be made between computational efficiency and accuracy, and trade-offs must be made between the modelling accuracy for the different aspects considered in the analysis.

An explicit qualitative assessment of uncertainties can also be used as a basis for comparing different analyses and informing the decision maker of their uncertainties (Aven *et al.* 2014). As an example, one can consider methods designed to analyse cascading outages. A number of such methods have been developed, each focusing on different subsets of the mechanisms and aspects involved in cascading outages. Considerable efforts have already been devoted to reviewing and validating such methods (Vaiman *et al.* 2012, Bialek *et al.* 2016), but there are still many open questions that may limit their credibility in decision making. More explicit classification and assessment of their uncertainties, scope and purpose could help inform system operators of which methods are most suitable for different problems.

Completeness uncertainty is not included as a separate dimension in Figure 7, but if an aspect is not covered in an analysis, the modelling uncertainties related to this aspect can be regarded as high. However, to fully characterize the completeness uncertainty dimension of the analysis one needs to identify and uncover "unknown unknowns". It has been argued that to do so, the analysis needs to be placed in a sufficiently broad framework and avoid starting out with a too narrow view of the problem (Feduzi and Runde 2014, Aven 2016). A qualitative mapping of relevant aspects to the analysis as proposed in this paper can contribute to transforming "unknown unknowns" to "known unknowns", or in other words making implicit assumptions and uncertainties explicit. Communicating such uncertainties associated with the completeness of the analysis can change, from the perspective of the decision maker, a "unknown unknown" to a "known unknown". To give a simple example: When deciding on system protection schemes to mitigate cascading outages and the analysis does not model the dynamics of rotor angle stability, the decision maker should be aware that the type of cascading events characterized by generators losing synchronism is omitted from the analysis.

As mentioned in Section 2.2, the time scale of the decision problem is relevant for what information is available during the analysis and hence what is uncertain and what is known. For instance,

the system operator knows the operating state to a good approximation during real-time system operation, whereas this information is not available for an analysis for long-term planning purposes (Vaiman et al. 2012). For the example of cost-benefit analysis including the contributions of wind-related failures, the analyst needs to assume a selection of operating states expected to be representative of the future, and this is associated with additional uncertainties. For the example of preventive rescheduling in preparation of a major storm, more information is available on the operating state over the planning horizon, although this is still imperfect information as one may have to consider the forecast uncertainties.

3 CONCLUSIONS AND FUTURE WORK

This paper proposes a qualitative framework for analysing HILP events in power systems that may complement or guide more quantitative analysis. Mapping relevant aspects of such HILP events to a bow tie model provides the analyst with a broad overview of the set of problems at hand and a starting point for detailed analysis. Although the full set of aspects is too comprehensive to analyse quantitatively, the qualitative framework provides a basis for decomposing and delimitating the problem: Defining precisely the purpose of the analysis, one can then choose what aspects need to be modelled accurately and which aspects one is choosing to omit. Omitting and neglecting aspects of the overall problem introduce uncertainties in the analysis, but by being explicit about what is omitted and assumed one reduces the amount of "unknown unknowns" in the analysis and may thus support more well-informed decisions.

Further work will test the applicability of the framework in case studies of real problems related to HILP events. The approach for defining the purpose of an analysis and delimitating the problem presented will also be used to guide the development and application of methods for quantitative analysis of HILP events. Furthermore, the classification of models and input data for the analysis may form the basis for considering which methods are most appropriate for handling different types of uncertainties related to modelling choices and input data.

Safety assessment: Perspectives for next generation nuclear plants

A. Carpignano, S. Dulla & A.C. Uggenti
NEMO group, Dipartimento Energia, Politecnico di Torino, Italy

ABSTRACT: Safety assessment and risk analysis are recognized as a priority in the development of next generation nuclear systems (Generation-IV reactors and full-scale fusion reactor—DEMO-) and demand a reconsideration of the safety philosophy currently applied to the existing nuclear stations. Since their innovative physics and technology and the preliminary design phase of some of the concepts, their safety assessment has to rely on the basis of nuclear safety and technological neutral methodology. In order to satisfy this necessity, a bibliographic survey on nuclear and non-nuclear international standards and best practices is performed. By comparing them, this work tries to reach a new and more systematic approach, based on functional safety, suitable for dealing with the unique challenges of the innovative nuclear facilities, in order to guarantee that safety achievement is intended to be "built-in" rather than "added-on" by influencing the concept evolution from its earliest stages.

1 INTRODUCTION

The contemporary research activity in the nuclear field is focused on the development of nuclear facilities able to satisfy the four goal areas identified by the Generation IV International Forum (GIF, 2014) in its Technological Roadmap in order to advance nuclear energy in its next generation: sustainability, safety and reliability, economic competitiveness, proliferation resistance and physical protection. The attempt to answer this request with a fully innovative technology is the rationale associating all Generation IV reactor designs and the proposed concepts for a full-scale fusion reactor (EUROfusion website).

The nuclear energy systems must be designed so that, during normal operation or anticipated transients, safety margins are adequate, accidents are prevented and off-normal situations do not deteriorate into severe plant conditions (RSWG of the GIF, 2008). Therefore, safety assessment and risk analysis, in both operational and accidental conditions, are recognized as an essential priority in the development of these next generation nuclear systems. Because of their innovative physics and technology and the preliminary design phase of some of the concepts, their safety assessment has to rely on the basis of functional safety and technological neutral methodologies. This demands a reconsideration, a modernization and an adaptation of the safety philosophy currently applied to the existing nuclear stations and a constant innovation and development of safety assessment methods to continue to advance the state of the art and improve their adequateness.

In 2002 GIF selected six systems from nearly 100 concepts as the Generation-IV fission nuclear plants: the Gas-cooled Fast Reactor (GFR), Sodium-cooled Fast Reactor (SFR), Lead-cooled Fast Reactor (LFR), Molten Salt Reactor (MSR), Very-High-Temperature Reactor (VHTR), Supercritical-Water-cooled Reactor (SCWR) (GIF, 2014); on the other hand the DEMOnstration fusion power reactor (DEMO) is foreseen to follow the advancements of ITER (International Thermonuclear Experimental Reactor) by 2050 (EUROfusion website). These systems present a wide range of new technologies that create issues if the traditional safety approach adopted for Light Water Reactors (LWRs) is considered: for example, the MSR design is characterized by a liquid nuclear fuel, therefore the evaluation of the Core Damage Frequency (CDF) in terms of core melting as an indication of severe accident is no longer applicable. Moreover, due to the online refueling envisaged for MSR, also in normal operation conditions the fuel is not localized in the core (as it happens for the LWR) but it is spread in several subsystems and occupies different positions in the reactor, making inconsistent the traditional definition of physical barriers (cladding, primary circuit, containment building). A general comment, valid for all these innovative nuclear systems including fusion machines, is that, in many cases, the design is still in development therefore a safety assessment performed at the components level is not useful since their architecture will evolve in time: instead, a functional approach allows to identify the functional deviations challenging the system since the early design and, consequently, to include safety features in a holistic optics.

This work starts investigating the safety challenges of the new generation of nuclear plants and performing a bibliographic survey on nuclear and non-nuclear safety international standards and best practices; the objective of the paper is to present an iterative methodology that is coherently applicable since the conceptual phase of the design and aims at influencing the direction of the concept and design development from its earliest stages; hence the safety will be intended to be "built-in" rather than "added-on".

2 SAFETY CHALLENGES FOR NEW GENERATION NUCLEAR PLANTS

The majority of current nuclear safety regulatory requirements is based on LWRs technology and necessitates changes to suit to a new spectrum of novel, advanced, next generation plants (Southern Company, 2017). In Probabilistic Safety Assessment (PSA), the risks associated with the reactor accidents are highly design, plant and site specific; this is demonstrated for any kind of reactor. In particular, dealing with next generation nuclear plants implies a much larger range of risks variability with respect to an LWR: fundamental differences in the physical processes are present, as well as in the plant responses associated with the reactor transients and accidents. This is due both to the use of different materials for the reactor fuel, moderator and coolant and to different safety design approaches for the implementation of radionuclides barriers (Southern Company, 2017). Because of these differences, the LWR risk metrics, for instance the Core Damage Frequency (CDF) and the Large Early Release Frequency (LERF), are neither relevant nor useful for many advanced nuclear reactors; some plants, in fact, may not involve the core damage state that was defined for LWR and, even in the case, its meaning and risk framework can be fundamentally different from LWR (INL, 2011). Consequently, PSA for advanced reactors may be structured differently than the traditional Level 1, 2 and 3 model for LWR PSA: it is expected to include out of core sources of radioactive material (especially in the case of online refuel, as for the MSR) and to adopt adequate and more general risk metrics (INL, 2011); the latter may lead to an appropriate definition of severe accident, detached for the core melting concept. Additionally, while the traditional LWR risk assessment was developed following the "one-reactor-at-a-time" approach, in next generation nuclear plants the risk associated to multi-unit sites becomes certainly relevant and, especially after the Fukushima Daichi accident, even dominant (Fleming, 2017). Advanced non-LWRs are expected to be constituted by several modules, located in the same site: this increases the possibility of common cause failures/domino effects, due to the potential for sharing of systems and structures or hazards involving more than one reactor (e.g. external hazards). This influences the traditional frequency-consequence tolerability criteria.

Lastly, a major difference between the risk assessment methodologies (e.g. PSA) of LWRs and next generation nuclear plants is the following: the former were introduced after the plants were designed and licensed, limiting the risk-informed applications to additional systems or provisions for plants that were already built and operated; on the other hand, the latter are primarily used as tool to support the design and to expand the range of the risk-informed decisions (Southern Company, 2017).

3 OVERVIEW OF SAFETY ASSESSMENT METHODOLOGIES AND STANDARDS

A huge set of prior activities, policies, standards, practices and requirements support the design and the licensing of LWRs.

IAEA (International Atomic Energy Agency) standards provide the fundamental principles, requirements and recommendations to ensure nuclear safety. They serve as a global reference for protecting people and the environment and contribute to a harmonized high level of safety worldwide (IAEA, 2006): as stated in the fundamental safety principles of the IAEA Safety Standard for protecting people and environment, (IAEA, 2006), "the fundamental safety objective is to protect people and the environment from harmful effects of ionizing radiation"; this fundamental safety principle is detailed in ten safety principles on the basis of which safety requirements are developed and safety measures are implemented in all nuclear facilities and activities, and for all stages over the lifetime of a facility or a radiation source. These principles inspire the "General Safety Requirements" and the "General Safety Guide" that, for each technical area, are declined into a number of "Specific Safety Requirements" and of "Specific Safety Guides" that provide all the guidance necessary for implementing the general principles. While the ten safety principles are general enough to be applicable also to non-LWRs, all the other documents and standards are referred specifically to LWRs. Similarly, the Nuclear Regulatory Commission (NRC) regulations and in particular the Title 10 of the Code of Federal Regulations Part 50 (10 CFR 50) (USA NRC, 2017) establish Principal Design Criteria (PDC) derived from the General Design Criteria (GDC) that are specifically

referred to LWRs (Appendix A of 10 CFR 50). Considering the fact that the last USA commercial non-LWR was shut down in 1989 (Fort St. Vrain, a High-Temperature Gas-cooled Reactor—HTGR), the update of these documents is on-going but is especially challenging because of lack of specificity in the technology/designs that will be ultimately submitted to NRC for review, of lack of maturity of design and of the unavoidable technical skills gap (Lee, 2016).

Traditionally, the PSA is performed only after the definition of the detailed design and of the site: in this case, if the tolerability criteria are not fulfilled, it could be necessary to modify also the preliminary design.

Nowadays a widely accepted approach in the process industry is the one described in the IEC EN 61508, whose major idea is that the safety of systems must be studied and pursued from the early design by risk analysis tools; one of its main activities is to define the Safety Instrumented Functions (SIFs) that must be further and deeply analysed in order to understand the effective risk reduction needed and the necessity to implement them in terms of safety systems and in terms of additional safety requirements. Functional safety assessment in the context of IEC EN 61508 constitutes a milestone for safety to drive the design (IEC EN 61508, 2005). The IEC EN 61513 provides requirements and recommendations for the overall I&C architecture of a Nuclear Power Plant (NPP) which may contain both hard-wired and computer-based technologies; it aims at translating the general requirements of 61508–1, 61508–2 and 61508–4 for nuclear application sector and, similarly to the IEC EN 61508, it introduces the concept of a safety life-cycle for both the whole architecture and the individual system, highlighting the relations between the safety objectives of the NPP and the requirements for the I&C architecture (IEC EN 61513, 2013). Nevertheless, the need to maintain the traditional safety approach for nuclear applications makes the 61513 misrepresenting the nature of the 61508; instead, it represents an intermediate step included into a rigid process that was developed for and it is still suitable to LWRs, but difficult to apply to concepts of the next generation. Hence, the philosophy of the 61508 can inspire the safety assessment of advanced nuclear plants, but redefining the strict framework defined for LWRs.

A schematic representation of the two approaches is shown in Figure 1.

Other methodologies, such as the Integrated Safety Assessment Methodology (ISAM) and the International Project on Innovative Nuclear Reactors and Fuel Cycles (INPRO) are always inspired by the IAEA general principles but at the same

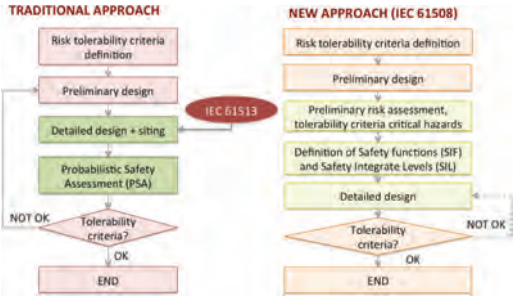

Figure 1. Schematic of the traditional and the new approaches to safety assessment.

time aim at implementing the concept of a safety driven design. The ISAM (RSWG of the GIF, 2011) is meant to combine both probabilistic and deterministic tools, both quantitative and qualitative methods and evaluations, some focusing on high-level issues, others on more detailed issues. It aims at providing a robust guidance, based on a good understanding of risk and safety issues, contributing to the achievement of Generation IV safety objectives. The INPRO assessment (IAEA, 2008) is a stepwise approach with a hierarchic structure: Basic Principles (BP), User Requirements (UR) and Coordinated Criteria (CC), which must be fulfilled by an Innovative Nuclear System (INS) to determine if the system is sustainable or not. This approach aims at providing a tool to analyze a nuclear installation in order to:

- Evaluate if it is compatible with the objective of sustainable energy development,
- Compare different plants or components to find a preferred or an optimum solution tailored to the needs of a specific region or a State and
- Identify possible improvements.

These two approaches represent guidelines that must be reviewed, completed and adapted, when needed, also using traditional risk analysis tools in order to better suit the unique case of each of the next generation nuclear plants. They define an inspiring philosophy but do not constitute an operational framework, which still has to be defined for advanced concepts through tailored criteria, requirements and consolidated operational safety assessment methods.

4 PERSPECTIVES OF SAFETY ASSESSMENT METHODOLOGIES

4.1 *Risk metrics*

Each nuclear plant must fulfil Quantitative Health Objectives of individual risk (QHO), used as a

basis for determining whether a level of safety ascribed to a plant is consistent with the safety goal policy (Whipple, 2012). In the LWR framework these objectives are embodied by LERF and CDF, which may not be consistent for some of the new generation nuclear plants, therefore they shall be reviewed (INL 2011). Although ISAM tries to adapt the CDF definition to all kinds of reactors, in some cases, especially those precluding the core damage states defined for LWRs, this results problematic and it may be appropriate to use a set of the risk-metrics that have the capability to define the significant contributions to risk and provide information to demonstrate defense in depth adequacy. The proposal for advanced reactors needs to be TI-RIPB (INL, 2017):

– Technological-Inclusive (TI), namely applicable to any design independently from the implemented processes;
– Risk-Informed (RI), since each decision must be an opportune derivation of both probabilistic and deterministic principles;
– Performance-Based (PB) because the risk and safety analysis lead to the formulation of performances requirements of Structures, Systems and Components (SSCs) in order to avoid accidents, or at least mitigate them.

Some proposed indexes include the frequencies of event sequences grouped in accident families having the same plant response and the same offsite radiological consequences, the integrated risk of a given consequence (e.g. site boundary dose), the individual fatalities (as compared to the existing limits for LWR) and the cumulative frequency of an early or latent effect. Moreover, some specific risk metrics can be defined for each reactor, depending on the specific characteristics.

These values can be expressed in the form of mean values and uncertainties percentiles (5th and 95th percentiles) and compared to the frequency-consequence evaluation criteria, as the one defined in Figure 2.

Furthermore, the integrated risk evaluation of the entire plant is performed taking into account four evaluation criteria (INL, 2017):

– the total frequency of exceeding a site boundary dose of 100 mrem shall not exceed 1/plant-year according to the annual exposure limits in 10 CFR 20;
– the total frequency of a site boundary dose exceeding 750 rem shall not exceed 10^{-6}/plant-year according to NRC Safety Goal Policy Statement on limiting the frequency of a large release;
– the average individual risk of early fatality within 1 mile of the Exclusion Area Boundary (EAB) shall not exceed 5×10^{-7}/plant-year according to the NRC Safety Goal QHO for early fatality risk;
– the average individual risk of latent cancer fatalities within 10 miles of the EAB shall not exceed 2×10^{-6}/plant-year according to NRC safety goal QHO for latent cancer fatality risk.

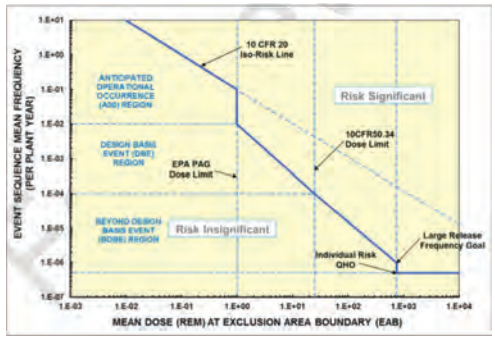

Figure 2. Frequency/consequence evaluation criteria (INL, 2017).

It is worth to note that the traditional classification of PSA Level 1, 2 and 3 starts from the concept of CDF and LERF, therefore the update of the risk metrics implies a new modernized PSA concept.

According to the "Basis for the Safety Approach for Design & Assessment of Generation IV Nuclear Systems" (RSWG of the GIF, 2008), one of the objectives to be pursed for the advanced designs optimization is their rationalization by the deliberate adoption of the ALARP (As Low As Reasonable Practicable) principle applicable to the full spectrum of design conditions. The UK Health and Safety Executive (HSE) defined an ALARP region (or tolerability region) between the acceptable and unacceptable risk regions: the comparison between advantages and disadvantages (i.e. between the reduction in risk and the cost of achieving it) on a quantitative or qualitative basis establishes what is "reasonably practicable" to be carried out in order to reduce the risk (HSE, 2001). This optimal risk reduction is translated in the implementation of innovative provisions looking for further risk reduction (prevention of the initiators and consequences mitigation) on a cost-benefit basis (RSWG of the GIF, 2008). In a frequency-consequence graph the ALARP area is usually represented by a range of values, but in Figure 2 it degenerates in a line. Since the uncertainties characterizing both the considered designs and their analyses, the ALARP principle should represent a key point for the definition of the acceptability criteria.

4.2 *Iterative risk assessment*

The risk assessment process for an advanced nuclear plant is proposed to be iterative rather than serial (as for the PSA Level 1,2,3) so that it can be introduced at an early stage of design and be consistent with the level of detail of the evolving design and successively with the site characteristics. Moreover, it is supposed to provide a logical and structured method to guide the design and evaluate its safety characteristics in a systematic and exhaustive manner. A very preliminary PSA is introduced when the reactor design is still conceptual: it is focused on internal events involving radioactive sources and it is simplified according to the level of knowledge regarding the definition of the design and physical phenomena occurring in the reactor. The challenges for the reactor are defined in terms of Initiating Events (IEs), with the correspondent plausible causes and consequences. The traditional list of IEs defined for the LWRs can inspire the advanced reactors ones, but it cannot be exhaustive and sometimes it is not even coherent; different technologies and phenomena have to be analyzed and can produce a completely new list of accident initiators, as in the case of fusion device (Pinna, 2017). The events leading to similar "reactor end-state" will be grouped together and the event involving the worst consequences will be selected as Postulated Initiating Event (PIE) to represent the entire group. The first group of PIEs is identified at a sufficiently early stage of the design to enable the designer to select the events worth to be considered to enhance the plant safety. At this level, methods following a functional approach can be used, whose suitability is assessed also in non-nuclear standards (IEC EN 61508, 2005). As the design matures and more design details become available, the set of PIEs will be updated and broadened to gradually address other plant systems and operational states. At the same time, the selected events will be studied through deterministic analyses in order to define more accurate events sequences. When the deterministic inputs are modified, the design changes and the PSA model evolves as well. Progressively all the internal hazards will be included (not only radioactive releases but also, for example, internal fire and floods) and, when the site characteristics become available, also external hazards (e.g. earthquake) can be taken into account. At the end, the analysis can be refined introducing information about human factor (Southern Company, 2017). This approach is expected to converge faster to a successful design rather than try to adapt and satisfy the LWR requirements.

4.3 *Preliminary PSA*

The PSA model begins with a systematic search of initiating events. Since the preliminary design stage of some of the new generation plants, a functional approach has been selected, suitable to define possible accident initiators when a sufficient design detail is not yet available to allow more specific evaluations at the component level. This methodology has already been applied on fusion devices, in particular to analyse the Primary Heat Transfer System (PHTS) of EU DEMO, with a WCLL (Water Cooled Lithium Lead) and a DCLL (Dual Coolant Lithium Lead) breeding blanket (Pinna, 2017), (Carpignano, 2016).

In order to identify functional deviations able to compromise system safety (in terms of Postulated Initiating Events, PIEs) as completely as reasonable, two approaches can be implemented at the same time: the Functional Failure Mode and Effect Analysis (FFMEA), a bottom-up approach, that focuses on the identification of the functions of the system and on the analysis of the consequences of the loss of each of them and the Master Logic Diagram (MLD), a top-down approach, that after the selection of a top event identifies its possible elementary causes. A list of PIEs is completed and for each of them a brief description of plausible causes, consequences, involved components, preventive and mitigation actions is provided. In addition to the identification of PIEs, this approach allows identifying lack of information on some systems, procedures or phenomena, to point out the potential limitations of the design and to make suggestions to enhance the safety of the concept. An example of application of this methodology is shown in (Uggenti, 2017). The complexity of the application of this methodology is reflected in the number of listed Postulated Initiating Events, between 25 and 30 for the three analysed systems, derived from an FFMEA of around 1000–1200 lines.

Successively, each accidental scenario has to be classified into frequencies and consequences severity macro-categories. Accordingly to (INL, 2017) the event sequences include relatively frequent events classified as Anticipated Operational Occurrences (AOO, with a frequency higher than 10^{-2} events per plant year), infrequent events classified as Design Basis Events (DBE, with a frequency between 10^{-4} and 10^{-2} events per plant year) and rare event classified as Beyond Design Basis Events (BDBE, with a frequency lower than 10^{-4} events per plant year). The severity of the consequences can be evaluated in terms of release of radioactive material (since the preliminary design, it can be evaluated in percentage with respect to the total amount) or in terms of damages to the asset (taking into account the possibility to restart the system immediately or after a while or its impossibility).

One or more risk matrices can be built using consistent definitions of technological-inclusive

risk metrics and severe accidents: according to the risk level of each unprotected accidental sequence, a number of provisions (or lines of defence) needs to be defined. This number is then compared to the number of existing barriers already present in the preliminary design and eventually suggesting new provisions to accomplish the requirements and to help sketching the final architecture of the system, using a more traditional approach.

5 CONCLUSIONS

For non-LWRs, the frequencies of accidents involving release of radioactive material may be very small and even those accidents with releases may involve very small source terms compared with releases of LWRs core damage accident. Therefore, the total risk may be very small (Southern Company, 2017). Nevertheless, it is necessary to understand the principal risk contributors in order to try to reduce the risk sources at the early design phase (Van der Börst, 2001): risk importance measures can be defined for any kind of risk metrics and it may be useful to calculate the risk significance both in relative and absolute basis, comparing it against risk goals rather than only against baseline risks.

The evaluation of the sources of uncertainty has to be performed without delay: uncertainties need to be evaluated both for frequencies and consequences through the performance of quantitative uncertainty analysis, where information is available to perform this function, and sensitivity analyses, to address other sources of uncertainty that are more difficult to quantify. To this aim, these uncertainties have to be considered in the frequency-consequence evaluation criteria. This uncertainty treatment then becomes an input to a risk-informed evaluation of Defence in Depth (DID).

A major limitation of preliminary nuclear risk assessment is due to the fact that all the efforts are concentrated on the nuclear island, while the remaining "traditional" components, for example all the components constituting the Balance of Plant, and the siting are usually only sketched: it is common to ignore the precise architecture of a system or the number of its redundancies, increasing the source of uncertainties in the risk evaluation: a design process to connect the research approach to a more engineering approach would be necessary to increase the realism and the accuracy of the safety evaluations.

In conclusion, it is worth to highlight that, due to their standardization, the LWRs safety assessment, and consequently their safety architecture, is prescriptive (what to do) or proscriptive (what to avoid doing), since historically the safety process standards are rules-based. The variegate nature of the next generation nuclear facilities imposes safety process standards to be simple and based on stable, general principles, as suggested by the IEC EN 61508, already implemented in some process industry sectors involving many diversified plants and technologies (e.g. Oil & Gas, chemical plants). Goal-based standards focus on the final objective of the safety assessment (what is necessary to achieve) and suits to new technologies (not only nuclear ones) better and more cost-effectively, by exploiting all the potentialities and the versatilities of the risk analysis.

Scenario dependency of safety targets for platform doors

B. Hulin
NTC-Systems GmbH, Gilching, Germany

ABSTRACT: Platform barriers for railways shall protect passengers from different events like being crushed by a train or falling off the platform onto the track. Passenger can access a train through automatically operating platform doors that are integrated into the platform barriers. From a safety perspective, platform doors are an electronically controlled system, whose risks need to be analysed and reduced to an acceptable level. One of the most discussed points, in that relation, is the allocation of safety (design) targets for different functions of platform doors. This paper proposes the application of SIRF for the determination of safety targets for functions of platform doors. Beside a theoretical reasoning for using SIRF the paper gives examples for its application to platform doors. Especially, the hazard 'vehicle starts moving and doorways are open' is analysed for its criticality and the related functions are assigned with safety targets. It is shown, that this process highly depends on the scenario even if the starting conditions are equal. This leads to the conclusion that all scenarios for the same situation have to be analysed. The conclusion is that SIRF can be applied to platform doors easily, and delivers reasonable results.

1 INTRODUCTION

Access points of many recent transportation systems are limited by special barriers like platform barriers with platform doors. There is especially the need for such barriers within automated transportation systems like unmanned people movers or metro systems (see EN 62267 (CENELEC 2009)). Platform doors are usually implemented as screen doors that are automatically opened for boarding a train.

Platform barriers as well as their integrated platform doors are for protecting passengers from falling off the platform or being struck or crushed by a train. Insofar, platform barriers including their platform doors shall reduce the risk of injuries or deaths.

From a safety perspective, platform doors are an electronically controlled system that needs to be assessed for risk. In this context, the safety related functions with their safety targets are to be determined.

Safety targets (see CLC/TR 50451 (CENELEC 2007)) or design targets (see Regulation 2015/1136 (EU 2015)) can be defined amongst others as TFFR, THR, MTBF or SIL. A safety target is allocated to a functional safety requirement. The safety target of a functional safety requirement is the maximum criticality of all hazards related to it.

For the determination of safety targets for functional safety requirements there is available a huge amount of methods such as risk graph, risk matrix, and so on (Summers 1998). Each method has its own pros and cons and is best suited for some domains or some applications.

A good method for the determination of safety targets for railway vehicles is SIRF (EBA 2012)[1]. SIRF (Sicherheitsrichtlinie Fahrzeug) is a German tailoring of the EN 50126 (CENELEC 1999) for safety assessment for functions of railway vehicles. It was first released in June 2011 by the German national railway safety authority and has been applied successfully in many projects in Germany and Austria for main line and urban railway vehicles (e.g. metros, tramways and people movers).

As this method is used for the determination of safety targets of functions all over the railway vehicle including vehicle doors, the author argues that this method can be applied for platform doors, too, even if they do not belong to the structural subsystem vehicle.

This paper discusses this argumentation and concludes that an application of SIRF for platform doors is possible and reasonable. The main part of this discussion are examples of the hazard 'vehicle starts moving and doorways are open' with different situations and accident scenarios.

Since this is the first publication that applies SIRF to platform doors the method is described, first of all.

1. SIRF is freely available at www.eba.bund.de.

2 METHOD

2.1 *Generic process*

SIRF assumes initially a well defined system in which the main functions of this system are defined[2]. Starting from these functions a Functional Hazard Assessment (FHA) is conducted (Milius & Gayen 2004). For this, railway experts combine function failures with different operational situations and scenarios (Einer & Käser 2004). The result of the FHA are hazards with an estimation of its criticality. Then, a function receives the highest criticality of all hazard that are related to this function.

2.2 *Terminology of SIRF*

For the determination of safety targets, SIRF uses five parameters[3].

- S_A – number of affected persons
- S_V – degree of injury
- W – probability of the occurrence of the expected severity[4] after a function failure
- E – mean duration of exposure to a hazard
- V – possibility of avoidance of the severity of a harm by the person at risk, after the occurrence of the primary hazard

As described in SIRF, parameters S_A and S_V shall be estimated for a realistic worst-case outcome of a primary hazard within the considered scenario. Their combination $S = S_A \cdot S_V$ is an estimate of the expected outcome expressed by a severity of harm.

Parameter W is alternatively often referred to as inevitability of the transition from a function failure to the related severity of harm. Since the severity is scenario dependent and parameter W refers to a severity of harm, W is scenario dependent, too. An ontological analysis of the parameters can be found in (Hulin et al. 2016). Note, that SIRF-parameter W has a different meaning to the parameter W of the risk graph.

2.3 *Estimation of hazard criticality*

The parameters mentioned above are estimated qualitatively by experts. For that, SIRF defines certain values for each parameter.

The combination of these values results in a value which is called indicator. The calculation of this indicator I is carried out using equation 1.

Table 1. Mapping table.

Interval of indicator I	Safety target
]0; 21[	SIL 0
]21; 36[	SIL 1
]21; 72[	SIL 2
]72; 122[	SIL 3
]122; 281[	SIL 4

$$I = \frac{S_A \cdot S_V \cdot W \cdot E}{V} \tag{1}$$

Then the mapping of the inidicator to a safety target is done according to Table 1.

3 APPLICATION TO PLATFORM DOORS

3.1 *Justification*

Even if SIRF is defined only for railway vehicles some projects have shown its suitability for some other railway subsystems, especially platform doors and emergency lighting in tunnels. The reason for the application of SIRF to non-vehicle-functions was to use as less different risk assessment methods as possible in projects in which a complete railway system (consisting of vehicles, tracks, platform barriers, power supply and so on) was installed.

From a theoretical point of view, the functions of vehicle access doors are nearly the same as for platform doors. Amongst others these are "provide external access" to the vehicle (see EN 15380-4), "ensure exiting" the vehicle (see DIN 25002) and "provide passenger emergency exits from inside the vehicle". A special function for vehicle doors is "keep doors closed between two stations". A special function of platform doors could be "provide emergency exit from the track to the platform". Moreover, there exist some interface functions like "align train doors with platform doors".

Most of potential accidents that could happen with platform doors are similar to those of vehicle access doors. For example 'being crushed be the door leaves' or 'falling down through an open door' are an potential accidents for both types of doors.

Moreover, hazards like 'unintended door opening' or 'too fast closing of doors' are equal for both vehicle access doors as well as platform doors.

3.2 *Example 1: One open doorway*

3.2.1 *Initial situation*

All scenarios in this section start from the same operational situation: A driverless passenger train is standing at the platform. At the edge of the

2. A good overview of functions for railway vehicles can be found in EN 15380-4 and E DIN 25002.
3. Since SIRF is a German directive without an official and agreed English translation, we translated the definitions of terms for safety target determination on our own.
4. Severity S is the product of S_A and S_V.

platform a barrier containing platform doors is installed. All doors of the platform as well as of the vehicle are sliding doors with a passage width of 0.8 *m*. With this width it is possible that at most two persons can stay simultaneously in one door. Due to efficiency of air conditioning in the railway vehicle all doors are closed independently of each other as soon as possible and a door is opened only on passenger request. All platform doors as well as all train doors are closed except one doorway[5]. Travellers are boarding the train through this one open doorway.

3.2.2 *Hazard and potential function failure*

The hazard which is considered in this section is 'one doorway is open and vehicle starts moving'[6].

In this case, the potential accident 'shearing of persons' can occur. For the accident it does not matter which potential function failure is the cause for the hazard—e.g. the 'vehicle starts moving with one open doorway', 'one doorway remains open while the vehicle starts moving', 'omission to prevent persons passing through the one doorway while vehicle accelerates' or a 'door interlock signal is sent while one doorway is open'.

These potential function failures can be part of the vehicle, of the platform door system, of the control system or of a combination of some of these systems.

For this example, the potential function failure 'vehicle starts moving with one open doorway' is analysed.

3.2.3 *Analysis of accident scenarios*

The probability of shearing a person between stationary installations and vehicle parts is higher with than without platform barriers since only small vehicle movements are necessary to shear a person.

There are several accident scenarios with shearing of persons within the afore mentioned context. While one person looses just his arm another person could be killed. As mentioned before, due to the doorway width of 0.8 *m* it is imaginable that one or two persons are staying at the doorway simultaneously. This variability of accident scenarios can cause different outcomes. For each outcome (specified as a severity of harm) the conditional probability W of this outcome after the potential function failure 'vehicle starts moving with one open doorway' has to be estimated separately.

For the severity 'death of person' after the assumed potential function failure, parameter W is estimated conservatively with 'high' since in the largest part of the time period in which the one doorway is open we assume persons passing through this doorway. The reason for this assumption is that the doors are just opened on passenger request and passengers yield such a request for boarding or exiting and doors will be closed right after the doorway is cleared. Moreover, the time period for a person entering the vehicle usually increases with the number of persons standing in the corridors and the entrance area of the vehicle.

In the scenario that several persons are killed by this potential function failure we estimate parameter W with 'low' since it is very seldom that two persons are staying in the doorway at the same time. An affecting of many persons by only one doorway is impossible and, consequently, for these cases parameter W is assigned as 'incredible' ($W = 0$). A complete overview of all estimations of probability W of a certain outcome can be found in Table 2.

For all accident scenarios that relate to the hazard 'one doorway is open and vehicle starts moving' the exposure to the hazard is estimated with 'low' ($E = 1$) and the avoidance is seen as 'not or nearly not possible' ($V = 1$). The reason for the estimation of parameter E is that persons are just exposed to the hazard during boarding and exiting. The estimation of parameter V results from the consideration of the time period for an effective human reaction. It can be that due to the starting train movement persons are shocked or fall down and thus are suddenly limited in the ability to react effective.

The graph of the SIRF indicator is shown in Figure 1. Neither direct nor indirect proportionality between severity and the indicator is given. There can exist several local minima and maxima in such a graph. Consequently, a certain SIL can result for different severities. Moreover, it can be that the highest SIL of all credible scenarios starting

Table 2. Potential outcomes of hazard 'one doorway is open and vehicle starts moving'.

Number of persons	Degree of injury	S	Prob.	W	SIRF Indic.
No	none	0	high	3	0
One	minor injury	6	high	3	18
Several	minor injury	10	low	1	10
One	serious injury	12	high	3	36
Many	minor injury	16	incredible	0	0
Several	serious injury	20	low	1	20
One	death	27	high	3	81
Many	serious injury	32	incredible	0	0
Several	death	45	low	1	45
Many	death	72	incredible	0	0

5. A doorway consist of both a platform door and a corresponding vehicle access door. A doorway is called open if both doors are open.

6. The term 'vehicle' is more generic than the term 'train'.

from one situation to one potential accident is not the scenario with the highest severity. In Figure 1 the highest credible severity is 45 when several persons are killed since a severity $S = 72$ with many deaths is not credible with one open doorway. For a severity $S = 45$ SIRF returns a SIL 2 while for a severity $S = 27$ it returns SIL 3.

3.3 *Example 2: Variable number of open doorways*

3.3.1 *Description*

Let us now analyse the values of the SIRF indicator in dependence on the number of open doorways. The basis for this example is the same initial situation as described in section 3.2.1 for example 1 except that the number of doorways is variable. Therefore, the hazard is 'doorways are open and vehicle starts moving' with the function failure 'vehicle starts moving with open doorways'.

The potential accident 'shearing of persons' is the same as for example 1.

3.3.2 *Analysis of accident scenarios*

Of course, with increasing number of open doorways the worst case severity increases, too. More interesting is the relation of the number of open doorways to SIRF parameter W and the SIRF indicator for an invariant severity.

For that, we analysed three different severities: severity $S = 72$ is for deaths of many persons, severity $S = 45$ for deaths several persons, and severity $S = 32$ for many seriously injured persons. SIRF parameters E and V remain equal to example 1 with $E = 1$ and $V = 1$. Parameter W is the only parameter that changes with the number of open doorways for a constant severity. If less than 6 doorways are open it is incredible that many persons[7] are killed and, therefore, W is equal to 0 and the SIRF indicator is equal to 0, too. With 22 or more open doors the probability for the affection of 'many' persons is very probable and thus parameter W is assigned with 3. The death of 'several' persons[8] is classified as 'very probable' ($W = 3$) for 4 or more open doorways. This results in a SIRF indicator of 135 which can be mapped to SIL 4.

The relation of the indicator and the number of open doorways are shown in Figure 2.

The graphs that show the relations for many affected persons climbs at the same positions (see Figure 2) whereas the graph which is based on the deaths of several persons climbs in other positions. These different gradients produces an intersection

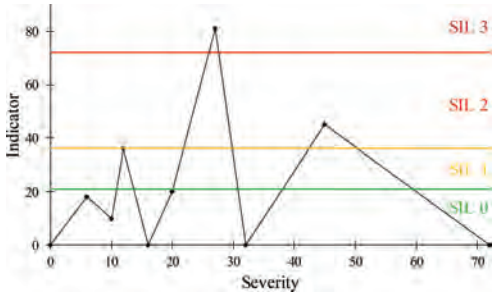

Figure 1. Relation between SIL an severity.

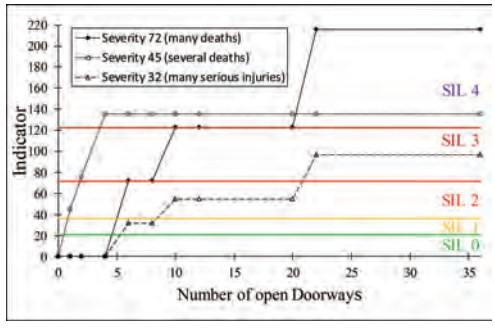

Figure 2. Relation between SIL and number of open doorways.

between graphs for severity $S = 72$ and for severity $S = 45$.

In this example, this intersection is meaningless for the SIL allocation since SIL does not change. However, for other graphs or other scenarios such intersections are indications to a change of priority of accident scenario for the determination of criticality and thus for SIL allocation.

4 COMPARISON OF RESULTS

The French national railway safety authority (called EPSF) claims the safety target TFFR $\leq 10^{-7}$ for the function failure 'authorized traction with one or more open doors' (see SAM C 305 (EPSF 2013)). This safety target which corresponds to a SIL 2 is for main lines without platform doors. Since, the situation is quite different without platform doors, safety targets are not easily comparable to the results of the examples of this paper.

A safety target of SIL 3 for platform doors functions whose failures can cause deaths is presented in Lecomte (2008). However, he just does not deduce it.

Due to the European Regulation 2015/1136 (EU 2015) the function failure 'vehicle starts moving

7. SIRF defines 'many persons' with 'more than 10 persons'.
8. SIRF defines 'several persons' as more than 1 but at most 10 persons.

with one open doorway' is assigned to a target frequency TFFR ≤ 10^{-7}. The reason for that is that the resulting potential accident is classified as 'critical accident' which is 'typically affecting a very small number of people and resulting in at least one fatality' (see Article 1 of (EU 2015)). For this function failure the safety target determined with SIRF in example 1 (see section 3.2) is a little bit more restrictive.

Moreover, Regulation 2015/1136 (EU 2015) defines 'catastrophic accidents' that are 'typically affecting a large number of people and resulting in multiple fatalities'. For function failures that could lead to such accidents 'an occurrence of failure at a frequency less than or equal to 10^{-9} per operating hour' is required. The regulation, however, does not define what a 'large number' and a 'very small number' of people means. This is defined in Jovicic (2017). In this guideline Jovicic (2017) estimates for the function failure 'train moves off at station with one bodyside door open' for the situation 'more than one door open' during passenger transfer TFFR ≤ 10^{-9}.

This safety target of Jovicic (2017) is equal to SIRF for trains that start moving with four or more open doors. For two or three open doors, however, the safety target of Jovicic (2017) is more restrictive than that of SIRF with SIL 3 (see Figure 2 and the explanation of example 2).

5 CONCLUSIONS

In this paper SIRF is applied to platform doors for safety target determination. It is shown that a determination is possible and useful with SIRF. Compared to safety targets of railway doors and European Regulations results are similar.

Some specialities of SIRF for safety target determination has been discussed in this paper. One very helpful speciality to better shape severity is the consideration of two parameters S_A and S_V for it.

The safety target is highly dependent on the initial situation and the way an accident happens. The consequence is that the worst case scenario for a class of potential accidents does not lead necessarily to the highest safety target. Therefore, all scenarios within a class of potential accidents have to be considered.

A general framework for integrated risk assessment of nuclear/non-nuclear combined installations on market-oriented nuclear industry

K. Kowal, S. Potempski & Pawel M. Stano
National Centre for Nuclear Research, Poland

ABSTRACT: Development of new nuclear technologies tends toward decentralized small-medium size and modular installations with parameters tailored to a specific applications, resulting from the needs of the market wider than the energy sector, e.g. the production of process heat, hydrogen or hydrazine, which is of great importance for chemical industry. The High Temperature Reactors (HTR) and Dual Fluid Reactors (DFR) are the examples of the attempts for building such industrial applications. However, the implementation of these concepts poses a challenge for safety assessment due to the interfaces between nuclear and non-nuclear parts of the installation, which were not taken into account within the hitherto completed safety studies. This is a driven force for development of new framework for integrated risk assessment of nuclear/non-nuclear combined installations. This article is an attempt to sorting out the most demanding problems related witch this issue and to indicate possible paths for the solutions.

1 INTRODUCITON

Seeing the intensive development of new nuclear reactors technologies over recent years, one can expect major changes in the widely understood nuclear industry. So far, the innovation in nuclear reactors has been induced mostly by the technology-push (i.e., public R&D expenditures) and the demand-pull (i.e., NPPs construction) incentives (Berthélemy 2012), but the main stakeholders were focused mostly on the nuclear power generation.

Current trends in development of the new reactor technology tend toward decentralized small-medium size and modular installations with parameters tailored to a specific applications (Locatelli, Bingham & Mancini 2014). These solutions are considered rather as an energy source at site for different industrial processes than the way to electricity production on an industrial scale. The main driving force behind these concepts is the reduction of the emission of greenhouse gases from industrial processes. It seems that the nuclear market will soon evolve towards greater fragmentation and wider field of applications from which the non-electric services will play an increasingly important role.

The general concept and key technological solutions for non-electric nuclear applications have been already developed. However, they have not reached the same industrial maturity as for the generation of electricity. Nevertheless, expecting the progression in this type of nuclear technology applications, the International Atomic Energy Agency performed the initial target market analysis which showed that there is an increased interest in non-electric applications facilitated by the recent development of advanced reactor concepts (IAEA 2002).

The market oriented restructuring in the nuclear industry requires, however, an accurate estimation of the costs and benefits of nuclear applications in comparison with the non-nuclear suppliers of similar services and, what is much more important, appropriate frameworks, methods and tools for integrated risk assessment of nuclear and non-nuclear installations combined together in one complex structure. The High Temperature Reactors (HTR) or Dual Fluid Reactors (DFR) are the examples of the attempts for building industrial applications based on the Generation IV technologies.

For example, in the nearest future the best opportunities for cogeneration will be application of HTR for the chemical industry (Jackowski et al. 2017). In this respect within NC2I-R (Nuclear Cogeneration Industrial Initiative—Research and Development Coordination 2015) a review has been made taking into account the following main processes compatible with HTR capabilities:

- refinery distillation steam,
- refinery distillation superheated steam,
- petrochemicals—reaction enthalpy,
- steam as utility for industrial complex,
- and paper steam (drying).

Use of DFR, in turn, is expected in the following industrial processes (Huke et al. 2015):

- mixed process heat and electricity generation,
- medical isotope production with high efficiency,
- the hydrogen-based chemistry e.g., production of synthetic fuels suitable for the vehicles,
- and radiotomic chemical production—utilization of intensive radiation for radiotomic induction of chemical reactions requiring high doses (Stannet & Stahel 1971).

Implementation of new technologies encounters, however, new problems, among others with safety demonstration (inadequate core damage definition, interfaces between nuclear and non-nuclear installations, etc.), licensing processes (inadequate legislation), and social acceptance (nuclear technology in the place of work, close to industrial centers). The paper aims to discuss these kind of issues as a part of general framework for the integrated risk assessment of nuclear/non-nuclear combined installations.

2 THE LICENSING PROCESS ORGANIZATION

Nowadays, the licensing process of the newly designed reactors, seems to be one of the most burning challenges. It have to be developed with respect to all specific features of the nuclear technology and related chemical installation. Preliminary analysis of the HTR licensing issues has been made within NC2I-R and HTR-PL projects with consideration of the Next Generation Nuclear Plant guideline (NGNP 2010). However, development of a new framework for integrated licensing process for joint nuclear-chemical installations is highly expected.

Figure 1 shows two models of the licensing process organization for joint nuclear-chemical installations. One of them assumes separation of paths leading to receive the operation permission for nuclear and chemical parts of the installation, while the second one is a proposal for integration. The structure of regulatory bodies, their competences and communication, as well as the scope of the safety report or reports must be specified in details to make it applicable and this is a challenge for further studies.

3 RISK ASSESSMENT OF NUCLEAR/NON-NUCLEAR COMBINED INSTALLATIONS

Implementation of the integrated approach to the licensing process requires, among others, the integrated risk assessment for the whole installation consisting of a nuclear and chemical parts. This requires, in turn, consideration of insights coming from the Quantitative Risk Assessment (QRA) developed for the chemical part of the installation and Probabilistic Risk Assessment (PRA) developed for the nuclear one, including analysis of interfaces, mutual reactions and interdependencies.

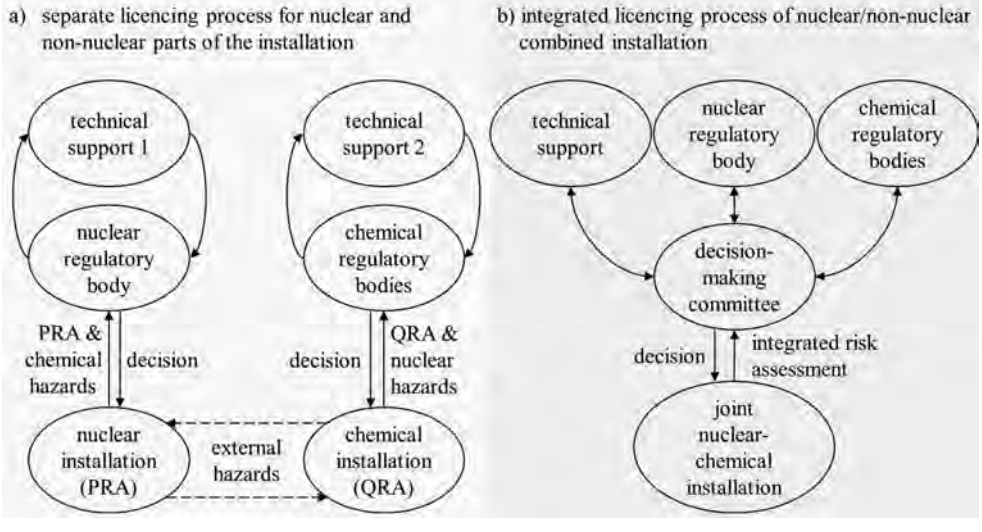

Figure 1. Two general models of the licensing process organization for the nuclear/non-nuclear combined installation; a). separation of the licensing processes for nuclear and chemical installations assuming different regulatory bodies and separate safety reports where the impact of the neighboring installation is treated as a set of specific (nuclear or chemical) external hazards; b). integrated licensing process where the object is defined as a joint nuclear-chemical installation and the integrated risk assessment is expected.

3.1 *Chemical QRA and nuclear PRA integration*

As a result of initiating event within the joint nuclear-chemical installation different systems on both parts (nuclear and chemical) can fail immediately or with a time delay. The time-sequence of the failures, however, is quite complex due to the interfaces between systems within each part of the installation separately and between the nuclear and chemical plants. Independently developed chemical QRA and nuclear PRA models do not describe properly the real state of the whole installation and thus need to be integrated. The integration of QRA and PRA models within the overall risk assessment framework can be proceeded with the following steps:

1. identification of postulated initiating events for the nuclear and chemical parts of the installation;
2. identification of systems which would be directly affected by the initiating events immediately after their occurrence or with a time delay;
3. identification of all possible interactions between the considered nuclear and chemical systems i.e.:
   a. internal interactions between systems within the nuclear installation;
   b. internal interactions between systems within the chemical installation;
   c. nuclear/chemical interactions (posing a challenge for safety of the chemical installation after failure of one or more nuclear systems);
   d. chemical/nuclear interactions (posing a challenge for safety of the nuclear installation after failure of one or more chemical systems);
4. specification of time-frames in which the whole installation remains in the specific states characterized by the systems affected and interactions within and between nuclear and chemical plant;
5. identification of all safety functions that must be performed in each time-frame and determination of their success/failure probability.

Figure 2 presents a simple example on how to deal with chemical QRA and nuclear PRA models developed for both parts of the installation. The following time-frames were established to define the periods in which a specific functionality is required:

- δt_0 – after initiating event occurrence and before the notification of effects on the nuclear systems;
- δt_1 – failure of nuclear system n_1 with possible or conditional effect on the chemical system ch_1;
- δt_2 – failure state of nuclear system n_1 and chemical system ch_1 (nuclear/chemical interaction);
- δt_3 – failure state of chemical system ch_1 and nuclear system n_2 (due to the internal interaction);
- δt_4 – failure state of chemical system ch_1 and nuclear system n_3 (due to the internal interaction);
- δt_5 – failure states of n_4 and n_5 nuclear systems due to the chemical/nuclear interaction witch system ch_1 or internal interaction with system n_3;

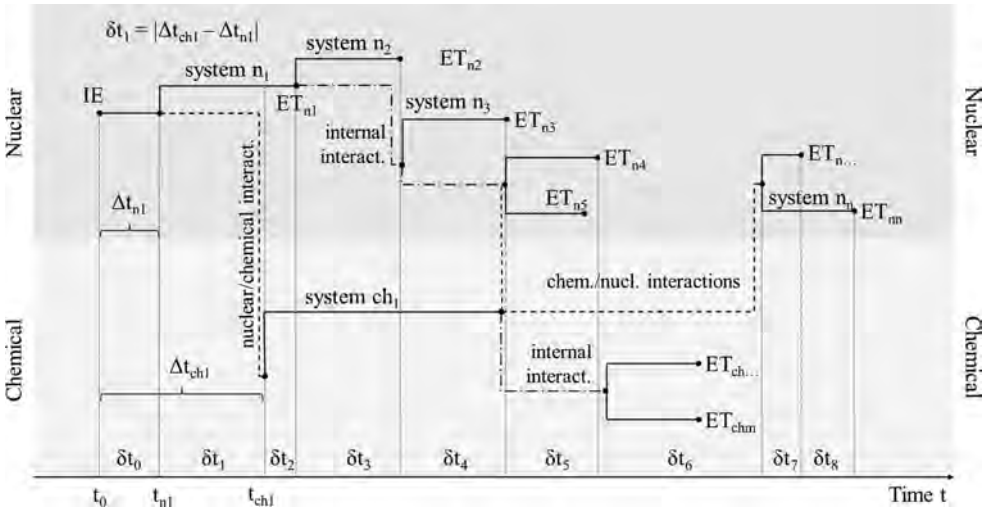

Figure 2. Example of integration of chemical QRA and nuclear PRA studies within the overall risk assessment framework for nuclear/non-nuclear combined installations: IE – Postulated Initiating Event; ET_{ni} – Event Tree for *i*-th system of nuclear installation; ET_{chi} – Event Tree for *i*-th system of chemical installation; δt_i – *i*-th time-frame to be considered in the integrated risk analysis.

- δt_6 – failure states of chemical systems due to the internal interactions in the chemical installation;
- δt_7 – failure state of nuclear system $n_{n...}$ due to the chemical/nuclear interaction with system ch_1;
- δt_8 – failure state of nuclear system n_n due to the chemical/nuclear interaction with system ch_1.

This concept has many advantages, among which the most important is possibility of modelling of a wide spectrum of failures sequences, including both nuclear and chemical parts of the installation, in response to the initiating event that occurred in one of them. Such approach, however, is not devoid of weaknesses among which the following should be mentioned here:

- numerically ineffectiveness of calculations based on large and complex failure three structures,
- multiple modelling of the same sequences of events appearing at different time frames,
- difficulties in adding new systems, interactions or time frames to the existing models.

3.2 *Block framework*

Apart from the failure tree approach presented above it is reasonable to consider alternative approach to modelling of failure sequences for combined nuclear-chemical installations that is based on the applications of Bayesian networks to risk assessment. An example of such a block framework is presented in Figure 3. This network corresponds one-to-one with the failure tree model discussed in Figure 2, and it is constructed from the following types of blocks:

- a collection of N initial events $(IE_1^n,\ldots, IE_N^n))$ defined for a nuclear plant and M initial events $(IE_1^{ch},\ldots, IE_M^{ch})$ defined for the chemical plant;
- a collection of n nuclear and m chemical systems potentially affected by previously defined initial events;
- logical gates that allow to introduce complex Boolean expressions.

The interactions between any two blocks i and j are defined by a pair of transition probabilities p_{ij}^{nch}

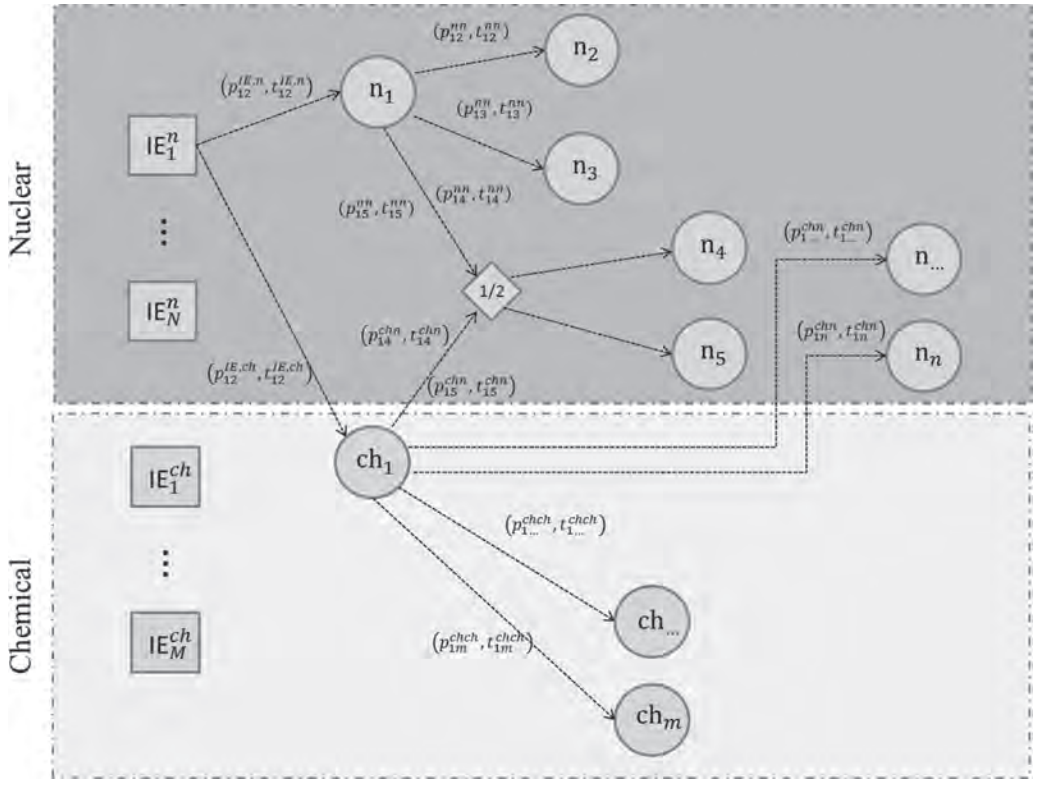

Figure 3. Block model corresponding to the failure tree described in Figure 2. For deterministic case, all the transition probabilities are set to 1. The transition times are set to match times in Figure 2, e.g., $t_{11}^{IE,n} = \delta t_0$; $t_{12}^{nn} = \delta t_1 + \delta t_2$; $t_{14}^{chn} = t_{15}^{chn} = \delta t_2 + \delta t_3 + \delta t_4$, etc.

and transition times t_{ij}^{nch} where the indexes in lower script indicate the direction of the connection (in this case from *i* to *j*) and the indexes in the upper script indicate to which type of installation the blocks belong (in this case *i* belongs to nuclear plant, whereas *j* belongs to chemical plant).

Such block framework has several advantages that might be particularly well suited to model joint nuclear-chemical installations. First of all, with such a model it is possible to model virtually all the combination of interactions between the systems in all the directions (back and forth). Secondly, merging independent block models into a single block model is relatively easy as it only requires defining new connections and transition parameters between systems belonging to distinctive block models and does not disturb the networks within the models.

This property is especially important for our considerations because thanks to it, it is possible to design safety models for nuclear plant, chemical plant, and interaction between plants independently and then combine them together only at the final stage of the analysis to obtain quantitative risk indicators. Furthermore, this property is scalable down, i.e., either plant can be broken down into smaller units, for which block models can be developed independently following the philosophy described above.

Finally, simulating block networks is very efficient numerically because the complete information about network can be stored in a simple matrix form. Consequently, computations of probabilistic risk measures require matrix algebra only. A general structure for the matrix of transition probabilities is presented below. The matrix of transition times is defined similarly.

$$\begin{bmatrix} \begin{bmatrix} p_{11}^{nn} & \cdots & p_{1n}^{nn} \\ \vdots & \ddots & \vdots \\ p_{n1}^{nn} & \cdots & p_{nn}^{nn} \end{bmatrix} & \begin{bmatrix} p_{11}^{nch} & \cdots & p_{1m}^{nch} \\ \vdots & \ddots & \vdots \\ p_{n1}^{nch} & \cdots & p_{mm}^{nch} \end{bmatrix} \\ \begin{bmatrix} p_{11}^{chn} & \cdots & p_{1n}^{chn} \\ \vdots & \ddots & \vdots \\ p_{m1}^{chm} & \cdots & p_{mn}^{chn} \end{bmatrix} & \begin{bmatrix} p_{11}^{chch} & \cdots & p_{1m}^{chch} \\ \vdots & \ddots & \vdots \\ p_{m1}^{chch} & \cdots & p_{mm}^{chch} \end{bmatrix} \end{bmatrix} \quad (1)$$

3.3 *Global uncertainty and sensitivity analysis*

In the context of HTR or DFR, where a nuclear facility is connected to chemical, from the perspective of safety analyst the structural differences between PRA (or QRA) models for both plants might be immense (in complexity, accuracy, purpose, etc.). Therefore, the uncertainty that is inherently associated with either of the model is further enlarged by the uncertainty about the way the plants, or their systems interact with each other. Consequently, for risk informed decision-making, a proper analysis of PRA models' results (as well as models' failures!) requires that the analysis of safety outputs should be accompanied by the identification of relevant uncertainties and the assessment of their impact on the final results. This is done by conducting uncertainty analysis (UA) and sensitivity analysis (SA) that aim to support decision-making by quantification of model uncertainties. The fundamental difference between the two is that the UA adopts a forward-looking approach, which is focused on investigating how the uncertainty in input variables (external uncertainty) and parameters (internal uncertainty) can affect the uncertainty of output variables. The SA adopts backward-looking approach, which is focused on investigating how sensitive the output variable is to fluctuations in uncertain input variables and parameters. Thus, in the face of prevailing un-certainties in models' parameters and input-output variables, the UA and the SA complement each other by looking at the same problem from two opposite directions.

In recent years a variety of methods have been developed to analyze models' uncertainty, from both UA and SA perspectives specifically to be used in the PSA (Borgonovo, Apostolakis, Tarantola, & Saltelli, 2003). At the same time, a number of spectacular failures in management of complex real-life processes, associated with nuclear industry, due to unrealistic uncertainty assessments have seen the light of day. Over four decades long stalemate around the Yucca Mountain nuclear waste depository is one example of the so-called "wicked problems" (Saltelli, Stark, Becker, & Stano, 2015), where uncertainty and disagreement about values affect the very framing of what the problem is and how to model it. Another example is handling the Fukushima Daiichi nuclear disaster, which provides a vivid illustration of how, in the face of "unknown unknowns" (Logan, 2009), safety assessments can become worthless in the blink of an eye. Better methods of ascertaining and managing model uncertainty are needed to realistically re-evaluate the safety features of the existing installations. Most importantly by paying more attention to structural uncertainty, which investigates issues such as: the selection of variables and processes to include in the model, how the variables and processes are described mathematically, how they interact, etc. When modelling complex phenomena, the structural uncertainty is likely larger source of uncertainty than the formerly mentioned uncertainty in input/output variables. Another open topic in uncertainty quantification is the assessment of human errors, especially in

highly stressful critical conditions during the accidents progressions.

In both PRA and QRA, which have been developed specifically to quantify various risks derived from operation of nuclear and chemical plant, respectively, the quantification of uncertainty is of crucial importance. However, despite much attention being devoted to studying uncertainty in the PRA context there exists no universally accepted standard for handling various types of uncertainties in a systematic way. Furthermore, in case of joint nuclear and non-nuclear installations all the aforementioned uncertainties are inherited from respective installations and further elevated by the model of interactions between the systems.

Although, many methods addressing structural uncertainty have been developed in recent years, this field of study is far from becoming mature. This is because the developed methods are usually highly subject-specific and it is not clear how they can be extrapolated and reliably applied to problems other than specified. For example, in the analysis of nuclear plants much focus is on prevention of accidents leading to core meltdown, while in the analysis of chemical plants the main attention is put on preventing fires and explosions. Each of these critical scenarios has its own typology, with different time scale, undesired effects, etc. and consequently with different types of uncertainties taken into consideration. It is not a surprise then, that each of these fields of scientific inquiry follows its more or less unique path of dealing with structural uncertainty and very little work have been done towards developing a global approach that would link structural uncertainty assessment with assessment of aleatory and epistemic ones in a synthetic manner.

Thus, to assure safety of joint nuclear and non-nuclear plants, a systematic approach needs to be develop that would allow to perform global UA and SA, i.e., taking into consideration the main sources of uncertainty for both plants jointly, but also investigate what are new sources of uncertainty that are due to interactions between the installations.

4 CONCLUSIONS

Many safety problems concern the mutual dependence of nuclear and chemical parts of the installations where the nuclear reactors are considered to be used as an energy source for various chemical processes. In order to enhance safety of such joint nuclear and non-nuclear installations, a systematic approach needs to be developed that would allow to perform integrated licensing process. Many efforts has to be made to accomplish this challenge. Development of a new framework for integrated risk assessment is one of them. In this article, two methods for integration of chemical QRA and nuclear PRA were proposed as an contribution to this task. The first one, based on the failure tree structure, is very informative, but indeed, not perfect and thus needed to be improved. The alternative approach in a form of block framework has more advantages and the authors believe that it can be applied in real studies.

Assessment and management of ageing of critical equipment at seveso sites

M.F. Milazzo, G. Ancione & G. Scionti
Università degli Studi di Messina, Messina, Italy

P.A. Bragatto
INAIL, Monteporzio, Italy

ABSTRACT: The Directive Seveso III points towards the introduction of plans for a safe management of ageing of critical facilities at major-risk. Such plans have to cover all phases of the life cycle of the equipment and take into account current deterioration mechanisms (i.e. internal and external corrosion, erosion, thermal and mechanical fatigue, etc.). Due to this requirement, there is a need of procedures to check the equipment conditions, especially at the final stages of its life cycle, and evaluate the adequateness of actions for its control. Currently, managers adopt Risk-Based Inspection (RBI) standards, nevertheless it is essential to demonstrate the integration of ageing management within the overall management of major hazard plants. This paper discusses the adequateness of the measures, usually adopted to control the ageing phenomenon in primary containment equipment, whose deterioration could generate a major accident. In order to evaluate the status of such items, a shortcut method has been developed. It represents a first attempt to develop a tool for ageing monitoring. The first release of the method is static and appropriate for independent auditors and inspectors acting on behalf of Seveso Authorities. The second release, which is currently under development, is considered dynamic as information about process variables, external data, inspection information and etc. are continuously collected and processed, in order to provide an overall picture of the ageing of systems in a form of an index. These indexes allow the real-time forecasting of the equipment deterioration process and its management based on the industrial risk acceptance levels. The core of the method is a dynamic model of the strengths that accelerate the degradation processes and factors that slow down them. Based on this model a "digital twin" of a complex plant can be built, by integrating smart sensors and other smart devices.

1 INTRODUCTION

The new requirements of the last European legislation on the control of major accident hazard, the "Seveso III" Directive, include the monitoring of the risk due to equipment ageing (EU Council, 2012). The introduction of plan for the safe management of ageing has to cover all steps of the lifecycle of critical equipment, for this reason there is a need of procedures to verify the status of facilities and evaluate the adequateness of actions made by plant managers.

1.1 *The issue of ageing in process industries*

Recently, the safe ageing of equipment has become the latest hot issue for several industries, in particular those at major accident hazard. The term *ageing* does not refer to the time elapsed from the date of production, testing or commissioning of the equipment, but it is related to its condition and how it changes over the time (Wintle et al., 2006). Ageing of a component reveals itself as a general form of deterioration that is usually associated with the in-service time and reduces its reliability (Horrocks et al., 2010). Ageing increases the risk of loss of containment and other failures and has been proven to be a determining factor in many accidents in process industry (Wood et al., 2013).

Nuclear industry started a decade ago to pay attention to this problem, when it has been realised that the age of most in-service reactors was exceeding the designed lifetime. The guideline, published by IAEA (2009), defined the basic principles for managing ageing of the equipment in nuclear plants, with the aim to safely extend their life beyond the limits defined during the plant's design phase. According to IAEA definitions, there are two terms to be distinguished, i.e. ageing and obsolescence. Both terms basically refer to effects of the time on complex technical systems. In this frame, ageing includes processes that gradually change the physical characteristics

of the equipment over the time or with the use; whereas obsolescence refers to its becoming out of date by comparing with current knowledge, standards and regulations and technology, this makes the equipment inadequate. The consequences of obsolescence include the incompatibility between old and new equipment and the non-compliance of old equipment. Amongst degradation processes, corrosion plays a primary role, thus in many cases, ageing and corrosion are confused each other. The word ageing is often used with a negative connotation, and understood as degradation, even though the concept of "ageing management" clearly implies the idea that ageing processes may be controlled, in order to slow-down and minimise their effects. In the present paper, the focus is just on ageing; obsolescence is out of the scope of this research, as well as consequences of ageing of workers, managers and organisation.

In chemical industry and in the oil & gas sector, the issue of ageing is particularly relevant, as most European refineries have already been in service for forty or more years and it is supposed they will have to continue to be operating, given the difficulties to build new ones. A study promoted by the European Commission a few years ago analysed a hundred worldwide major accidents in oil refineries, which were due to inadequate management of ageing and corrosion, this investigation revealed the relevance of the problem (Wood et al., 2012). A more recent study, promoted by OECD (2017), outlined the impact of ageing also in process industry, including the chemical sector. A fundamental guideline for ageing management in chemical industry has been published by the HSE (Wintle et al., 2006).

A keystone for ageing management is the replacement. In many cases, deteriorated or damaged systems may be dismissed and replaced by new ones having equivalent features. As an example, in a typical process plant there are thousands of valves, which can lose their functions, due to deterioration processes; these components usually have an affordable cost and comply with standard rules, thus replacement may be reasonably proposed. The case of larger items, which have an unsustainable replacement cost as well as complex authorisation procedures, is different; replacement is very difficult and discourages the executives in a way that these items are considered practically "no-replaceable", thus, to extend the in-service life as long as possible becomes a priority for the maintenance engineers. In order to comply with the definitions of common engineering practices, i.e. HSE document (Wintle et al., 2010), these no-replaceable facilities are denoted as "*static primary containment systems*", i.e. systems for which the concern of ageing is much higher than other equipment, such as rotating machinery (e.g. pumps) and control systems.

1.2 *The issue of ageing in the framework of the European Seveso legislation*

The previously mentioned report of the European Commission (Wood et al., 2012) showed the relevance of ageing in refining industry. This oriented the EU Council to add, into the new Directive on major accident prevention, the requirement to define a management program for a safe ageing of critical equipment for all Seveso establishments.

For about a decade and more, the oil and gas industry has trusted in the popular Risk-Based Inspection (RBI) practice, as defined by the recommended documents API 580 (API, 2016) and API 581 (API, 2016a). As discussed by Bragatto et al. (2012), the traditional RBI approach is valuable, but it must be integrated within a dynamic management system for major accident prevention. The main limit of these American standards is that several industries, other than refineries, are classified at major accident hazard according to the Seveso legislation, but they are not included in the field of application of API580/581 and, thus, lack of clear guidelines. As discussed by Bragatto and Milazzo (2016), the Seveso II Directive stresses also the need to share with controlling authorities some aspects of risk management and consequently increases the need to reduce the uncertainties of RBI models. Such uncertainties are associated with different aspects: firstly, uncertainties derive from an inadequate knowledge about the failure modes and related probabilities; further uncertainties are introduced in the following steps of the application of the method (Milazzo & Aven, 2012).

1.3 *Audit of ageing programs*

The integrated safety management system, required by the new Seveso legislation, has to be verified by competent authorities in order to judge about the overall adequateness from the point of view of the previously discussed ageing issue. In order to meet the needs of establishment executives and controllers (auditors and inspectors), a shared model for the adequateness verification is essential.

This paper aims at discussing the main elements to be integrated in an effective approach for both monitoring and inspecting critical equipment at Seveso establishments. In the following text, a piece of equipment is defined critical, if it is involved in a sequence of events leading to a top-event, as identified by the fault tree analysis or equivalent methods; top-events could escalate and give major consequences. Equipment, containing an amount of hazardous

substance equal at least the 20% the threshold indicated by the Seveso III Directive, are also included in the category of "critical items". Therefore, not all equipment in a Seveso establishment has to be considered "critical", but only systems that are explicitly identified in the risk assessment as defined by Seveso III Directive (Safety Report).

This paper is structured as follows: Section 2 discusses scope and objectives of the research. Section 3 describes the ageing model, i.e. a list of factors that affect the phenomenon is given as well as correlations amongst them. Section 4 summarises a short-cut method for external audits, which supports to verify the adequacy of ageing management plans. Section 5 is focused on the use of the ageing model by its integration in a more sophisticated tool so-called ageing sensor. Finally, conclusions and a short discussion about further developments are given in Section 6.

2 SCOPE AND OBJECTIVES

The scope of this research is to discuss how to integrate the main factors, affecting the ageing of facilities, in an effective tool for monitoring and inspecting critical equipment at Seveso establishments. The quantitative analysis of top-events, through the fault tree technique or equivalent methods, shows those that should be considered credible and, by referring to a frequency threshold, allows selecting those to be analysed from the consequence point of view. Even if the likelihood threshold is set at 10^{-6} event/year, it could be possible that, due to deterioration processes, the failure probability does not respect the traditional bath curve trend, but shows an increasing trend when the equipment is close to end of life. Thus, it could be possible that some top events, which were not considered credible because having frequency $<10^{-6}$ event/year, become credible as failure probabilities are higher than expected due to ageing.

The main objectives of this research are summarised below: (1) to provide auditors and inspectors with a trustable short-cut method for ageing controlling at Seveso establishments; (2) to easily achieve the update of the conditions of the equipment when required. The short-cut method is based on a previous preliminary study (Bragatto et al., 2017), from which a simple and effective approach has been developed. The tool is useful for the management of equipment operability and is currently under testing in a few Italian establishments. Concerning the elaboration of the ageing status, the most ambitious future goal is to have a day by day monitoring. It must be pointed that, even if the ageing of machinery is also important, in this paper it has not been discussed, since the focus is only on major accidents.

3 AGEING MODEL

3.1 *Factors affecting equipment ageing*

The ageing status of a plant is described by a model that collects a number of factors that contribute to the equipment deterioration. The management of ageing aim at understanding these factors, assigning the proper weight to their contributing to the deterioration and finally understanding the relationships amongst them. According to these considerations, the safe management of ageing appears a complex issue, which needs three essential elements:

1. *Knowledge* (K) – it is the understanding of all deterioration mechanisms, affecting the equipment during its lifetime;
2. *Information* (I) – it refers to the collection of the documents that describe the past of the equipment starting from the early stage of lifetime, i.e. design criteria, materials of construction and each change made during lifetime;
3. *Data* (D) – it represents information collected by means of non-destructive tests, i.e. measurements that have to be processed in order to contribute to the monitoring of equipment integrity and functionality.

These key-elements allow depicting a complete picture of equipment. It is clear that, if knowledge about deterioration mechanisms is poor or information over the entire lifetime is lost, the measurement data are not enough for a good decision-making, because past actions could have earlier brought the facility to compromising conditions.

To describe the *ageing model*, factors affecting the phenomenon have been grouped in two categories *hardcore* and *softcore*. *Hardcore* includes direct factors (managerial factors), those that are linked to measurements and corrective actions contrasting deterioration mechanisms that are known (i.e. it is correlated to *Data*). *Softcore* includes indirect factors (physical factors), i.e. those elements that are correlated to *Information* and *Knowledge* and have the maximum control in predicting when the equipment has to be removed from service.

As shown in Figure 1, the core of the model is represented by the deterioration processes, which have either a physical or a chemical nature and sometimes both them. The scheme gives the dependence of these processes by a number of accelerating and slowing-down factors over the time, respectively, placed downward and upward. It can be also observed that, beyond those mentioned above, there are other factors that had an effect in the past (i.e. *design criteria*, *processes*, *materials*, *environment, repairs* and *age/in-service time*), their consequence is due to choices that were previously made, whose effects cannot be corrected anymore.

It must be pointed that *repairs* is an accelerating factor that refers to modifications, which are not included in the management of changes; whereas *modifications* has to be intended as a factor that influences the equipment age and, in some cases, has the power to reset it (*age re-conditioning*).

3.2 *Relationship amongst factors*

Accelerating and retarding factors, shown in Figure 1, are not independent in their actions on the degradation phenomenon. In this section a description about how they are related to each other is given. Relationships are summarised in Figure 2 in the form of arrows connecting related factors.

It should be noted that *defects*, *damages*, *failures* and *accidents/near-misses* are a direct consequence of the *deterioration mechanisms*. Defects refer to a structural damage, identified by inspection, which does not compromise the operating of the system, thus, its repair is not necessary; whereas damages refer to something that compromises the operability and compels repairs or replacement. Failure is the end of the containment capacity of the system; therefore, it manifests itself through a loss of containment. Finally, accidents are scenarios occurring after the loss of containment (fire, explosion or dispersion of a toxic substance). The factors discussed above represent different modalities of manifestation of the ageing phenomenon, which proceeds according to a precise sequence of evolution, which is the following: defects → damages → failures → accidents/near misses. All four factors contribute in turn increasing the degradation rate (accelerating factors). The *number of unplanned stops* of the plant directly contributes in accelerating the deterioration as it makes the equipment subject to various types of stress. Amongst the factors, which act directly by slowing-down the deterioration, there are *physical protections* (e.g. cladding and lining), *maintenance*, *inspection program* and *inspection results*. The inspections allow the identification of defects, which may be the quicker the more effective their planning. *Inspection policy* (or program) should be based on *risk assessment* and the knowledge of *inspection technique* and *scheduling*. A risk-based inspection system is influenced by the *inspector qualification* and the *audit of management system* (*SMS*). This last factor includes *change of property* (or ownership) and *experienced personnel loss* due to staff change (accelerating at the softcore level) and *documentation along lifecycle and risk assessment* (retarding at the softcore level), and *maintenance* (retarding at the hardcore level). The *process control* is a factor that acts on the monitoring and control of operating parameters of equipment, for which the choice was made during the process design phase (see Figure 1).

Finally, other factors that directly contribute to ageing are *environment*, *materials*, *processes* and *design criteria*. Their action, as discussed in the previous section, is independent and cannot be eliminated because associated with past choices.

3.3 *Model simplifications*

The model, described from the relational point of view in Section 3.2, can be simplified as shown in Figure 3. A short discussion on simplifications is given below.

A comprehensive knowledge of deterioration mechanisms and control techniques is the sound basis for recognized inspection practices, such as API 581 (2016a), which is the distillate of decades of scientific research and experience in oil and allied industries. Where there is a lack of knowledge, such as in a few chemical industries, inspection strategy is a relevant element; this is

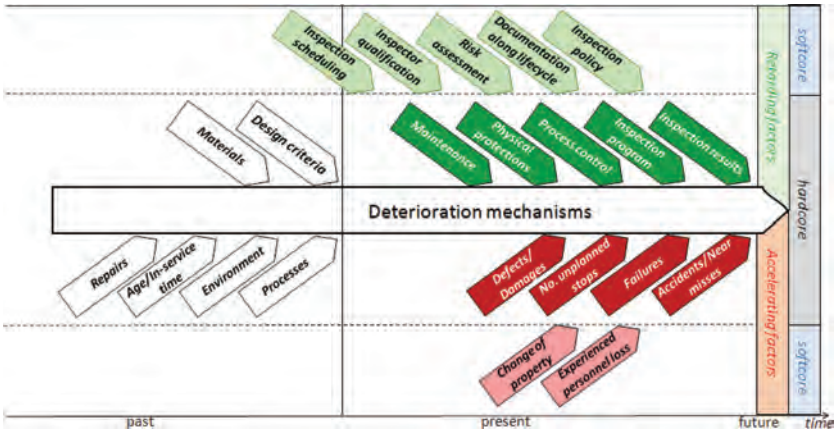

Figure 1. Ageing model.

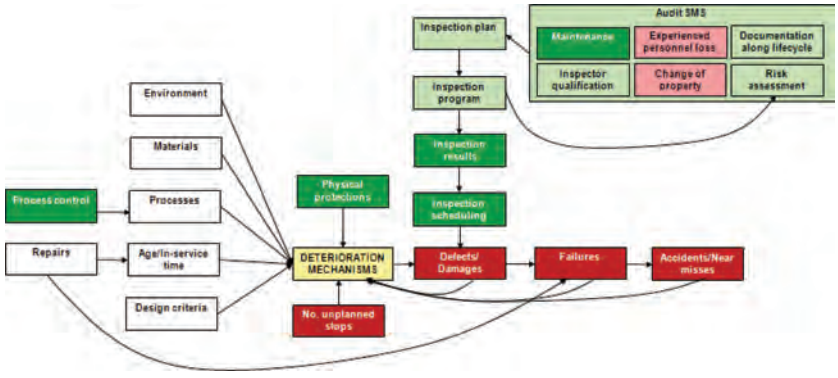

Figure 2. Relationship amongst accelerating and retarding factors.

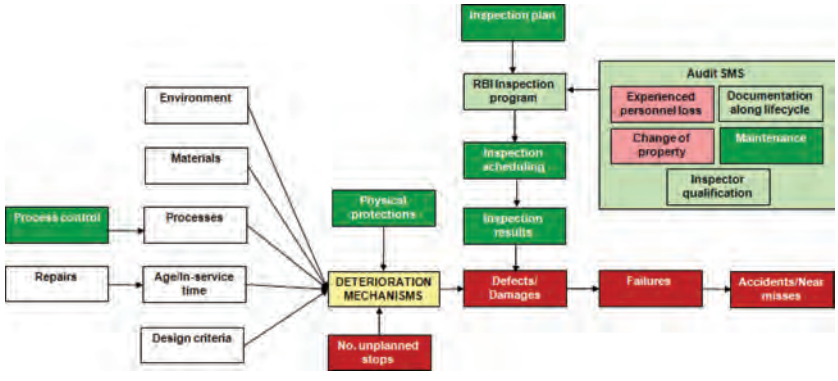

Figure 3. Simplified model for ageing.

particularly important for the knowledge if the inspection technique (*Inspection program*). If the *inspection program* is risk-based, a periodic update is certainly considered in the inspection planning; the approach could ideally be dynamic, especially if the use of an *ageing sensor* is exploited. In this case, *risk assessment* and *inspection program* are merged in the factor *RBI inspection program*.

The *failures* factor has previously been linked to *repairs* because usually a failure requires the need for an intervention. In the hypothesis of intervening before a possible loss of containment, given the effectiveness of the dynamic system for inspection planning, it is possible to not consider the link between the two factors.

4 SHORT-CUT METHOD TO ASSESS AGEING MANAGEMENT PLANS

To support the auditors in performing the assessment of the adequacy of ageing management plans, a short-cut method has recently been proposed (Bragatto et al., 2017). It is an index approach, which is simple and easy-to-use.

The method consists in the assignment scores to accelerating and retarding factors with respect to the ageing. These scores can be in the form of penalty for accelerating factors and of compensation for retarding ones. If the cumulated compensations are greater or equal to the cumulated penalties, the activities that are in place for the ageing management are adequate.

On the contrary, the ageing management system must be improved by the adoption of some technical and/or managerial solutions that increase the scores for retarding factors.

This approach is characterised by proportionality in applying countermeasures to the ageing phenomenon. Hence, if penalties are low, little compensation is required, whereas if they increase, it is necessary also to increase prevention activities to get a higher compensation. The industrial manager can choose technical and/or managerial solutions to be applied in order to offset the penalties, according to his/her preferences. As an advantage of the method, compared to traditional check-lists,

there is a greater clarity in the evaluation process and a quantification of the weight to be attributed to each factor. Unfortunately, as other index methods, it introduces uncertainties. The method and its main steps are represented in Figure 4. Each score (penalty or compensation) is assigned by referring a four-level scale. Such levels are identified as: 1 = low; 2 = medium; 3 = medium-high; 4 = high. A sign will be also associated with the score that will be negative for penalties and positive for compensations.

Accelerating and slowing down factors are those given in Figure 1. To simplify the work of the auditor and/or the industrial manager, some factors have been grouped in a new one and, thus, these have been considered sub-factors of the new factors. The new factors are: (i) *audit of SMS* includes *risk assessment*, *documentation along lifecycle*, *change of property*, *experienced personnel loss and maintenance*, (ii) *inspection management* refers to *inspection program*, (iii) *inspection effectiveness* includes *inspection program* and *inspector qualification* and, finally, (iv) *inspection results* includes *inspection scheduling*.

Tables 1 and 2 show the criteria for assigning scores to accelerating and retarding factors, these are based on the following definitions:

- *Age*/*In-service time* = ratio "current age/maximum designed age" or "current operating hours/maximum in-service hours".

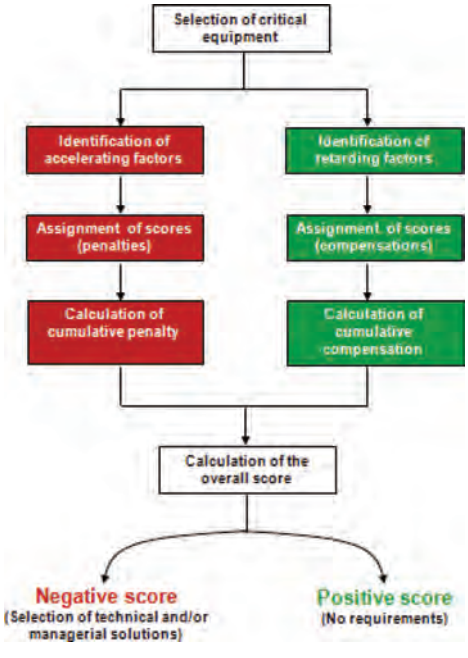

Figure 4. Flow-chart illustrating the method for the assessment of ageing management plans.

- *No. unplanned stops* = ratio "no unexpected stops/total stops" over a reference period.
- *Failures* = actual failure rate over the reference period (f) compared to the failure rate of data from international databases (f_{ref}).
- *Accidents*/*Near-misses* = ratio number of incidents and near misses due to ageing and the total number of registered events over a reference period.
- *Deterioration mechanisms* = average value among three scores related to the consequences of the degradation (i.e. dimension of leakage), the ability to detect the main damage mechanisms (by an inspection technique) and the velocity of propagation of the phenomenon- To quantify the score indications are given by Bragatto et al. (2017).
- *Defects*/*Damages* = percentage of serious damage, detected over the reference period, compared to the number of critical equipment.
- *Audits SMS* = average value between two scores related to audits conduction (internal and external) on the SMS and their results.
- *Inspection management* = main characteristics of the structure of the inspection management.

Table 1. Criteria for the assignment of scores for accelerating factors.

Factor	Score	Value
Age/In-service time	1	≤ 90 %
	2	90 ÷ 100 %
	3	100 ÷ 120 %
	4	120 %
No. of unplanned stops	1	≤ 10 %
	2	10 ÷ 25 %
	3	25 ÷ 60 %
	4	> 60 %
Failures	1	$f \leq 0.5 \cdot f_{ref}$
	2	$0.5 \cdot f_{ref} < f \leq f_{ref}$
	3	$f_{ref} < f \leq 2 \cdot f_{ref}$
	4	$f > 2 \cdot f_{ref}$
Accidents/ Near-misses	1	≤ 5 %
	2	5 ÷ 15%
	3	15 ÷ 35 %
	4	> 35 %
Deterioration mechanisms	1 2 3 4	Average score accounting for: (i) consequences, (ii) ability to detect mechanisms, (iii) propagation velocity
Defects/ Damages	1	≤ 1%
	2	1 ÷ 3 %
	3	3 ÷ 5 %
	4	> 5%

Table 2. Criteria for the assignment of scores for retarding factors.

Factor	Score	Value
Audits SMS	1	Average score accounting for: (i) % of minor non-compliances, (ii) % of greater non-compliances
	2	
	3	
	4	
Inspection management	1	compliant with the legislation
	2	risk-based integrated with inspection plan
	3	updated after changes
	4	periodically updated
Inspection results	1	Average score accounting for: (i) system functionality test results, (ii) system integrity test results, (iii) inspections planning (scheduling)
	2	
	3	
	4	
Inspections effectiveness	1	Average score accounting for: (i) effectiveness of inspections, (ii) inspector qualification
	2	
	3	
	4	
Process control	1	unregistering local control system
	2	control system with data recording
	3	data recording system with automatic blockage
	4	control system with data recording + automatic blockage + certified blockage
Specific protections	1	Average score accounting for: (i) inspection intervals, (ii) protection's conditions
	2	
	3	
	4	

- *Inspection results* = average value among three scores accounting for the inspections planning and the results of tests that verify the functionality and integrity of the systems.
- *Inspections effectiveness* (it is partly included in *inspection program*) = average value among three scores accounting for extension and degree of coverage of techniques, likelihood of damage detecting and qualification of inspectors. Reference should be done to UNI 11325-8 (UNI, 2013) and API 581 (API, 2016a).
- *Process control* = main characteristics of the installation control systems of process variables.
- *Physical protections* = average value among three scores accounting for the type of coating, the frequency of the controls and the actual condition of the material.

In Table 1 and 2, the score for factors, which takes into account various sub-factors, is calculated by averaging the scores of the various subfactors (see Bragatto & Milazzo, 2016).

5 VIRTUAL SENSOR FOR AGEING

The first version of the ageing model, which does not take into account the relationships amongst accelerating and retarding factors, is implemented in the short-cut method for the ageing monitoring and control at major hazard establishments presented in Section 4. To evaluate the status of critical equipment, a static model appears the most appropriate for auditors acting on behalf of Seveso Authorities.

Nevertheless, a dynamic model, which also accounts for the interaction amongst factors, could be more effective for industrial managers. For this reason, a second release of the method is currently

under development within a system, called *virtual sensor* for ageing and made up by hardware and software. The model is considered dynamic as information about process variables, external data, inspection information and etc. are continuously collected and processed, in order to provide an overall picture of the system's status in a form of an index (overall ageing score). This index allows the real-time forecasting of the equipment deterioration process and its management based on the industrial risk acceptance levels. Based on this model, a *digital twin* of a complex plant can be built, by integrating sensors and other smart devices collecting information from the equipment and the establishment.

Therefore, the *digital twin* is made up of measured data, managed information and models for the physical evolution of equipment. It simulates the real evolution of equipment, anticipating possible failures. This set of "data-information-knowledge" can be recalled from every "location" (e.g. cloud, DCS, etc.) through a device that constitutes the interface with the user.

6 CONCLUSIONS

Due to the legislation requirement, in the context of major hazard establishments, inspections planning and maintenance activities are essential elements to guarantee a safe ageing of installations. These must be based on in-depth knowledge of all damage mechanisms and backed up by appropriate controls. The proposed model (in its various versions), by accounting for the interaction amongst accelerating and slowing-down factors and its dynamics, is aimed at supporting the auditing activity and promoting an ageing management based on *knowledge*, *information* and *data*. At the present the second release of the method is under development and implementation within a system, called *virtual sensor*. It will work based on a *digital twin* of a complex plant and achieve a dynamic monitoring of the ageing status of the overall establishment.

ACKNOWLEDGMENT

This work is part of an Italian research project entitled "SmartBench" that is supported by INAIL (Istituto Nazionale per l'Assicurazione contro gli Infortuni sul Lavoro) and funded within the call BRIC 2016.

E. Niel
Department of Industrial Engineering, Ampere Laboratory, National Institute of Applied Science Lyon, Villeurbanne, France

ABSTRACT: Fault prognosis has become a major scope for complex and interconnected systems. Such significant events as fault events can cause partial or total stop of attempted functionalities. Prevention failure events are an issue to preserve performance, availability and safety of both operators and equipment. The aim of prognosis is to prevent fault events before their occurrence. Fault/repair management refers to event control, and so it is relevant to the domain of Discrete Events Systems (DES), for which stochastic finite state automaton and Petri Nets (PN) have been used to prognosticate fault state. They are based on predictions of fault event at least m-steps in advance.

The proposal is based on the time notion, which is crucial for fault prognosis. Indeed one can give the remaining time before the occurrence of fault event. The goal is to prevent the occurrence of a fault event at τ – *timeunits* in advance. This approach is based on labeled and T-temporal Petri Net, which has the advantage of a formal character for the assessment of properties and of sufficiently generic in order to apprehend a high level of complexity.

1 INTRODUCTION

The availability of complex systems can be ensured solely by control fault events, which can occur at any time triggering partial or total down of the system. The criticality of complex systems requires failure report before its occurrence beside the detection of failure and report of dysfunction alarms, avoiding the accidental down of the system. Prognosis allows meeting these requirements and giving visibility on the evolution of the system, thus, allowing the prediction of future failures. Several fault prognosis methods have been developed; some have adopted a stochastic approach (Ammour et al. 2017) (Dutta and Biswas 2015) (Chen and Kumar 2014), while others have chosen non-stochastic (Takai 2012) (Kumar and Takai 2010) (Takai 2015), one for state automaton or Petri Net. These approach are interested in prediction of failure m-steps in advance, based on a stochastic process that cannot predict in time. The challenge of each community working on this topic is to predict perfectly the future reality.

For visibility of the future, one must master the present and have enough information about the past. The verification of time constraints an extension of Petri Nets (PN) (Chen et al. 2017) called temporal Petri Nets (Berthomieu 2001), is part of these modeling methods. Tow modeling methods are proposed, the first one, combine T-temporal PN with labeled PN (Yin and Lafortune 2017) to give an extension of PN, called extended labeled T-temporal PN. In this extension, clock and label are associated with transitions. The second method, integer Watchdog techniques (Kovacs et al. 2007), it generates alarms to indicate the existence of a fault in the system. However, the goal is to exceeds detection and aims to prevent fault and hence comes the interest an improvement of the method; that allows for more expressivity of the model in order to determine τ-time units in advance and the occurrence or not of a failure in the system.

The first proposal, introduces the notion of INIT and EXC events, which represent respectively the initialization and exceeding time of the clock, thus, allowing the distribution of the system to operating modes (Nominal, Degraded and Failed), in order to control risks. Following this distribution, we can determine the relevant, non-relevant and critical places. From the first relevant place in degraded mode, one can prevent the occurrence of a fault event τ – time units in advance. Considering that the system cannot remain in degraded mode indefinitely, the notion of cycle execution of degraded mode is introduced. By exploiting

the temporal constraints of transitions, it would be possible to calculate the minimum time of a mode execution, yet it would be interesting to be able to calculate the maximum time of a mode execution. Then, the notion of execution cycle can help to calculate a temporal estimate of execution at the latest by a mode, which allows to have a time estimation interval for a mode execution at the earliest and latest. If the extended PN is not safe but bounded (places contain more than one token), the multi-clock is introduced. The second method, represents the watchdog approach based of the labeled T-temporal PN (Ru and Hadjicostis 2009); the alarm places generated by the watchdog become indicator places from which one can prevent a fault occurrence by computing the earliest and latest time of its occurrence.

The paper is organized as follows: the first section is dedicated to the representation of Petri nets and their extensions integrating time constraints. In the second section, the rules of transition from the T-temporal PN to the extended T-temporal PN are determined. The third section will be devoted to modeling the system using the various methods mentioned above. The fourth section will detail the proposed prognosis approach. The fifth section will push the boundaries of the proposed method by introducing multi-clocks in the model. The paper will be concluded with a conclusion.

2 PRELIMINARY

2.1 *T-temporal Petri Nets*

T-Temporal PN (Berthomieu 2001) (Sadou and Demmou 2009) (Zuberek 1991) (Jiacun 1998) is a tuple: $TR = (P, T, Pre, Post, M_0, I^S)$, where: I^S is the static interval function. It is represented by temporal constraints that can be associated with places, arcs or transitions.

This differentiation in the representation does not influence semantics. In this paper, the temporal constraints in T-temporal PN are associated with transitions by rational bounded intervals. $I^S(t) = [min, max]$ avec $0 \le min \le max$ and max can be ∞. The firing of a transition can only occur after a minimum of time units (*min*) and at the latest a maximum of time units (*max*). For example in Figure 1; T_1 is fired at earliest a UT and at latest b UT.

2.2 *Labeled Petri nets*

Labeled PN (Yin and Lafortune 2017) (Li 2017) (Jiacun 1998), adds to PN a label alphabet and a function for labeling transitions with these labels.

Labeled PN is a quadruplet $LR = (R, M_0, \Sigma, \lambda)$, with:

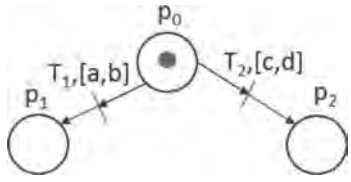

Figure 1. T-temporal Petri Nets.

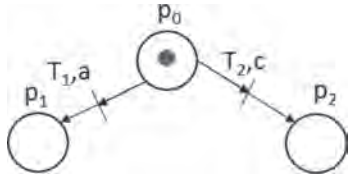

Figure 2. Labeled Petri Net.

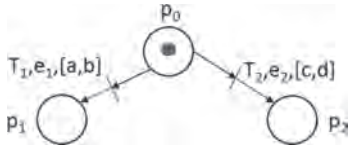

Figure 3. T-temporal labeled Petri Net.

- (R, M_0): Marking PN.
- Σ: finite Set of events.
- $\lambda : T \to \Sigma$ The function for labeling transitions that assigns a label (*event*) to each transition.

The model of Figure 2 can be considered as the execution of PN in Figure 1 by identifying events a and c respectively at transitions t_1 and t_2.

2.3 *Labeled T-temporal Petri nets*

Labeled T-temporal PN (Peres et al. 2011), is a n-uplet $LTR = (P, T, Pre, Post, M_0, I^S, \Sigma, \lambda)$, where:

- $\lambda : T \to \Sigma$ is the labeling function;

Figure 3 represents a T-temporal labeled PN:

3 FAULT PRONOSTICS BASED ON EXTENDED PN

The prognostic method proposed in this paper is based on the temporal estimation of the occurrence of a future event. Modeling the system on extended T-temporal labeled PN. In order to analyze the risks, the system must be distributed into operating modes (nominal, degraded, faulty); Once the modes of operation are identified, it is necessary to determine the places which are relevant or not and which are critical. The aim of prognosis is to calculate the time estimate of the execution of the degraded mode in order to determine in advance the earliest possible occurrence of a failure or entering in the failure mode.

3.1 *Extended PN*

The proposed modelisation in this section is based on T-temporal labeled PN, which are adapted to our approach, that consider critical systems such as real-time systems. An extended PN is a 5-tuplet $(P,T,\sum,Init,Exc,X,C)$, with:

- Init: the time initialization function of the clock.
- Exc: the time exceeding function of the clock.
- X: Set of Clocks.
- C: Set of temporal constraints.

The semantics differ from that of T-temporal labeled PN, Firing of a transition in extended T-temporal PN is possible by checking both the time constraint and the occurrence of the event. Firing transition allows knowing if the event occurred before, simultaneously or after the time constraint.

The integration of temporal constraints in the PN is expressed by their associations with places, arcs or transitions. Extended T-temporal labeled PN is modeled by associating temporal constraints with transitions; the goal is to determine if during the firing, an event has occurred on the intended time or not. Two notions have been introduced: initialization and exceeding clock noted, Init and Exc respectively. This modeling method gives more expressiveness, in order to predict the future evolution of the system. The Init sets the time clock when firing transition. The Exc checks whether the event occurred before or after time clock exceeding. To introduce the method, the rules of transition are modeled from T-temporal PN to extended PN (see Figure 10).

In the above model the firing of the transition will occur once the event appears; the reset of the clock x is automatic done after the firing transition. *Init* is associated with the first transition to reset the x time clock to 0 and set the guard. The transition is associated with $\{b,Exc(x,30)\}$. It is fired after the occurrence of event b, before or simultaneously with the expiration of time clock.

The expression $\{Exc(x,30),b\}$ allows the firing of the transition after checking the occurrence of event b, after the expiration of the time clock.

The equivalent model does not include an Init in the modeling, since the clock initialization is not expressed in the T-temporal PN. The expression $\{c,Exc(x,30)\}$ checks whether event c occurred before or simultaneously with the expiration of the time clock.

The only condition for firing the transition in the first model is based on the occurrence of event c; no guard and no initialization of the clock are indicated. The equivalent model will remain the same constraint. The notions of Init and Exc refer to the research realized by KHOUMSI on timed PN (Ouédraogo et al. 2006) (Khoumsi 2009) (Khoumsi 2005). Which consists of reformulating the prognosis problem in real time in a non-real time form, by transforming the timed automaton into finite state automaton called SEA (for Set-Exp-Automaton).

3.2 *Example of model*

3.2.1 *Modeling of T-temporal labeled PN*

In order to implement the rules of passage from the T-temporal PN to the extended PN, the model T-temporal labeled is used in (Figure 8). It is assumed that the PN of the Figure 9 is a safe one and event c always respects the temporal constraints with which it is associated in the model (to

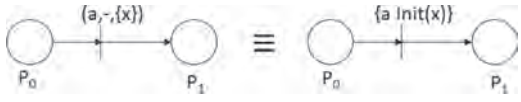

Figure 4. Rule 1.

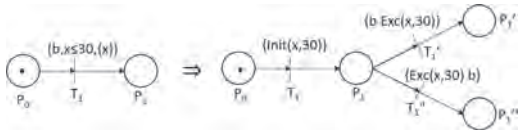

Figure 5. Rule 2.

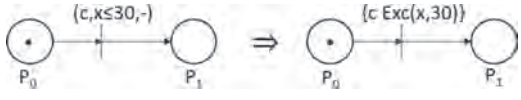

Figure 6. Rule 3.

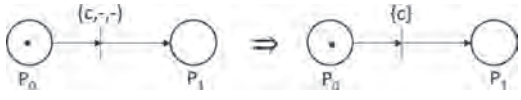

Figure 7. Rule 4.

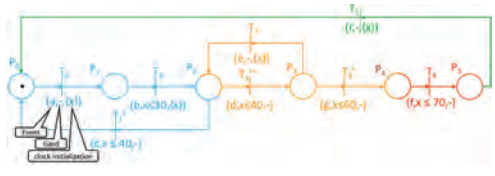

Figure 8. Example of T-temporal labeled PN model.

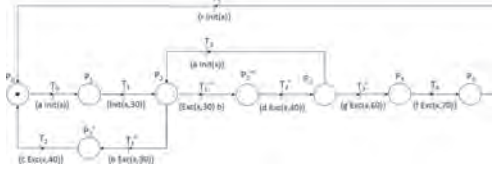

Figure 9. Extended PN model.

avoid the presence of a non-nominal behavior). Each transition is associated with a triplet *event, guard, reset*; The guard represents a temporal constraint that can be >, ≥, <, ≤ then a specified number of time units. It is possible that the guard may not be mentioned if the firing of the transition depends solely on the occurrence of an event.

- $P = \{P_0, P_1, P_2, P_3, P_4, P_5\}$ Set of places.
- $T = \{T_0, T_1, T_1', T_1'', T_3, T_3', T_4, T_5\}$ Set of transitions.
- $\Sigma = \{a, b, c, d, e, f, g, r\}$ Set of events, where f is a failure event and r a repair event.
- $\Sigma = \Sigma_n \cup \Sigma_d \cup \Sigma_f \cup \Sigma_r$.
  - $\Sigma_n \{a, b, c\}$: Set of nominal events
  - $\Sigma_d \{d, e, g\}$: Set of degraded events
  - $\Sigma_f \{f\}$: Set of failure event
  - $\Sigma_r \{r\}$: Set of repair
- x: Clock.

The clock reset is mentioned by x, an uninitialized clock is represented by –.

3.2.2 *Extended PN model*

Figure 10 represents system modeling with extended PN. Two notions have been introduced in this modeling; the Init, which is used to define both the time constraint and the initialization of the time clock when necessary. The notion of Exc allows checking the exceeding of the time clock; it is formed by two parameters: the first one indicates the clock and the second one indicates the temporal constraint to check. The model below represents the extended PN. It is assumed that this PN is safe:

3.3 *Description of the prognostic method*

3.3.1 *Steps of the prognosis method*

The prognostic approach is based on the verification of the future occurrence of a failure event at the earliest and latest. The first step is to provide temporal modeling of the system on extended PN (see next section) or on PN with Watchdog technique (see section 3.4), in order to exploit the time constraints represented in the model. To analyze the risks, the second step indicate the possible operating modes in the system (Nominal, Degraded, Failed). The nominal mode corresponds to operating mode

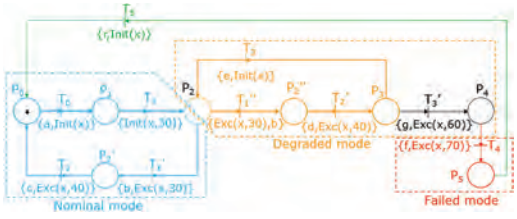

Figure 10. Operating modes of the system.

of the system without time constraints disrespect, while the degraded mode corresponds to system operation with degradation (presence of partial failure) but without stopping the system and failed mode represents the failure state. The third step determines whether places belong to the operating modes to identify which places are relevant or not and which are critical places. The relevant places can be nominal, degraded, critical or failed, depending on the mode in which they are represented. When a place is represented in both nominal and degradation mode, it is referred to as a non-relevant place. The critical place is an intermediate place between two modes: degraded and failed. The firing of transition leads to the failed mode.

Definition 1:

$P = P_r \cup P_{nr}$, where:

P_{nr} is the set of non-relevant places P_r is the set of the relevant places of the extended PN with $Pr = P_{rn} \cup P_{rdeg} \cup P_{rfail}$ and T the set of its transitions, where:

- P_{rn} is the set of relevant place p_r which belongs to nominal mode. p_r is called the nominal place, denotes p_{rn}. All p_{rn} places constitute the set of places in nominal mode, $\forall p_{rn}, p_{rn} \in P_{rn}$
- P_{rdeg} is the set of relevant place p_r which are only for degraded mode. p_r is called the degraded place, denote p_{rdeg}. All p_{rdeg} places constitute the set of places in degraded mode, $\forall p_{rdeg}, p_{rdeg} \in P_{rdeg}$
- P_{rdef} is the set of relevant place p_r which are only for failed mode. p_r is called the failed place, we denote p_{rfail}. All p_{rfail} places constitute the set of places in failed mode, $\forall p_{rfail}, p_{rfail} \in P_{rfail}$

Definition 2:

A place is said to be an relevant if and only if it belongs to one of the sub-sets $P_r n, P_{rdeg}, P_{rfail}$. A place is said to be critical if and only if it is between the degraded and faulty mode.

The introduction of time-constraints into transitions in modeling provides a time estimation of the execution time of a degraded mode, which is essential for calculating the earliest future failure occurrence. Thus, the number of execution of the degradation mode will make it possible in step four to evaluate the time occurrence of the future failure.

3.3.2 *Prognosis based on extended PN*

Step 1: Model of the system based on extended T-temporal PN.

Modeling by extended T-temporal PN is based on Init/Exc which are associated with transitions, as show in Figure 9. This association will tie the event to the clock to determine whether the event occurred at the right time. *Init*(x); means that the clock x will be initialized to zero without assigning a time-constraint. *Init*(x,30) means that clock x will be initialized to zero with a time-constraint

of 30 TU(*time – units*). *Exc*(*x*,30); verify if clock x has exceeded the time-constraint of 30 TU. Note that a transition with an Exc is not necessarily preceded by a transition with an Init. $\{b, Init(x)\}$; means that the initialization of the clock is dependent on the occurrence of event b. For the function Exc, associating the event with the time- constraint can be expressed in two ways: $b, Exc(x,30)$ means that the appearance of event b must occur before or simultaneously with the expiration of 30 TU, however $\{Exc(x,30), b\}$ means that the event will certainly occur after the exceeding time of 30 TU.

Step 2: Designation of the operating modes: nominal, degraded and faulty.

The repartition of the operating modes of system is done three modes, as show in Figure 10.

Step 3: Determination of relevant places: nominal, degraded, critical and failed. This nomination of places is intended to reinforce the proposed prognostic method (see Figure 11). Following the identification of operating modes, the places of the model are labeled either as relevant or non-relevant places.

Step 4: Evaluation of the execution time of the degraded cycle.

Let us take the example of Figure 11. The firing of T_1", indicates the change from nominal to degraded mode. this firing allows to calculate the execution time of the degraded mode (τ), which is equal to the summing of the time constraints associated with the transitions in this mode, it is possible to determine the earliest time to the failure event f occurs. $\tau = 10TU + 20TU; \tau = 30TU$. Indeed, since the clock is not initialized when firing T_2', the time constraint associated with event d is equal to $10TU = 40TU - 30TU$. However, it is possible that the degraded mode runs n-fold before changing to the failed mode. Using the concept of counter execution cycle.

3.3.3 *Counter of execution cycle*

A system cannot remain in a degraded mode indefinitely. It becomes necessary to compute the number of executions of this mode in advance. In fact, if the execution of a degraded mode is repeated more that n times, it can be sure that the system will be leaded to the failed mode. The problem is to how to compute the number of cycle executions. To do this, we add a place, associated to the degraded mode, in the model. This place (P_6) in the Figure 12 will contain a number of tokens equal to the number of possible cycle execution of the degraded mode, before leaded to the failed mode. It assumed that this number is fixed by expertise (equal to 4) in the example.

In this example, the firing of T_3, means that a cycle of degraded mode has been executed, and a token has been consumed in P_6. At this level, there are 3 execution possibilities before reaching the failed mode. Suppose that we repair the partial failure after the first execution cycle of degraded mode, the system will be leaded to the nominal mode. The next future partial failure will lead again the system to degraded mode. at this stage, the number of tokens in P_6 is equal to 3, while it should be 4. In this case the prediction of failure cannot be accurate. To avoid this problem, the notion of reset arcs, will maintain the exact number of tokens (4 tokens) in P_6.

3.3.4 *Notion of reset arcs*

To introduce the notion of reset arc, (Akshay et al. 2017) which represents the model of an access code verification system, the number of tokens, represents the number of possible attempts. After T_1 (Enter Code) is fired, if the entered code is correct (T_2 reached), the model reset the number of tokens in the place P_0 (Trials). However, the Arc reset allows this withdrawal action. PN with reset arcs (Comlan et al. 2015) is a 4-uplet $N_R = \langle P, T, W, AR \rangle$ with $\langle P, T, W \rangle$ a PN as defined in Definition 1 and $AR : P \times T \to 0,1$ is the set of reset arcs (AR) if there is a reset arc that connects p to t, otherwise $R(p,t) = 1$. In the example in Figure 13.

- P = {*Trials, InputCode, SystemAccess, Retry Code*};
- T = {*EnterCode, CorrectCode, WrongCode*};
- AR = {*CorrectCode*};
- M_0 = (3, 0, 0, 0).

The integration of the reset arc in the model is intended to initialize the counter for the execution cycle of the degraded mode once the fault has been repaired.

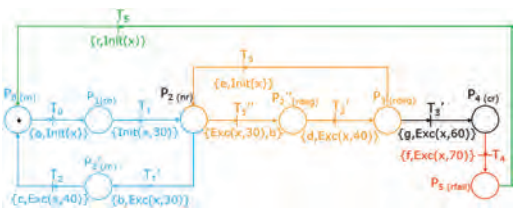

Figure 11. Relevant places on extended PN.

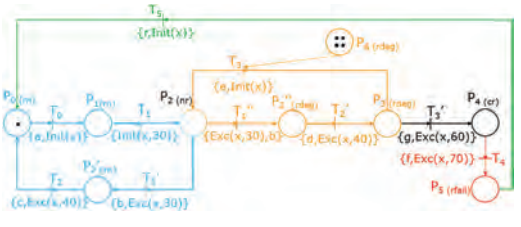

Figure 12. Execution cycle counter on the extended PN model.

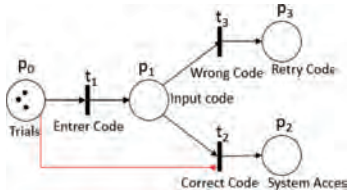

Figure 13. Reset arcs.

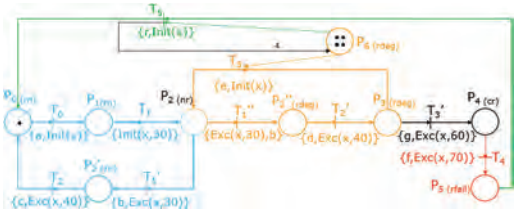

Figure 14. Reset arcs on Extended PN.

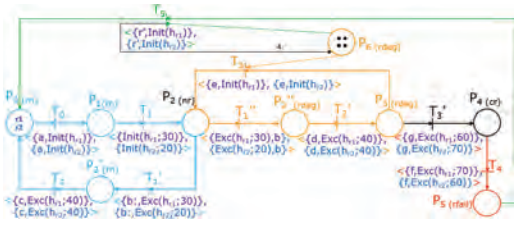

Figure 15. Modeling on Extended colored PN.

In the model of Figure 14, the firing of the T_5 transition represents the repair of the system, which can occur either before completing the possible execution cycles of the degraded mode, or after the occurrence of a failure event. In both cases, the reset arc ensures the emptying of the P_6 place. After firing T_5 transition, the P_6 place can be initialized with tokens equivalent to the number executions of the degraded mode. Assuming that the extended PN is safe, to predict a possible failure event f. The firing of the first transition of the degraded mode gives a visibility of the evolution of the system and makes it possible to determine a temporal estimation, at the earliest and at the latest of a failure events occurrence.

3.4 *Multi-clock approach*

When the assumption that the PN is safe is not verified, by introducing the notion of colored and timed PN (Soares 2017) (Jiacun 1998). The aim is to associate a clock to each token, in order to check their evolution in the system separately. Thus, in the same transition, several temporal constraints can be set depending on the clock associated with each one.

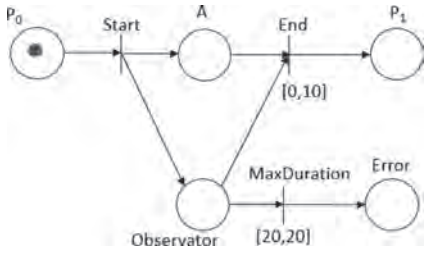

Figure 16. Watchdog on PN.

In the case of multi-token/multi-clock, the temporal estimation of the failure occurrence depends on the clock related to tokens and the time-constraints associated with transitions (see Figure 15. Let's take the case of token r1; if it ever changes from nominal to degraded mode following the firing of T_1", the temporal estimation at the earliest, of the occurrence of a failure event. $\tau_{min}(r1) = 30TU$, but for the token r2, $\tau_{min}(r2) = 50TU$. Taking into account the execution cycle of the degraded mode, the estimation at the latest of the failure occurrence is: $\tau_{max}(r1) = 150TU$ for the token r1 and $\tau_{max}(r2) = 170TU$ for the token r2. Thus, using the concept of multi-token/multi-clock assures prognosis, in advance the occurrence of a failure at the earliest and at the latest, although of parallel execution if the PN is not safe.

4 FAULT PROGNOSIS BASED ON WATCHDOG TOOL

4.1 *Watchdog concept*

In order to overcome a perplexity in diagnosis, T-temporal PN can be used to model alarms by integrating the watchdog mechanism. Based on experience and considering that the risks are known a priori, the watchdog mechanism (Kovacs et al. 2007) (Kovács et al. 2006) (Jerbi et al. 2006) verifies that an action has occurred before a given deadline, and signals the presence of an error in the system if a delay is exceeded. Figure 16 shows the watchdog mechanism on a T-temporal PN. It checks the maximum duration of a task, represented by the place A. The transition Start corresponds to the beginning of the task. Its firing creates a token in the place Observer, so the transition *MaxDuration* will be sensitized and triggers the countdown of his firing interval [20.20].

The place Observer will be marked either by the firing of the transition Start, i. e. when the task is completed, or when the firing interval of the transition *MaxDuration* is completed before the end of A: "*MaxDuration*" is then fired and the place Error is marked. This marking means that the execution time of task A is longer than 20 Time units.

4.2 *Application of watchdog on T-temporal PN*

The model in Figure 9 incorporates the watchdog mechanism. In order to exceed the limits of watchdog (Kovacs et al. 2007, Combacau 1991) and exploit it to the failure prognosis, a new method is proposed to interpret alarms. For example, to signal the change from nominal to degraded mode, the exceeding time of the occurrence of event b is checked when the transition T_2' is fired.

Upstream place of T_2', represents a waiting place (P_0') Downstream place (P_1'') of T_2', represents an indicator of the evolution from nominal to degraded mode. This makes possible the prediction time of the future failure occurrence; the temporal estimation of the occurrence failure on the model in Figure 17 can be predicted from firing the transition T_2'. The latest estimate of the occurrence of a failure is computed by summing the possible execution time of the degraded mode (possible number of cycles multiplied by run-time of the degraded mode) plus the temporal constraints related to transitions T_3'' and T_7. When transition T_3'' is firing, failure f is certain.

4.3 *Prognostic method with watchdog*

If the permitted number of the cycle execution of the degraded mode $n = 4$ (see Figure 18),then the temporal estimation at the earliest of the occurrence of a failure $\tau_{min} = 30TU$ and at the latest $\tau_{max} = 120TU$. So the time interval in which a failure can occur after T_2' firing is $[30UT, 120UT]$.

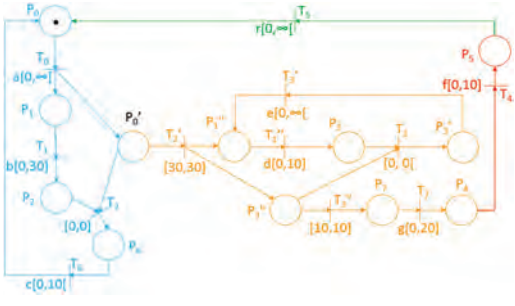

Figure 17. Watchdog on T-temporal PN.

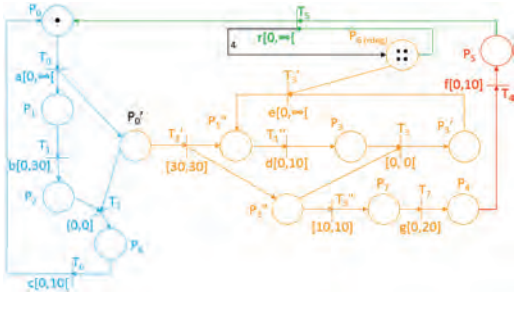

Figure 18. Watchdog on T-temporal PN with reset arc.

5 WATCHDOG VS EXTENDED PN

Following the two modeling represented in sections III and V, it is possible to follow evolutions of the system. In the model based on the Watchdog, the watchdog mechanism is extended, which was limited to fault detection, determining the switching from nominal to degraded mode. Thus, it would be possible to predict the future occurrence of a failure event. Extended PN model reduce the state space of the PN model compared to the Watchdog while maintaining the same properties. The two methods give a visibility on the evolution of the system and provide a temporal estimation of the failure at the earliest and at the latest time. The advantage of Watchdog method over extended PN is that there exists a modelisation and simulation tool called Little Parametric Tools (LPT) proposed by Karen GORDARY in (Godary-Dejean 2008). This advantage does not discriminate against the prognostic method with extended PN, but allows us to integrate into our perspectives the development of a modeling and simulation tool adapted to the extended PN proposed.

6 CONCLUSIONS

Existing prognostic methods are based on a stochastic or non-stochastic approach, to verify the occurrence in the future of a failure event, modeled by Petri net or automaton. The method of prognosis in this paper is based on a temporal approach; which allows the prediction of the occurrence of a failure in advance, by a temporal estimate of the appearance at the earliest and at the latest. Two modeling methods were proposed: The first is a modeling on extended Petri nets, integrating the concepts of initialization and expiration of clocks, the second method, proposes to integrate the watchdog technique in order to adapt it to the prognosis.

The prognosis approach begins with a distribution states of the system on operating mode (nominal, degraded, failed), in order to identify correct localization in each place. Thus, it would be easy to determine which places are relevant or not. Following this identification and from the first entrance date in degraded mode, one can predict the time at the earliest and at the latest of the failure occurrence.

After verification of the approach on both modeling methods, it is concluded that the two modeling methods give the same temporal estimate. the only difference is that the state space in PN with watchdog technique is more important than

the extended PN, which reduces system modeling complexity. That's why extended PN modeling is retained. Future works will consist to formalize the partial prognosability (Prognosis is possible for some parts of the system but not for others) on extended PN by verifying their property and the construction of the local prognoser.

ABSTRACT: The paper presents a Probabilistic Risk Assessment (PRA) method for the security of supply of a gas network. The method is based on a procedure for automatic generation of fault trees, which estimate the probability of disruption of the gas delivery from terminals/storages to each consumer nodes in the gas network. The method allows probabilistic analyses of the availability of the demand nodes and of the overall availability of the gas network. To assess the importance of each network component, risk achievement worth and risk reduction worth importance measures are utilized. The aim of the developed method is to assess potential weakness in the gas network as well as to be used as an analysis tool during expansion planning and maintenance scheduling activities. The framework developed in the paper leverages on steady-state analysis of the gas network performed using a physical flow/pressure model. The impact of a component failure on the gas supply interruption at different demand nods is assed and contrasted to the PRA results. The framework is exemplified with reference to the reduced UK gas network. The results provide insights to support a robust reliability assessment of the gas network. Moreover, the probabilistic mapping of the most important components in the gas network provides the means for assessing optimal strategies for maintenance schedule as well as to prioritize improvements of the gas network aiming for effective risk reduction.

1 INTRODUCTION

In the past decades, the consumption of gas in Europe increased significantly (Weisser, 2007). Natural gas is considered of the essence for the energy security in the European Union, by comprising a quarter of the primary energy supply to electrical power generation, households, feedstock for industry and fuel for transportation. Considering the decrease of domestic gas production and thus the higher import dependence, the need to address security of supply has increased (EU, 2010). As a response, the Regulation (EU) No. 994/2010 of the European parliament and council of 20 October 2010 concerning measures to safeguard security of gas supply and repealing Council Directive 2004/67/EC was released.

The International Energy Agency (IEA) shows that, in many IEA member countries, the electricity generation sector is especially dependent on natural gas, with tendency to grow. In 14 countries, gas accounts for over 20% of the electrical energy generation and more than 30% in nine countries, while in five countries more than half of the generation is dependent on gas (Simpson and Min, 2011). A sense of comfort exists over the gas markets capability to successfully adjust to demand or supply shocks due to low gas prices, along with expectations for continued well-supplied gas markets over the medium term. However, the IEA global security review shows that the current situation about gas security comfort may change suddenly as market conditions change (IEA, 2016).

Researchers have placed significant effort in modeling gas networks to provide accurate assessments of the network behavior, which can be of significance for the security of supply. In (Osiadacz, 1987), a thorough description of steady state and transient simulation models for gas network analysis is presented. Security of supply is investigated during conflicts and crisis in Europe in (Carvalho et al., 2014), and resilient response strategies to supply disruption events under relevant scenarios are provided. Furthermore, (Antenucci and Sansavini, 2017) identifies the contingencies that can jeopardize the coupled gas and power systems security under increasing gas demand scenarios.

A probabilistic model that studies the security of supply in a gas network is presented in (Praks et al., 2015). The model utilizes Monte-Carlo simulations along with graph theory to perform analyses on a real size gas network, i.e. an unspecified part of the EU gas network. Even though the model provides comprehensive simulation of the security of supply in a gas network, it lacks the support of a physical model. A fault-tree based analyses of the security of supply in a gas network is shown in (Praks et al., 2014). The paper argues that the application of a fault tree method on a real size gas network requires an automatic fault trees generation algorithm.

The limited choice of methods for the assessment of the gas network security of supply is the main motivation behind this research. The framework presented herein aims at assessing the reliability of a gas network by gaining insights from the application of both probabilistic and deterministic analyses. A PRA method based on the fault tree technique is developed. The method uses a procedure for the automatic generation of fault trees for a selected gas demand node. The unwanted event, i.e. the top event is defined as the "node not supplied with gas". The risk of having gas demand not supplied is a function of the gas network architecture and of the failure probabilities of the components of which the network is comprised. A global risk measure is introduced to evaluate the overall gas network security of supply. Different importance measures are employed to assess the importance of each network component with respect to each individual demand nodes, as well as to entire gas network. A physical analysis model is employed to assess the behavior of the gas flows, thus the gas properties in the system. Combining the PRA model analyses with the physical model analyses results in a complimentary platform capable of performing robust risk analyses of the security of supply of gas networks. Thus, the obtained results, besides providing various risk measures, bring together the complimentary insights from two conceptually different models.

The paper is structured as follows: Section 2 describes the PRA methodology used to assess the gas network reliability; Section 3 presents the physical model for simulating the gas network operational conditions; Section 4 presents the performed analyses and the obtained results; Section 5 gives conclusion remarks.

2 PRA METHOD FOR GAS NETWORKS RELIABILITY ANALYSES

The PRA supported by the fault tree and event tree analyses has been extensively used for risk evaluations in various engineering domains, i.e. nuclear power plant safety, aerospace design, power system reliability, etc.. The fault tree is a deductive analytical method, where an undesired system state is specified and the system is then assessed in relation of its operations and environment to find all relevant ways in which the undesired event can occur.

In this paper, a method for probabilistic risk assessment of gas networks is presented. The method exploits a procedure for the automatic generation of fault trees that was originally proposed for power system reliability analyses (Volkanovski et al., 2009). Herein we adapt the method for its application to real-size gas networks. The graphical representation of the procedure for the automatic generation of fault trees is shown in Figure 1.

The procedure starts by defining the adjacency matrix (Figure 1) of the corresponding network graph. The adjacency matrix of a graph, also known as the connection matrix, is a square matrix A (v_i, v_j) such that the element $A_{i,j}$ is equal to one when there is an edge from vertex i to vertex j, and equal to zero otherwise (Biggs, 1993). The adjacency matrix is used to determine all possible flow pats that connect a demand node with all the source nodes in the gas network. For example, if demand node 1 is connected to the source node 4 through node 2 and node 3, two possible paths can lead from node 1 to the source node 4. In the process of identifying a path from a demand node to a source node, no single component can be used twice in the same path. This constraint prevents the path from looping, i.e. repeating the same set of components in the same connectivity path. In addition, a path is only completed if it starts with a demand node and ends with a source node.

The two identified pats (Figure 1, Connectivity Paths: path one [1 2 3 4] and path two [1 3 4]) through which the demand at node 1 can be served from the source node are the foundation for the creation of the fault tree. It is a top-down procedure where the fault tree is created starting from the demand node and continues by unfolding the identified paths. The demand at node 1 is not supplied with gas if node 1 fails or the interruption of gas delivery to node 1 occurs, which is the first gate in the fault tree which is being written by the procedure for automatic generation of fault trees and represented by Boolean OR. The interruption of gas to node 1 occurs if both the gas pipeline between node 1 and node 2, which is on the first path, and the gas pipeline between nodes 1 and node 3, which is on the second path, do not deliver gas to node 1. This is the second gate in the fault tree and it is represented by a Boolean AND. The gas pipeline between node

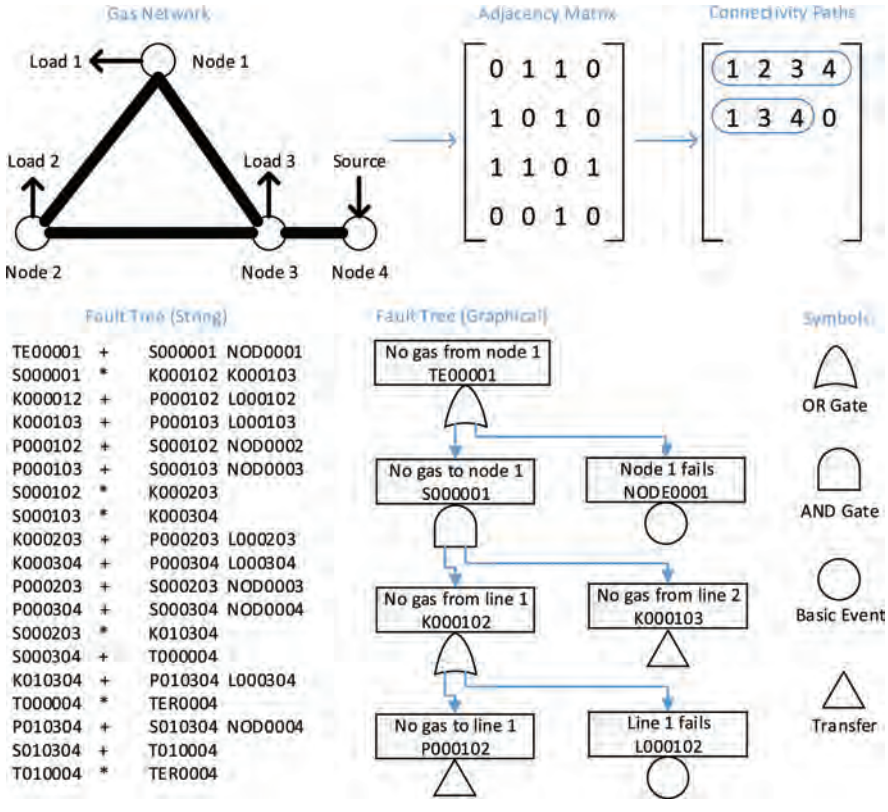

Figure 1. Graphical representation of the procedure for automatic fault tree creation.

1 and node 2 does not deliver gas to node 1 if either the pipeline fails or there is no gas delivered to the pipeline from elsewhere, which is represented by another OR gate. The process of unfolding the first path ends when the source at node 4 is reached. The same operation is repeated for the second path. The output of the algorithm for the automatic generation of fault trees for node 1 is a string-based fault tree given in the lower left part of Figure 1. The "*" denotes AND gate, while "+" denotes OR gate. The first line "TE00001 + S000001 NOD0001" denotes the occurrence of the top event "no gas from node 1" (TE00001) due to either there is "no gas to node 1" (S000001) or "node 1 fails" (NOD0001). The rest of the lines follows the same rationale. The graphical equivalent of the fault tree is presented in the lower mid part of Figure 1. The representation of each symbol is given in the lower right part of Figure 1.

2.1 *Fault tree quantification*

The method, when applied on a real-size gas network, results in large fault trees, comprising tens of thousandths to few hundred of thousandths lines. Solving a large fault trees efficiently is known to be a challenging problem (Contini and Matuzas, 2011). In general, fault trees can be converted into equivalent set of Boolean logical equations. The quantitative analyses of a fault tree is represented by the Rare Event Approximation method (Roberts et al., 1981):

$$Q_L = \sum_{i=1}^{n} Q_{MCS_i(BE_1,\ldots,BE_m)} = \sum_{i=1}^{n} \prod_{j=1}^{m} Q_{BE_{ij}} \quad (1)$$

where Q_L is the top event probability of occurrence, n is the number of minimal cut sets (MCS), i.e. the smallest set of basic events that induce the top event when occurring simultaneously, $Q_{MCS_i(BE_1,\ldots,BE_m)}$ is the probability of occurrence of ith MCS, which is comprised of m basic events, and $Q_{BE_{ij}}$ is the probability of occurrence of the jth basic event within the ith MCS.

2.2 *Network risk measure*

In this paper, a unique fault tree for each demand node in the gas network is created by employing

the proposed procedure. The fault trees are solved using the Rare Event Approximation method (Equation 1), and the probability of each demand node not being supplied with gas is obtained.

The risk of a gas demand not being supplied is a function of the gas networks architecture and of the probabilities of its components. A global risk measure is defined (Volkanovski et al., 2009) to assess the overall gas network security of supply:

$$U_{GS} = \sum_{i=1}^{LN} Q_{L_i} \frac{L_i}{\sum_{i=1}^{LN} L_i} \tag{2}$$

where U_{GS} is the gas system unavailability, Q_{L_i} is the probability of failure of gas supply to the ith demand node, LN is the number of nodes with load demands, L_i is the gas demand at the ith node.

2.3 *Importance measures*

The performance of a system (e.g. gas network, power system) depends on its components. Some components contribute more to the failure of the system than others. Therefore, the concept of importance plays a major role in the quantification of risk in engineered systems. In this paper two of the most frequently exploited importance measures in PRA are utilized, i.e. the Risk Achievement Worth (RAW) and Risk Reduction Worth (RRW). The RAW estimates the value of risk increase if the failure probability of a basic event is equal to one (component out of service):

$$RAW_j = \frac{Q_L\left(Q_{BE_j} = 1\right)}{Q_L} \tag{3}$$

where RAW_j is the risk achievement worth of basic event j, the $Q_L\left(Q_{BE_j} = 1\right)$ is the top event probability when the probability of occurrence of basic event j, Q_{BE_j}, is equal to one. The RAW determines the maximum increase of risk due to occurrence of the basic event j, i.e. identifies the components that need to be efficiently maintained such that the reliability of the system will not decrease (Volkanovski et al., 2009).

The RRW estimates the value of risk decrease if the failure probability of the basic event is equal to zero (the component never fails):

$$RRW_j = \frac{Q_L}{Q_L\left(Q_{BE_j} = 0\right)} \tag{4}$$

where RRW_j is the risk reduction worth of basic event j, the $Q_L(Q_{BE_j} = 0)$ is the top event probability when the probability of occurrence of basic event j, Q_{BE_j}, is equal to zero. The RRW determines the maximum reduction of risk due to perfect reliability of the component associated to the basic event j, i.e. identifies the redundancy level of a component associated with the basic event j (Volkanovski et al., 2009). In most cases, the basic event is associated with component unavailability (van der Borst and Schoonakker, 2001).

2.4 *Network importance measures*

A fault tree is created for each node with gas demand L_i, and the probability of failure of gas supply (Q_{L_i}) to the ith node is calculated. The RAW and RRW importance measures are calculated for each demand node, resulting in a unique set of importance values for each component (basic event). The importance values of the same basic event with respect to different nodes may significantly differ among each other. Hence, a component may be very important for some demand nodes and irrelevant for other demand nodes. In order to estimate the importance of each component on a global level, i.e. for the overall gas network, the network importance measures are introduced, i.e. the network risk achievement worth (NRAW) and the network risk reduction worth (NRRW) as shown in (Volkanovski et al., 2009).

3 PHYSICAL MODEL SIMULATION OF GAS NETWORKS

For a reliable representation of the gas system, several components need to be modelled, including pipelines and non-pipe elements, such as compressors, terminals and storages. Gas flow within a pipeline is represented with a steady state model. Pressure-drops in the network are modelled via the Panhandle "A" equation (Osiadacz, 1987):

$$p_1^2 - p_2^2 = 18.43 \cdot \frac{L \cdot Q^{1.854}}{E^2 \cdot D^{4.854}} \tag{5}$$

where p_1 and p_2 represent the pressure at the beginning and at the end of a pipeline, L is the pipeline length, Q is the volume flow rate through the pipeline, E is the efficiency factor and D is the pipeline diameter. The newton-node loop method is employed for solving the system of equations which define the entire network (Osiadacz, 1987). This iterative method is based on the Kirchhoff's second low, which states that the sum of the pressure-drops around any closed loop in the network is zero.

Compressor stations are modelled as fictitious branches, and a constant pressure ratio between the pressures at the sending and receiving node

of each compressor is considered. Terminals and storages injections into the network are proportional to their delivering capacity. The gas flow is allowed in both directions in the modeling of the network components.

3.1 *Physical importance measure: Total gas curtailment*

The importance of a component is evaluated by the induced change in the operation of the gas network. In fact, when a component is removed, the way the gas flows into the network varies and pressures change accordingly. However, in case pressures exceed the minimum or maximum safety pressures, actions are implemented in order to restore the normal operating conditions. In particular, in case of minimum pressure violation, gas curtailments are enforced in the location of the violation. The Total Gas Curtailment (TGC), which follows the basic event in order to bring the system back within safety margins, is considered as importance measure. The chosen matrix addresses the impact of a single component removal on the entire network, and it is formally expressed as:

$$TGC_j = \sum_{n=1}^{N} GC_n\left(Q\left(BE_j\right)=1\right) \tag{6}$$

where TGC_j is the importance measure for the basic event *j, N* is the number of nodes in the system and GC_n is the gas curtailment at node *n.*

4 ANALYSES AND RESULTS

The framework developed in this paper is applied to the UK gas network. The simplified transmission grid is constituted by 61 pipelines and 21 compressor stations that work with a constant pressure ratio. Safety operations are bounded in the pressure range of [38 85] bars. The gas system counts 9

Table 1. Top event probabilities for all demand nodes in the UK gas network.

terminals and 9 storage facilities. The UK gas network topological data is adopted from (Qadrdan et al., 2010), including the maximum supply capacities of different terminals and the characteristics of the storage facilities.

The failure probability data is adopted from (Praks et al., 2015). Considering one-year inspection time, the failure probability (complete rapture) of gas pipeline in European gas transmission system is 3.5E-5 per kilometer, the failure probability of a compressor is 2.5E-1, the failure probability of the gas terminal is 1.5E-1, and the failure probability of a gas storage is 1E–1. The failure of a compressor does not necessarily interrupt the gas flow through the compressor station, i.e. the gas flows through the compressor bypass. The failure probability of the bypass is based on the failure probability of a disconnection valve, i.e. "valve fail to open". Due to lack of specific data, for valves used in the bypasses at compressor stations a value of 1.6E-3 is taken from (IAEA, 1988).

4.1 *Probabilistic risk analyses of the UK gas network*

The fault tree method is applied for each load demand node in the UK gas network, thus the failure probability of gas supply at each node is calculated and the obtained results are presented in Table 1. In all of the fault tree analyses, the maximum number of basic events in a minimal cut set is truncated at 10, while the minimum failure probability of minimal cut set is 1E-15.

The first column from Table 1 represents the nodes with gas demands, while the second column represents the average gas demand per node in m^3/h. Node 41 is the node with the highest demand of gas, with average requirement of 1.77E+06 (m^3/h). The total average gas demand in the network is 1.90E+07 (m^3/h), while the total gas supply capacity is 3.78E+07 (m^3/h) including the gas storages which can provide gas for only limited number of time. The third column represents the top event probability of each demand node. The fourth column represents the weighting value of each demand node. The fifth column represents the weighted failure probability of gas supply at each node, calculated as the product of the top event probability and the weighting factor of the respective node. The total gas network failure probability is 3.00E-5 and is calculated with Equation 2 based on the individual demand node failure probability. Table 1 shows that in general the nodes with highest gas demands have the largest weighted probability of failure.

The network importance measures, NRAW and NRRW, for the UK gas network are calculated and given in Figure 2 a) and b), respectively. Furthermore, the RAW and the RRW results from the fault tree analyses performed for the largest load demand node 41 in the network are given in Figure 3.

Figure 2 shows the most important components in the gas network, according to the network importance measures presented in Section 2.4. The color defines the importance of each of the components shown in the figure, i.e. brighter colors are associated to components with higher importance values. According the NRAW, the most important gas pipelines to keep operational in the system are the pipeline between node 31 and node 32 with NRAW of 2726.8, and the pipeline between node 1 and node 3 with NRAW of 397.7. The pipeline between node

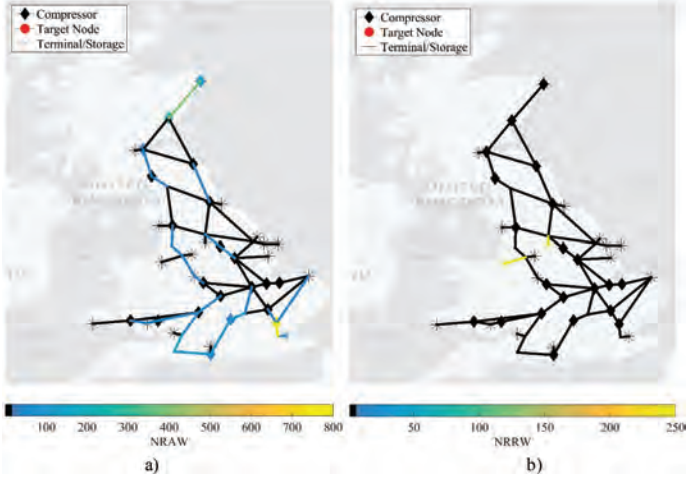

Figure 2. Representation of the most important components in the network according to: a) NRAW and b) NRRW.

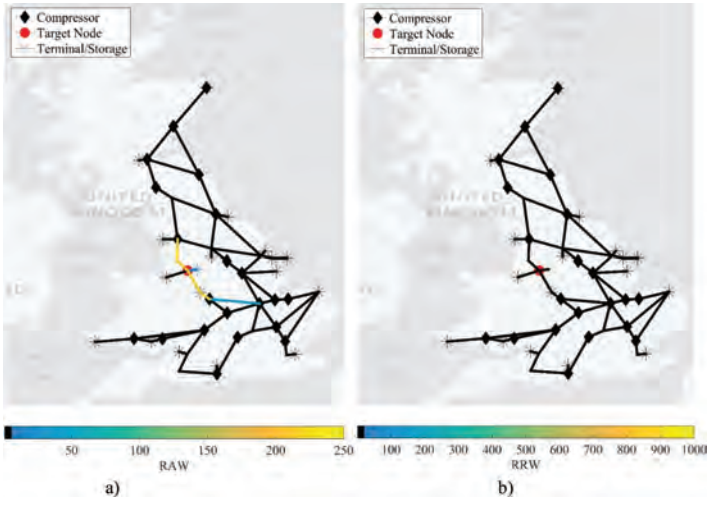

Figure 3. Node 41 component importance according to: a) RAW and b) RRW.

31 and node 32 is providing connection between the network and the gas terminal at node 59, IOG, which is positioned in the South of the island and it is the only terminal in the southern region besides the storages at node 68 and node 69 and the Bacton terminal in the South-East. The pipeline between node 1 and node 3 is connecting the network to the terminal at node 56, St. Fergus, which is the second largest gas source in the system and is positioned in the far North of the island. Furthermore, among the most important components in the gas network are the compressor bypasses between node 31 and node 32 with NRAW of 786.9, and between nodes 2 and 3 with NRAW of 242.4. Both bypasses are part of the compressor stations that provide connectivity to the terminals at node 59 and node 56, respectively. From the presented results, it can be deduced that performing maintenance simultaneously on any of the above components may significantly decrease the security of supply to the consumers in the gas network. For example, the simultaneous unavailability of the gas pipeline between node 31 and node 32 and the compressor station between node 2 and node 3, due to maintenance activities may have a significant impact to the gas network reliability. Based on the conducted analyses, it is possible to optimally prioritize the maintenance activities in the gas network, thus maximizing the security of supply.

On the other hand, Figure 2 b) shows the components with the highest risk reduction importance, i.e. the redundancy level of each of the components in the gas network. According to NRRW the most important components in the gas network are the gas terminal at node 61 and the pipeline connecting this node with node 41 and thus to the rest of network, as well as the gas storage at node 66 and the pipeline connecting this node with node 15 and thus the rest of the network, all with NRRW value of 243.7. Decreasing the failure probability of these components (e.g. by installing more reliable components) will result with increased security of supply. In other words, the obtained NRRW results can help in prioritizing feature improvements on the gas network, leading to the largest risk reduction.

Figure 3 a) and b) show the RAW and RRW values, respectively, for all gas network components when considering node 41 not supplied with gas as top event. The pipeline connecting node 41 to node 42 and the pipeline connecting node 42 to node 44 have the highest RAW of 214.6 and 214.5, respectively, making them the most important components with respect to the gas supply to node 41. On the other hand, the storage at node 65 is by far the most important component according to the RRW importance measure with value of 953.4, and the second most important component is the pipeline connecting node 13 to node 40 with RAW of 3.8.

4.2 *Steady-state simulations of the UK gas network based on the PRA results*

The physical model simulates the gas network behavior, and pressures and mass flows in the pipelines are computed. A steady-state analysis is performed for the loss of each network component and the consequent total gas curtailment is calculated (Table 2). Gas curtailments are specified for each gas demand node and for the entire network.

Table 2. The TGS effect of the 20 most important gas network components obtained using NRAW.

Component	Probability of failure	NRAW	TGS (m^3/h)	Risk
L 31-33	1.30E-03	2726.8	0	0
B 31-32	1.60E-03	786.9	0	0
L 01-03	2.45E-03	397.7	0	0
B 02-03	1.60E-03	242.4	0	0
L 39-54	2.10E-03	160.9	6.18E+04	1.30E+02
B 01-55	2.50E-01	105.1	0	0
L 34-36	1.51E-03	103.0	4.12E+06	6.20E+03
L 37-39	3.40E-03	92.2	7.17E+05	2.43E+03
L 35-38	5.08E-03	83.9	1.38E+06	7.03E+03
L 18-21	1.79E-03	49.9	4.53E+05	8.09E+02
L 47-49	2.10E-03	45.3	1.13E+05	2.38E+02
L 45-53	2.28E-03	43.2	1.59E+06	3.62E+03
L 33-59	8.05E-04	39.5	3.18E+05	2.56E+02
L 15-19	2.24E-03	36.1	5.71E+05	1.28E+03
TER-59	1.50E-01	34.8	3.18E+05	4.77E+04
L 47-54	2.45E-03	33.9	0	0
L 50-52	1.58E-03	30.1	0	0
L 48-50	1.54E-03	30.1	0	0
L 40-41	1.23E-03	29.5	1.41E+06	1.73E+03
B 04-05	1.60E-03	28.6	0	0

The first column from Table 1 represents the component/basic event name, such that the letters denote the component type (i.e. L stands for pipeline, B stands for compressor bypass, C stand for compressor, TER stands for gas terminal and TES stands for gas storage), while the numerical digits represents the nodes where the respective components are connected. The second column gives the failure probabilities of the 20 most important elements according to NRAW, and the third column represents NRAW values of these components. The fourth column gives the calculated TGS for the respective components represented by the first column. The fifth column gives the product of the component probability and its TGC impact on the gas network. In the physical model the compressor station failure is represented only by a compressor failure without losing the flow of gas through the respective branch in the gas network, instead the compressor station ratio is equal to 1, i.e. the gas pressure before and after the compressor station is remaining the same. Therefore, the TGS of zero caused by compressor bypass failures is by default, since no such failure is simulated. The obtained results show that the TER-59 (i.e. the IOG terminal connected at node 59) is the one with the highest risk impact on the gas network. Furthermore, a high risk impact is expected by the loss of the pipeline between node 25 and node 38 (L 35-38) which is one of the main links providing connectivity between the South and the South-West part of the gas network, and from the pipeline between node 45 and node 53 (L 45-53) which is one of the main links providing connectivity between the South-West and the central part of the gas network. Remarkably, the loss of some elements, such as the pipeline between node 31 and node 33 (L 31-33) or the pipeline between node 1 and node 3 (L 01-03), induce no pressure violations in the network, despite their large NRAW values. Therefore, irrespective of the relevance of these components from a probabilistic and network connectivity perspective, gas network operations manage efficiently the gas re-routing via different terminals and storages to sustain gas supply.

5 CONCLUSIONS

A framework for gas network security of supply analyses is presented. The framework is based on a PRA method which employs a procedure for automatic generation of fault trees related to a specific top event, i.e. gas demand node not supplied. The risk achievement worth and risk reduction worth importance measures are utilized to estimate the importance of the network components for the security of supply of the individual demand nodes and the overall gas network. Furthermore, a physical model for the simulation of the gas network behavior is developed. The model is capable of computing gas pressures throughout the network and of enforcing curtailments if single or multiple contingencies occur. The physical model is utilized

to supplement the PRA method by providing accurate estimates of the gas network conditions.

The PRA results show the most important components, based on risk increase and risk reduction measures, for the security of supply to each individual node and the entire network. The NRAW importance measures provides us with results that can be used to prioritize the maintenance activities in the overall gas network, while the RAW can be used to schedule the maintenance activities with respect of each individual node. The NRRW importance measure provides us with results that can be used to prioritize future improvements in the overall gas network thus increasing the security of supply, while the RRW importance measure can be used to schedule potential improvements that will increase the security of supply of each individual gas demand node. Furthermore, the physical model results show that even though some components are identified as one of the most important, according to the PRA importance measures, their failure may not have significant effect on the gas supply, because of the capability of the gas network to perform efficiently and provide gas re-routing via different terminals and storages to sustain gas supply.

ABSTRACT: Liquefied Natural Gas (LNG) as ship fuel is considered a viable solution to marine environmental issues, due to the significant reduction in emissions with respect to conventional fuel oil. At the same time, safety issues may arise in port areas when LNG is used as a fuel due to its high flammability. The present work focuses on the safety assessment of LNG carriers approaching a bunkering terminal trough port channels located in an industrial area. A risk matrix approach is adopted to evaluate the risk level associated with the carrier approaching the harbour, considering the vulnerability of surrounding territory and potential interactions with industrial facilities located in the area. The methodology is applied to a case study of industrial interest showing the potential of the tool in supporting risk-based decision making.

1 INTRODUCTION

Liquefied Natural Gas (LNG) as ship fuel is considered as a viable solution to marine environmental issues, due to the significant reduction in emissions with respect to conventional fuel oil (Bittante et al. 2017). Therefore, due to the potential benefits related to this technology, several projects have been proposed for the realisation of LNG bunkering terminals in harbour areas, contributing to the development of LNG infrastructure network.

However, safety issues may arise in port areas when LNG is used as a fuel due to the high flammability of this substance, with the potential of severe fires and explosion scenarios (Jeong et al. 2017). Thus, in the stages of early development and selection of LNG bunkering and ship supply technologies in port areas, safety aspects will become crucial to develop sustainable and reliable technologies involving LNG as marine fuel.

Several studies were reported in the literature concerning the safety of LNG distribution chain, addressing the analysis of LNG regasification terminals, bunkering stations, ships fuel systems. Yun et al. (2009) proposed a risk assessment methodology for LNG terminals by incorporating Bayesian and LOPA (Layers of Protection Analysis) approaches. An inherent safety based approach was proposed in (Tugnoli et al. 2012) to estimate the safety aspects or alternative LNG regasification technologies.

Concerning the analysis of LNG for marine fuel application, several studies were presented (ABS 2014, ADN Administrative Committee 2014). Lee et al. (2015) compared the fire risk assessments of two types of LNG fuel gas supply systems. DNV (2012) conducted a site-specific quantitative risk assessment of LNG bunkering in an effort to determine a safe distance for passing ships at the Port of Rotterdam.

However, a structured methodology to perform feasibility studies for access of LNG supply ships in harbour areas close to sensitive urban areas and industrial parks is still lacking in the literature.

The present work shows a risk-based approach to support the feasibility study of LNG ships access to harbour areas. The approach integrates geometrical and ship size considerations, legislative framework and safety aspects, and is applied to a reference case study, located in the Port of Venice (Italy).

The paper is structured as follows: in Section 2 the case study object of the feasibility study is described; in Section 3, the overview of the methodology is presented; in Section 4 details on the safety and risk assessment are provided; Section 5 shows the results of the analysis, which are discussed in Section 6. Conclusions and recommendations are given in Section 7.

2 DESCRIPTION OF THE REFERENCE CASE STUDY

The case study is located in the Port of Venice, that is one of the most important industrial sites in Italy (Zonta et al. 2007). The port is strongly interconnected with the Marghera industrial area, known as "Porto Marghera". Figure 1 shows the overview of Porto Marghera area. The area is accessible through the Malamocco channel (see paths 3 and 4 in Fig. 1), which connects Porto Marghera with an artificial channel leading to the Adriatic Sea (paths 1 and 2 in Fig. 1).

Porto Marghera is the site selected for a new bunkering terminal for LNG storage and distribution. The bunkering station will be located in the Southern part of the industrial channel (path 5 in Fig. 1); in the following the channel is labelled as "SIC".

2.1 *Description of the SIC*

SIC is accessible through the basin located in the Malamocco-Marghera channel; a detailed view of SIC is shown in Figure 2. The channel length is about 4 km and the draft ranges between 6 and 10.1 m.

The LNG bunkering terminal will be served by LNG carriers accessing from the Northern Adriatic Sea through the path shown in Figure 1 towards the terminal located in the SIC. This ship traffic may increase the risk level of the surrounding area due to possible accidents involving the spill and consequent ignition of LNG from the carriers.

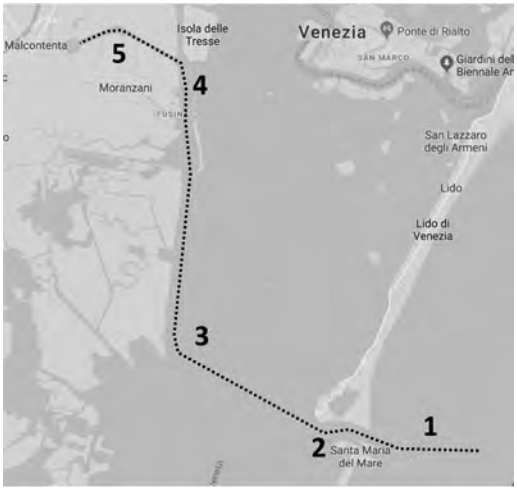

Figure 1. LNG carrier planned route through Porto Marghera: 1) roadstead in the Northern Adriatic Sea; 2) harbour inlet and artificial canal; 3) Malamocco-Marghera channel (before the industrial area); 4) Malamocco-Marghera channel (inside the industrial area), 5) SIC (Southern part of the industrial channel).

Figure 2. Detail view of SIC. The squared symbols indicate the location of the industrial berths, and the round symbols indicate the location of civil/commercial installations.

The critical areas along the LNG ship route are summarized in Figure 2. They are constituted by benches (either industrial or civil/commercial), industrial facilities, and the areas dedicated to civil activities or other services.

For what concerns the benches, along the route there are: 4 commercial berths located near the Fusina area (labelled with C in Fig. 2); 14 industrial berths (labelled with U in Fig. 2), 7 of which serving O&G facilities. The industrial activities are mostly chemical and petrochemical plants, and some smaller construction companies. There are some civil areas located close to the Malamocco-Marghera channel.

The civil installations of interest for this study are: two camping sites, e.g., Fusina and Darsena Fusina, the Venice Ro Port for passengers' transport (P01, P02, and P03 in Fig. 2, respectively), and smaller civil areas (beaches, little dockyards, etc.) located in the artificial canal connected to the Northern Adriatic Sea (path 2 in Fig. 1).

The new bunkering terminal location is foreseen at the end of the SIC, before the SIC final enlargement (e.g., between U4 and U5 in Fig. 2).

3 METHODOLOGY

3.1 *Overview*

The aim of the present work is to provide a methodology to perform feasibility studies for the access of LNG carriers to harbour areas. As shown in Figure 3, the methodology is based on two main parts.

The first part focuses on the nautical accessibility of the gas carriers with respect to both geometrical issues and legislative aspects. This part is aimed providing accessibility evaluations,

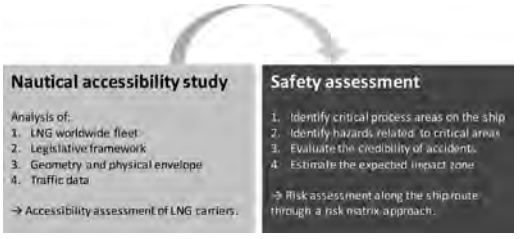

Figure 3. Overview of the methodology.

also considering possible mitigation or compensatory measures to eventually reduce suboptimal interactions of the LNG carriers with the current port configuration. In this way, potential events leading to collision or other manoeuvre upsets are identified and analysed in order to feed the safety assessment carried out in the second part of the methodology (see Fig. 3).

The safety assessment is aimed at investigating possible interaction between the LNG carriers and the neighbouring areas, either civil/commercial or industrial. Potential hazardous events affecting humans or process units in the surrounding industrial areas are considered. A risk register is compiled to determine the most critical scenarios and the associated vulnerability of the surrounding territory and industrial areas. Mitigation actions for critical scenarios are proposed to eventually reduce the risk level.

3.2 *Nautical accessibility study*

The nautical accessibility of LNG carriers is evaluated considering both geometrical aspects and the legislative framework (see Fig. 3).

Firstly, the type of gas tankers selected for the bunkering activities are analysed considering the worldwide LNG fleet. Secondarily, regulations and ordinances on the entry and the exit of port channel are analysed to point out the case specific legislative issues. Finally, the ordinary port traffic and the average residence time of each ship at the quay are estimated through historical data, in order to evaluate the geometrical compatibility with the gas carriers.

3.2.1 *LNG carrier selection for the case study*

The considered size of LNG carriers of interest in the present application feature nominal capacity ranging from about hundred cubic meters up to about 40,000 m^3. The current worldwide fleet of ships presenting these features consists of about 50 ships, considering those in activity and those in delivery by 2017 (Lloyd's Register Marine 2015).

In the present analysis, two reference carriers are considered (namely, ship A and B), which features are summarized in Table 1.

3.2.2 *Legislative framework and port data analysis*

There are no specific regulations for LNG carriers access to the port provided from the North Adriatic Sea Port Authority. Whereas, there are three ordinances from the Venice Harbour Masters of Italian Cost Guard concerning gas carriers sailing into the Venice Port areas (Ordinance 2009, 2010, 2016). The requirements specify minimum manoeuvre speed, draft in the area (between 7.95 m and 10.4 m), limitations for the navigation of dangerous cargo (e.g. interdiction in case of fog), mandatory tug service depending on gross tonnage and envelopment required, and maximum width of the convoy (never exceeding 1/3 of the minimum width of channels to be covered).

Given the legislative framework, port data concerning ship fluxes are analysed in order to evaluate the maximum time allowable for the LNG carrier transit and operations, according to the physical free space left by standard historical traffic. Thus, the most critical berths are identified as those which are located in correspondence of the smaller breadth of SIC. The three potentially critical areas and the corresponding channel breadth are reported in Table 2.

Data about critical berths are part of the physical compatibility assessment. In fact, the latter is the result of matching the data collected for berths above listed and the geometry of the LNG carriers defined in section 3.2.1.

The geometrical analysis of critical points along the SIC supports the risk assessment evaluating the likelihood of accidental scenarios not related to process failures, namely evaluation of ships

Table 1. Characterization of the LNG carriers for the case study.

Item	Units	Ship A	Ship B
Reference	–	Wartsila (WSD50)	ENI fleet (IGU 2016)
Capacity	m^3	30,000	65,000
Length	m	170	216
Breadth	m	29.5	34
Draught	m	8	9.5

Table 2. SIC width in correspondence of critical berths, see Figure 2 for berth location.

collision scenarios. Risk linked to accidental scenarios following conventional upsets/failures in the carrier LNG is object of the safety assessment summarized in Section 3.3.

3.3 *Overview of the safety and risk assessment*

The second part of the method focuses on safety aspects related to the ships approaching a bunkering station in port area (Fig. 3). The assessment of possible interaction between the LNG carrier and the neighbouring areas, both civil and industrial, follows a risk-based approach adopting risk matrix analysis. The first step is the evaluation of the critical areas in standard LNG carriers to perform hazards identification and to determine potential release events. Secondarily, the likelihood of scenarios following an accident leak (expressed in annual probability) is evaluated through standard failure frequency databases and event tree analysis (ETA). Then, the consequences evaluation is carried out through the use of standard literature models (Mannan 2005), implemented on the software DNV PHAST 7.1, and following a threshold-based approach (see Section 4.4.3). Finally, the credibility of the accidental scenarios and their consequences are combined through a risk matrix and the results are summarized in a risk register (see Section 5.2).

4 RISK-BASED ANALYSIS OF LNG CARRIERS APPROACHING HARBOUR AREAS

4.1 *Evaluation of critical areas on the LNG carrier*

The safety assessment is based on the identification of critical areas on the LNG carrier in order to determine the potential accidents. Collision with other ships moving in the channel is excluded from the present analysis, according to the results of the likelihood assessment and geometrical considerations (see Section 5.1). Thus, all the accidental release events are associated to process units exposed to the external environment, such as equipment and pipelines on the open deck. This is due to the fact that the structural failure of the main LNG storage vessels due to process failures is not considered as a credible event (Uijt de Haag & Ale 1999).

The reference LNG carriers shown in Section 3.2.1 and considered for the analysis, despite featuring relevant differences in the total inventory, share the same types of process equipment on deck with similar geometries. Thus, since the structural failure of the storage vessels is excluded, the potential release events are the same for both types of carriers.

During navigation in port areas, there are three critical zones onboard located on deck, from which an accidental release may develop. The possible leak sources are summarized in Table 3.

4.2 *Identification of release scenarios*

The Purple Book (Uijt de Haag & Ale 1999) guidelines for quantitative risk assessment of inland waterway transport are adopted to identify the release scenarios and for the estimation of related frequencies. The structural failure of one or more tanks is not considered credible, while possible damage to the connections is taken into account.

For "gas tanker" ships category, the Purple Book considers two release diameters (3″ = 76.2 mm and 6″ = 152.4 mm equivalent diameter) and it provides the related occurrence frequencies. However, it is worth to consider the following limitations about the applicability of the guideline to the present case:

- the approach was determined for navigable channels with length greater than 1 km, and it is suggested to perform an area-specific study for more reliable data;
- data refer to ships with maximum capacity of 4000 m^3, which are smaller than the ships of interest in the case study. Despite this, excluding the structural failure of the storage vessels, the equipment and the pipeline systems over-the-top shall be roughly identical regardless of the ship's capacity;
- in the present case study, major release diameters (6″) are excluded, considering the typical piping configurations.

Table 3. Critical areas characterization. T = temperature; P = pressure.

	Operating conditions		
Description	Phase	T (°C)	P (bar)
Liquid piping system on deck	liquid	−161 ÷ −141	1 ÷ 4
Boil Off Gas (BOG) piping/over-the-top vapour connections	vapour	−161 ÷ −141	1 ÷ 4
Steam piping manifold on deck	vapour	40	2

The reference release diameters selected in the present analysis are summarized in the following:

1. Large size release: equivalent diameter of 3″ (= 76.2 mm)
2. Small size release: equivalent diameter of 10 mm.

The latter rupture type is the reference minor rupture in for fixed process vessels (Uijt de Haag & Ale 1999).

In order to estimate the duration of the release scenarios, the liquid and vapor connections on the deck are not considered directly opened to the storage vessels (e.g., the lines are isolated through shut down valves in closed position). Thus, leakages from those sources will last since the entire inventory inside the pipes has been released. Whereas, the BOG piping and the over-the-top vapour connections are assumed in open connection with the storage tanks. In this case, the release will last since the emergency shutdown (ESD) system will close the valves. Following the indication of the IGC code (IMO 2016), ESD valves in liquid piping systems shall close fully and smoothly within 30 s of actuation. In this analysis, further 30 s are considered for detection and actuation, reaching a total release time of 60 s, in normal ESD operating conditions. In case of ESD system failure, the total release time is extended to a maximum time of 30 min.

4.3 *Frequencies evaluation*

The evaluation of the annual probability or accidental frequency linked to a single scenario is carried out based on the indications of Purple Book (Uijt de Haag & Ale 1999). The frequency (f_i) of the i-th accidental event (fire, explosion, dispersion, etc.) is calculated as follows:

$$f_i = F \cdot P_r \cdot P_{e,i} \quad (1)$$

where F = initial accident frequency (1/y), P_r = probability of having the release following the accident; $P_{e,i}$ = probability of having the i-th event given the considered release.

F is a function of the frequency of damage to a ship per unit distance (events/year per vessel per km) which depends on the type of channel. A conservative value of 1.4×10^{-6} events/(year × vessel × km) is considered in the present analysis (Uijt de Haag & Ale 1999); a single vessel is assumed to be involved in case of damage, and 20 km are considered as length of the ship route obtaining $F = 2.8 \times 10^{-5}$ 1/y.

The probability P_r expresses the possibility of having a release following a serious accident to the ship. This value depends on the type of ship and on type of size of the release; indications reported in the literature (Spouge 2005, Uijt de Haag & Ale 1999) allowed determining $P_r = 0.025$ and $P_r = 0.2025$ for large and small size release respectively.

Once the incidental release has occurred, the LNG can ignite immediately giving rise to a pool/jet fire. Otherwise, it may spread out forming a pool on the surface of the channel. The pool evaporation generates a vapor cloud, which can ignite resulting in a flash fire or even a vapour cloud explosion (VCE). Each event described above has a probability of occurrence, expressed through the term $P_{e,i}$; where i is an identifier of the type of scenario. Standard ETA (Mannan 2005) is carried out to quantify $P_{e,i}$ for each scenario.

The accidental scenarios related to the BOG piping and to the over-the-top vapour connections may be mitigated by ESD activation (see Section 4.2). In case of ESD system failure the resulting hazardous scenario is not mitigated. In this study, the ESD system is assumed as a SIL 2 "low-demand-mode" level. Thus, ESD failure probability is derived from the IEC 61508 standard (IEC 2010) and set equal to 10^{-2} and implemented in the ETA. More details on the ETA are reported elsewhere (Chemical Controls 2017).

4.4 *Consequences evaluation*

Consequence assessment is based on standard literature models for physical effect analysis (Mannan 2005) implemented in DNV GL Phast 7.1 software package. The main settings and assumptions are shown in the following.

4.4.1 *Schematization of LNG composition*

LNG is a liquid mixture of hydrocarbons composed mainly of methane, with small amounts of ethane, propane, nitrogen and other typical components of natural gas. In the present work, the presence of other compounds in addition to methane is neglected since it is not significant for the purpose of evaluating the consequences. The physical properties of LNG are taken from (Lentner et al. 2017, Mannan 2005).

4.4.2 *Meteorological conditions*

Two reference meteorological conditions are assumed in this study:

- F/2 – Pasquill stability class "stable" and wind speed of 2 m/s,
- D/5 – Pasquill stability class "neutral" and wind speed of 5 m/s.

Other relevant atmospheric parameters are summarized in Table 4.

4.4.3 *Threshold based approach for physical effects assessment*

The maximum damage distances (or vulnerability radii, r_{vul}) for the accident scenarios considered in the present study are evaluated through conservative threshold values, which are summarized in Table 5. Threshold values are derived from Italian legislation on land use planning (DM 2001). Either damages to humans (in terms of irreversible effects) or industrial equipment are considered.

4.5 *Definition of the reference risk matrix*

Once the likelihood/probability and consequences are quantitatively evaluated, the risk associated with each LNG accidental scenario is estimated through a reference risk matrix. The matrix is built upon likelihood and consequences classification following criteria derived from a previous study related to the oil and gas sector (Petrone et al. 2011).

Table 6 shows the criteria chosen for the classification of likelihood, based on the evaluated annual probability of each considered scenario.

Table 7 summarizes the criteria considered for the consequence assessment. Consequences are classified upon the comparison of damage distances (r_{vul}) against a set of reference distances associated with the position of sensitive targets. Two categories of sensitive targets are considered, namely:

Table 4. Atmospheric parameters set up for the consequences evaluation.

Parameter	Units	Value
Air temperature	°C	20
Water temperature	°C	20
Pressure	kPa	101.3
Relative humidity	%	50
Surface roughness length	mm	0.2
Solar radiation	kW/m^2	0.4

Table 5. Threshold values implemented in the present study, derived from (DM 2001). LFL = lower flammability limit; VCE = vapor cloud explosion.

	Threshold value	
Event	Humans	Industrial equipment
Flash Fire	LFL/2	–*
Pool Fire	5 kW/m^2	12.5 kW/m^2
VCE	0.07 barg	0.3 barg
Flare/Jet Fire	5 kW/m^2	12.5 kW/m^2

*Escalation is not credible.

Table 6. Probability/likelihood qualitative classification criterion.

Probability/likelihood (F)	Qualitative rating
$f_i < 10^{-6}$ 1/y	Practically non credible occurrence
$10^{-6} \le f_i < 10^{-4}$ 1/y	Rare occurrence
$10^{-4} \le f_i < 10^{-3}$ 1/y	Unlikely occurrence
$10^{-3} \le f_i < 10^{-1}$ 1/y	Credible occurrence
$10^{-1} \le f_i < 1$ 1/y	Probable occurrence
$f_i \ge 1$ 1/y	Likely/Frequent occurrence

Table 7. Consequences qualitative classification criterion, r_{vul} = vulnerability radius, S_w = ship width.

Consequence severity	Qualitative rating
$r_{vul} < 1$ m	Slight effect
$1 \text{ m} \le r_{vul} < S_w$	Effects internal to the source (ship)
$S_w \le r_{vul} < d_U$	Effects external to the source (ship) & no interaction with targets
$d_U \le r_{vul} < d_P$	Damages to other units & possible single fatality
$r_{vul} \ge d_P$	Multiple fatalities

- P—installations or activities characterized by the presence of people (ferries, campsites, buildings, etc.)
- U—other units characterized by the presence of dangerous goods (ground-based plants, cargo ships, etc.)

The minimum distances between the source of the accidental release (e.g., the LNG carrier) and the sensitive targets are defined as follow:

- d_P – minimum distance between the LNG carrier and the type "P" installations;
- d_U – minimum distance between the LNG carrier and the type "U" installations.

The comparison against r_{vul} and the reference distances (e.g., d_P and d_U) allows for the classification of consequences according to the criteria summarized in Table 7.

Risk associated with each accidental scenario is finally assessed as the combination of the likelihood and the severity in the reference risk matrix shown in Figure 4 (see Section 5).

The matrix is divided into three zones:

- Low risk level: continuous improvement and acceptable risk;

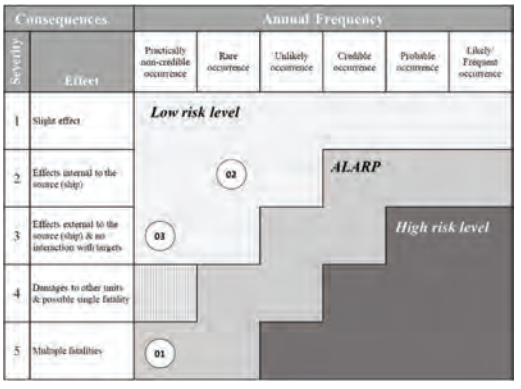

Figure 4. Example of risk matrix application, showing risk results for the scenarios listed in Table 8 (indicated by the numbered circles in the matrix).

- Medium risk area or ALARP (As Low AS Reasonably Practicable) zone;
- High or intolerable risk level: mitigation and prevention measures are mandatory to reduce the risk at acceptable levels.

Events with severity in class 4 (damages to other units & possible single fatality, see Table 7) and likelihood in class 1 (practically non-credible occurrence, see Table 6) may be associated with low or ALARP risk level (see Fig. 4) depending, respectively, on the absence or presence of dangerous goods in the impacted units. In fact, physical effects due to accidental release from the target unit will only be economic damages, if there are not hazardous substances in the installation; otherwise human may be affected by the release of hazardous substance from the target units, which is damaged by the primary accidental scenario associated with the LNG carrier.

The results obtained from the risk matrix are then summarized in the risk register. An example of risk register is shown in Section 5.2.

5 RESULTS

5.1 *Geometrical assessment and legislative framework*

The legislative framework (see Section 3.2.2) showed no particular limitations or restrictions for what concerns the LNG carrier access to the harbour, thus preliminarily supporting the feasibility of the LNG supply to the future terminal.

The results of the geometrical envelop analysis show that there are not suboptimal interactions for LNG carrier of small size (e.g., Ship A in Table 1). On the other hand, suboptimal geometrical interactions occur in about the 50% of the year-scale time, for large LNG carrier (e.g., Ship B in Table 1), in accordance with the legislative framework and the historical traffic data. Thus, it may be needed the selection of small size gas carriers (e.g., Ship A in Table 1) to avoid any poor or limiting interactions with the standard/historical harbour operations.

It may be concluded that ships collision, impact, grounding, and impact with berths are not credible scenarios. Explanation is that: piloting, tugs service, and speed reduction within the channels are mandatory (Ordinance 2009, 2010) for the cargo ships of interest; and that minimum distance between ships in the convoy and the transit of the latter in one direction (Ordinance 2009) ensure minimum or no interaction between ships. Moreover, impact of the LNG carrier with other moored ships has a practically non-credible likelihood in the range of 10^{-8} to 10^{-9} 1/y (Uijt de Haag & Ale 1999). Thus, the risk analysis focuses on the scenarios following a random process failure (see Section 4.2), excluding all other scenarios.

5.2 *Safety assessment results*

In this Section, the results of the risk-based analysis described in Section 4 are shown for a set of representative scenarios.

A total number of 45 scenarios is obtained from hazard identification, including fire and explosions events, following the release of either liquid or vapor natural gas. The risk register is compiled including all the mentioned scenarios, providing an ID to each identified event, the description of the event and the risk-based classification; this includes frequency and consequence class evaluation, and finally, the risk level. An example is shown in Table 8 for three most critical events associated with the LNG carrier.

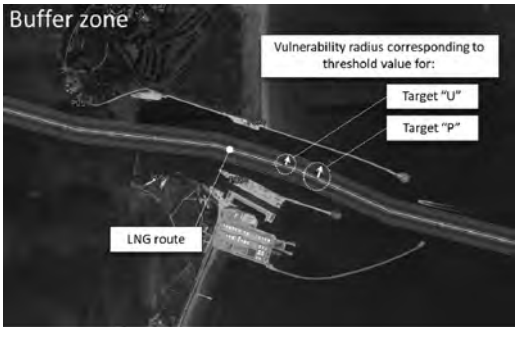

Figure 5. Example of buffer zone. For the definitions of threshold values and target type refer to Sections 4.5. The LNG route refers to path 2 in Figure 1. The points labelled with "P" are the minor civil installations in the area.

Table 8. Example of risk register showing risk analysis results. F = frequencies class; C = consequences class; R = risk level defined as low (L); medium (M); high (H) (see Section 4.5 for further details).

Source	ID	Scenario	F	C	R
Liquid piping system on deck	01	VCE	1	5	M
BOG piping/over-the-top vapour connections	02	Flare/Jet Fire	2	2	L
Steam piping manifold on deck	03	Flash Fire	1	3	L

Results are also reported in the risk matrix (see Fig. 4) in order to drive the strategy for risk reduction as discussed in Section 6.

The most critical scenarios evaluated in the present analysis are associated with major liquid releases, leading to pool spread and evaporation, with potential large fires and explosions. The consequences are represented through the use of buffer maps in order to trace the maximum extension of the scenarios. Figure 5 shows an example of buffer map.

The scenario showed in Figure 5 is a flare/jet fire following the accidental release of LNG from the liquid pipeline, at maximum operational pressure, from a minor hole of 10 mm, and F/2 meteorological conditions. The damage distance r_{vul} from the LNG route extends for 75 m and 62 m for targets type "P" and "U" (see Section 4.5), respectively. The LNG ship route is located in the middle of the channel, with an uncertainty of 15 m from the channel centreline (path 2 in Fig. 1). Thus, the same ±15 m uncertainty is applied to extend the consequences zone. The vulnerability radii are then moved along the LNG route obtaining the buffer zones, which help visualizing the possible targets with respect to the threshold values defined in Table 7.

6 DISCUSSION

The outcomes of the analysis demonstrate that the LNG carrier access induce a relevant risk level for the industrial and civil installations close to the channel, thus the analysis may constitute a preliminary driver to enhance safety measures and procedures in the development of the LNG terminal with a dual purpose: i) reducing possible suboptimal interactions between the LNG carrier and the current port configuration; ii) reducing the risk level by lowering likelihood and/or impact of the most critical events. Some prevention and mitigation actions are listed in the following in order to provide an example of utilization of the risk results obtained with the present methodology.

Prevention measures are aimed at reducing the credibility of the accidental scenarios. In the present case, the sequence of operations on LNG carrier before entering the harbour area is crucial to prevent the occurrence of critical scenarios. In fact, liquid is present on board because of the cooling down activities, which normally precede the loading/unloading operations. These activities are usually carried out in the roadstead. Carrying out the cooling down activities at berth removes (thus prevents) the accidental scenarios linked to the liquid pipelines system along the ship route. Implementing this prevention action, however, shifts the hazards from the ship route to the berth. Thus, a specific analysis should be performed to evaluate the risk of carrying out the cooling down operations at berth.

Mitigation measures reduce the impact of an accidental scenario by lowering the consequences. An example of mitigation action applicable to the case study is the utilization of fire-fighting tugs to reduce the effects of fire and explosion following LNG releases from the carrier. However, careful selection of fire-fighting tugs should be performed, accounting for the water-mist demand to effective fire-fighting, water suction pumps capacity, and depth of sea in the working area. Thus, it requires further studies for the most critical scenarios.

7 CONCLUSIONS

In the present work, a feasibility study was carried out to evaluate the geometrical, legislative and safety aspects associated with the access of LNG carriers in the port of Venice. The carriers supply LNG to a future bunkering terminal which is under development.

A specific risk-based analysis supported the identification and evaluation of potential accidents associated with the transit of LNG carriers in the harbour area through a risk matrix. The most critical scenarios were identified, providing indications for risk control, in terms prevention and mitigation actions.

The present method may support the planning of industrial harbour areas development in the perspective of a wider implementation of LNG bunkering and distribution terminals.

ACKNOWLEDGEMENTS

The authors wish to thank the financial and technical support of Venice Port Authority, which allowed developing and testing the present the methodology.

A framework for aggregating risk information across organisational levels—the case of Swedish municipalities

H. Hassel
Division of Risk Management and Societal Safety, Lund University Centre for Risk Assessment and Management (LURCAM), Center for Critical Infrastructure Protection Research (CenCIP), Lund University, Lund, Sweden

ABSTRACT: Performing risk assessments for hierarchical, multi-functional systems, such as a municipality, is an activity that requires input from a multitude of actors. In such systems risk assessments can be performed at many system levels and support different types of decisions. For issues that are constrained to a specific sub-system, such as a municipal department, decisions can be preferably taken at sub-system level. However, for other issues, such as those crossing many sub-systems and system levels decisions should preferably be taken at higher system levels, e.g. at the municipal level. At the same time, these decisions require extensive information from the sub-systems. The aim of the present paper is therefore to outline a framework for how risk information can be aggregated—with application in the context of Swedish municipalities. The research builds on previous work by the authors where a method for performing risk and vulnerability assessments in municipal departments has been developed using an action research approach. The method will soon be implemented in each municipal department in the municipality of Malmö, Sweden, and the next step is to develop the aggregation of these assessments. It is argued that this aggregation is facilitated by ensuring that key aspects of the risk assessments in the municipal departments are harmonized. At the same time, too much standardisation may also reduce the utility of the assessments for the municipal departments.

1 INTRODUCTION

Performing risk assessments for hierarchical, multi-functional systems, such as a municipality, is an activity that requires input from a multitude of actors. In such systems, risk assessments can be performed at many system levels and support different types of decisions. For issues that are constrained to a specific sub-system, decisions may preferably be taken at sub-system level. However, for other issues, such as those crossing many sub-systems and system levels, decisions should preferably be taken at higher system levels. At the same time, these decisions require extensive information from the sub-system level which has to be aggregated and synthesized to become meaningful and possible to use as a basis for risk reductions at system level.

However, limited research has been conducted in research field of risk assessment and management on this topic. The issue is addressed by Ayyub et al. (2008) who argue that to facilitate aggregation of risk to higher levels of abstractions all levels "should share a common analytical framework" (Ayyub et al., 2008, p. 791). Furthermore, the UK Cabinet Office has a similar argument when claiming that a benefit of having a standardized risk assessment approach is that it "facilitates regional aggregation of local risk assessments" (UK Cabinet Office, 2005, p. 41). Klaver et al. (2008) provide similar arguments but also stress the need for using consistent scales for impact, probability and risk evaluation as well as using a common list of threat classes. Furthermore, David (2009) argues that one must be cautious when attempting to aggregate "risks" that are not independent, since a simple "summation" would not capture dependencies that may exist between them.

Although not specifically in the context of RVA, Kramer argues that information sharing, which is a precondition for risk aggregation, can be "impeded by differences in how information is coded and categorized" (Kramer, 2005), thus stressing the need for common ways of describing risk-related information. On the other hand, Vaughan (1997) argues that there are many obstacles in knowledge and information sharing founded in the very nature of complex organizations that have multiple, specialized units—creating so called "structural secrecy". She warns that too much information sharing in too standardized ways may actually result in units simply getting less knowledge about other units in the organization, e.g. due to information overload.

Other studies presented in Månsson et al. (2015) and Månsson et al. (2017) have shown that inconsistencies in how risk information is expressed in the Swedish crisis management system reduce the possibilities of aggregating risk information. In addition, an experimental study (Månsson et al. 2017), showed that semi-quantitative or quantitative ways of expressing risk information may facilitate risk aggregation compared to qualitative ways. Although, these two studies provide some clues on how to accomplish successful aggregation of risk information, they mainly focused on aggregation of likelihood and consequence information; however, in a risk and vulnerability assessment there is potentially additional information that should be aggregated. An example is information about interdependencies between critical societal functions.

In none of the referred studies above, however, a comprehensive analysis has been made regarding what the challenges actually are for aggregations/syntheses and what processes and methods are needed to overcome these challenges in order to accomplish an appropriate synthesis of RVAs. Hence, there is very little guidance for how to go about in establishing and implementing such a process in practice. This is troublesome since establishing a process able to generate a consistent, high-quality picture of risk and vulnerability at a higher level, which as much as possible utilizes the information from lower level RVAs, is far away from straightforward.

In the Swedish crisis management system, which is the context of the present paper, several public actors are obliged to perform Risk and Vulnerability Assessments (RVAs) (SFS 2006:544). In this system, aggregation of risk information is intended to play a key role. Information from municipal RVAs should be used as input at regional RVAs; and regional RVAs should be used as an input to the national RVA. However, even though this system has been in place for more than 10 years, there are still many needs for improvements before risk aggregation can be successfully accomplished across societal levels.

Rather than attempting to solve all these problems in the Swedish crisis management system, the present paper delimits its focus to the municipal and municipal department level. The aim of the RVAs carried out in the Swedish municipalities is to increase risk awareness and knowledge of decision makers and to implement effective risk reduction measures (SFS 2006:544; MSB 2015:5). The scope of the analysis is primarily the *municipal organization*, where the aim is to ensure that critical activities can continuously be performed also in times of crises, but secondarily also to create a risk picture for the municipality as *a geographic region*. The present paper mainly focuses on the organizational perspective.

In order to establish a successful risk and vulnerability assessment process, many municipalities in Sweden, especially larger ones, have decided to push extensive analytic activities down to the municipal department levels. The main reason for this is that much of the opportunities, mandate and budget to implement improvements occur at this level. In addition, the local ownership of the analysis process is important and the expertise necessary for good quality assessments exist at the department level. See Cedergren et al (forthcoming) for further discussions of challenges and success factors related to municipal risk and vulnerability analyses in Sweden.

At the same time, even though relevant risk information can be acquired at municipal department level, some critical risk information will probably not be apparent until risk information from departments is somehow put together, aggregated and synthesized at the municipal level. This aggregated risk information can then both be used at the municipal level to make decisions that concern the municipal organization as a whole as well as be fed back to the municipal department level in order to improve the next iteration of the department level assessments.

The aim of the present paper is to describe a general framework for how risk aggregation can be accomplished in order to support system-level decisions. This model is then applied in the context of the municipality of Malmö. The research builds on previous work by the authors where a method development process has been initiated in collaboration with the municipality of Malmö in southern Sweden, focusing on RVA in municipal departments. The method development process, grounded in action research and design science, has been described previously in Cedergren and Hassel (2017) and a first version of the method has been presented in Hassel and Cedergren (2017). The developed method is currently being implemented in each municipal department in the municipality of Malmö, Sweden, and this paper will provide a basis for the next step of the RVA process in Malmö.

The outline of the paper is as follows: in Chapter 2, a generalised model for aggregation of RVAs is described, in Chapter 3 the model is applied in the context of the municipality of Malmö to outline initial ideas regarding aggregation of risk information, and in Chapter 4 the results are discussed and conclusions drawn.

2 A GENERALISED MODEL FOR AGGREGATION

The general model for aggregation of RVAs is presented in Figure 1. It was developed in an iterative process where the point of departure has been the

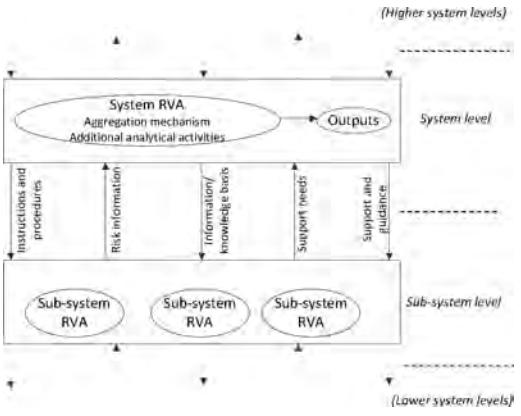

Figure 1. An overview of the model for aggregation of risk information.

research referred to above and the author's experience from the Swedish RVA-system. The author has interacted with practitioners in meetings and workshops who have expressed their needs and challenges related to the aggregation process.

The model should be seen as recursive, meaning that the displayed relationships between system and sub-system levels could be repeated between the system level (e.g. municipal) and higher system levels (regional, national or international) as well as between sub-system level (e.g. municipal departments) and even lower system levels (e.g. specific units). The model will be briefly described in what follows.

2.1 *Instructions and procedures*

First, *instructions and procedures* for the sub-system RVAs need to be formulated. The purpose is to ensure and facilitate the subsequent aggregation of risk information from the sub-system RVAs at the system level. It is especially the form of the risk information that needs to be harmonized and made consistent since aggregation would otherwise be extremely difficult and time-consuming. In addition, the method and analysis processes as a whole could also be harmonized although this is not strictly necessary. At the same time, since information across different RVAs must be using commensurate scales these must be either absolute/quantitative or be using common scale descriptions, definitions, categorizations, etc.

2.2 *Risk information to the system level*

Secondly, *risk information* must be submitted from the sub-system, i.e. RVAs must be conducted at the sub-system level and presented in a way that is in accordance with the instructions and procedures (see above). Of special importance here is not to compromise with information security. Hence, creating trust between the involved actors and organizations is a crucial precondition for successful aggregation—and a potential large issue especially when private actors are involved and sensitive information are being processed. Of course, in order to handle the information in way that do not compromise information security some type of information infrastructure need to be in place where information can be shared in a secure and efficient way.

2.3 *Aggregation mechanism*

Thirdly, there has to be an *aggregation mechanism* at the system level that can collect, store and process the risk information from the sub-systems in order to produce the desired *outputs* at the system level. In addition, in most cases it is likely that *additional analytical activities* need to be performed at the system level as aggregation is not likely to be a mechanical, additive process due to interconnectedness between the sub-systems (David, 2009). In special circumstances, where sub-systems do not have any significant relationships/interactions, the aggregation process can be mechanistic—e.g. aggregating/adding risk metrics from the sub-systems into risk metrics for the system, or comparing importance of sub-system elements across sub-systems.

These three aspects are the necessary components of an aggregation process; however, they should be complemented by three additional aspects in order to ensure high quality RVA processes at both the system and sub-system level. Hence, the following three aspects described below can be added to the model.

2.4 *Information and knowledge bases to the sub-system level*

Fourthly, *information and knowledge bases* should be provided from the system level to the sub-system levels. This can concern information that all sub-system RVAs are in need of but which would require extensive data collection efforts. This activity can then be more efficiently performed by the RVA coordinating actor at the system level which also would ensure a consistent knowledge basis concerning aspects that ideally should not vary across the sub-system RVAs (such as the likelihood of external events, such as floods, hurricanes, etc.).

2.5 *Support needs and guidance*

Fifthly, in order to develop the quality of the RVA processes, both at sub-system and system level *support needs* should be communicated from the sub-system; and sixthly *support and guidance* should

then be provided by the RVA coordinating actor at system level. Again, the reason is primarily efficiency-related—if several sub-system RVAs struggle with the same problems then a coordinated effort to reduce these problems is likely to be preferable compared to each sub-system working with quality improvements *only* on their own. Note that this has both to do with improving the quality of the assessment on the sub-system level and increasing the possibilities of a successful aggregation on the system-level.

3 APPLICATION OF THE GENERAL MODEL OF AGGREGATION FOR MUNICIPAL RVA IN SWEDEN

Below the general model for accomplishing system-level aggregation will be applied in the context of municipal RVA in Malmö, Southern Sweden. The authors have been extensively involved in the RVA development process there for more than 1.5 years. Currently RVAs are conducted in the municipal departments and the next step is to aggregate the output from these assessments. The description below is the results from the first round of discussions about how the aggregation could be accomplished. It is likely that the aggregation process will be further developed as more experience from the RVA processes have been gained.

3.1 *Instructions and procedures for the sub-system RVAs*

It is not always that organizations at higher system level has legal mandate to provide instructions that the lower system levels have to oblige to. In Sweden, the Swedish Civil Contingencies Agency has developed regulations for municipal RVAs (MSB 2015:5); however these are only stipulating *what* should be included in the assessment not *how* the assessment should be performed. In addition, a number of reports have been developed by MSB providing some general guidance (MSB 2011, 2013, 2014).

In the present paper the focus is on municipal RVA where the municipality of Malmö decided to develop a method that all municipal departments should use. The authors of this paper participated in the development of this method and the points of departure for the method development have been presented extensively in previous papers by the authors (Hassel and Cedergren, 2017; Cedergren and Hassel, 2017; Cedergren et al. forthcoming).

Note that the aim of the method is to assist municipal departments to create robustness in their organisation by identifying the main sources of risk and vulnerability which should be targeted by risk reduction measures. It is only a secondary aim that the output of the RVAs should be aggregated at municipal level (which is the focus of the present paper).

To support the municipal departments in conducting the assessments a method handbook has been developed, educational activities have been and will be arranged, and computer software developed where the analysis can be documented. In addition, the municipality of Malmö are currently developing short movies that can be used by the municipal departments.

The method consists of three main steps which are conducted every year, i.e. the RVA is successively made both broader and deeper over time. The method has been described in detail (although a previous version) in Hassel and Cedergren (2017) but will be summarized below.

3.1.1 *Step 1 – Mapping the municipal department*

First, a mapping of the functions performed by the municipal department is conducted. This mapping includes determining how critical each function is for safety and functionality of the municipality of Malmö as well as mapping of dependencies that each function has. When mapping dependencies the strength of the dependencies is judged based on to what extent the function needs the dependency in order to be maintained as well as to what extent there are alternative back-up solutions in place.

3.1.2 *Step 2 – Analysing undesired events*

Secondly, an identification of what undesired events can happen is performed. Then a selection of events are analysed. The focus is primarily how the department's functions are affected in the event and to what extent they can still perform their critical functions. The extent of the negative consequences for the municipality of Malmö is judged, based on their capability to continue to perform their functions during the event. Finally, potential causes are identified, indications/trends coupled to the event is identified and the likelihood of the event is judged.

3.1.3 *Step 3 – Create a decision basis for implementing improvements*

Thirdly, the information from the two first steps are visualised in order to identify functions, dependencies and events that are particularly critical. This visualisation is then used as a basis for suggestions risk reduction measures where risk reduction measures are first identified and then evaluated. The evaluation is made based on the measures' effects on the risk level, their costs and potential side-effects.

3.2 *Risk information from sub-system RVA to system level*

The sub-system RVAs produce several outputs that can be used as input to the system-level RVAs.

All this information is stored in a computer software that can be accessed by the RVA coordinating unit at the system level. A selection of the most relevant risk information that is uploaded includes the following:

- Time until reaching severe consequences when the function cannot be performed.
- Dependencies that each function have.
- Importance of each dependency for the functions.
- Extent of back-up solutions available for each dependency.
- List of undesired events.
- Description of each undesired events.
- Functions that are prioritized in each event.
- Capability to continue performing each prioritized function in each event.
- Description and estimation of negative consequences in each event due to reduced capability in the municipal departments functions.
- Causes, trends and indications of events.
- Estimation of likelihood of the event.
- Strength of knowledge judgements for each estimation.
- Suggested risk reduction measures.

3.3 *Aggregation mechanism and complementing analytical activities*

The purpose of the aggregation process is primarily that it should provide information and insights that can be used a basis for system-level improvements. A secondary purpose is that some information should be fed back to the municipal departments, and this will be further explored in section 3.4.

As mentioned previously, according to the regulations in Sweden the municipal RVA has two perspectives—the municipality as an organisation and the municipality as a geographical region. Note that this paper takes the former perspective and leave the latter for future research as it is a much more complex task requiring extensive input from non-municipal actors.

The aggregation in the municipality of Malmö will be performed by the central RVA coordinating unit. Below a number of outputs from this aggregation is described—this list of outputs is likely to be expanded later on in the process.

3.3.1 *Identification and ranking of joint dependencies*

A municipal department may identify that a particular dependency is very critical for being able to perform their functions. In some cases they might be able to justify taking actions to reduce the criticality of this dependency by e.g. investing in buffers, making the dependency more robust (if internal) or ensuring that external actors will be able to deliver the resources or services they are dependent on (e.g. by improving contracts). However, if many municipal departments are critically dependent on the exact same resources or services, then measures might be warranted *even though* each municipal department cannot justify it on an individual basis. Additionally, in some cases risk reduction taken at system/municipal level might become much more effective than each municipal department taking separate actions concerning the same dependency.

In order to create this output the dependencies need to be described in a standardised, consistent way. Previous experiences from dependency assessments where no standardisation was used proved aggregation was very challenging since the level of detail with which dependencies was described varied greatly (Johansson et al. 2016). Therefore, the method of RVA for the municipal departments include a list of dependencies from which the municipal departments can choose from must be established. Since it is difficult to foresee all possible dependencies at the outset of the assessments, this list must be dynamic and continuously updated.

Furthermore, the ranking of the joint dependencies should logically be a combination between how many municipal departments that have the dependency and how critically dependent they are. Hence, the rating of dependency criticality must be comparable across the municipal departments which is accomplished by used common scales.

3.3.2 *Identify dependency chains*

In the assessments at municipal department level only first-order dependencies are identified since higher-order dependencies both can be difficult to realise/have knowledge about and be time consuming to identify. However, by aggregating information about first-order dependencies, dependency chains can be constructed that provide insights about second—and higher-order dependencies.

Information about dependency chains may be important for the municipality as a whole since it could provide insights on where resources should be directed to break potential cascading effects at an early response stage (both considering preventive measures and measures as an event is unfolding).

Of course, only a partial view of the municipality can be obtained based on dependency information from municipal departments. In order to obtain a more holistic view, additional actors need to be consulted and included, such as private and other public actors.

3.3.3 *Identify undesired events*

Each municipal department performs an identification of potential undesired events. Since

event identification is also a requirement for the municipal RVA the list of events from the municipal departments can be used as an input, although some type of categorisation is likely to be needed.

3.3.4 *Inform estimations of event consequences for the municipality as a whole*

An essential part of a risk and vulnerability assessment at a municipal level is the estimation of the negative consequences of undesired events for the municipality as a whole. In the assessments performed by the municipal departments no consequence estimation is carried out considering the total consequences for the municipality. However, the dependency information, assessment of capabilities and consequence estimations collected from each municipal department can provide a necessary partial input to the estimation of the consequences of undesired events at the municipal level.

Note that it is unlikely that a mechanical procedure can be used for determining consequences at municipal level based on information from municipal departments. The reason is that the functions of each municipal department are typically tightly coupled together so there is no additivity in the consequences estimated by each municipal department. Notwithstanding, the information from the municipal departments is crucial in order to understand how the municipality as a whole will be affected. But additional information from other relevant actors must also be included and the consequence estimations should be made in a deliberative process where the information from the municipal departments is used as an input.

Furthermore, in order for the municipality to be able to make consequence estimations concerning some specific events it must be ensured that all municipal departments have included these events in their assessments. Therefore, the method for RVA used by the departments will both address events that each department has identified on their own as well as a number of events that the RVA coordinating unit has selected to be common for all departments.

3.3.5 *Create a prioritized list of critical functions, dependencies and events*

In order to get the most effect from the resources available for risk reduction, it makes sense to identify the most critical functions, dependencies and events for the municipality as a whole. By doing so the RVA coordinating unit could assist the municipal departments with a responsibility for the most critical functions, dependencies and events. Either this could be to provide financial support but it could also be to assist in getting political attention.

Again, in order to establish these system-wide criticality lists, the scales for judging criticality are designed so they are common for all departments.

3.3.6 *Improve estimations of the likelihood of events*

Estimating the likelihood of undesirable events is part of the municipal RVA. Since each municipal department make likelihood estimations, although they have a possibility to waiver the estimation if they judge their expertise to be insufficient, these estimations could be used as a basis for the likelihood estimations at the municipal level. Especially those departments that have rated their knowledge concerning the likelihood as being high could be consulted. In order to enable this the strength of knowledge, see e.g. Flage & Aven (2009), concerning the various estimations is included the RVA method used by the municipal departments.

3.4 *Provision of information and knowledge bases from system level to sub-system RVA*

In addition to providing risk information that can be used for improvements at the municipal level, the aggregation process can lead to insights that can be fed back to the RVAs in the municipal departments in order to improve the quality of these assessments. Below, a number of such possibilities will be described.

Feeding back information about *dependency chains* to the municipal departments can lead to insights regarding how reduced capability to perform their functions can give rise to downstream effects. In that way their estimations of how critical their functions are can be improved. Due to the same reasons, this can also improve the estimations of consequences of events. In addition, the municipal department's understanding of how they may become affected by undesired events may also be improved since they get more knowledge about their upstream higher-order dependencies.

Aggregating and categorizing the undesired events that have been identified in each municipal department can also give rise to insights to other municipal departments that can also occur there, i.e. creating an "event repository".

In a similar way the estimation of the likelihood of events can be improved. As mentioned previously the departments can opt not to provide a likelihood estimation—if they judge their expertise concerning this to be very limited. Then information from the aggregation process can be fed back to the municipal departments so that likelihood estimations from departments that judge their level of expertise as being high can be provided to the those departments that lack expertise.

Of course, it may be the case that basically no municipal departments have the required knowledge concerning some event likelihoods. In that case the RVA coordinating unit could conduct some additional analytic activities where appropriate expertise

is identified and involved to obtain a well-founded estimation that may be fed back to the municipal departments. This would be a much more efficient approach than forcing each department to do it on an individual basis.

In order for the municipal departments to be able to accurately assess how their functions will be affected in various events and the negative consequences this would entail, it is important that the departments have good knowledge about the potential *direct impacts* of those events (i.e. what areas of the city would be flooded? How many persons would be incapacitated in a major epidemic? etc.). Such knowledge is not necessarily something that each department would have; however, as in the case of likelihood estimations, the RVA coordinating unit could make an effort to find the appropriate expertise and provide the departments with appropriate information.

3.5 *Provide support and guidance to sub-system level*

In order to both improve the quality of the RVAs in the municipal departments and to increase the possibility of accomplishing aggregation, the RVA coordinating unit should provide continuous support and guidance to the municipal departments. In the case of Malmö this will be done through at least three annual workshops where each of the three steps of the method is addressed. In relation to each step, support needs should be indicated by the each department. In addition, support needs should be identified through assessments of the quality of the department's analyses performed by the coordinating unit. Key here is to identify whether significant mistakes or misinterpretations have been made in the analysis.

4 DISCUSSION & CONCLUSIONS

In the present paper a general model for performing aggregation of Risk and Vulnerability Analyses has been suggested. This model has then been applied to sketch out some initial ideas on how to accomplish aggregation in the context of municipal RVA, with a special focus on how analyses for municipal departments can be aggregated to the municipality of Malmö.

The model and the specific application in Malmö need to be concretized and evaluated. This will be done in the coming year as the Risk and Vulnerability Analyses performed in the municipal departments are being conducted which of course is a precondition for the aggregation process.

It is argued that this aggregation is facilitated by ensuring that key aspects of the risk assessments in the municipal departments are harmonized. At the same time, too much standardisation may also reduce the utility of the assessments for the municipal departments.

Another key point of the proposed aggregation model is that sharing of risk information between system levels must be two-way rather than only from bottom-up. As information is fed back to the subsystems it is critical that information is presented in a compact and easy-to-use way otherwise it is likely that it will not be used as time and resource constraints for municipal departments is a significant challenge (Cedergren et al., forthcoming).

A subsequent aim of the aggregation process is also to be able to include relevant risk information from other actors, such as private actors and other public actors. Therefore, a study regarding what information these other actors are willing to share should be initiated. It is of utmost importance that trust relationships with these actors are built so they feel they are able to share potentially sensitive information with the municipality.

ACKNOWLEDGEMENTS

The authors would like to express their gratitude to the municipality of Malmö that has provided partial funding for the present project as well as contributed with critical insights regarding municipal RVAs. We are also grateful to partial funding from the Swedish Civil Contingencies Agency.

Toward the integration of uncertainty and probabilities in spatial multi-criteria risk analysis: An application to tanker oil spills

M. Spada
Laboratory for Energy Systems Analysis, Paul Scherrer Institute (PSI), Villigen PSI, Switzerland

V. Ferretti
London School of Economics and Political Science, London, UK

ABSTRACT: Quantitative risk assessment supports decision-making processes in an increasing variety of contexts. Within the domain of environmental decision-making, the spatial distribution of impacts, vulnerabilities and consequences associated to different risk-mitigation alternatives calls for a different framework, i.e. spatial multi-criteria risk analysis. In this paper, we propose the combined use of a hierarchical Bayesian modelling approach and Geographic Information Systems to integrate uncertainty and model probabilities into an overall risk map. The research aims at testing the operability of the integration between Bayesian modelling and spatial analysis in the context of spatial risk processes for resource allocation. To this end, we applied the model on a case study dealing with tanker oil spill risk in the Mediterranean Sea. The innovative contribution of the study stems from both the context of application point of view and the use of Bayesian modelling to calculate not only probabilities but an overall spatial risk measure.

1 INTRODUCTION

A rapidly emerging field of research within both the discipline of quantitative risk analysis (e.g. Fischhoff, 2015) and the now broad and consolidated literature on spatial decision support systems (e.g. Malczewski and Rinner, 2015) is spatial risk analysis, as demonstrated by the recent special issue on the topic in the Risk Analysis Journal (http://www.sra.org/sites/default/files/pdf/SpecialissueproposalforRiskAnalysis_Jun20.pdf). This growing interest may be explained by the following factors: (i) impacts of both positive and adverse events have heterogeneous spatial distributions across the territory, (ii) land vulnerability is characterized by spatial heterogeneity, (iii) risk-mitigation alternatives also lead to different spatial consequences, and (iv) recent advances in both decision modelling and Geographic Information Systems (GIS) technologies make it possible to bring the two fields together towards the formalization of an analytical framework for spatial risk analysis (e.g. Ferretti and Montibeller, 2017).

Despite several applications conducted in different domains (e.g. natural hazards management, health issues, etc.), the criteria they employ are often risk factors with deterministic preference modelling replacing probabilistic information. Furthermore, evaluations of spatial risks have often neglected the multi-dimensional nature of spatial impacts, such as infrastructure damage, lost lives, lost crops, etc., which typically occur in such decision problems (e.g. Ferretti and Montibeller, 2017).

There are several reasons that can explain the above weaknesses. First, the lack of publicly accessible spatial data about vulnerability and probability of occurrence spatial distributions; second, the need to involve risk analysts to facilitate probability elicitation using appropriate protocols (e.g. structured expert judgment elicitation protocols, Dias et al. (2018)); third, the need to allocate enough time to the necessary preliminary phase of expert training in probabilities elicitation (e.g. Keeney and Winterfeldt, 1991).

However, preliminary ideas and suggestions on how to formalize a framework for spatial risk analysis and how to spatially elicit preference information have recently been proposed (e.g. Keller and Simon, 2017, Ferretti and Montibeller, 2017).

In this paper, we propose the combined use of a hierarchical Bayesian modelling approach (e.g. Kalinina et al., 2016, Spada et al., 2014) and GIS to update prior probability maps and obtain an overall risk map. The research aims at testing the feasibility and operability of the integration between hierarchical Bayesian modelling and spatial analysis in the context of spatial risk processes for resource allocation. To this end, we applied the model on a case study dealing with tanker oil spill risk in the Mediterranean Sea. The main reasons for the selection of this context of application can be summarized as follows: (i) international

relevance of the phenomenon, (ii) availability of historical data collected in the PSI's Energy-related Severe Accident Database (ENSAD), and (iii) the strong spatial dimension of the phenomenon (e.g. the geographical heterogeneity of both vulnerabilities and impacts in the areas affected by oil spills).

The innovative contribution of the present study stems from two aspects. First, the context of application, i.e. tanker oil spill risk distribution, is an innovative one for the use of a Bayesian modelling approach. Indeed, Bayesian modelling in the spatial domain has been mostly used for ecological studies (e.g. He et al., 2006, Tucker et al., 1997), health concerns (e.g. Saravana Kumar et al., 2017), archeological analysis (e.g. Ford et al., 2009), and natural hazards (e.g. Liu et al., 2017) to name the most recurrent ones. In the area of maritime transportation, few applications of the Bayesian approach do exist, but they are mainly non-spatial (e.g. Goerlandt and Montewka, 2015, Bouejla et al., 2014). The second reason why this study is innovative is linked to the Bayesian modelling approach. Indeed, while many applications use a Bayesian network approach (e.g. Landuyt et al., 2015), we test a hierarchical Bayesian model not only to update an initial estimate of the probability of occurrence of tanker oil spills (e.g. Burgherr et al., 2015), using information concerning the distribution of past accidents in the geographical region under analysis, but also to generate an overall risk map.

The reminder of the paper is organized as follows. Section 2 provides an overview of the proposed methodological approach. Section 3 explains how the method has been applied to model tanker oil spill risk in the geographical region under analysis and, finally, section 4 discusses conclusions and future developments arising from this study.

2 METHOD

This study is part of a larger research project funded by the Swiss National Science Foundation aiming at the development of a methodology able to integrate Bayesian modelling, Geographic Information Systems (GIS), multi criteria decision analysis and structured expert judgement elicitation protocols to comprehensively assess spatial risks associated to adverse events. This paper focuses on the integration between the Bayesian inference and GIS and represents a preliminary test of the operability of the proposed approach.

Bayesian inference is an alternative to the classical statistical inference. In the latter, also known as frequentist inference, only repeatable events have probabilities, while in Bayesian inference probability describes both epistemic and aleatory uncertainty (e.g. O'Hagan, 2003). Indeed, Bayesian analysis combines data representing the entire likelihood function with prior knowledge about the parameters, which may come from other data sets or the modeler's experience and physical intuition (e.g. Reis Jr and Stedinger, 2005). The *a priori* distribution describes what is known before observing any data, while the likelihood reflects the information about the parameters contained in the data. Parameters estimation is made through the posterior distribution, which is computed using Bayes' Theorem (e.g. O'Hagan, 2003):

$$p(y|\theta) \propto L(y; \theta)p(\theta) \quad (1)$$

where $p(y \mid \theta)$ is the posterior distribution for the parameter θ given the observed data y, $L(y; \theta)$ is the likelihood function, and $p(\theta)$ is the *a priori* distribution of parameter θ. The proportionality ($\propto$) refers to the direct sample of the parameter values from the posterior distribution, which is commonly assessed using a Markov Chain Monte Carlo (MCMC) method (e.g. Andrieu et al., 2003).

To combine the Bayesian inference and GIS, different issues could arise due to the spatial dimension of the problem: (i) lack of local data (i.e. spatial heterogeneity in the distribution and density of the data), and (ii) potential spatial correlation among locations, to name the two most relevant ones. To cope with these challenges, a spatial hierarchical Bayesian model is employed in this framework as will be explained in the following paragraphs (e.g. Cooley et al., 2007, DiMaggio, 2012, Eastwood et al., 2014, Juan et al., 2016).

A spatial Bayesian hierarchical method produces parameter (θ) estimates for each individual analysis unit (e.g. location) by borrowing information from all analysis units (e.g. Eckle and Burgherr, 2013). This procedure is known as Bayesian "borrow of strength" effect (e.g. Zhu et al., 2006). In this way, the approach compensates lack of data for individual analysis units (e.g. Kalinina et al., 2016).

Based on this premise, equation (1) could be rewritten as follows:

$$p(y|\theta) \propto L(y; \theta)p(\theta|\varphi)p(\varphi) \quad (2)$$

An extra level is added to the standard Bayesian theorem for the hierarchical Bayesian approach. In this level, the parameter (θ) can be described with a distribution, which is conditional on the hyperparameter (φ). The distribution of this hyperparameter ($p(\varphi)$) is a hyperprior distribution. Therefore, when estimating the posterior for the parameter (θ), information from the hyperprior is used in addition to the information from the prior and likelihood.

Finally, to overcome the spatial heterogeneity in the distribution and density of the data and the potential spatial correlation among locations, in the spatial Bayesian hierarchical model they are

included as prior knowledge about the parameter (θ). This is possible, since they are commonly seen as "unexplained variance" in a model (e.g. DiMaggio, 2012, Eastwood et al., 2014). Based on this premise, by considering a set of *i* locations, the parameter for each location of interest (θ_i) is transformed into a log scale (making relationships additive rather than multiplicative) and is set equal to an intercept term (a_i) and two random effects, one non-spatial, i.e. the spatially unstructured latent covariates, (ρ_i) and the other spatial (λ_i), i.e. spatially correlated latent covariates in the model (e.g. Rodrigues and Assunção, 2012):

$$\log \theta_i = a_i + \rho_i + \lambda_i \quad (3)$$

The spatially structured component is described as a conditional autoregressive (CAR) Gaussian process ($\lambda \sim CAR.normal(W, \tau_\lambda)$) where the conditional distribution of each λ_i, given all the other λ_i 's, is normal with μ = the average λ of its neighbors and a precision (τ_λ) proportional to the number of neighbors. W represents the matrix of neighbors that defines the neighborhood structure. The non-spatial component of the model (ρ_i) is defined as normally distributed with $\mu = 0$ and precision (τ_ρ). The model is completed by assigning additional (hyperprior) distributions to the precision terms τ_λ and τ_ρ (e.g. Clements et al., 2006, Cooley et al., 2007). More details about each step are going to be discussed in the case study section.

3 CASE STUDY

The proposed methodology has been applied to tanker oil spills due to the strong spatial nature of the phenomenon (e.g. Vieites et al., 2004, Burgherr, 2007).

Crude oil and its refined products are a driving factor of many economic activities. Furthermore, the oil demand is expected to increase worldwide in the coming decades and it will continue to have the highest share in the global primary energy mix (e.g. International Energy Agency (IEA), 2015). However, oil spills are one of the major causes of ocean pollution, producing ecological disasters of wide public concern. Furthermore, linked to the damage caused to the environment are the high costs to fisheries, related industries, and tourism in the affected areas. This is especially true along the major oil tanker transport routes (e.g. Burgherr, 2007, Psarros et al., 2011).

In this study, only accidental spills from tankers were taken into account, whereas spills from acts of war and operational spillages allowed by international or national regulations, such as the International Convention for the Prevention of Pollution (MARPOL) were excluded (e.g. Burgherr, 2007).

The geographical region under analysis is the Mediterranean Sea including the Bosporus strait. This area has been selected since (i) it is still the shortest route from Asia to Europe; (ii) about 16% of the global maritime traffic and 33% of the global seaborne oil (almost 8 million oil barrels per day) is carried through the Mediterranean Sea, which represents only 0.8% of the ocean surface; (iii) is one of the most affected areas with a major number of spill events (REMPEC, 2011).

3.1 *Data*

The data used for the case study analysis come from ENSAD, which is the most authoritative database for energy-related accidents worldwide (e.g. Burgherr et al., 2017). ENSAD comprehensively collects information about accidents in the energy sector and assigns them to energy chains and activities within those chains. Accident data go back to 1970 and cover fossil, nuclear, hydropower and new renewables technologies. In contrast to databases that rely on a single or few information sources, the multitude of sources considered by ENSAD is thoroughly verified, harmonized, and merged to ensure (1) a worldwide coverage, (2) consistently high data quality across regions and over time, and (3) a high degree of completeness. ENSAD focuses on severe accidents, which are distinguished from small accidents based on seven criteria, i.e. ≥5 fatalities, ≥10 injured persons, or ≥10,000 metric tons (t) of hydrocarbons released, etc. (e.g. Burgherr et al., 2017).

With reference to oil spills in the Mediterranean Sea including the Bosporus strait, the ENSAD database registered 106 events, including small accidents (e.g. <10'000 t spilled oil), in the period 1970–2012. In this study, we updated the information about oil spills in the Mediterranean Sea until the end of 2016 by using the following sources:

- Analysis, Research and Information on Accidents (ARIA) database
- Failure and Accidents Technical information System (FACTS)
- Hazards Intelligence (HINT)
- Centre of Documentation, Research and Experimentation on Accidental Water Pollution (Cedre)
- European Maritime Safety Agency (EMSA)
- Regional Marine Pollution Emergency Response Centre for the Mediterranean Sea (REMPEC)
- Center for Tankship Excellence (CTX)
- igma by Swiss Re
- Other sources, such as newspaper, national and local publications, technical reports, etc.

In addition to severe accidents, also accidents with smaller consequences (<10,000 t and ≥0.1 t) have been included. All the accidents collected from the aforementioned sources were homogenized

prior to analysis, in order to avoid possible double counting. The final dataset comprises a total of 271 fully geo-referenced tanker oil spill accidents in the Mediterranean Sea including the Bosporus straight for the period 1970–2016.

3.2 *Overview of tanker oil spills in the Mediterranean Sea*

Figure 1 displays maritime accidental tanker spills by year and severity for the period 1970–2016. Most of the accidents (161) result in a release <7 t, followed by 59 and 57 accidents with a release between 7–700 t and >700 t, respectively. According to the severe accident definition in ENSAD (section 3.1), only 16 accidents out of 271 could be considered as severe with 3 out of them even extreme since they account for a release bigger than 100,000 t. Although the annual maxima of historically observed spills exhibit some variability, the data suggest a decreasing trend until 2000 followed by a generally constant spill rate in the period 2000–2016, which is also confirmed by decadal averages and in accordance with previous studies (e.g. Psarros et al., 2011, Burgherr, 2007). Furthermore, the relatively constant numbers of annual spills in the period 2000–2016 could be explained by the introduction of the regulation 13 F of Annex 1 of MARPOL (The Marine Environment Protection Committee (MEPC), 2003), which effectively mandated double hulls for new built oil tankers of 5000 dead weight tonnage and above starting from year 2000. However, the general trend in Figure 1 should not be taken as evidence that a catastrophic spill accident (e.g. 100.000 t or greater) can be excluded in the future, but the frequency of such an event may be expected at a lower frequency (e.g. Burgherr et al., 2012).

Figure 2 depicts the spatial distribution of the oil spills in the Mediterranean Sea including the Bosporus strait for the period 1970–2016. Historical observations show different "hot spots", such as the Gibraltar and Bosporus straights, the Peloponnese, the North Tyrrhenian Sea, the Malta and Lebanon areas. This is not always correlated with the average number of tankers per year (in 2012, http://medgismar.rempec.org/) navigating in a location shown as a 0.5° × 0.5° grid. Indeed, the Gibraltar and Bosporus strait as well as the Malta and Peloponnese areas show rather large average numbers of tankers per year, while the corresponding numbers are relatively low for the Northern Tyrrhenian Sea and Lebanon. The "hot spots" in the latter cases could be explained by the fact that most of the accidents happened in ports.

The final updated dataset is subdivided into two periods: 1970–2011 and 2012–2016. This has been done in order to use the former as input for the model presented in section 3.3 and the latter as a validation of the model.

3.3 *Model setup*

Risk is the potential for realization of unwanted, negative consequences of an event. In other words, risk can be defined as the product of probability/frequency and magnitude/severity of consequences (e.g. Committee on Foundations of Risk Analysis, 2015).

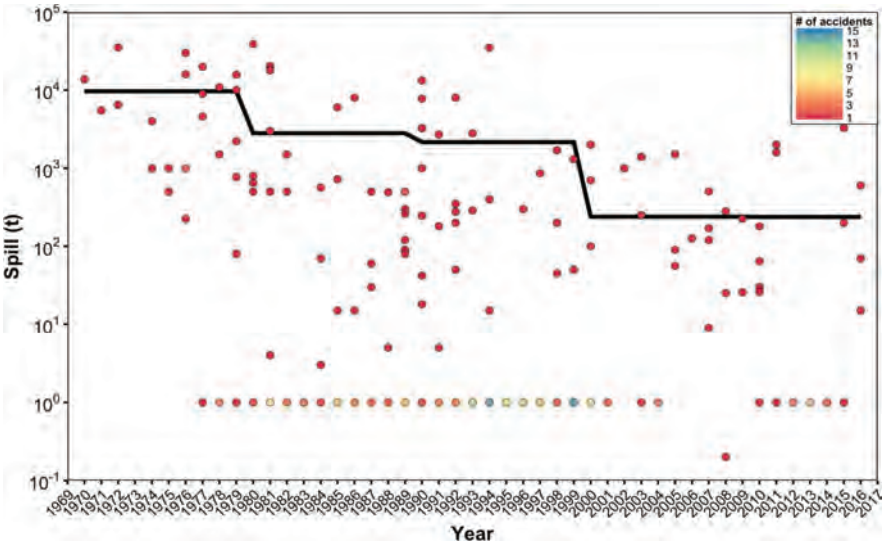

Figure 1. Distribution of tanker oil spills by year and severity in the Mediterranean Sea including the Bosporus strait. The bold black line indicates decadal averages. The colors indicates the number of accidents with the same spill size (t) in the same year.

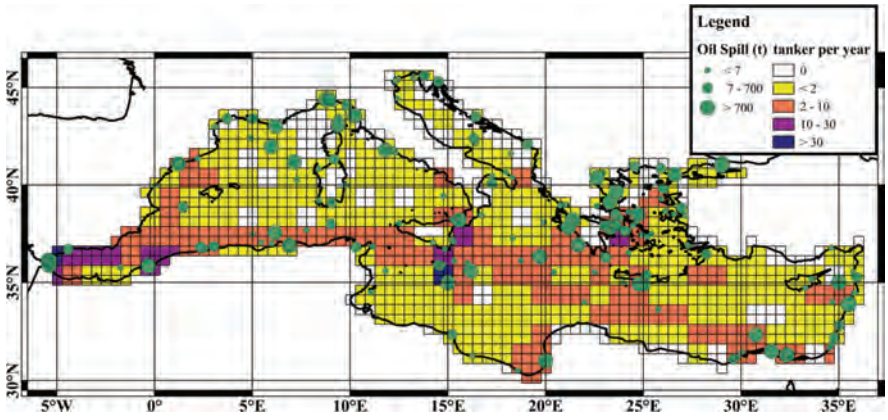

Figure 2. Spatial distribution of tanker oil spills by severity in the Mediterranean Sea including the Bosporus strait in the period 1970–2016. The average number of tankers per year (2012) navigating in the area is shown in a $0.5° \times 0.5°$ grid size (modified from AIS data from REMPEC (http://medgismar.rempec.org/)). White cells indicate areas where no tanker per year data are available.

In this study, the number of accidents per year gives the frequency, while severity measures the extent of the consequences of each accident. Furthermore, the frequency of accidents was normalized by the unit of tanker-year to allow for comparative evaluation of the modeled parameters among different areas in terms of accidents per tanker (e.g. Burgherr, 2007). It is also important to note that at a first approximation, the frequency of spills is not considered as a function of the number of tankers.

Essentially, accidents can be considered rare, independent events so that the frequency can be modeled as a Poisson distribution (e.g. Spada et al., 2014). Therefore, the frequency is modeled applying the Bayesian procedure described in section 2. In equation (2), the likelihood is described by the Poisson model. In a standard Poisson model, the variance is required to be equal to the mean. However, when dealing with spatial statistics, the Poisson models have more variances, and these are called over-dispersed Poisson models (e.g. DiMaggio, 2012). These variances are identified as either spatially-correlated effects or heterogeneity effects (section 2). The essential idea is that the probability of values estimated at any given location (e.g. the frequency at one area) are conditional on the level of neighboring values (frequencies on the neighboring areas).

Based on these premises, the parameter of interest, the frequency rate λ, is modeled as the combination of a normal distribution and the spatial random effects (section 2). For each area, the normal distribution is described by a mean and a standard deviation. This is the step where information between areas is exchanged in the hierarchical model. Both parameters of the hyper distribution are modelled with non-informative priors, so that they have no influence before the data is introduced. The parameters are modelled with normal and gamma distributions (e.g. Eckle and Burgherr, 2013), respectively.

The spatial random effects are modeled using a combination of the intrinsic conditional autoregressive (CAR) prior, which is smoothed based on the weight related to the number of the neighboring areas and their tanker-year normalization values, and a standard normal prior as described in section 2.

Once the posterior distribution for the mean frequency in each area is estimated, it is normalized by the corresponding tanker-year resulting in the expected accidents per tanker.

The severity is modeled as absolute numbers of oil spilled (tons) per accident. The expected oil spill in each area is modeled using a Lognormal (LOGNO) distribution (e.g. Burgherr et al., 2015). In this case, at a first approximation, the spill is considered independent from the area; therefore, no spatial random effects are included. The LOGNO distribution is commonly described by two parameters, namely the scale σ_i and location μ_i, which are used to define the mean value and variance of the distribution (e.g. Spada et al., 2014). In this study, the LOGNO distribution employed for the Bayesian Hierarchical modeling is described by mean and precision parameters, where the latter is the inverse of the variance. Hierarchical models are defined for the mean and standard deviation of the posterior and are modeled using a normal and gamma distributions, respectively. All the hyperparameters of both the mean and standard deviation are thus modeled with non-informative distributions.

The MCMC algorithm is run for 30,000 iterations, following a burn-in of 3,000 updates, which is also used to train the model, for both frequency

and severity cases. According to the Gelman-Rubin diagnostic (e.g. Gelman and Rubin, 1992), the simulated chains converged adequately in the MCMC practice implemented in this study for both cases. Furthermore, the models for both frequency and severity distributions have been validated using the Deviance Information Criterion (DIC), which tests how good the proposed model predicts a replicate dataset which has the same structure as the observed one, e.g. the historical observations (e.g. Gelman, 2003).

Finally, the risk in each area is estimated as the product of the expected accidents per tanker and the expected amount of oil spilled, giving the expected spilled oil in tons/tanker for each of the area in Figure 3.

3.4 *Results and discussion*

Figure 3 shows the risk of tanker oil spills in terms of expected tons of spilled oil per tanker. Areas of relatively high risk (1E-8–1E-9 tons/tanker) could be identified in the Tyrrhenian, Adriatic and Ionic Sea, in the north and west side of Sardinia, in the area of Mallorca, in the northern part of Libya and in north and east sides of Cyprus. In most of the cases, these results are driven by the comparatively large historical spills in areas with relatively low tanker traffic expressed in tanker-year (Figure 2).

Areas with a high spill risk (>1E-8 tons/tanker) could be identified in the Bosporus strait and different port areas along the Mediterranean coasts, such as in the Northern Tyrrhenian Sea, in Southern France, in the northern coast of Algeria, in the eastern side of the Peloponnese area and in Crete. This reflects the risk during port operations like loading and unloading of the tanker in ports and potential accidents due to grounding or collisions.

Relatively low risk areas (<1E-10 tons/tanker) could be found in the southern part of Spain, in the northern part of Algeria, in the Sicilian Sea, around Malta and in the Peloponnese region excluding its eastern side. These results are driven by generally low (or even absent) accidents recorded in the area combined with relatively high tanker-year (Figure 2). This result could be explained by the fact that these are open sea areas, and thus areas with limited possibilities of, for example groundings and collisions. Furthermore, in the relatively low risk areas, the result should not be taken as evidence that a spill accident can be excluded in the future, but that a spill event may be less expected than in areas of higher risk (e.g. the one with >1E-8 tons/tanker).

Finally, the remaining areas in the Mediterranean Sea show a risk level of the same order of magnitude (1E-10–1E-9 tons/tanker).

To validate our model, the oil spill accidents in the period 2012–2016 have been considered. In this period, a total number of 19 oil spills have been recorded in the Mediterranean Sea. Most of them in the Greek area and in particular in the Peloponnese and on the eastern Greek coasts.

Largest spills (>700 t) happened in areas of relatively extreme risk in the model (Figure 3), while smaller spills (<7 t) in areas of average risk in the sea, i.e. 1E-10–1E-9 tons/tanker, with the exception of an event in Cyprus (1 t released), which falls into the relative high-risk category (1E-9–1E-8 tons/tanker). Furthermore, one spill accident of 15 t in the Peloponnesus area falls into the relative low risk category (<1E-10 tons/tanker).

In general, historical observations in the period 2012–2016 are generally in good agreement with the model in terms of spill sizes/tanker, thus validating the proposed approach.

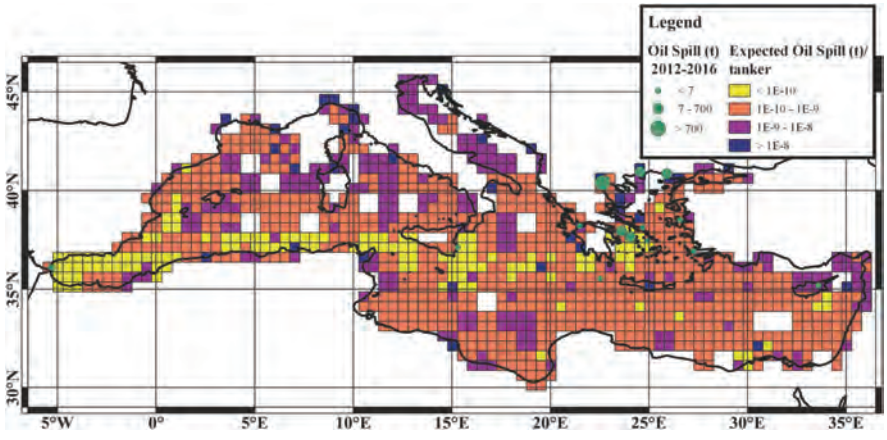

Figure 3. Spatial distribution of the Expected oil spill (t)/tanker in the Mediterranean Sea including the Bosporus strait. The oil spills (t) recorded in the period 2012–2016 used to validate the model are also shown.

4 CONCLUSIONS

In this study, we tested the operability of a spatial hierarchical Bayesian model by applying it to study the oil spill risk of tankers in the Mediterranean Sea.

A comprehensive and up to date database of oil spill accidents was used both as input to the model and for validation purposes. In particular, the results of the validation step confirm that the proposed methodological approach represents a promising tool for dealing with quantitative spatial risk assessments. Indeed, the proper consideration of the spatial component inherent in accidents that can have consequences spread over a geographic region, plays a vital role in supporting spatial monitoring procedures and risk mitigation measures.

The main benefits associated with the proposed methodological approach can be summarised as follows: (i) ability to deliver quantitative results at high spatial resolution, for example in comparison to previous studies (e.g. Burgherr et al., 2015), (ii) possibility to combine expert knowledge with empirical data (e.g. Choy et al., 2009), (iii) accountability for uncertainties and lack of data, and (iv) possibility of integrating sensitivity analysis to improve the interpretability of the parameters (e.g. Roos et al., 2015).

On the other hand, the following limitations should be acknowledged. First, we are using a simplified approach, which does not model the causality between influencing parameters (e.g. size of the tanker, marine currents, wind, spill cause, type of location such as ports, open sea, narrow strait, etc.). Second, the model is assessing an average number of accidents per year, rather than taking into account the actual yearly trend (i.e. traffic patterns).

Finally, we envisage several future developments of this research. The first one refers to the study of how structured expert judgement elicitation protocols could be included in the development of the spatial Bayesian model. Indeed, the facilitation of the quantitative expression of subjective judgement plays a crucial role in the context of probability and risk assessments. However, the presence of the spatial dimension, where basically every pixel of the map becomes an alternative to be assessed, makes this task a particularly challenging one (e.g. Ferretti and Montibeller, 2016), thus opening interesting avenues for future research. The second direction for future developments concerns the combination of the present methodological approach with multi criteria decision analysis to account for multiple impacts associated with the adverse event (e.g. Ferretti and Montibeller, 2017). The third direction of further research concerns the inclusion modelling of data about spatial vulnerabilities within the spatial multi impact Bayesian approach.

ABSTRACT: A global dataset of refinery accidents for the years 1990–2016 was analyzed to evaluate the capacity of 16 attributes to differentiate between accidents that cause or not fatalities. For this purpose a Dominance-based Rough Set Approach (DRSA) analysis was carried out. The quality of approximation and accuracy measures confirmed that the established information table is able to distinguish outcome levels in terms of fatalities. Furthermore, the suitability of the extracted rules to describe hidden relationships in the accident dataset was demonstrated. Although, the predictive capacity of the decision rules was not satisfactory, the rules still proved to be useful to identify the attributes that contribute most to assign an accident to the correct outcome class. In summary, this study provided a number of new and substantial insights on worldwide refinery accidents, which complement and extend previous findings for accident frequencies and associated trends as well as different types of consequences.

1 INTRODUCTION

The field of risk assessment and management is a rather young scientific discipline, with most of its fundamental ideas, principles, concepts and applications going back to the 1970s and 1980s (Aven, 2016). One of the first articles addressing risk as a contemporary societal problem was published in Science in 1969 (Starr, 1969). The following publications provide a broad discussion of the concept of risk (Aven, 2012) as well as foundational issues (Aven and Zio, 2014) and important developments in the field (Greenberg et al., 2012, Thompson et al., 2005).

Early developments and applications of probabilistic risk assessment can be traced back to NASA's space program in the 1960s (Cooke, 2009), the aerospace industry (Keller and Modarres, 2005), and the development of nuclear energy in the same period (Otway and Pahner, 1976). In 1975, the US Reactor Safety Study (WASH-1400) marked a major milestone in probabilistic risk assessment (US NRC, 1975), and subsequently spread to other disciplines and countries (Rasmussen, 1981).

The need for systematic and consistent, comparative risk assessment of energy technologies has been recognized since the 1980s (Fritzsche, 1989, Inhaber, 1979). Since then, it became a central element both in the comprehensive evaluation of the risk performance of energy technologies (Burgherr and Hirschberg, 2014), and in the broader context of sustainability assessment (Cinelli et al., 2014, Hirschberg and Burgherr, 2015, Santoyo-Castelazo and Azapagic, 2014). Recently, an increased interest can be observed to assess the frequencies and consequences of accidents over-time, and to compare them among energy chains, chain stages, activities and

infrastructure types as well as for different configurations and locations. The systematic exploitation of existing datasets to extract such useful information is a very important and promising research avenue (Burgherr et al., 2015, Burgherr et al., 2017, Cinelli et al., 2017, Spada and Burgherr, 2016).

In the industrial realm, risk assessment and management is often carried out according to ISO 31000 (ISO, 2009a, Luko, 2013), and ISO 31010 provides a list of 31 risk assessment techniques (ISO, 2009b, Luko, 2014). Other studies present overviews of risk analysis methodologies for specific facilities such as industrial plants (Tixier et al., 2002) or distinguish between formal and informal risk handling strategies for utility companies (Mascini and Bacharias, 2012). In contrast, Jonkman et al. (2003) and Johansen and Rausand (2014) address risk metrics from a more scientific perspective, but their discussion is also relevant for industry, authorities and other stakeholders. Lastly, loss modeling of industrial and insurance companies is often based on historic incident and accident data and the use of empirical and actuarial models and other approaches (Klugman et al., 2008, Daniell et al., 2018, Mannan, 2012).

In this study, the risk of accidents in refineries is analyzed. Within the oil chain, accidents during transports of crude oil and refined products clearly dominate with a share of about 75%, whereas exploration & production (E&P) and refinery activities follow distantly with roughly 10% each (Burgherr and Hirschberg, 2014). Furthermore, E&P and refinery facilities usually represent multi-billion dollar assets, property damage losses in these two sectors are the dominant contributors in the hydrocarbon industry, and refineries exhibit an increasing trend in frequencies and extent of losses (Marsh, 2016).

Recent publications address a variety of topics, including accidents at specific facilities (e.g., Chettouh et al., 2016, Mishra et al., 2014, Saleh et al., 2014), learning from past accidents (e.g., Moura et al., 2017a, Moura et al., 2017b, Russell Vastveit et al., 2015), occurrence of major accidents (Amyotte et al., 2016), and a sustainability metric for petroleum refinery projects (Hasheminasab et al., 2018).

In a previous study, two of the authors analyzed the frequencies and consequences (i.e., fatalities, injured persons) of refinery accidents among four country clusters (Burgherr et al., 2016). This provided interesting insights and conclusion on how refinery configuration and regional differences reflecting the mode of operation are important factors potentially affecting overall refinery risk.

In the current investigation, this retrospective analysis is extended to determine the combined influence and relevance of selected attributes (e.g., country group, accident type, event chain steps, etc.) of refinery accidents on the outcome level (e.g., fatalities). Such knowledge on the potential impact of an energy accident can be used as one piece of information for the selection of response mode and resource allocation. According to the class of risk provided by the model, the Decision Makers (DMs) can decide how many resources to allocate to respond. Retrospective analysis for patterns recognition and decision support model development have been recently applied in different studies, e.g., investigation of antimicrobial activity (Pałkowski et al., 2014), selection of sustainable project portfolios (Zaras et al., 2012), and natural gas accidents (Cinelli et al., 2017), among others.

In the current research, a dataset of refinery accidents extracted from PSI's Energy-related Severe Accident Database (ENSAD) was analyzed to address three main objectives:

1. Assess the information structure of accidents from ENSAD to distinguish the events that did cause or did not cause fatalities.
2. Investigate the relationships between a set of descriptors (attributes) for the energy accidents and the outcome level (fatalities or no fatalities).
3. Study the capacity of the attributes to distinguish between accidents that cause or not fatalities.

2 METHODS

2.1 *Accident data*

The refinery accident data used in this study were extracted from PSI's ENSAD. The ENSAD has first been released in 1998 (Hirschberg et al., 1998), and since then regularly updated and extended (Burgherr et al., 2015, Burgherr and Hirschberg, 2014). Currently, the database is migrated from a standalone MS-Access to an new, interactive, web-based GIS database named ENSAD v2.0 (Burgherr et al., 2017). In ENSAD, complete energy chains are considered because accidents can occur during all stages and activities, and not just the actual power and/or heat generation (Burgherr and Hirschberg, 2008). In general, the focus of ENSAD is on so-called severe accidents because accidents with larger consequences are a major concern for industry and authorities, but also receive most attention by the general public (Burgherr and Hirschberg, 2014). To be classified as severe an accident has to fulfil at least one of seven threshold criteria, for example ≥ 5 fatalities, ≥ 10 injured persons, etc. (Burgherr and Hirschberg, 2008).

For the current study on global refinery accidents all accidents in ENSAD with at least one fatality or one injured person during the years 1990–2016 were taken into account. The lower

fatality and injury thresholds for refinery accidents were possible because a dedicated search for smaller accidents was carried out to ensure a sufficiently complete coverage. This larger dataset allows analyzing a broader set of accident attributes compared to the previous study conducted in 2016 (Burgherr et al., 2016).

In total, the refinery accident dataset comprised 698 accidents, of which 277 resulted in at least one fatality, 597 in at least one injured person, and 176 had both consequences.

2.2 *Refinery data*

Information on refinery configuration and characteristics was retrieved from the World Wide Refinery Survey (WWRS) of the Oil & Gas Journal (Penn Energy Research, 2010). The coupling between the ENSAD and WWRS databases was based on georeferenced refinery locations (i.e., geographic coordinates). WWRS data include details on refinery units and processes as well as corresponding capacities expressed in barrels per calendar day (bbl/cd), the Nelson Complexity Index (NCI) and the Equivalent Distillation Capacity (EDC). In some cases, an accident could not be assigned to a specific refinery in the WWRS database: (1) the accident description did not allow identifying the correct refinery if several are located in the same area (10 cases); (2) the refinery can be located, but is not included in the WWRS list, which is mostly the case for small, private refineries (32); or (3) the accident description is so incomplete that the refinery can only be assigned to a country, but no specific location (8).

Additionally, five more refinery attributes were based on data from Swiss Re, providing additional information on regional differences in refinery hazards. First, each refinery accident was assigned to one of four regional country clusters, representing different plant operation styles (Pannatier, pers. comm.). Generally, loss burden differs among clusters, which is attributable to operational hazard factors such as mode of operation, attitude towards safety, turnaround period, maintenance, etc. The four clusters were given the following names:

- "USA": USA, Canada, UK, Australia
- "Europe": Europe, Singapore, South Korea, Japan, Saudi Arabia, Gulf States, Egypt
- "Russia": Russia, Former Soviet Union, Eastern Europe
- "Other": South America, Africa, Maghreb, other Middle East, rest of Asia

Second, all refinery units were allocated to three complexity classes G1, G2 and G3 to reflect increasing fire and explosion hazard (see Table 1), based on a Swiss Re expert categorization (Pannatier, pers. comm.). The class G0 includes all units that do not belong to one of the three other classes. An overview of refinery units considered and their assignment to a complexity class is shown in Table 1.

Three refinery unit attributes were defined, namely (1) the unit in which the accident started; (2) the complexity class of the unit where the accident started; and (3) the complexity class of the most hazardous unit(s) in a refinery.

Third, a Swiss Re Hazard Index (SR HI) was calculated for all refineries, combining the capacity, complexity and toxic hazard of a refinery with weight factors three, two and one, respectively.

2.3 *Overview of accident attributes*

Table 2 shows an overview of the 16 attributes that were used to analyze the previously defined dataset of refinery accidents. Ten attributes concern specific accident characteristics, whereas the other six provide information about refinery configuration and operational hazard. Out of these, three were directly taken from the WWRS database, and three were established using information from Swiss Re and WWRS.

2.4 *Dominance-based Rough Set Approach (DRSA)*

The dataset of refinery accidents developed in this study can be seen as an information table, where characteristics of the accidents are condition attributes (independent variables) and the

Table 1. Assignment of refinery units to complexity classes (CC) G0 to G3.

G0	G1	G2	G3
Crude Unit	Vacuum Distillation	Catalytic Cracking	Catalytic Hydro-cracking
Coking	Catalytic Reforming	Isomerization	Alkylation
Thermal Cracking	Catalytic Hydrotreating		Polymerization
Hydrogen Production			Lubes
Hydrogen Recovery			
Coke			
Sulphur			
Asphalt			

Table 2. Overview and description of refinery attributes. O-U: ordered, but direction unknown; O-K: ordered and direction is known; N-O: not ordered.

Attribute name	Description and values	Unit	Ordering
Year	Year in which an accident occurred: 1990–2016.	yr	O-U
Country Cluster	Country clusters represent different plant operation styles (see section 2.2): USA, Europe, Russia, Other.	–	N-O
Start Unit	Name of refinery unit in which the accident started (see Table 1).	–	N-O
Start CC	Complexity class (CC) of refinery unit where accident started: G0, G1, G2, G3.	–	O-K
High CC	Unit(s) with highest complexity class (CC) in a refinery.	–	O-K
No Acc	Number of accidents that occurred in an individual refinery during the period of observation.	–	O-U
Nelson Complexity Index (NCI)	A measure for refinery complexity, replacement costs, and values (Johnston, 1996 and references therein).	–	O-U
HI	Swiss Re Hazard Index (HI) (see section 2.2).	–	O-U
CRUDE	Crude capacity of refinery	bbl/cd	O-U
EDC	Equivalent Distillation Capacity is another measure to compare refineries. is another means of comparing refinery costs, for which a refinery's atmospheric distillation capacity is multiplied by its overall complexity rating, resulting in complexity barrels (Johnston, 1996).	cbbl/cd	O-U
Acc Type	Type of accident: Technical Failure (TF), Human Factor (HF), Human-Technical (HT), Natural Hazard (NH), Intentional Attack (IA; not included in current analysis).	–	N-O
EC1 to EC5	Event chain steps 1 to 5; sequence of events as given in available information sources. In total, 27 values are used, e.g., explosion, fire, release, etc.	–	N-O
Fatalities (i.e., outcome of the accident)	Number of fatalities that an accident caused. Two outcome levels are distinguished: no fatalities vs. fatalities.	–	O-K

presence or not of fatalities is the decision attribute or outcome level (dependent variable). To achieve the research objectives, Dominance-based Rough Set Approach (DRSA) analysis (Greco et al., 2001, Słowiński et al., 2015) was applied to the refinery information table using the jRS library and jMAF software package (Błaszczyński et al., 2013). The method is well suited for this case study as it can handle quantitative and qualitative information without the need of transforming them into numerical or binary values, and it accepts inconsistencies in the dataset.

Another important characteristic of the present dataset is that it is not always known a priori whether the condition attributes are of the gain—or cost—type in relation to the fatalities. Gain-type means that the greater the value of an attribute, the less likely the accident causes fatalities; conversely, cost-type means that the lower the value of the attribute, the less likely the accident causes fatalities. DRSA is capable of discovering this type of information, named global monotonicity (Blaszczyński et al., 2012). Furthermore, local monotonicity can also be discovered, meaning the interval of attribute values in which an attribute shows a gain—or cost-type behavior in the discovered pattern (see Table 3). The applied transformation is non-invasive, i.e., it does not bias the matter of discovered relationships. With reference to the set of refinery attributes, those without an indication of their preference order for which global and local monotonicity were studied are "Year", "No Acc", "NCI", "HI", "CRUDE", and "EDC" (O-U type in column Ordering, Table 2).

The relationships between the values of the attributes of the energy accidents and the cause or not of fatalities were discovered by means of decision rules, which are objective cause-effect patterns hidden in the refinery dataset. A decision rule is in the form of EàH, namely "if E, then H". E is the condition part (also called premise or evidence) and H is the conclusion part (also called decision part). Sets of decision rules, which are essential for this analysis, were induced using the Variable Consistency Dominance-based Learning from ExaMples (VC-DomLEM) algorithm (Błaszczyński et al., 2011b). Accidents that consistently cause either fatalities or not are assigned to what are called lower approximations. VC-DomLEM uses accidents that belong to such lower approximations as training examples to induce sets of certain decision rules, which may be later used to classify new accidents.

Sets of rules, induced by VC-DomLEM, may be used to construct more accurate ensemble classifiers in variable consistency bagging (Błaszczyński et al., 2009, Błaszczyński et al., 2010). Another

Table 3. Selected examples of decision rules obtained from the DRSA of the refinery accident dataset for accidents causing fatalities or not. Mbbl: million barrels; Supp.: Support; Conf.: Confidence. Other abbreviations see Table 2.

Year	Country cluster	Start Unit	Start CC	No Acc	NCI	HI	CRUDE Mbbl/cd	EDC	Acc Type	Supp.	Conf.
Rules for accidents that **did not cause fatalities**											
> 2002 ↑	Europe				≤ 5.4 ↓					11	0.92
> 2010 ↑	Other				≤ 6.3 ↓		≤ 110 ↓			13	0.93
	USA			≤ 4 ↓			≤ 96 ↓		HT	11	0.92
	USA		≤ 0			≤ 18.57 ↓	≤ 149.5 ↓		TF	15	0.82
> 2011 ↑	Russia				≤ 7.4 ↓					13	0.93
Rules for accidents that **caused fatalities**											
[2002;2004]		Alkylation							HF	10	0.91
[1996;2004]		Crude						≥ 1521 ↓	HF	11	0.85
≤ 2007 ↑						≥ 18.42 ↓	[126.9;189]		HF	11	0.79
≤ 2011 ↑			≥ 2			≥ 21.28 ↓			TF	12	0.80
	USA		≥ 2		≥ 10.65 ↓	≥ 20.0 ↓			TF	15	0.75

extension of the bagging approach is applied when the analyzed dataset suffers from class imbalance. In our case, Neighbourhood balanced bagging (NBBag) was used to increase the predictive capabilities of constructed rule classifiers (Błaszczyński and Stefanowski, 2015). Moreover, the strategies, which were used to evaluate our proposition, consisted in learning the decision rules from a subset of the original accident dataset and testing them on the remaining accidents to evaluate whether they assign the correct fatality class or not.

The capacity of the attributes to distinguish between accidents causing or not causing fatalities was assessed through a relevance measure called confirmation (Błaszczyński et al., 2011a, Greco et al., 2001). It assesses the degree to which presence of an attribute in the condition part of a rule confirms correct prediction (i.e., fatalities or no fatalities) on a subset of accidents the rules were not extracted from. The higher the value of the relevance measure (i.e., confirmation measure) the more important for correct prediction the attribute is.

3 RESULTS

3.1 *Quality of classification and accuracy*

The ENSAD-based refinery accident dataset is close to unitary classification quality (0.99 on a 0–1 scale), which means that there are very few inconsistent accidents that have the same values for the attributes and either caused fatalities or did not. In other words, the 16 attributes selected to develop the information table are relevant to differentiate between accidents causing or not causing fatalities. This is confirmed by the accuracy for not causing or causing fatalities with values of 0.98 and 0.97 (also on a 0–1 scale), respectively.

3.2 *Decision rules*

Decision rules represent unique patterns hidden within the dataset and they unveil the cause-effect relationships between the values of the attributes and the outcome level, i.e., the fatalities class in this case. Decision rules do not only include important condition attributes, but they also contain a minimal number of elementary conditions that are necessary for representation of the cause–effect relationships existing in the information table, from which all inessential and redundant information is removed.

Decision rules are induced by DRSA using the VC-DomLEM algorithm. Table 3 shows ten representative rules, five for the description of accidents causing fatalities and five for not causing fatalities. These decision rules can be viewed as interesting patterns among all patterns that can be found to describe features of the refinery accident dataset. The rules are characterized by useful parameters, including the support (i.e., the number of accidents that support the rule) and the confidence level. The selected rules have all a strong confidence level, close or above 0.75. This indicates that at least 75% of the accidents in the dataset with the stated values for the condition attributes lead to fatalities or not.

In the following, some rather simple explanatory examples for the interpretation of the rules given in Table 3 are briefly discussed. Accidents after 2002 in the cluster Europe with a NCI smaller 5.4 caused no fatalities. For Russia the same was only true after 2011 and for a higher threshold of NCI, indicating a general better performance of Europe. The same combination of attributes for the cluster Other ranks between Europe and Russia, but additionally crude capacity has to be lower than 110,000 bbl/cd. In contrast, accidents with fatalities tend to have higher values for NCI, HI, crude capacity and EDC. Additionally, fatal

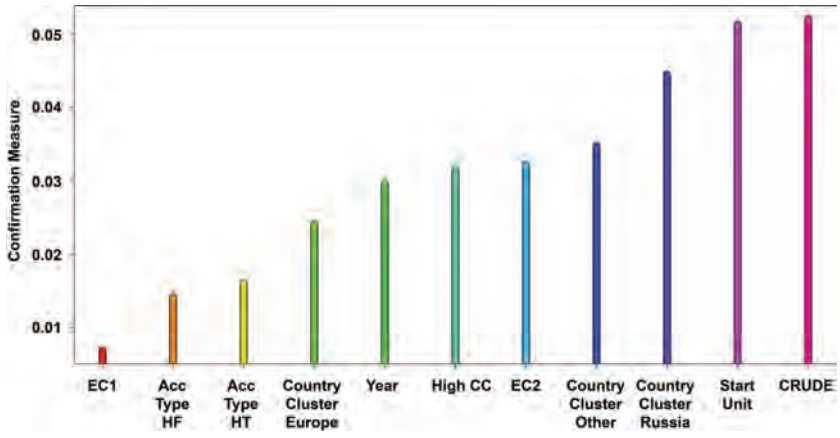

Figure 1. Confirmation measure for attributes most relevant to distinguish between accident outcomes in terms of fatalities.

accidents for combinations of these attributes generally appeared to occur more likely in the earlier years of the observation period. Finally, accidents starting in higher hazardous units (i.e., higher complexity class) cause more often fatalities, and even still in more recent years.

3.3 *Relevance of attributes*

The predictive capacity of the rules was tested by means of 10-fold cross-validation, but unfortunately the predictive accuracy of DRSA decision rules was not satisfactory. In fact, only 48% of the accidents causing fatalities and 53% of those not causing fatalities were assigned the correct class. Nonetheless, these rules can be used to extract the attribute relevance, which indicates to what extent attributes are relevant (useful) to distinguish between accidents causing fatalities or not.

The confirmation measure used for the computation of the attributes relevance quantifies the extent to which the presence of an attribute in the rule suggests a correct class (Figure 1). Attributes CRUDE, Start Unit and the Country cluster are the most relevant for discerning between the accidents in terms of the outcome. Other attributes which are still relevant, though at a lower extent, for correct prediction are the first and second event chain (EC1, EC2), the highest complexity class (High CC) of the unit(s) present in a refinery, the year when the accident took place, and the type of accident.

4 CONCLUSIONS

For the current analysis refinery accident data from ENSAD for the period 1990–2016 were combined with selected refinery characteristics using data from the WWRS database and from Swiss Re. The results demonstrated that the application of the Dominance-based Rough Set Approach (DRSA) analysis to such a complex dataset is feasible and useful to gain detailed insights about the structure and to reveal hidden relationships between accident attributes and their outcome in terms of fatalities.

The quality of approximation and accuracy measures confirmed that the information table based on 16 attributes is useful to differentiate between accidents causing or not fatalities. Furthermore, the extracted decision rules helped to evaluate hidden relationships in the accident dataset that go beyond traditional measures such as aggregated risk indicators or frequency-consequence curves. In particular, aspects of the monotonicity of attributes could be addressed as well as how higher (gain-type) or lower (cost-type) attribute values contribute to a reduced likelihood that an accident results in fatalities.

Finally, the decision rules were tested with regard to their predictive capacity to use the set of rules to assign potential future accidents to the correct outcome level. Although, the predictive accuracy was not satisfactory, the rules still proved to be useful to identify the attributes that contribute most to assign an accident to the correct outcome class.

In summary, the current study provided a number of new and substantial insights on global refinery accidents; thus extending and complementing a previous study by Burgherr et al. (2016).

Potential avenues of future research include options to enhance the predictive capacity of the

rules, which could be achieved either by adjusting the present attributes or by considering additional attributes. This is an essential aspect for decision makers and other stakeholders. They are, for example, concerned with the development of low-probability high-impact scenarios, pre- and post-event strategies to mitigate potential consequences of future accidents or the improvement of general safety culture.

ACKNOWLEDGEMENTS

This study was partially carried out under a collaboration agreement between PSI's Technology Assessment group and the Risk Engineering department of Swiss Re Corporate Solutions Ltd.

This research was also partly conducted at the Future Resilient Systems at the Singapore-ETH Centre, which was established collaboratively between ETH Zurich and Singapore's National Research Foundation (FI 370074011) under its Campus for Research Excellence and Technological Enterprise programme.

A novel navigational risk analysis method using interval type-2 fuzzy sets

C.L. Fan, D. Zhang, J.F. Zhang & H.J. Yao
Intelligent Transportation Systems Research Center, Wuhan University of Technology, Wuhan, P.R. China
National Engineering Research Center for Water Transport Safety, Wuhan, P.R. China

ABSTRACT: Navigational risk is critical to the shipping industry, particularly to the inland water due to its sensitive environment. To this end, this paper proposes a novel method for navigational risk analysis, incorporating Analytic Hierarchy Process (AHP), interval type-2 fuzzy sets (IT2FSs), and a similarity measure. In light of literature review, a hierarchical model for navigational risk analysis is developed including three levels: objective level, criteria level, and factor level. Then, weights of criteria and associated factors are obtained using AHP, and factors are evaluated by experts using IT2FSs. Then, results of the degree of similarity between aggregated experts' evaluation and 7-member IT2FSs representing 7 grades of risk are obtained and used to determine the degree of navigational risk of the objective level. The application of the proposed method is illustrated by assessing navigational risk of 5 vessels cruised in the Yangtze River. The proposed method provides room for more flexibility in modeling and handling subjective uncertainties in navigational risk analysis. Also, the proposed method identifies navigational risk of multiple vessels, which is useful in enhancing situation awareness of safety.

1 INTRODUCTION

Risk assessment is a critical issue in the maritime transport system. Due to market demand and development of high technology, vessels in this system have been more specific in their functions, much larger in their sizes, much faster in their cruise velocities, and much more in their quantity. This transformation, however, produces an increasing threat to navigational safety by ship collisions, grounding accidents, etc., and also to ecosystem by emissions, oil spill, ship's ballast water and sediments' discharge, etc. It has been estimated that potential losses of a 19,000 TEU containership sinking is up to US$ 1 billion and it would take two years to remove all the containers from the foundered mega containership (Allianz 2015). Therefore, it is necessary to control and manage such risk. To this end, Formal Safety Assessment (FSA), proposed by the UK in 1993 (Wang 2000), was approved by International Maritime Organization (IMO) in 2002 as principles of risk management and a systematic process, which has been broadly used and developed in maritime industry around the world (Görçün & Burak 2015, Hu et al. 2007, Montewka et al. 2014, Zhang et al. 2011, Zhang et al. 2013). The last update of the FSA guidelines was in 2015 (IMO 2015), which illustrates the framework of FSA includes 5 modules: Identification of hazards; risk analysis; Risk control options; Cost–benefit assessment; Recommendations for decision-making. The first two modules of FSA are the interest of this paper.

Traditionally, navigational risk has been assessed by statistical method (Chen et al. 2015, Jin 2014, Kujala et al. 2009, Meng et al. 2014, Wang et al. 2013), simulation (Huang et al. 2017, Lušić & Čorić 2015, Montewka et al. 2010, Qu et al. 2011, Wang et al. 2009), or evaluation of risk factors (Kum & Sahin 2015, Thieme et al. 2017, Tian et al. 2013, Xu et al. 2016, Øien 2001). However, maritime transportation is a large-scale physical and socio-technological system. Such complicated characteristics lead to that navigational risk assessment entails more specific methods which can effectively deal with epistemic uncertainties, e.g. discord in ship-ship or ship-shore communication, imprecision in ship identification, temporal and spatial differences, etc. These uncertainties have been handled by many methods, e.g. Bayesian Networks (Akhtar & Utne 2014, Brito & Griffiths 2016, Hänninen & Kujala 2012, Martins & Maturana 2013, Zhang et al. 2013), Dempster-Shafer theory of evidence (Li & Pang 2013, Talavera et al. 2013, Zhang et al. 2016), etc.

Navigational risk assessment also faces with data uncertainty (Hänninen 2014), i.e. the lack of data in detail and the difficulty in evaluating the credibility and validation of the data, and with ambiguity in seafarers' decision making in some cases.

To overcome these problems, experts' judgements have been an appropriate alternative to objective data. Experts' subjective opinions have been modeled by many studies using fuzzy set theory (Karahalios 2014, Zhao et al. 2009) or integrated fuzzy methods, e.g. Fuzzy Evidence Reasoning (Yang et al. 2014), Fuzzy Analytic Hierarchy Process (AHP) (Andrew et al. 2014, Beşikçi et al. 2016, Celik et al. 2009, Pak et al. 2015), etc. However, most of these studies are based on Type-1 fuzzy sets (T1FSs) introduced by Zadeh (1965), whose membership grade, or the height is a crisp number within [0, 1]; however, determining an exact membership function for a fuzzy set is not always possible without a loss of information (Gorzalczany 1987), which often causes biased conclusion (Liu et al. 2017). To overcome this, the concept of type-2 fuzzy sets (T2FSs) is also introduced by Zadeh (1975) as an extension of T1FS, characterized by primary and secondary membership. Nevertheless, T2FSs have not been widely applied due to complicated computation. To reduce such heavy computation effort, interval type-2 fuzzy sets (IT2FSs) is proposed by Gorzalczany (1987) with that all the values of secondary membership of T2FSs are equal to 1. IT2FSs can not only represent uncertainty better than that of T1FSs and simplify the computation compared with T2FSs (Hu et al., 2013), but also produce more accurate and robust results (Dereli & Altun 2013). Therefore, IT2FSs have been widely used in decision making, risk analysis, etc.

Regarding risk analysis using IT2FSs, there are mainly three methods which are using IF-THEN rules (Rahib et al. 2016), ranking IT2FSs (Bozdag et al. 2015), and measuring the degree of similarity (Chen & Chen 2008, Chen & Chen 2009, Chen & Sanguansat 2011, Sen et al. 2016, Wei & Chen 2009). Among them, the last one is the most popular. However, selecting a reasonable similarity measure is an open subject, depending on the real application environments (Deng et al. 2011). The similarity measure proposed by Chen & Sanguansat (2011) is adopted in this paper.

This paper aims to assess navigational risk. A hierarchical structure for identifying navigational risk factors is constructed with three levels: objective level, criteria level, and factor level. Values of relative importance of certain criteria with respect to the objective, and of relative importance of certain factor with respect to corresponding criteria are quantified using Analytic Hierarchy Process (AHP) (Saaty 1980). To evaluate risk factors, linguistic terms and corresponding IT2FSs are utilized. Then, measuring the degree of similarity between the aggregated evaluation of factors and seven grades of risk represented by IT2FSs is used to transform the aggregated result into corresponding linguistic term.

The rest of this paper is organized as follows. Section 2 presents a model for navigational risk analysis incorporating three levels—objective level, criteria level, and factor level, and corresponding grades for describing the objective level and evaluating the factor level. Based on this model, Section 3 illustrates the proposed method. Using the proposed method, navigational risk of 5 vessels is introduced in Section 4. Section 5 concludes this paper.

2 NAVIGATIONAL RISK ANALYSIS MODEL

2.1 *Evaluation model for navigational risk*

For navigational risk analysis, a model with three levels is established based on Tian et al. 2013, Zhang et al. 2011, Zhang et al. 2013, and Zhang et al. 2016, and shown in Figure 1. The objective level aims to assess the navigational risk; the criteria level comprises four kinds of criteria—static information of vessel, dynamic information of vessel, environment, and management; the factor level includes 18 factors without directly taking into account human factor which is an important parameter for navigation safety (Fan et al. 2017, Kujala et al. 2009). The reason is that it is difficult to directly determine the risk of human because human is the source of success as well as failure (Hollnagel 2014). In contrast, human behavior is partially represented, i.e. dynamic information of vessel partially represents watch officers' decision; shipowner stands for organization factor; the maintenance situation of navigational aids par-

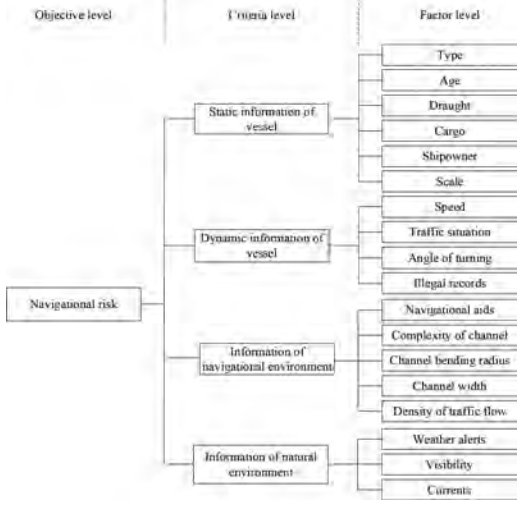

Figure 1. A hierarchical structure for navigational risk.

tially indicates the administration level. Factors in the factor level are as follows:

1. Static information of vessel includes 6 factors: shipowner, type, age, scale, cargo, and draught. For example, the attribute of cargo may lead to different navigational risk. The ratio of channel depth to vessel draught generally is larger than one, otherwise, the accident of grounding may happen.
2. Dynamic information of vessel contains 4 factors: speed, angle of turning, illegal records, and traffic situation. For example, if a vessel has many ship detention times per year by Port State Control officer or Flag State Control officer, this vessel may be critical from the view of department of administration.
3. Information of navigational environment covers 5 factors: density of traffic flow, aid facility, channel width, channel bending radius, and complexity of channel. For example, vessels benefit a lot from navigational aids which are performed and maintained well, while little from a complicated channel with a lot of bridges over it.
4. Information of natural environment incorporates 3 factors: visibility, weather alerts, and currents. For example, good visibility normally contributes to broader horizon of watching. Higher weather alert information poses a significant threat to the navigation safety.

2.2 *Evaluation grades for risk of objective level*

Navigational risk is divided into 7 grades, ranging from very low to very high, described in Table 1 from the perspective of frequency and consequence of accidents. These 7 linguistic terms are represented by 7-member trapezoidal IT2FSs, LT_k, $k = \{1, 2, \ldots, 7\}$, shown in Table 2, which are adapted from Chen & Chen 2008, Liu 2011, and Wei & Chen 2009 by deleting absolutely low and absolutely high. The reason of ignoring these two absolute terms is due to that exactly defining the absolute situations in the navigational risk analysis is not only difficult from a systematic view, but also impractical from the reality.

2.3 *Evaluation grades for risk of factor level*

Factor risk is divided into 3 grades depending on factor attribute, ad hoc condition, and considering experts' views. 3 grades for factors with respect to 4 kinds of criteria are described in Table 3, Table 4, Table 5, and Table 6, respectively. These 3 grades are represented by 3-member trapezoidal IT2FSs—L, M, and H listed in Table 2. The reason of using this 3-member trapezoidal IT2FSs is for simplification in expert's evaluating the risk of factor for a specific vessel.

Table 1. Grades of navigational risk.

Linguistic term	Explanation of linguistic term
Very low (VL)	The risk is very low due to the frequency of accident or the consequence of accident is very low.
Low (L)	The risk is low due to the frequency of accident or the consequence of accident is low.
Fairly low (FL)	The risk is fairly low due to the frequency of accident or the consequence of accident is fairly low.
Medium (M)	The risk is medium due to the frequency of accident or the consequence of accident is medium.
Fairly high (FH)	The risk is fairly high due to the frequency of accident or the consequence of accident is fairly high.
High (H)	The risk is high due to the frequency of accident or the consequence of accident is high.
Very high (VH)	The risk is very high due to the frequency of accident or the consequence of accident is very high.

Table 2. 7-member linguistic terms and their corresponding trapezoidal IT2FSs.

k	Linguistic terms	LT_k, Trapezoidal IT2FSs
1	Very-low (VL)	[(0, 0, 0.02, 0.07; 1.0), (0, 0, 0.02, 0.07; 0.8)]
2	Low (L)	[(0.04, 0.1, 0.18, 0.23; 1.0), (0.04, 0.1, 0.18, 0.23; 0.8)]
3	Fairly low (FL)	[(0.17, 0.22, 0.36, 0.42; 1.0), (0.17, 0.22, 0.36, 0.42; 0.8)]
4	Medium (M)	[(0.32, 0.41, 0.58, 0.65; 1.0), (0.32, 0.41, 0.58, 0.65; 0.8)]
5	Fairly high (FH)	[(0.58, 0.63, 0.80, 0.86; 1.0), (0.58, 0.63, 0.80, 0.86; 0.8)]
6	High (H)	[(0.72, 0.78, 0.92, 0.97; 1.0), (0.72, 0.78, 0.92, 0.97; 0.8)]
7	Very high (VH)	[(0.93, 0.98, 1.0, 1.0; 1.0), (0.93, 0.98, 1.0, 1.0; 0.8)]

3 PROPOSED METHOD

The motivation behind the development of the proposed method is to improve the flexibility in the navigational risk analysis. Flexibility is reinforced due to IT2FSs better modeling and handling uncertainty of experts' judgements when the exact membership function of T1FSs is unknown. Four steps of the proposed method are as follows:

Table 3. Grades of risk of factor with respect to static information of vessel.

	Grade of risk		
Factor	L	M	H
Type		general cargo	dangerous cargo
Age	between 10 years and 15 years	other	larger than 25 years or unknown
Draught	largely less than channel depth	normally less than channel epth	slightly less than channel depth
Cargo	container	general cargo	dangerous cargo, unloaded, or overloaded
Shipowner	government	corporation	individual
Scale	largely matching the channel	normally matching the channel	slightly matching the channel

Table 4. Grades of risk of factor with respect to dynamic information of vessel.

	Grade of risk		
Factor	L	M	H
Speed	safety speed, or obey the local regulation	other	largely less or larger than safety speed, or seriously violate the local regulation
Traffic situation	no foreign vessels	one foreign vessels around own ships	multiple foreign vessels around own ships
Angle of turning	equal to or less than 15 degree per second	less than 30 degree but larger than 15 degree per second	equal to or larger than 30 degree per second
Illegal records	less than 2 times per year	2 times per year	larger than 2 times per year or unknown

Table 5. Grades of risk of factor with respect to information of navigational environment.

	Grade of risk		
Factor	L	M	H
Navigational Aids	perfect in quality and enough in quantity	other	deficiency in quality and quantity
Complexity of channel	other	one obstructions in the channel	multiple obstructions in the channel
Channel bending radius	largely bigger than ship length	slightly larger than ship length	slightly larger than ship length
Channel width	largely bigger than ship length	slightly larger than ship length	slightly larger than ship width
Density of traffic flow	sparse	normal	dense

Table 6. Grades of risk of factor with respect to information of natural environment.

	Grade of risk		
Factor	L	M	H
Weather alerts	fourth level weather alert or no weather alert	second or third level weather alert	first level weather alert
Visibility	good	normal	bad
Currents	advection or no current	other	turbulent current

Step 1: Determine the evaluation model
Step 2: Calculate weights of criteria and factors
Step 3: Aggregate the degree of risk
Step 4: Measure the degree of similarity

Step 1: Determine the evaluation model
A hierarchical structure model including objective, several criteria, and some factors, is established to analyze navigational risk in an area during a specified period, e.g. a three-level model shown in Figure 1.

Step 2: Calculate weights of criteria and factors
In the established model shown in Figure 1, weights of criteria with respect to the objective and weights of factor with respect to corresponding criteria are obtained by AHP due to its simplicity of implementation, although some limitations exist in AHP (Ivanco et al 2017). To this end, experts' judgements are elicited. For detailed information of steps of AHP, please refer to Bian et al. 2017, Deng et al. 2014, Zhang 2011, Zhou et al. 2017. Finally, the weight of a factor with respect to the objective, the global weight of such factor, is the product of the weight of such factor with respect to corresponding criteria and the weight of corresponding criteria with respect to the objective.

Step 3: Aggregate the degree of risk
Regarding a vessel i, $i \in$ N+, the degree of risk of factor j, $\tilde{Z}_{ij}$, $j = \{1, 2, \ldots, 18\}$, is evaluated using L, M, and H shown in Table 2 and according to the grades of risk defined in Table 3, Table 4, Table 5, and Table 6. For example, given that an unloaded 1000GT oil tanker is cruising in Wuhan section of the Yangtze River during dry season with the speed of 10kn and the visibility is over 1.5km, grade of some factors' risk are as follows: "Type" and "Cargo" are H according to Table 3; "Speed" is L according to Table 4; "Navigational Aids" is L, "Channel width" is M, "Channel bending radius" is L, and "Complexity of channel" is H according to Table 5; "Visibility" is M according to Table 6.

After 18 factors are evaluated, the degree of risk of specified vessel i, $\tilde{R}_i$, is obtained by aggregating global weights of factors determined in **Step 2** and evaluation of factors $\tilde{Z}_{ij}$ based on a trapezoidal interval type-2 weighted averaging (TIT2-WAA) operator (Hu et al. 2013). Note that, the aggregation result is also a trapezoidal IT2FS. For detailed information about this proof, please refer to Hu et al (2013). Therefore, it is necessary to further analyze that what the aggregation result stands for.

Step 4: Measure the degree of similarity
To transform $\tilde{R}_i$ in **Step 3** into corresponding linguistic term represented by LT_k, $k = \{1, 2, \ldots, 7\}$, shown in Table 2, the degree of similarity between $\tilde{R}_i$ and LT_k, $S(\tilde{R}_i, LT_k)$, $k = \{1, 2, \ldots, 7\}$, is calculated based on measure proposed by Chen & Sanguansat (2011).

According to Chen & Sanguansat (2011), the lager the value of $S(\tilde{R}_i, LT_k)$, the more the similarity between $\tilde{R}_i$ and LT_k.

4 CASE STUDY

The verification of the proposed method was done through retrospective analysis of 5 vessels cruised in the Yangtze River in 2010, 5 accidents among them are from CJMSA (2010). Table 7 shows that 5 accidents with different grades and types happened in question.

[Step 1]: A three-level model is created in Figure 1. In which, the objective is to evaluate the navigational risk of these 5 vessels cruised in the Yangtze River shown in Table 7. Four kinds of criteria and eighteen factors are derived from Tian et al. 2013, Zhang et al. 2011, Zhang et al. 2013, and Zhang et al. 2016.

[Step 2]: Using AHP, a series of pairwise comparisons with respect to the criteria and factors are performed by three-expert committee to calculate weights of criteria with respect to the objective, and weights of factors with respect to corresponding criteria.

Taking the calculation of weights of criteria with respect to the objective as an example, the pairwise comparison matrix A is as follows:

$$A = \begin{array}{c} \\ \text{Static information of vessel} \\ \text{Dynamic information of vessel} \\ \text{Information of navigational environment} \\ \text{Information of natural environment} \end{array} \begin{array}{c} \begin{array}{cccc} \text{Static information of vessel} & \text{Dynamic information of vessel} & \text{Information of navigational environment} & \text{Information of natural environment} \end{array} \\ \begin{pmatrix} 1 & 1/2 & 2/3 & 1/3 \\ 2 & 1 & 4/3 & 2/3 \\ 3/2 & 3/4 & 1 & 2 \\ 3 & 3/2 & 1/2 & 1 \end{pmatrix} \end{array}$$

The largest eigenvalue of matrix A is 4.2492. The normalized eigenvector belonging to the largest eigenvalue of matrix A is: w = (0.1338, 0.2677,

Table 7. Basic information of 5 vessels.

i	Vessel name	Time	Type of accident	Grade of accident
1	Laoxiahe 828	2010.01.01	Grounding	FH
2	Fufa 888	2010.01.04	Collision	H
3	Jinzhou 656	2010.01.14	Collision	VH
4	Yuhan 805	2010.02.10	Grounding	FH
5	Xinpingjiang 1013	2010.03.05	Grounding	M

Table 8. Weights of criteria and factors.

Criteria evel	j	Factor level	Local weight	Global weight
Static information of vessel (0.1338)	1	Type (VT)	0.1596	0.0214
	2	Age (VA)	0.0641	0.0086
	3	Draught (VD)	0.2504	0.0335
	4	Cargo (VC)	0.3825	0.0512
	5	Shipowner (SO)	0.0428	0.0057
	6	Scale (VSP)	0.1006	0.0135
Dynamic information of vessel (0.2677)	7	Speed (VSE)	0.2643	0.0708
	8	Traffic situation (TS)	0.5693	0.1524
	9	Angle of turning (AT)	0.0609	0.0163
	10	Illegal records (IR)	0.1055	0.0282
	11	Navigational aids (NA)	0.4263	0.1298
Information of navigational environment (0.3045)	12	Complexity of channel (CC)	0.1591	0.0484
	13	Channel bending radius (CB)	0.0823	0.0251
	14	Channel width (CW)	0.1732	0.0527
	15	Density of traffic flow (DT)	0.1591	0.0484
Information of natural environment (0.294)	16	Weather alerts (WA)	0.5556	0.1633
	17	Visibility (NV)	0.1111	0.0327
	18	Currents (NC)	0.3333	0.0980

0.3043, 0.2940)^T. Since the ratio of consistency index to random consistency index, 0.0923, is less than 0.1, the constructed pairwise comparison matrix A is considered acceptable (Zhou et al. 2017), and the results of normalized eigenvector are values of weights of criteria with respect to the objective. Similarity, the weights of factors with respect to certain criteria are obtained by AHP. After that, the weight of a factor with respect to objective is obtained by multiplying the weight of the factor with respect to certain criteria and the weight of the criteria with respect to the objective. The weights of criteria and factor are shown in Table 8.

[Step 3]: According to the retrospective analysis of accident reports (CJMSA 2010), factors in **[Step 2]** are evaluated by expert committee using 3-member linguistic terms–L, M, and H–shown in Table 4. And evaluations of factors with respect to 5 vessels are shown in Table 9.

Regarding to vessel i, the degree of risk, $\tilde{\tilde{R}}_i$, is obtained by aggregating global weights of factors tabulated in Table 8 and evaluation of factors $\tilde{\tilde{Z}}_{ij}$ shown in Table 9 using TIT2-WAA aggregation operator, which is shown in Table 10.

[Step 4]: Based on similarity measure proposed by Chen & Sanguansat (2011), results of the degree of similarity $S(\tilde{\tilde{R}}_i, LT_k)$ with respect to each vessel are shown in Figure 2. According to Chen & Sanguansat (2011), $\tilde{\tilde{R}}_i$ can be transformed in a linguistic term represented by LT_k which is more similar to it. Therefore, the risk of these 5 vessels are as follows: Laoxiahe 828, Medium; Fufa 888, Medium; Jinzhou 656, Medium; Yuhan 805, Medium; Xinpingjiang 1013, Medium.

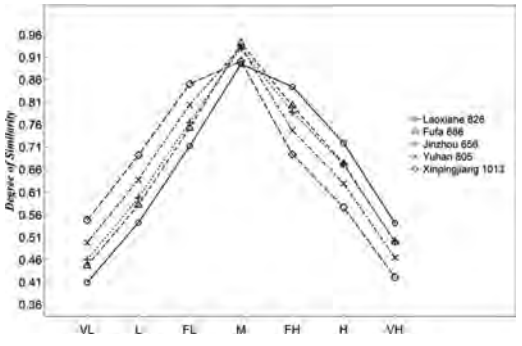

Figure 2. Results of similarity between aggregated experts' evaluation and 7 grades of navigational risk.

5 CONCLUSION

A novel method using IT2FSs for navigational risk analysis is presented in this paper. The main features of the proposed method are as follow: firstly, weights of risk factors are obtained using AHP; secondly, grades of the objective and factors are represented by IT2FSs; thirdly, degree of risk is determined by similarity measure.

Although the proposed model does not directly consider human factor, factors considered are evaluated only by 3-member linguistic terms for simplification, weights of criteria with respect to objective and weights of factor with respect to criteria are not constant but case by case, and the grades of risk are not absolutely equal to that happened in reality, 5 vessels as case study are used to illustrate the application of the proposed method.

In the future, we would specify measures to timely alleviate or effectively mitigate the identified risk, which is the third module of FSA.

Alternative life-loss rates for failures of large concrete and masonry dams in mountain regions of OECD countries

A. Kalinina, M. Spada & P. Burgherr
Laboratory for Energy Systems Analysis, Paul Scherrer Institute, Switzerland

ABSTRACT: High safety standards for dams in Switzerland require continuous assessment of their structural stability and effectiveness of warning system. Therefore, risk assessment needs to be performed for estimation of consequences, e.g. Life Loss (LL), in case of a dam accident. With the life-loss estimation methods available nowadays, e.g. the LIFESim system, physical processes within the specific dam-failure event can be simulated. This study demonstrated the importance of adjusting the LL rates in LIFESim to reflect study-specific characteristics of the dam type and failure mode. In particular, for application to Swiss dams, alternative LL rate distributions were built based on historical events of concrete and masonry dams in the mountain regions of OECD countries. The alternative LL rates distributions had different shapes and frequency ranges than those recommended in LIFESim. A simulation example of a hypothetical dam failure showed that the alternative and recommended LL rates lead to different LL estimates.

1 INTRODUCTION

Switzerland is the country with the highest density of dams in the world. Most of the dams were built to generate hydro-electricity (90% of all dams), but they also play an important role as flood control facilities. Swiss dams are constructed and operated under high safety standards. Historically no failures of Swiss dams have occurred; where a dam failure can be defined as a collapse or movement of part of a dam or its foundation leading to a disability of the dam to retain water (ICOLD, 2016). However, the ageing of many facilities and the increasingly stricter safety standards require that dam engineers and operators need to regularly assess and update potential risks associated with dams. An example is the assessment of consequences in terms of Life Loss (LL) due to a hypothetical dam failure. The results of such a risk assessment can help to justify, for example, costly facility upgrades or investments in the warning system required for risk mitigation.

To provide a transparent and quantifiable way to determine consequences, e.g. LL, associated with dam failures and subsequent floods, various methods and models are available nowadays.

1.1 *Methods for life-loss estimation*

Methods for LL estimation differ in complexity and modeling principles. Most of the approaches are purely empirical and LL estimates are based on regressions of Population At Risk (PAR) as a function of the whole downstream population and heterogeneous Warning time (Wt) (e.g. Lee et al., 1986; Brown and Graham, 1988). Another approach by Graham (1999) is more sophisticated and provides LL rates for a mix of subgroups of PAR based on Wt, flood severity, and warning effectiveness.

However, empirical approaches have limitations, which can be summarized as following (McClelland and Bowles, 2002). Firstly, empirical methods do not differentiate between characteristics of the dam failure (e.g. breach propagation or instantaneous failure) and flood severity, which might lead to the underestimation of the impact of the flood. Secondly, information on PAR, building structures, flow quantities, etc. represent averages and is not site specific. This strongly affects the LL results, because they depend on the gender and age distribution of PAR (Salvati et al., 2018). Thirdly, evacuation is not modelled and Wt is considered as a single value, which affects the number of people that are exposed to the flood and in turn the LL estimates.

To overcome these limitations in LL estimation, it is necessary to simulate physical processes and interactions, which cannot be achieved with empirical methods only. For this purpose, complex Geographical Information Systems (GIS)-based models have been developed in recent years allowing the dynamic simulation of flood consequences, including estimation of LL due to a dam failure. In contrast to empirical methods, these models estimate LL using modules with databases about evacuation, warning time, and loss of shelter to consider site-specific conditions. The most known

models are the Life Safety Model (LSM) (British Columbia, 2006) and the HEC-LifeSim model (USACE, 2017a). LSM is an agent-based model requiring detailed information for simulation, and thus it is more suitable for studies that model the behavior of the individual receptor (i.e. microscale simulation of the impact on a person or vehicle). In contrast, LIFESim scales up the simulation from the microscale to the mesoscale, i.e. simulation for the zone; therefore, it is more suitable for LL estimation for the specific area downstream of the dam.

1.2 *Study goals*

As discussed, the application of physically-based models in dam risk assessments could lead to better LL estimation. However, available models were developed by U.S. institutions that used LL rates empirically derived from historical data on flood events that mostly happened in the USA (see Section 2.2). The direct application of these LL rates to Switzerland would provide a potentially questionable approximation, since it has been shown that accident frequency and severity strongly depend on dam characteristics and location (Kalinina et al., 2017).

Therefore, this study aims to develop LL-rate distributions that can be considered representative for the topographical conditions and characteristics of dams in Switzerland. These LL rate distributions are used in modular LL estimation models to indicate proportion of life loss, P, for different flood zones and the corresponding relative frequency of exceeding this rate. To build these distributions historical failures of concrete and masonry dams in mountain regions of OECD countries were used, which can also be considered representative for Switzerland. Furthermore, the calculated LL rate distributions were used as input to the HEC-LIFESim model to simulate the LL resulting from an instantaneous dam failure. In this way it was possible to demonstrate the robustness of the physically-based model and the sensitivity of LIFESim simulation results to different LL rates. Therefore, this study provides quantitative insights on the recommendation of McClelland and Bowles (2002) that the historical observations underlying the method for LL estimation should be adjusted according to the type of event that is likely for a particular study setting.

2 METHOD

In this section, the spatial modular software HEC-LIFESim (USACE, 2017a) is introduced. Then, the motivation for developing alternative LL rates to be applied for failures of large concrete and masonry dams in mountain areas is explained and the methodology for constructing the alternative LL-rate distributions is given. Finally, a simulation example, that will be built to demonstrate the effect of different LL rates on LL estimates, is described.

2.1 *HEC-LIFESim software*

HEC-LIFESim (or LIFESim throughout this article) is a software developed by the Hydrologic Engineering Center (HEC) of the U.S. Army Corps of Engineers (USACE, 2017a). LIFESim is a spatial dynamic system for modeling life loss or economic consequences of a natural, dam or dike flood event. LIFESim is a modular system consisting of four modules built around databases. The modules exchange data through a geo-database with various information layers and tables, as shown in Figure 1.

Within LIFESim the aforementioned data can be combined with other GIS layers such as ESRI maps (ESRI, 2017), which allows for simulations that can represent real world conditions in a more realistic and accurate manner. In other words, LIFESim can overcome some of the limitations of the purely empirical approaches for modeling LL of a dam failure.

The four modules of the LIFESim system are represented as blocks in Figure 1: 1) flood routing module, 2) loss of shelter module, 3) warning and evacuation module, and 4) loss of life module. The flood routing module of LIFESim interfaces with an existing flood routing model (e.g. HEC-RAS 5.0.3 (USACE, 2017c)) and using hydraulic and

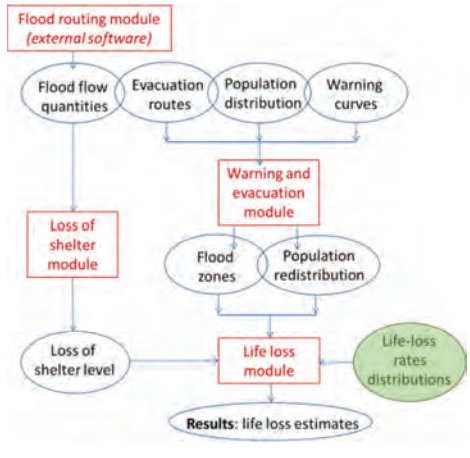

Figure 1. Simplified representation of the LIFESim approach for LL estimation (modified from Bowles, 2007).

timing editor it imports time series of flow quantities from hydraulic data source, e.g. depth time series at different points of the inundated area.

The loss-of-shelter module simulates the exposure of people in buildings during the flood event. For this, different flood zones are assigned to buildings and levels of buildings in the inundated area. In each flood zone, the physical flood environment is different, which is reflected in different historical rates of life loss. The three flood zones are defined by McClelland and Bowles (2000) by the interplay between available shelter and local flood depths and velocities, and can be summarized as follows:

- Chance zones in which flood victims are typically swept downstream or trapped underwater, and survival depends largely on chance;
- Compromised zones in which the available shelter has been severely damaged by the flood, increasing the exposure of flood victims to violent floodwaters.
- Safe zones are typically dry, exposed to relatively quiescent floodwaters, or exposed to shallow flooding unlikely to sweep people off their feet.

As input for the loss of shelter module, LIFESim utilizes the datasets of flow quantities in the simulation domain and the structure inventories obtained, for example, from HAZUS MH data (Federal Emergency Management Agency, 2003). Stability criteria for structures are set by default in LIFESim and can be changed for the specific study.

The warning and evacuation module simulates the spatial distribution of the population at risk from its initial distribution at the time when the warning is issued, to a new distribution with assigned flood zones when the flood arrives. For this module, the following information is required: GIS information on road layout, for example, from Highway Capacity Manual (TRB, 2000), information about population, for example, from HAZUS MH data (Federal Emergency Management Agency, 2003); evacuation destinations and emergency planning zones, which are location-specific and available as shape-files. Other evacuation parameters are set by default in LIFESim and can be changed for the specific study.

Finally, the loss-of-life module determines LL using the results of the aforementioned three modules. Based on the assigned flood zone categories (the loss-of-shelter module) and the value of PAR in this category (defined by the interplay between the flood map and the building inventory data), life-loss estimates are assessed using LL-rate distributions (McClelland and Bowles, 2002). For the simulations in this study, the recommended distributions were changed to alternative ones; this is indicated in Figure 1 in green and explained further in the text.

2.2 *LL rates distributions recommended in LIFESim*

For the estimation of LL, LIFESim recommends LL rates distributions developed by McClelland and Bowles (2002). To calculate the rates, the total PAR was determined and further divided into subgroups (subPAR), which help to customize the model to local conditions and to have homogeneous data for distinct areas. Three flood zones were then identified for each subPAR using the information about warning and flood severity. Finally, by estimating the ratio between the number of fatalities and the number of people in the particular flood zone of the particular subPAR, the P value was calculated for each case. Using the calculated P, the LL rates distributions were built for each flood zone (recommended distributions in Figure 3).

To construct the LL rates distributions, 38 unique flood events with 179 associated subPARs were used (Table 1). These events can be classified in three types: natural floods, floods due to a dam failure and floods due to a dike failure. Flood events due to a dam failure can be further classified in subgroups based on the dam type, among which the subgroup of floods resulting from failures of embankment dams is the largest. A similar prevalence of embankment dam failures was also found in datasets used to empirically estimate the dam-failure outflow in previous studies (Froehlich, 1995; Costa, 1985). In both cases, this can be explained by the fact that these dams commonly failed gradually; thus, data on characteristics (flow quantities, people) could be recorded. In contrast, instantaneous failures common for concrete dams give no chance to record detailed data, resulting in 8 events with 26 subPAR in Table 1.

Table 1. Flood events used by McClelland and Bowles (2002).

	Number of		
Type of event	Event	subPAR	Topography
Flood (river, flash, alluvial fan)	10	25	–
Dike	1	1	–
Dam:	27	153	–
– Embankment	16	121	–
– Buttress	1	1	mountain
– Gravity	2	8	mountain
	4	11	open/relatively flat area
– Arch	1	6	mountain
– Tailing	2	3	–
– Mill	1	3	–
Total	38	179	–

Furthermore, since the failure mode is different between embankment and concrete dams, it affects the nature of the floods and the subsequent impact on people. Thus, application of the LL rates derived on the data, which is highly dominated by embankment dam failures, can potentially bias LL estimates in studies of concrete and masonry dams (e.g. large dams in Switzerland). Therefore, the LL rates distributions need to be adjusted to reflect study-specific characteristics such as the dam type and failure mode.

2.3 *Alternative LL rates distributions*

To construct alternative LL rates distributions that are representative for large dams in Switzerland, a specific dam failure data set of large concrete and masonry dams in mountain regions of OECD countries was compiled. For this purpose, the historical experience contained in PSI's Energy-related Severe Accidents Database (ENSAD) was searched for relevant events.

The ENSAD database was developed at the Paul Scherrer Institute (PSI) in the 1990s (Hirschberg et al., 1998). Its goal is to enhance the comparative evaluation of different energy systems covering human health, environmental and economic impacts. ENSAD covers a broad range of full energy chains and continuous data collection ensures up-to-date information. Data from ENSAD are used for comparative risk assessment of energy technologies, to detect weak points in the energy infrastructure, and ultimately to support decision-making processes concerning energy supply options. For a detailed overview on ENSAD and its applications see Burgherr and Hirschberg (2014) or Burgherr et al. (2017).

The ENSAD comprises a worldwide dataset of more than 1,000 historical dam accidents in the period 1798–2017, 70% of which were in OECD countries. Each accident record has a set of characteristics, which together provide an exhaustive description of the event. Categories for some characteristics, e.g. dam type, dimensions, are adopted from other databases (ICOLD, 1995), while for others they are created to meet specific needs of ENSAD.

For this study, the ENSAD hydropower dam section was queried for dam failures that meet the following criteria: dams made of concrete and masonry; dams located in mountain areas (to be representative for the Swiss topography); dams in OECD countries (to ensure similar levels of safety as in Switzerland, see Hirschberg et al. (1998)). Consequently, calculated LL rates based on dam failure data fulfilling the above criteria can be considered a reasonable approximation for Switzerland.

For each dam failure, data about the total number of fatalities (i.e. life loss) and the population in the downstream area were searched. The latter is indicated in ENSAD only as the name of the town nearest to the dam. However, for this study, relatively homogeneous areas, subPAR, had to be defined, i.e. the total PAR had to be subdivided in areas that are different in terms of the flood severity, warning time, or flood severity understanding. Therefore, additional information on downstream population was collected from local reports, interviews, newspapers, etc. to be able to define homogenous subPAR. For example, for the Gleno dam failure, a total of 356–500 fatalities were reported by different sources; however, the total number of people affected, and the number of fatalities was certainly known only for the Bueggio Village. The availability of the information for this village defined the decision to treat this village as one homogeneous subPAR. Finally, the life-loss rate, P, was determined as the ration of LL to the population in the subPAR. For some subPAR, P was defined based on key words. For example, if the town was "washed out", than P of 0.99 was assumed with the confidence interval between 0.9 (people can survive even in a washout of the support surface) and 1 (resulted substantial destruction can lead to the complete population loss).

Furthermore, for each subPAR, the flood zone was defined based on warning time and flood severity. For this study, only one flood zone was assigned to each subPAR.

2.4 *Simulation example*

The simulation example was created to show that different LL rates defined in the model lead to different LL estimates. Therefore, to demonstrate the relevance of using LL rates that reflect dam and failure characteristic specifics for the study, e.g. studies for Swiss dams.

For the simulation, the failure of a hypothetical dam was assumed. The simulation example was built using the well-documented example project provided for the LIFESim program (USACE, 2017b). This project is not fully representative for the Swiss-dam study; however, certain data reflect the Swiss conditions. In particular, the dam-failure outflow hydrograph can be considered representative, since it reflects the instantaneous failure mode common for failures of concrete and masonry dams. For the instantaneous failure, no advance warning was initiated, i.e. dam failure warning was not issued prior to the dam failure. The area downstream of the dam is flat and open (see Figure 2), which corresponds to a hypothetical town at the end of a Swiss valley. Data for the structural inventories, emergency planning zones, road networks

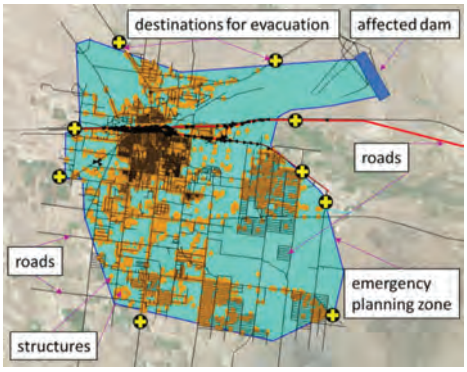

Figure 2. A map of the area flooded in the dam-failure event and symbols used for components of the LIFESim simulation (modified from USACE, 2017b).

and evacuation destinations were provided in the example project and originally taken from the sources mentioned in Section 2.1. The data for flow quantities were simulated in the HEC-RAS program (USACE, 2017d) and provided by USACE (2017b) as two-dimensional map.

Three simulations were created for this study. The first simulation corresponds to the application of the recommended LL rates by McClelland and Bowles (2002) (Section 2.2). The second simulation was run with the same model set-up except that the alternative LL rates were used (Section 2.3). For the third simulation, all downstream subPAR was assumed as a chance zone. This assumption was based on the methodology for determining PAR by the Swiss Federal Office of Energy (2017), whose procedure is based on PAR comprising the entire area affected by a dam-failure flood wave of at least 2 m height and intensity of at least 2 m2/s in a period of 2 h after a complete failure. Furthermore, this assumption was supported by McClelland and Bowles (2002) suggesting that when the buildings are about 6 meters high (i.e. one or two-story dwellings that are common for Swiss towns), then the entire PAR (alternatively, subPAR) is considered as a chance zone.

For all three simulations the simulation were done for several times of the day, namely at 12 p.m. (midnight), 6 a.m., 12 a.m. (noon), 6 p.m., and using 100 model runs for each combination to ensure convergence of results.

3 RESULTS

3.1 *Alternative LL rates distributions*

For the LL rates analysis, a dataset of 14 failures of concrete and masonry dams (buttress, gravity, and arch) located in mountain regions of OECD countries was established (Table 2). Four events from Table 1 were also considered, namely the Zerbino, St. Francis, Vajont, and Vega de Terra dams.

In the established dataset, dam name, country, and the year of the accident are given. The fatalities are indicated as the total number of fatalities resulting from the dam failure and as the number of fatalities in the defined subPAR downstream of the dam. The population at risk is also given as the total number for the entire downstream area and as the number of people for the defined subPAR. All information sources are given in Table 2. Finally, the flood zones were assigned to the calculated P values using information about warning time and flood severity (Table 2). Assigned flood zones are specified for each subPAR as letter indices (Table 2).

For each flood zone, the alternative LL rates distribution was constructed using the corresponding calculated P values (Figure 3). In addition, the confidence intervals were calculated for both alternative distributions using all the P values calculated based on different numbers of fatalities and people at risk found in the literature. Due to the lack of data for the safe zone among the failures in the new dataset, no fatalities were assumed in the safe zone.

For the alternative distribution of the chance zone, the range of P values is similar to the recommended P, i.e. between 1 and 0.4, with values of the alternative distribution potentially reaching 0.28 within its confidence interval (Figure 3). The recommended curve was built on a dataset with more realizations of high P with respect to the alternative distribution proposed in this study. This is shown for high P values (e.g. 0.8), which have a 0.9 and 0.7 frequency of exceedance for the recommended and alternative distributions, respectively. Furthermore, by considering the confidence intervals built for the alternative curve, the variability of possible P values is large for some P due to the limited data; thus, for the alternative distributions of the chance zone high P values can also increase to a frequency of 0.8.

For the compromised zone, the range for the alternative LL rates is smaller than for the recommended rates and the highest P does not exceed 0.13. However, taking into account the confidence intervals, realizations of 0.5 for P are also possible, which goes in line with the rates provided by McClelland and Bowles (2002).

3.2 *Simulation results*

Results for all three simulations are presented in Figure 4 and expressed in life loss as percentage of PAR (alternatively subPAR). The results are summarized using box plots showing the median

Table 2. Extended dataset for failures of concrete and masonry dams located in mountain regions of OECD countries.

N	Year	Dam name (country) & subPAR name	Fatalities in subPAR	Population in subPAR	Proportion of Life Loss, P	Warning	Flood Severity

of the modeled distributions and the bottom and top edges of the box indicating the 25th and 75th percentiles, respectively. The whiskers extend to the maximum and minimum of the data not considering outliers, and the outliers (i.e. points distant by twice or three times the standard deviation (Ruan et al., 2005)) are plotted individually.

For simulations 2 and 3, the results were calculated using the alternative distributions shown in Figure 3 (solid lines). The confidence intervals of these distributions could not be taken into account due to specifics of the software settings.

The relative patterns of the results between different times of the day are similar across all three simulations. In particular, the highest values of P were calculated at 12 p.m. and the lowest at 12 a.m. For the former, this could be explained by the fact that most people are asleep and not aware

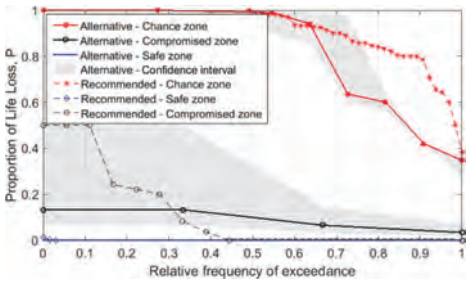

Figure 3. Historical LL rates distributions developed by McClelland and Bowles (2002) and LL rates distributions developed specifically for concrete & masonry dams in mountain regions of OECD countries with the confidence intervals (minimal and maximal values).

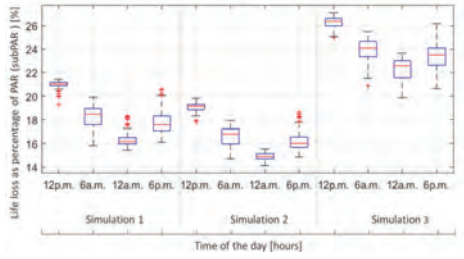

Figure 4. Simulation results for Life Loss as percentage of PAR: Simulation 1) using recommended life-loss rates by McClelland and Bowles (2002); Simulation 2) life-loss rates developed for dams in mountain areas; Simulation 3) test case with merged chance and compromised zone and safe zone without LL.

of a possible warning. On the other hand, at 12 a.m. most people are awake and at their duties; they can react faster to possible warning. The uncertainty range is higher for 6 a.m. and 6 p.m. results, because potentially at that time of the day people are traveling from home or back home; and it is quite uncertain how many people in traffic are exposed to the flood.

Comparing results between the first two simulations, the P values calculated in the second simulation are in general 10% lower than those calculated in the first simulation. This is due to the fact that, in the chance zone, the same P values have lower probabilities in the alternative distribution than in the recommended one, and in the compromised zone, the possible range of P values is in general lower (see Figure 3). The median values of P in the second simulation are shifted to lower values of the results range (i.e. distributions are left skewed) with respect to the first simulation. This can be explained by the fact that more severe P values in the chance and compromised zones in Figure 3 have lower frequency of exceedance (e.g. for a frequency of exceedance of 0.68, P is equal to 0.8 and 0.9 in the chance zone for the alternative and recommended distributions, respectively). On the other hand, probabilities for lower values of P (i.e. closer to 0.4) do not differentiate to such a high extent.

Furthermore, uncertainty in the results of the second simulation is generally lower than in the first simulation, unless in the case of the simulation at 12 p.m. Generally lower uncertainty ranges can be explained by the fact that the alternative distributions are flatter (especially the one of the compromised zone); then, sampling from the P values in the alternative distribution could potentially result in the sample with smaller range of P values.

Finally, comparing the results of the third simulation, it can be concluded that in general the defined P values are the highest among all simulations. Furthermore, uncertainty of the calculated values is significantly higher than in the results of the first two simulations. Moreover, the results show larger left skewness with respect to the other simulations results, because compromised zones became now chance zones and for all ranges of probabilities LL rates were higher. Thus, neglecting existence of compromised zones with their higher potential of people to survive, leads to potential overestimation of the overall life loss.

In general, lower rates for life losses reflected in the alternative distributions and results of the simulations are supported by the following circumstances. On the one hand, the alternative dataset of concrete and masonry dams is built exclusively for OECD countries, whereas the recommended LL rates include also events in non-OECD countries (e.g., China). Generally, higher population density downstream of non-OECD dams and differences in safety culture and awareness of people living downstream of non-OECD dams, could potentially result in higher life loss. On the other hand, mountain topography could leave higher survival chances for people located on higher altitudes in the downstream area. In contrast, in embankment dam failures, a flat area is commonly affected downstream of the dam; which makes the available shelter to be very remote.

4 CONCLUSIONS

To maintain or further improve the high safety levels of dams in Switzerland it is important to evaluate the performance of existing or planned risk mitigation measures at dams, and to estimate potential LL consequences of selected dam failure scenarios.

Generally, the LL estimation in dam risk assessment is a complex process, depending on many

parameters and circumstances. Available dynamic modular systems for LL estimation (e.g. LIFESim) can overcome known limitations of the purely empirical methods, because they allow modeling of physical processes within the dam-failure event, e.g. evacuation, population distribution. These models can also go beyond LL estimates and, for example, define times of the day with the highest risk for PAR, as it was demonstrated in the current study.

Furthermore, this study demonstrated the importance of adjusting the LL rates distributions to reflect study-specific characteristics such as the dam type, failure mode, etc. The LL rates derived from historical failures of concrete and masonry dams in mountain regions of OECD countries had different shapes and frequency ranges than the generic ones in LIFESim. The LL estimates calculated using the recommended and alternative LL rates gave different LL estimates in the simulation example of the hypothetical dam failure carried out in this study.

In summary, the importance of defining study-specific alternative LL rates distributions for dam risk assessment was demonstrated. Potential future extensions rely on the reduction of the width of the confidence intervals for the alternative LL-rate distributions considered representative for large concrete dams in Switzerland. To reduce the rather large uncertainty ranges, continuous update of information is suggested. In particular, more dam accidents need to be included and better information on subPAR, flood severity and warning availability to be provided for the events in the existing list of historical failures of concrete and masonry dams. Finally, the concept will be improved and implemented in more details to a real case study reflecting Swiss conditions.

ACKNOWLEDGMENT

This research project is part of the National Research Programme "Energy Turnaround" (NRP 70) of the Swiss National Science Foundation (SNSF). Further information on the National Research Programme can be found at www.nrp70.ch. It is also integrated within the activities of the Swiss Competence Center on Energy Research—Supply of Electricity (SCCER SoE). The authors express their sincere thanks to Dr. Christopher Robinson, who provided valuable feedback to this work.

An experimental assessment of the MCS BDD algorithm in RiskSpectrum

O. Bäckström, R. Gamble, P. Krcal & W. Wang
Lloyd's Register, Stockholm, Sweden

ABSTRACT: The fault tree linking method for building Probabilistic Safety Assessment (PSA) models of nuclear power plants models accident sequences—combinations of safety system failures following an initiating event—by relatively small event trees. Failures of individual safety systems are modelled by fault trees. Such a model allows us to analyze selected accident scenarios or scenarios leading to a specific consequence. The analysis algorithm implemented in RiskSpectrum decomposes function events which fail along a sequence into minimal cutsets and (optionally) summarizes successful function events in an aggregate event, a so called *success module*. First order algorithms for quantification of a list of such minimal cutsets yield an approximate result. The new MCS BDD algorithm implemented in RiskSpectrum aims at improving this approximation. When computing resources suffice, it has the capability to quantify the minimal cutset list exactly. We evaluate the performance of this algorithm on real life models.

1 INTRODUCTION

A Binary Decision Diagram (BDD) is a data structure for encoding Boolean functions (Bryant 1986). It has been applied to fault tree analysis by Rauzy (1993) and Coudert & Madre (1993). Since then, it has been successfully used in many domains for a complete solution of fault trees (Rauzy 2006). However, the size of event/fault tree models emerging from Probabilistic Safety Assessment of nuclear power plants is prohibitive for an exact analysis by the means of BDDs.

The current standard practice for solving large fault tree models from the nuclear Probabilistic Safety Assessment is to decompose the tree structure into a list of Minimal c utsets (MCS). Further, first order algorithms, such as rare event approximation or Min Cut Upper Bound (MCUB), are used to quantify this minimal cutset list.

The MCS BDD algorithm implemented in RiskSpectrum presents a new method of minimal cutset list quantification. A key to its efficiency and accuracy is a heuristic procedure which assigns certain nodes for the exact treatment and certain nodes for a treatment similar to a ZBDD (Minato 1993, Jung et al. 2004). This provides us with an improved quantification for minimal cutset lists with high probability events and with a small set of high importance events. Also, it allows for event tree success quantification dependent on the failed events. In the optimal case, if the complete success information is generated, the algorithm has the capability to quantify success exactly.

In this paper, we evaluate the current implementation of the MCS BDD algorithm on real life models. The focus of the assessment lies in the following aspects:

Improved accuracy—for which types of analyses do we obtain a considerable decrease in conservatism of the results?

Success quantification—we demonstrate the capability of the algorithm to quantitatively assess the event tree success. We also discuss sensitivity of the algorithm to various model parameters.

Importance factors—we study effects of the new quantification method on the Risk Increase Factor. To what extent is this importance factor affected and where is the biggest gain?

Efficiency—the algorithm allows for user control of the trade-off between the result accuracy and the calculation resources. We investigate the effect of different settings on the calculation time and the MCS list value. Especially, we ask when one can rely on the built-in automatic parameter adjustments and in which situations one needs to steer the algorithm by fine-tuning the parameters manually.

2 BACKGROUND

A Binary Decision Diagram is a rooted binary directed acyclic graph with nodes labeled by decision variables and leaves representing one of the two values: True or False. The MCS BDD algorithm applies pivotal decomposition to the MCS

list in order to build a BDD. It selects a basic event from the MCS list as the node decision variable and builds its child BDDs from smaller MCS lists with possibly smaller cutsets. A leaf is built when the MCS list to be processed is empty or it contains an empty cutset. Figure 1 schematically depicts one step in BDD building.

One of the approximations in the analysis of large fault trees by the minimal cutset decomposition is the quantification of the resulting minimal cutset list. MCS BDD is an algorithm that has the potential to quantify the MCS list exactly. This would, however, lead to inacceptable calculation times (and possibly exceed computer memory capacities) for large real-life models like those from nuclear PSA. A complete BDD quantification of a MCS list with success modules can unfortunately be achieved only for very small cases. Therefore, we need to trade absolute accuracy for reasonable calculation times.

The MCS BDD algorithm adopts a highly pragmatic approach. It searches for events where a precise BDD quantification has the greatest effect and treats other events in an approximate way. First, we describe the most important heuristics in the MCS BDD algorithm and then we motivate them by describing types of models where this brings the greatest advantage.

For presentation purposes, we have the following assumptions on MCS lists (for the full description of the algorithm see Bäckström et al. (2014), Bäckström et al. (2016). We assume that an input MCS list contains independent basic events and possibly also success modules. A success module is a summary characterization of function events which succeed along an event tree sequence. Technically, it is also a MCS list containing cutsets which fail one of these function events. A success module is then interpreted as 'negated' in cutsets. For a more detailed description of success modules, see RiskSpectrum (2013). Cutsets are grouped according to the initiator (a frequency basic event) and a success module and then treated separately. This means that we can without loss of generality assume that there is only one initiator and only one success module in the MCS list.

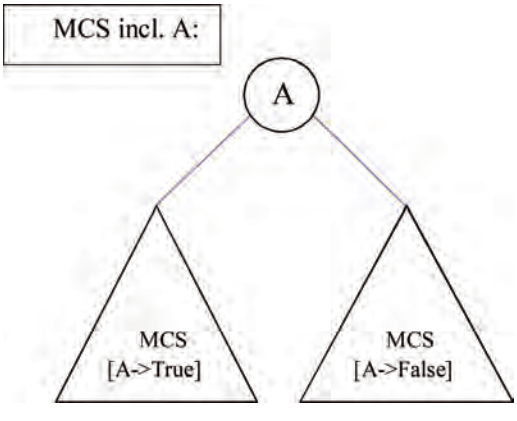

Figure 1. The minimal cutset list with cutsets containing the basic event A is decomposed into two smaller MCS lists which are then processed recursively.

2.1 *Main ingredients in MCS BDD*

The algorithm first defines the MCS list which shall be transformed into a BDD. Then, it builds the BDD. Finally, it computes the probability/frequency of the MCS list from the BDD. In the following we detail the most important parts of the process and by this also explain the main heuristic ingredients:

- Selection of the most important cutsets
- Exact and approximate nodes
- Success module quantification

2.1.1 *Selection of important cutsets*

The greatest contribution to the MCS list probability/frequency typically comes from a small portion of the minimal cutsets. The first heuristics splits the MCS list into two parts, based on the cutset values. The part which represents almost the complete MCS list value is treated by the MCS BDD algorithm. The remaining part is quantified by the Min Cut Upper Bound algorithm.

This heuristics works as a variant of a probabilistic cutoff, but its effect is purely conservative. The greater the part that is treated by the MCUB, the greater the over-approximation of the MCS list value is and also the easier is it to build the BDD.

2.1.2 *Exact and approximate nodes*

The algorithm produces BDD nodes and recursively creates their inputs from smaller MCS lists. Each node that is added is either included as an exact or approximate node. The process of determining the node type (exact or approximate) is equally important as the selection of pivotal element in the RiskSpectrum implementation.

The exact method directly follows from Shannon non-intersect decomposition. We split the MCS list (which is a probabilistic Boolean function) by a pivot basic event A (a decision variable in the formula) into two parts:

- Cutsets which are consistent with A. We remove A from these cutsets, if it is there. This corresponds to evaluating the Boolean formula with A = True.
- Cutsets which are consistent with ¬A. This removes all cutsets containing A. This corre-

sponds to evaluating the Boolean formula with A = False.

Formula 1 shows how to calculate the probability of a Boolean function, where A is one of the decision variables.

$$P(f) = P(A) \cdot P(f[A]) + P(\neg A) \cdot P(f[\neg A]) \quad (1)$$

By f[A], f[¬A] we denote the Boolean function f where A = True, A = False, respectively.

The approximate treatment splits the MCS list by a pivot basic event A into two parts:

- Cutsets which contain A. We remove A from all of these cutsets.
- Cutsets which do not contain A.

This is following the same principle as ZBDD quantification. The usual quantification yields the same result as the rare event approximation—a direct sum of the cutset probabilities. The algorithm implemented in RiskSpectrum makes use of the independence assumption of basic events. It uses the Min Cut Upper Bound approximation on independent or positively correlated cutsets. The quantification in the approximate method is performed according to Formula 2.

$$P(f) = P(A) \cdot (P(f_A) + P(f_{\neg A}) - P(f_A) \cdot P(f_{\neg A})) + (1 - P(A)) \cdot P(f_{\neg A}) \quad (2)$$

By f_A and $f_{\neg A}$ we denote cutsets that contain A and that do not contain A, respectively. Moreover, the event A is removed from cutsets in f_A. This formula quantifies both parts in the same recursive way and then it removes product of their probabilities. Note that this way of calculating the MCS list probability gives a lower value than the MCUB approximation on the whole MCS list (and by this also a lower value than the rare event approximation). Even if the whole MCS BDD was built just from approximate nodes, the result would be more precise than the MCUB quantification.

There are conditions that have to be satisfied to guarantee that the approximate method does not yield an under-approximation of the exact value. A pivot basic event A cannot be treated by the approximate method if f_A and $f_{\neg A}$ are negatively correlated due to the fact that the same event occurs in f (non-negated) and at the same time it appears in a success module.

This has shown to be a significant drawback of the approximate method, as it either adds a restriction on using approximate nodes or it limits the exact quantification of success modules.

Exact nodes and approximate nodes can be mixed. Approximate nodes make the analysis very efficient, exact nodes give a better result and allow for more precise success quantification. The MCS BDD algorithm has to balance these desirable properties. It searches for the best candidates for the exact treatment and treats the remaining basic events approximately.

2.1.3 *Success module quantification*

Success modules are quantified by the same technique. We build an MCS BDD for the success module and append it to the MCS BDD for the minimal cutset list. The success module BDD uses only exact nodes. Therefore, we can quantify its (independent) value exactly.

Disregarding dependencies between the cutsets and the success module contributes to the conservatism of the result. If we want to reduce this conservatism, we need to take these dependencies into account. However, this limits the possibilities of applying the efficient approximate treatment of nodes in the whole BDD. Therefore, we select only the most important events in the success module and disregard dependencies for the remaining ones.

2.2 *MCS BDD parameters*

Users have a possibility to steer the search for events to be treated exactly/approximately as it affects the calculation speed and the accuracy of the result. This can be done by setting algorithm parameters manually before building the BDD. The algorithm has the capability of an automatic adjustment of these parameters. This allows users to use default values for most (if not all) analysis cases in their models. The following parameters can be specified by a user:

- *MCS limit* ranges from 0 to 1 and expresses the percentage of the MCS list value above which cutsets are treated by MCS BDD.
- *Q limit* and *FV limit* parameters are used to determine the node treatment method—exact or approximate and the treatment of dependencies between events in the success module and the failure part. These parameters range from 0 (only exact) to 1 (only approximate).
- *BDD nodes limit* bounds the number of nodes that a BDD can use and by this it limits the complexity of the BDD generation.

If the algorithm cannot succeed in building a BDD with the given combination of parameters then it automatically adjusts the parameters MCS limit, Q limit and FV limit and attempts generating a BDD again. This is repeated until the algorithm successfully returns a BDD structure.

2.3 *Purpose of MCS BDD*

MCS list quantification by the new algorithm improves the accuracy of the MCS list value. Situ-

ations in which first order approximations suffer from a significant over-approximation are:

- Events with high probabilities
- Success quantification

The goal of the experimental evaluation is to assess to what extent the implementation fulfils its purpose. Additionally, we evaluate the possibilities that the algorithm parameters give users in steering the quantification.

3 EVENT TREE QUANTIFICATION

Quantification of event tree success necessarily requires handling of non-coherent fault trees (Nusbaumer & Rauzy 2013, Bäckström et al. 2012). Function event success brings negated 'events' into minimal cutsets. RiskSpectrum summarizes successful function events by a new type of event—a success module, which is simply a minimal cutset list containing basic event combinations which cannot occur in quantified sequences. Moreover, not-logic in fault trees might introduce negated basic events into minimal cutsets.

We have performed two types of assessment. The first one compares the sequence or consequence value calculated by the MCS BDD algorithm to the value computed by the Min Cut Upper Bound algorithm. By this, we analyze the accuracy increase obtained from the new algorithm. We investigate cases with significant differences closer in order to identify factors driving the accuracy increase. Large real-life models are used.

The second type of assessment compares quantification of sequences and consequences with success modules to reference values calculated by an analysis of structures which contain only function event failures (Nusbaumer & Rauzy 2013). Models with newly built event trees based on industrial PSA models are used.

3.1 *Comparison to min cut upper Bound*

We have evaluated the accuracy of MCS BDD on 15 real-life models. We split them into two categories—models which quantify event tree success (by means of success modules) and models which use event tree success only to remove basic event combinations which do not belong to the analyzed sequence. The latter group of models disregards the success probability both in the first order quantification algorithm as well as in the MCS BDD algorithm. We have analyzed individual sequences and also sequences grouped according to the accident consequence (consequence analysis cases).

3.1.1 *Analyses without ET success quantification*

First, we present results from the group of models which do not quantify Event Tree (ET) success. The results reflect only how efficiently the MCS BDD algorithm deals with dependencies between minimal cutsets. Table 1 shows decrease of the MCS list frequency from the value calculated by MCUB in percent of the new value calculated by MCS BDD. It lists the number of cases analyzed in the model, the maximal decrease, number of analysis cases with the decrease above 25%, number of analysis cases with the decrease above 10% and the minimal increase.

All of these results have been calculated with the default settings: the MCS limit has been set to 1E-3, Q limit and FV limit have been set to 1E-2. The vast majority of the MCS BDD results end up between the second and the third order approximation, which is an expected result. Exceptions rather indicate an improvement potential in the calculation of the second/third order approximation than in the MCS BDD algorithm.

Obtaining an increase of the MCS list value, even though very small, is unexpected. It could be traced to a less efficient quantification of modules in the MCS BDD algorithm and should be resolved in future versions. Most of the increases can be removed when we increase the MCS BDD accuracy by the algorithm settings.

Analysis cases with the greatest value decrease can be often identified by one property: they contain high probability events with high Fussel-Vesely importance.

3.1.2 *Analyses with ET success quantification*

As the next step, we present results from analyses where function event success in event trees is quantified by the means of success modules. Apart from dependencies between cutsets, the MCUB algorithm does not take into account dependencies between failed basic events in a cutset and basic events from the success module in this cutset.

Table 1. A summary of the MCS list value decrease with the MCS BDD algorithm compared to the MCUB algorithm. Event tree success is not quantified.

Test model	Number of cases	Max (%)	# > 25%	# > 10%	Min (%)
M-01	1200	28.8	1	15	–1.8
M-02	375	103	48	112	0
M-09	2700	89.8	160	320	0
M-10	24000	17.3	0	19	–0.83
M-11	640	309	223	323	–0.01
M-12	6000	42.9	318	712	–0.09
M-13	3400	40.8	47	188	–0.99

This might result in additional conservatism of the result.

Figure 2 illustrates this issue. Consider the second sequence. The function event "A AND B" succeeds and its corresponding success module contains the cutset {A, B} = SM. The second function event fails and produces the cutset {IE, A, SM}. The quantification method used in the MCUB algorithm calculates values of events and modules independently. The cutset value is then P(IE)*P(A)*(1-(P(A)*P(B)). This is an overly conservative quantification. We know that A has failed in this cutset. Therefore, the probability that the success module has not failed is only 1-P(B). This gives us the cutset value P(IE)*P(A)*(1-P(B)) which the MCS BDD algorithm returns (provided that the event A is considered as important by the algorithm heuristics). Moreover, the whole success module will be calculated by the means of MCS BDD.

Table 2 shows decrease of the MCS list frequency from the value calculated by MCUB in percent of the new value calculated by MCS BDD. It lists the number of cases analyzed in the model, the maximal decrease, number of analysis cases with the decrease above 25%, number of analysis cases with the decrease above 10% and the minimal increase.

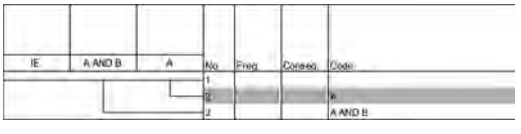

Figure 2. An event tree where the success quantification of the first function event depends on the second function event.

Table 2. A summary of the MCS list value decrease with the MCS BDD algorithm compared to the MCUB algorithm. Event tree success is quantified.

Test model	Number of cases	Max (%)	# > 25%	# > 10%	Min (%)
M-02	800	27.1	2	17	–65.6
M-03	3	–2.4	0	0	–21.4
M-04	4200	469.3	360	625	–3.4
M-05	4000	867	120	331	–2.3
M-06	7000	157	80	530	–0.7
M-07	9700	107.8	100	350	–3.0
M-08	660	0.48	0	0	–5.6
M-11	1100	1132	350	500	–64.4
M-14	3700	5.1	0	0	–0.01
M-15	2100	300.6	53	377	–22.7
M-16	910	72.1	2	27	–0.1

In some cases the MCUB results may be significantly lower than the value calculated by the MCS BDD algorithm. The cases where this has been found underestimate the success module value in the MCUB calculations. This is because the MCS list in the success module is itself quantified by MCUB which gives a conservative estimate of a cutset list. This means that we overestimate its value and then calculate its 'negation' (1-P(SM)). This in its turn means that the success module value becomes underestimated. Normally, the conservatism from the MCUB is rather limited and other approximations applied during success module creation have more significant effect. The extensive evaluation revealed cases where the difference is greater than 50% of the MCS list value. For these cases, we have investigated the success module and verified that the MCUB algorithm underestimates the success module. Note that RiskSpectrum offers a possibility to identify candidates for this effect using the second order quantification of success modules.

Mostly the MCS BDD yields a lower result—due to the increased accuracy and the treatment of dependencies between failed MCS and the success MCS. The lower results generated by the MCS BDD are mainly an effect of the treatment of dependencies between failed events and the success module. The MCS list value in some of the analysis cases decreased several times. This is typically the case when the success module contains one of the important events in the failed part of cutsets and this event occurs in combination with high probability events in the success module. This means that in all combinations where the event is failed the success module will have a very low probability.

The default settings (1E-3, 1E-2, 1E-2) seem appropriate also for analyses with quantified event tree success.

All results have been studied, and a few analysis cases per model have been reviewed to ensure that the differences in results can be explained, and that the MCS BDD produces a better estimate of the MCS list. We summarize comments on a selection of analysis cases.

Model 7 – Several sequences with MCS BDD results significantly lower than MCUB estimates have been studied in detail. The result is overestimated due to a number of high probability events. The results without success modules show the same behavior. Calculating the MCS list value up to the 6th order confirms this hypothesis.

Model 7 – two sequences yield a very low result (zero) with the MCS BDD and non-zero in MCUB. The reason is that the success module

contains an event which is a part of all cutsets in the failed part of the MCS list. This event is combined with another event in the success module which has probability one. Since the event is failed the success module probability will be zero and the value of all cutsets becomes zero as well.

Model 11 – Eight analyses with high differences were studied in detail. Four sequences with significantly different results contain many high probability events re-occurring in most important cutsets. This causes a very big overestimate from the MCUB algorithm. One analysis case has a difference in >1000% of the top value. We have shown by a reduced MCS list that the MCUB analysis indeed yields a very big overestimate in this case due to high probability events. Four analysis cases that have results more than 50% higher with the MCS BDD have big dependencies between failed basic events and basic events in the success module. Dependent quantification of success modules can take these dependencies into account and thus reduce the conservatism in the MCS list value.

3.2 *Comparison to exactly calculated ET success*

A collection of models with non-coherent structures have been set up for the assessment purpose. Most of them are based on real-life models. In each test model, the evaluated event tree has an initiating event (IE) and three function events (F1, F2, F3). Figure 3 depicts such an event tree.

Success of each function event contributes to the success module, which means that cutsets for all sequences but the last one (failure of all function events) contain success modules. Each function event takes a fault tree as input. Table 3 lists relevant features affecting the evaluated test cases for each model.

Results produced by the MCS BDD algorithm are compared to values obtained by the method which avoids function event success and quantifies only combinations of function event failures (Nusbaumer & Rauzy 2013). Function event failure combinations are also decomposed to MCS lists which are then quantified by the means of

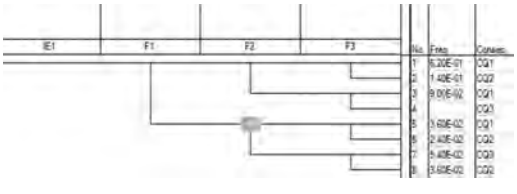

Figure 3. An example event tree used in assessment of non-coherent structure quantification.

EXACT1	0.0	0.0
EXACT2	1.1	0.1
EXACT3	62	1.0
EXACT4	0.0	0.0
EXACT5	0.0	0.0
EXACT6	1.0	0.3
EXACT7	0.1	0.0
EXACT8	125.1	0.0
EXACT9	2.0	0.1
EXACT10	0.1	0.1

MCS BDD. This allows us to assess accuracy of function event success quantification in MCS BDD. Table 4 contains the comparison of these two methods.

For the test model EXACT3, three sequences differ by 14%, 19% and 62%. This is due to the accuracy of success modules. It shall be noticed that the accuracy of the success module is possible to adjust, but this has not been done in this evaluation (only when results are investigated). Sequences with low frequency in the model EXACT4 get a lower value than the reference value. This is due to cutoff application during MCS generation. The value gets slightly above the reference with a lower cutoff. One low frequency sequence in the model EXACT7 is below the reference value. This is the same cutoff issue.

In the model EXACT8, two low probability sequences differ by 99% and 125%. This is due to

success module accuracy. Increasing the success module accuracy gives differences 0.7% and 2.7%, respectively. The model EXACT10 contains four sequences with values below the reference value by 0.1%. One consequence is below the reference value by 0.1%. This is a cutoff issue during generation of minimal cutsets

Parameters used to generate the MCS BDD were set to zero for small models (EXACT1, EXACT2), ensuring exact treatment of all nodes. For other models, the MCS limit has been set to 1E-5, Q limit and FV limit have been set to 1E-3.

4 IMPORTANCE—RISK INCREASE FACTOR

The new quantification procedure does not only affect MCS list values, but also other measures such as importance factors. One of these measures most affected by inaccuracies not handled by the first order calculation is the Risk Increase Factor (RIF), also called Risk Achievement Worth (RAW).

A RIF of a component is defined as the factor of power plant risk increase when the component is unavailable (Vesely et al. 1983). Whenever any failure mode of this component occurs in a fault tree, it needs to be considered as failed (Bäckström et al. 2016). The method implemented in RiskSpectrum (RiskSpectrum 2016) calculates RIF for an object by setting the failure probability of all events in this object to one, recalculating the MCS list of the analysis case and dividing the obtained value by the nominal MCS list value.

We have evaluated RIF calculations with the MCS BDD algorithm on three models (a sample model and two real-life models). For selected basic events and event groups, we have calculated the RIF value by re-running the analysis with the analyzed basic events marked as failed in the model.

The results for basic events are summarized in Table 5. We report the maximal decrease of RIF in percent of the new RIF value (Max) and the minimal increase of RIF in percent of the new RIF value (Min).

Table 5. A summary of risk increase factor values for basic events in three evaluation models. Two models have been analyzed with and without event tree success quantification.

Test model	Number of basic events	Max (%)	# > 10%	# < 0%	Min (%)
S	126	3.0	0	2	–0.2
S(Succ)	126	3.3	0	4	–1.3
R1	320	12	37	66	–4.8
R1(Succ)	320	12	37	52	–4.8
R2	470	19	2	93	–1.9

The changes in RIF values are rather moderate. The decrease of RIF values for many basic events is relatively surprising. This decrease is small, less than 5% in all cases. The explanation of this phenomenon lies in the increased accuracy also when calculating the nominal MCS list value—the value of the MCS list generated by the original analysis.

Table 6 contains manually calculated RIF values for sample basic events from the model S and R1. It shows the RIF value calculated by the MCUB quantification, by the MCS BDD algorithm and manually with newly generated results, quantified by MCS BDD.

One can see that the MCS BDD quantification improves RIF values in the sense that it brings them closer to the actual RIF. This is even the case if the RIF value increases for a basic event, exemplified by the basic event BE-01896.

Apart from individual basic events, RiskSpectrum analyzes RIF also for groups of basic events (which could be defined in multiple ways as components, according to attributes, or directly as groups of basic events). Table 7 shows differences in RIF

Table 6. RIF values for sample basic events calculated by the MCUB quantification, MCS BDD and a manual calculation with a newly generated MCS list.

values for groups of basic events when calculated by the MCUB algorithm, MCS BDD or manually.

The evaluation of the RIF values calculated by the MCS BDD algorithm shows that it can achieve lower (more exact) values for groups of basic events, in some cases one order of magnitude. For smaller and simpler models, it achieves the values one gets from a calculation re-generating the MCS list without the event(s) under study.

5 MCS BDD SETTINGS

The heuristics balancing scalability and accuracy of the MCS BDD algorithm can be steered by the following settings:

MCS limit—specifying the part of the MCS list which should be converted into a BDD, while the rest of the MCS list is quantified by the MCUB algorithm.

Q limit—specifying from which probability are events treated exactly when building the BDD.

FV limit—specifying from which importance are events treated exactly when building the BDD.

Node limit—absolute bound on the number of BDD nodes. If more nodes are needed, the algorithm increases other limits and restarts.

Exact usage of these limits is described in RiskSpectrum (2016). In general, the lower the MCS, Q and FV limits are, the bigger and more precise the generated BDD is, within the size defined by the Node limit. At the same time, we can expect longer generation times for larger and more precise BDDs.

Table 8. Differences in calculation times and MCS list values with varying calculation settings.

Settings	M-02 Time (s) /avg. diff. to default (%) /Max or min diff. to default (%)	M-10 Time (s) /avg. diff. to default (%) /Max or min diff. to default (%)	M-05 Time (s) /avg. diff. to default (%) /Max or min diff. to default (%)
Default	0:21 / N/A	1:19 / N/A	1:55 / N/A
1E-1, 1E-2, 1E-2	0:09 / 2.2 / 42.4	0:28 / 0.5 / 11.1	0:45 / 0.6 / 79.9
1E-5, 1E-2, 1E-2	0:46 / 7E-3 / –3.2	4:04 / 0.0 / –1.7	1:48 / 0.0 / –0.9
1E-3, **1E-1**, 1E-2	0:12 / 0.02 / 0.4	0:30 / 0.0 / 1.9	2:44 / 0.05 / 3.4
1E-3, **1E-4**, 1E-2	0:56 /–0.02 / –5.7	7:43 / 0.0 / –1.2	9:40 /–0.02 / –3.9
1E-3, 1E-2, **1E-1**	0:09 / 0.02 / 0.4	0:32 / 0.0 / 1.9	2:47 / 0.2 / 59.1
1E-3, 1E-2, **1E-4**	0:26 /–0.05 / –5.7	7:17 / 0.0 / –1.2	9:37 /–0.03 / –12.4
1E-3, **0, 0**	5:26 / 3E-3 / –5.8	N/A	N/A

Table 8 shows the MCS list values and BDD generation times with different settings. Default settings are 1E-3, 1E-2, 1E-2 for the MCS limit, Q limit and FV limit, respectively. We always write setting values in this order.

The evaluation shows surprisingly small differences in the resulting MCS list values. This can be explained by the automatic parameter adjustment and it confirms the choice of default setting values. Adjusting the settings manually makes sense in individual analyses when one suspects that the accuracy could be substantially increased by a larger BDD. In this case, one needs to accept longer calculation times, as it might require adjustment of the Node limit setting.

6 CONCLUSIONS

Experimental assessment of the MCS BDD algorithm implemented in RiskSpectrum leads to the following conclusions.

Heuristics used in the quantification algorithm have proven to be very efficient. It is possible to derive results with relatively high accuracy. The frequency estimate of a minimal cutset list might be several times smaller for cases where first order approximations give overly conservative results. This is the case in presence of high probability events which occur multiple times in cutsets with a high contribution.

More importantly, the MCS BDD algorithm allows for very accurate quantification of event tree success, both for individual sequences and (even more) for groups of sequences defined by a consequence to which they lead. Limitations in accuracy of several cases reported in this paper stem from the bounds on the success module accuracy with default settings. Improving the success quantification by lifting these bounds will be investigated in future work.

The new quantification also improves estimates of importance factors. We have evaluated the effect on the Risk Increase Factor, where especially the values for basic event groups might improve dramatically, in some cases by an order of magnitude.

Finally, the combination of default setting values and the automatic setting adjustment result in acceptable calculations times in commercial applications.

J.L. Barros, P.P. Santos & J.M. Mendes
Center for Social Studies, University of Coimbra, Portugal

ABSTRACT: The concept of Social Vulnerability (SV) is characterized by its multidimensionality. In the present study, Social Vulnerability was analyzed and evaluated according to the methodology developed by the Center for Social Studies of the University of Coimbra, which presents as innovative feature the incorporation of the Criticality and Support Capability components. Social Vulnerability was calculated for the 278 municipalities of mainland Portugal using factor analysis. The evaluation and calculation of the Criticality was carried out using 22 variables, selected from an initial number of 90, and the calculation of Support Capability was performed using 12 variables, from an initial number of 145 variables. The obtained outputs should be a working basis for the managers and stakeholders, authorities at different levels, and all the community with the objective of adopting adaptation and mitigation measures to natural and technological risks.

1 INTRODUCTION

The concept of Social Vulnerability (SV) is characterized by its multidimensionality, adding not only the social characteristics of the individual, but also their social and economic relations, as well as the physical and social environment where the individual is inserted (Tapsell et al., 2010). The differentiating characteristics of SV make it imperative not only in the characterization and understanding of the degree of exposure of the communities, but also in their capacity for resisting and recovering in face of hazardous events.

Historically, the concept of Social Vulnerability has emerged as an explicit critique of the dominant and conventional paradigms of analysis of disasters, with Hewitt (1983). The Sendai Framework for Disaster Risk Reduction resumes the concept of vulnerability as the conditions determined by the physical, social, economic and environmental factors or processes that increase the susceptibility of a community to the impact of hazards (UNISDR, 2015). Thus, the scientific community as recognized the need of considering social vulnerability as a particular dimension of vulnerability, developing distinct approaches for its measurement (e.g., Angeon and Bates, 2015; Rufat et al., 2015; Fatemi et al., 2017).

As noted by Wisner et al. (2004) the vulnerability to hazards is a multidimensional process that consists in a multiplicity of components related with historical, political, economic, environmental and demographic factors, which produce inequalities, dynamic pressures such as rapid urbanization and social pressures and unsafe living conditions that originates unequal exposure to risk.

There are multiple and distinct methods of measuring vulnerability (Birkmann, 2006; Fuchs et al., 2012; Birkmann, 2013; Birkmann et al., 2013;). In the present work, Social Vulnerability to natural and technological risks was analyzed and evaluated according to the methodology developed by the Center for Social Studies of the University of Coimbra (CES) and its Risk Observatory (OSIRIS) (Mendes et al., 2011). According to Mendes et al. (2011) the concept of SV is associated with the degree of exposure to natural and technological hazards and extreme events, depending closely on the resilience of individuals and communities.

Social Vulnerability must be a planning tool, supporting the implementation of a territorial model in which decision-making on risk management would be more efficiently applied.

The study is divided into 5 sections: a) Presentation of the area of study; b) methodology for the calculation of Social Vulnerability and its components; c) results at municipal level; d) discussion of the results; e) conclusions of study.

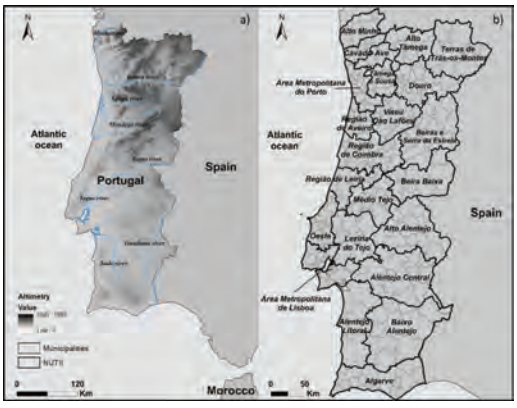

Figure 1. Location of the studied area: a) Continental Portugal (NUT I); b) Territorial organization in NUT II and LAU I (municipalities).

2 STUDY AREA

The present study was based on the calculation of SV for the 278 municipalities of mainland Portugal, with a total area of 89,089 Km^2 and a resident population of 10,044,484 inhabitants according to the 2011 Census (INE, 2012). In administrative terms Portugal is divided into three NUTS (Nomenclature of Territorial Units for Statistics) which is subdivided into three levels, defined according to population, administrative and geographical criteria and in two LAU (Local Administrative Unit), in accordance with Decree-Law 244/2002, changed in 2015 by regulation nº868 / 2014. The work presented here supports its analysis at the level of NUT III, which is composed of 23 territorial units and LAU I, which is composed of 278 municipalities (Figure 1b).

3 METHODOLOGY

The principal objective of this work is to evaluate the Social Vulnerability at municipal level in mainland Portugal. This evaluation will be assessed using principal component analysis (PCA), a technic also used by different authors like Cutter et al. (2003), Schmidtlein et al. (2008), Mendes (2009), Barros et al. (2015), with adaptations according to regional and local specificities, expressed in the type of variables and unit of analysis to be selected. For PCA was used the software SPSS®, version 23. The data that supports this evaluation were obtained using information from the Census 2011 (INE, 2012) and PORDATA database (PORDATA, 2017). In this study the conceptual understating of Social Vulnerability defined by Mendes et al. (2011) was adopted, where SV is composed by two components: Criticality and Support Capability. The evaluation of Social Vulnerability was based on PCA where redundant variables are eliminated and the remaining are normalized and grouped into factors. The PCA was carried out based on a set of premises where it stands out: a) the calculation of the Pearson correlation matrix analysis; b) the variance rate parameters (should be greater than 60%) and the Kaiser-Meyer-Olkin (KMO) sample measurement (should be greater than 0.6) with the purpose of eliminating redundant data (Comrey et al., 2009) and select the more PCA-robust dataset; c) the use of Varimax rotation to better identify the principal components. This process is done for both Criticality and Support Capability. After obtaining the respective scores in each municipality, Social Vulnerability is calculated by combining the two components mentioned above using the following equation:

$$\textit{Social Vulnerability} = \textit{Criticality} \times (1 - \textit{Support Capability}) \quad (1)$$

The results obtained are grouped into different classes that vary from very low to very high in accordance with the standard deviation (SD) and the following categories: "very low," <1 SD; "low," [–1, –0.5 SD]; "moderate," [–0.5, +0.5 SD]; "high," [0.5, 1 SD]; "very high," ≥ 1 SD (Cutter et al. 2003).

3.1 *Criticality*

The calculation of Criticality for all municipalities of mainland Portugal was carried out using 22 variables grouped into seven groups (Table 1). PCA identified 6 factors (FAC) based in the 22 explicative variables. These factors present a variance rate of 73% for the 278 municipalities under study, with a KMO of 0.726 and all communalities above 0.6.

3.2 *Support capability*

The Support Capability was performed using 12 variables grouped into four groups (Table 2).

Table 1. Groups of variables used in the calculation of municipal criticality.

Groups	Number of variables
Social support	3
Housing conditions	2
Demography	2
Economy	9
Education	2
Housing	3
Health	1

Table 2. Groups of variables used in the calculation of municipal support capability.

Groups	Number of variables
Economy	4
Civil protection resources	4
Building characteristics	2
Health facilities	2

Table 3. Criticality components.

FAC	Name	Explained variance (%)
1	Risk groups	30
2	Economic conditions	13
3	Disadvantaged population	12
4	Level of income	7
5	Employment	6
6	Dependent population	5

Based on the variables presented in Tables 2, 3 FAC's were retained, presenting a variance rate of 65% for the 278 municipalities under study, with a KMO of 0.705 and all communalities above 0.6.

4 RESULTS

4.1 *Factors of criticality*

As mentioned above the Criticality assessment identified 6 factors with different percentages in the explained variance (Table 3).

4.1.1 *Factor 1 – Risk groups*

The factor named "Risk Groups" explains 30% of the model variance where the proportion of the population under 5 years old is the dominant variable. This factor describes the most vulnerable population through the variable mentioned above and this FAC is also explained by the following variables: proportion of population with difficulties; proportion of students by secondary educational establishment and students by pre-school educational establishments. The FAC 1 is also composed by variables that are related with housing, namely: the proportion of rented accommodation and the proportion of seasonal housing. These characteristics are important because according with Cutter et al. (2003) and Mendes et al. (2011) the type of accommodation in which an individual resides reflects, in most cases, their personal, social and economic characteristics. The last variable in this factor is the average value of social security pensions which allows identifying economically and financially fragilized populations.

4.1.2 *Factor 2 – Economic conditions*

The factor 2 explains 13% of the variance where the proportion of employees on behalf of others is the dominant variant. This FAC is also constituted by the following variables: proportion of self-employed workers as an isolated employer; proportion of self-employed workers; persons employed in the primary sector; average value of social protection pensions; proportion of seasonal households. In this FAC it is considered that the better the economic condition, the greater the capacity to face and recover from hazardous events.

4.1.3 *Factor 3 – Disadvantaged population*

Factor 3 is related with the disadvantaged people and contributes with 12% of the model variance. The variable dominant is beneficiaries of the Social Integration Income (RSI) and Minimum Guaranteed Income (RMG). The proportion of housing units with renting below 100 euros, the proportion of buildings built before 1919 and the proportion of employed population in the primary sector are the other variables present in this FAC. This FAC represent, in the most cases, the population with low-income, low socio-professional and highly economic and social dependent on institutional aid.

4.1.4 *Factor 4 – Level of income*

Factor 4 explains 7% of the variance and is composed by the following variables: customer deposits in banks, savings banks and mutual agricultural credit, which is the dominant variable, and purchasing power ratio. This factor is related with the economic capacity of the population.

4.1.5 *Factor 5 – Employment*

This factor explains 6% of total variance and is composed by two variables: the proportion of employed population in the tertiary sector (dominant variable) and proportion of population employed in the secondary sector.

4.1.6 *Factor 6 – Employment*

Factor 6 explains 5% of the variance and is composed only by the variable proportion of social housing supported by social and supported income, being directly related with economic power of the population.

4.2 *Criticality factors' cartography*

The analysis of the factor 1 (Figure 2) shows that the highest values related with risk groups are located mainly in the municipalities of the central and inland areas of Portugal. This fact is directly related, in the most cases, with the areas where high percentages of elderly population and low percentages of young population are observed. In factor 2, a clear distinc-

tion is observed between the north and south areas (highest values) with the center region. These highest values of criticality related with low economic conditions are located, essentially, in the municipalities belonging to NUT III of Alto Tâmega, Terras de Trás-os-Montes and Douro (in the north) and in the Baixo Alentejo, Alentejo Litoral and Algarve southern areas, where the primary sector still plays a very important role in the regional economy.

There are also areas where there is an important proportion of self-employed workers as an isolated employer and the proportion of self-employed workers, mostly related with the primary sector. Factor 3 is related with disadvantaged population, and we can observe in the Figure 2 that the highest values of this factor emerge along the valley of Douro river and south of the Tagus river in municipalities with high percentages of population beneficiary of the RSI and RMG, living in low-rent housing and old buildings and work in the primary sector.

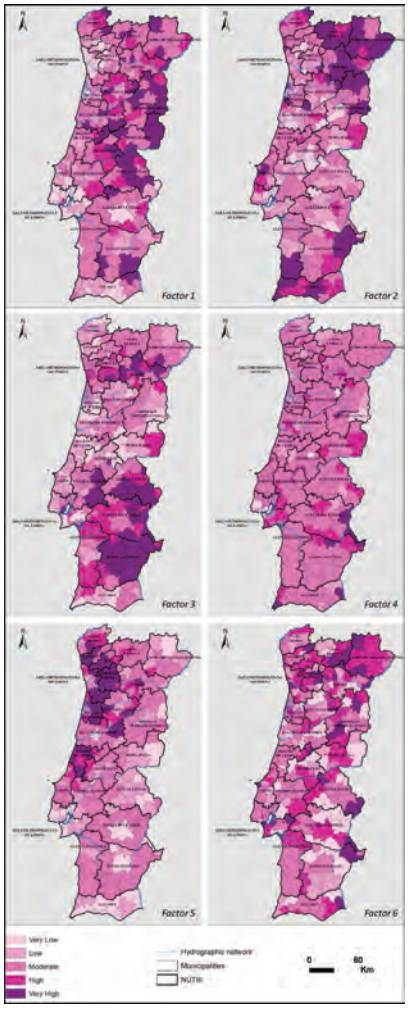

Figure 2. Cartography of the three factors that compose the criticality.

The analysis of cartography of factor 4, named level of income, allows concluding that a great territorial homogeneity exists in the different variables that compose this factor. In factor 5, related with employment, namely the population employed in secondary and tertiary sector. In this analysis we considered that employment in the secondary sector are more vulnerable. This fact is related with the predomination of small and medium enterprises, with value added (VAB) lower than tertiary sector and with greater fluctuation in productivity and employment in time of crises. The cartography identifies the highest values in the coastal northern zone of Tagus river highlighting NUT III Região de Leiria, Região de Aveiro, Área Metropolitana do Porto, Tâmega e Sousa, Cávado e Ave, which stand out as areas with strong industrial and commercial dynamism. The factor dependent population (factor 6) presents highest values north of the Tagus river, and mainly those municipalities on the right margin of the Douro river.

4.3 *Factors of support capability*

The Support Capability assessment identifies 3 factors that resulted from PCA with different percentages in the explained variance (Table 4).

4.3.1 *Factor 1 – Civil protection resources*

The factor 1 explains 30% of the total variance and is related with the municipal civil protection capability. The dominant variable is the number of fire-fighter corporations per 1000 inhabitants. The other variables of the model are: firefighters per 1000 inhabitants, average number of inhabitants per covered spaces (which represents shelter facilities), pharmacies per 10 000 inhabitants and density of road network.

4.3.2 *Factor 2 – Economic an environmental dynamic*

This factor explains 22% of the variance and is composed by the following variables: urban waste

Table 4. Support capability components.

FAC	Name	Explained variance (%)
1	Civil protection resources	30
2	Economic and environmental dynamic	22
3	Logistics and services capacity	12

collected, in kg per inhabitant, proportion of collective households, ATMs per 1000/inhabitants and accommodation capacity in hotel establishments per 1000 inhabitants, which is the dominant variable.

4.3.3 *Factor 3 – Logistics and services capability*
This factor is related with the economic dynamism and explains 12% of the variance. The dominant variable is ATMs per 1000 inhabitants. The other variables that compose the factor 3 are hospitals per 1000 inhabitants and insurance agencies per 1000 inhabitants.

4.4 *Support capability factors cartography*

Figure 3 shows the cartographic representation of each FAC expressing Support Capability.

Factor 1 is related with civil protection resources and with the analysis of the Figure 3 we can observe that the lowest values are located in the metropolitan Lisboa and Porto areas, as well as in adjacent municipalities. This factor is directly related with population density where a relatively reduced number of resources serves a greater number of inhabitants, when compared with less urbanized areas. The factor economic an environmental dynamic (factor 2) express mainly the urban character of the different municipalities. We can observe that the majority of the municipalities analyzed presents moderate values, with the lowest values principally concentrated in the northern margin of the Tagus river.

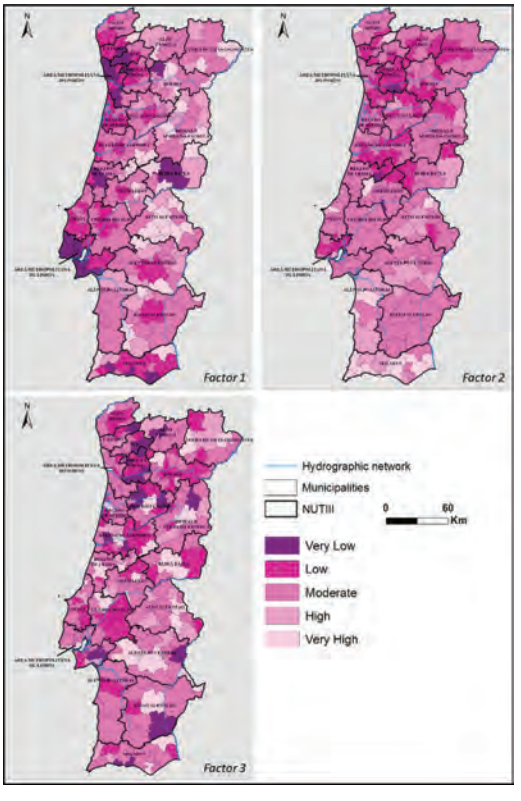

Figure 3. Cartography of the three factors that compose the suport capability.

4.5 *Criticality at municipal level*

Figure 4 presents the cartographic representation of Criticality for mainland Portugal.

We can observe that the lowest values or Criticality are mainly concentrated in the coastal area, especially in the Algarve region, and in the main regional capitals of Lisboa, Leiria, Coimbra and Porto, and their neighboring municipalities. The highest values arise predominantly at northern

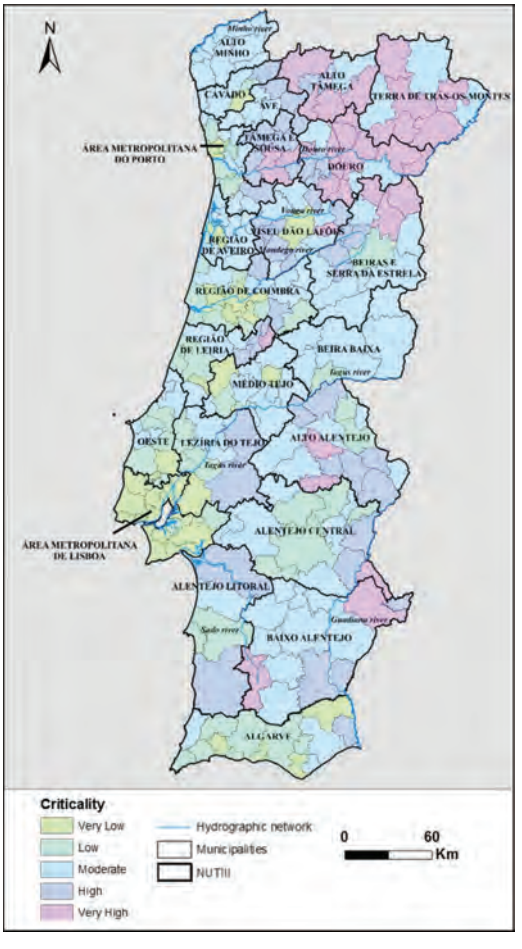

Figure 4. Criticality in mainland Portugal.

municipalities, namely in Alto Tâmega, Trás-os-Montes and along the Douro river valley. We also observe high Criticality values in the central region of Portugal, where stands out the surrounding municipalities of Viseu (located in NUTT III Viseu Dão Lafões), and along the border with Spain in the municipalities belonging to NUT III of Alto Alentejo, Alentejo Central and Baixo Alentejo.

4.6 *Support capability at municipal level*

Figure 5 shows the cartographic representation of each FAC belonging to Support Capability.

The analysis of Figure 5 allows observing that the metropolitan area of Lisboa (with the exception of the municipality of Lisboa and Oeiras) and Porto (with the exception of the municipality of Porto) presents very low and low values of Support Capability. This fact is also noted in the majority of municipalities and NUT III surrounding these areas. This fact permits to conclude that, in most cases, such low values are directly related with high population density. On the other hand, we observe that the highest values are predominantly located in the inland municipalities, especially in areas south of the Tagus river, in municipalities characterized by the availability of the resources for a small number of inhabitants.

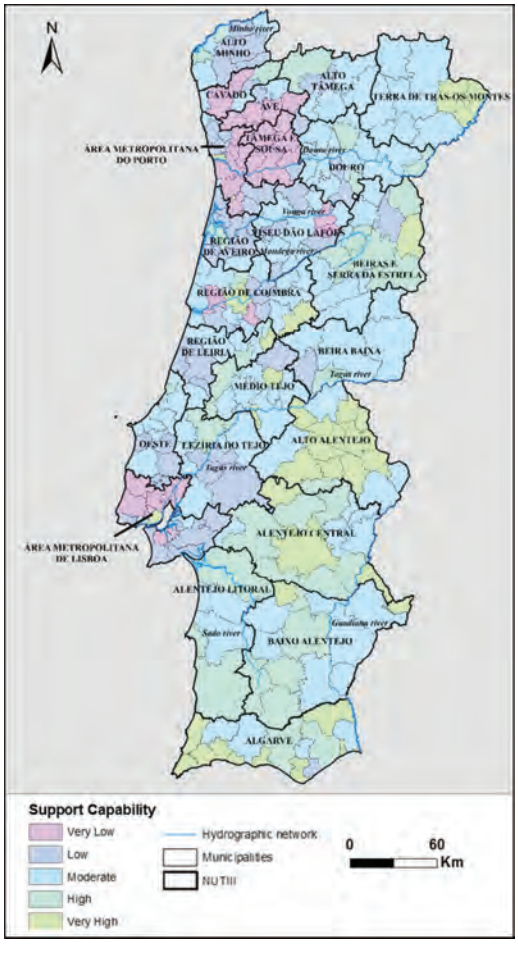

Figure 5. Support capability in mainland Portugal.

4.7 *Social vulnerability at municipal level*

The application of equation 1 that combines the Criticality and Support Capability results in the calculation of Social Vulnerability for the 278 municipalities of mainland Portugal. The analysis allows observe that the highest values of Social Vulnerability are concentrated in the northern areas, namely in municipalities located along the Douro river valley, in the region of Tâmega and Sousa, Ave, southern area of the Porto metropolitan area, Alto Tâmega, Terras de Trás-os-Montes and Viseu Dão Lafões.

In terms of lowest values we can observe that they are concentrated in areas in southern part of the country where stands outs the region of Baixo Alentejo and Algarve where the majority of municipalities has values of Social Vulnerability ranging from low to very low.

5 DISCUSSION

The analysis and evaluation of Social Vulnerability allows to conclude that we can divide, in general terms, the mainland Portugal in two areas: the area at north and the area at south of the Tagus river where the high and very high values are mainly located in the northern part. The reasons for this spatial distribution depends on several factors.

In terms of Criticality the most important factors at the municipal level are those related with the risk groups, the economic conditions and the disadvantaged population. In the total of 278 municipalities we observe that 40% of them present moderate Criticality, 30% values that varies from very low to low and 30% varying from high to very high.

About the Support Capability we can observe a relation between the highest values and the high density of population. The most important factors are associated with variables related to the civil protection resources (factor 1) and variables related to economic and environmental dynamics (factor 2). We also conclude that 39% of analyzed municipalities presents moderate Support Capability, 34% values that varies from very low to low and 27% varying from high to very high.

In terms of Social Vulnerability it possible to conclude that the final values are strongly influenced by factors related with the weak economic power of the resident population, the fragility of its economic fabric and the presence of significant percentages of dependent and disadvantaged population.

The present methodology allows compare and differentiate regions and municipalities in terms of whose characteristics of criticality, capacity of support and social vulnerability would not be evidenced in another way. The spatialization of each component and associated variables are important for the definition, application and promotion of measures related with social policies, housing, distribution and reinforcement of collective equipment, the implementation of a model of economic development more balanced in terms of employment in the inland areas and urban planning policies. The implementation and the success of this measures are important to reduce asymmetries between regions and municipalities. For the success of this measures are important promote and encourage the inter-municipal resource sharing in the sense of corresponding to the character multidimensional and multidisciplinary of Social Vulnerability and associated components.

6 CONCLUSIONS

The present work presents the calculation of Social Vulnerability for the total of 278 municipalities of mainland Portugal in accordance with the methodology presented by Mendes et al. (2011). The character multidimensional of this methodology that combine the Criticality and Support Capability allows not only the calculation of Social Vulnerability as also because of its strong territorial component, defining the Territorial Vulnerability of the analyzed areas.

The multidimensionality of this study, that is based in an extended set of variables from various dimensions like social support, housing, demography, economy, education and health allows the applicability in several risk governance dimensions. The cross-referencing of these data with existing regional or local information may result in programs that promote capacity and social cohesion. The outputs resulting from the present study allow the observation and comparison, among different places. This fact can and should be a work tool for analysis and application by different stakeholders, from multiple sectors and authorities at national, regional and local level.

The knowledge and the consciousness of the territorial distribution of Social Vulnerability and its components (Criticality and Support Capability) as well as their consideration in risk management—where spatial planning instruments are a central part of the process, is a key tool for the definition and application of multidisciplinary and multi-scale risk management strategies that not only consider the physical aspects of the territory, but all its social and institutional dimensions. In fact, the implementation of municipal and local measures that address high SV contexts would first require the existence of an adequate institutional building, drawn upon the best risk governance practices.

ABSTRACT: Complex systems are prone to catastrophic failure as the complexity causes the system to collapse by itself. Wind energy system, which is fast growing source of electricity, is rapidly evolving into complexity and size, leading to inherently and unavoidably hazardous by their own nature. The wind turbine failures have significant impact on public health and safety risk, productivity and economy. Although design plays a major role in developing safer and reliable system, yet achieving desired operational safety and reliability remains a difficult task for the wind turbine manufacturers. In order to ensure better safety and reliability during operation, effective design and maintenance measures need to be taken. Criticality analysis of the wind turbine components or its subsystems is one way to achieve these objectives. Criticality analysis helps to identify critical failure modes or items, which in turn, assists in formulating optimal design and maintenance procedures so that better operational safety and reliability of the wind turbines can be obtained. The conventional FMECA, which is used for criticality analysis, takes care of the effect of failure on components, but does not consider the causal relations or interdependencies among failures. This paper presents an effective method of criticality analysis of wind turbine energy system using fuzzy based digraph models and matrix method by taking into account the causal relations/ interdependencies among failures. This will help to identify the critical failure modes /units of wind turbine energy system. The proposed method is useful in criticality assessment of wind turbines in design as well as in operation stages.

1 INTRODUCTION

Wind energy is a clean and renewable that offers several advantages. In order to capitalize on it, the economically leading countries have been harvesting wind energy over past many decades [1]. However, the efficiency of the wind turbine system is limited by the failures of its elements [2–5]. The critical issues related to reliability and maintenance of wind energy systems have not been addressed fully and these still remain big challenges in operating and maintaining the wind power system [6]. The large wind energy system has numerous elements at its various hierarchical levels, and each elements follow different failure patterns [7–8]. This makes the system more complex and thus leading to hard to access faulty units, difficulty in maintenance and poor reliability. The operations and maintenance cost, which are directly affected by unreliability of the elements of the wind turbine, can be reduced when the whole system continue to function without failure, or with reduced failure rate [9]. It is, therefore, crucial to achieve and sustain high operational reliability. Although, several researchers have studied reliability aspects of wind turbine systems [10–13], yet there are limited findings on how to evaluate the criticality of the elements of wind turbine with respect the failure characteristics such as failure patterns, failure interdependencies, etc. Tools like FMEA may be good in assessing criticality, but lacks in expressing failure dependencies [14]. In reality, the failures, which are the loss of functions, are interrelated, i.e., the failure (i.e., deteriorated function) of one unit does have causal relation with the failure of other unit, which is connected through physical structure [15]. The studies, which ignore this, will provide inaccurate results. It is, therefore,

essential to consider the failure interdependencies through structure while evaluating criticality. The well known structure models; Graph/digraph models and matrix methods, which are effective to model failure dependencies [15–16], are extensively employed for various engineering applications. Application of these tools in criticality analysis of wind turbine energy systems is not yet explored. It is found that FMEA based models have been used in recent years for criticality assessment of wind turbine systems [14], but these are limited to modelling of failure modes, and have not considered the failure interdependencies. Several studies have been carried out on solving engineering problems in a fuzzy environment using fuzzy theory [17]. There are not many literatures found in the application of fuzzy theory in the failure studies of wind turbine systems. This paper presents a methodology of criticality analysis of wind turbine energy system based on fuzzy decision making and digraph model and matrix methods. The method is effective in indentifying critical units in wind turbine energy system taking into account the failure modes and their interdependencies.

2 METHODOLOGY

The proposed method is based on structural models i.e., digraph models and matrix, and fuzzy decision making methods. The selected wind turbine energy system is first described for obtaining structural knowledge, which helps to understand various units, and their interconnections. The common, but important failure modes and their causal relations/interdependencies for the units are then identified and represented using digraph model, and the resultant digraph, which is known as causality digraph, will be converted into causality matrix using matrix method. The matrix will be further processed for causality analysis and evaluation of criticality index for each unit of wind turbine system. The unit, which is having high criticality index, will be considered to be critical unit that will contribute to major breakdown and safety issues of the wind turbine energy system, whereas the unit with low criticality index, will be considered as low critical unit. In this way, the criticality of the wind turbine energy system is evaluated and critical units are identified. Subsequently, appropriate preventive/corrective action will be taken.

3 SYSTEM DESCRIPTION

A typical horizontal wind turbine energy system, which is shown in Figure 1, is considered for the analysis.

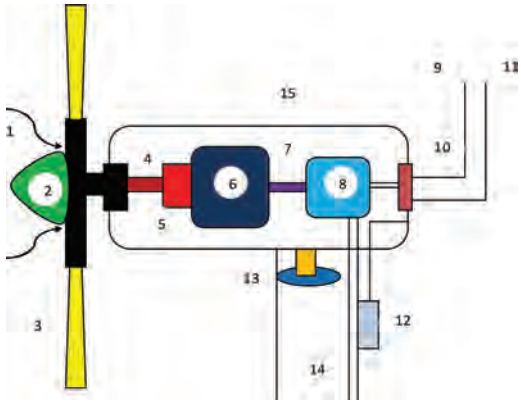

Figure 1. A typical horizontal wind turbine energy system.

The system consists of the following units, i.e., components and subsystems;

1. **Wind (fluid component)** – This sweeps over the turbine blades at high velocity and impart force on the blades to rotate.
2. **Nose and rotor hub** – The aerodynamic design coupled with rotor hub, streamline and distribute the wind over blades.
3. **Rotor blades** – These are attached to the nose and rotor, and spins at ample wind velocity.
4. **Drive train** – This is the combination of main turbine shaft and support bearing mechanism, which connects the blade with gear box, and transfer the rotational energy to the gear box, and then to the generator.
5. **Mechanical brake** – This is used to stop the turbine in order to prevent mechanical failures of the turbine components from high wind speed.
6. **Gear box** – This is used to increase the rotational speed of the turbine shaft with varied torque.
7. **High-speed turbine shaft** – This is the part of the drive train, which connects gearbox and generator.
8. **Generator** – This converts mechanical energy from gear box into electrical energy.
9. **Wind speed sensor** – It measures wind speed.
10. **Electronic control system** – When the wind speed is undesirably very high, the controller gets command from the wind sensor to stop the rotating drive elements through mechanical brakes. It also helps to re-start the rotation at low wind speed.
11. **Wind direction sensor (wind vane)** – This measures the direction of the wind, and sends the command signal to yaw drives to adjust the facing of the turbine with respect to wind direction.

There are many other types of sensor used for measuring position, and speed of all rotating elements. These are not shown in Figure 1.

12. **Yaw drive** – It receives the command signal from wind vane and rotates the turbine.
13. **Yaw motor (Hydraulically operated)** – It physically rotates the turbine based on the instructions from the yaw drive.
14. **Supporting parts (tower)** – It supports the entire wind turbine system high in the air. This also encloses the complete electrical wiring systems (Not shown in Fig. 1).
15. **Nacelle (Housing)** – This encloses entire turbine units.
16. **Electrical system (**Not shown in Fig. 1) – This consists of inverter to steady the output variables; current, and voltage, and transformer to raise or lower the voltage in AC transmission line.
17. **Hydraulic system (**Not shown in Fig. 1**)** – This consists of hydraulic pump, control valves, hydraulic motor and actuators. This is used to actuate yaw mechanism.

In order to develop causality digraph, most common failure modes of the units and their interdependencies are identified. This is discussed in the following line.

4 FAILURE DATA COLLECTION AND FAILURE MODE IDENTIFICATION

From the literature and extensive interaction with wind turbine manufacturing/installation company personnel, failure data were collected for wind turbine energy system. The percentage of failures for each unit of the system is given in Figure 2 and the down time per failure in terms of days for all units, is represented in Figure 3.

The collected failures were categorized into four major failure modes, which are listed below;

1. Surface crack, rupture and overloading (F_s)
2. Component looseness (F_l)
3. Circuitry failure (F_c)
4. Fuse blown (F_b)

The above failure modes contribute to the majority of the failures in the wind turbine energy system. This is shown in Figure 4.

These failure modes are causally interrelated/ interdependent. This means that one failure mode may be the result of the occurrence of the other failure mode, and vise versa. The failure modes and their interdependencies are presented in graphical representation by developing digraph models. This is described below.

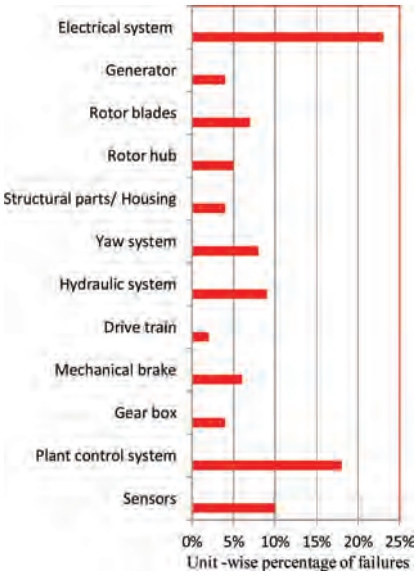

Figure 2. Percentage of failures of wind turbine energy system.

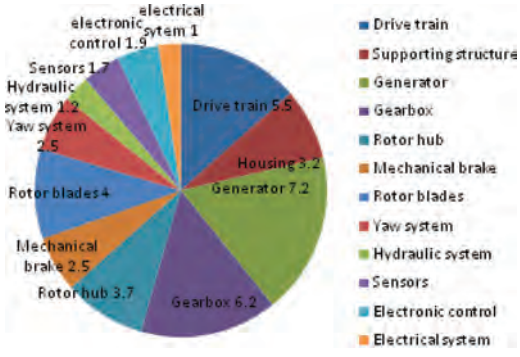

Figure 3. Down time per failure (Days).

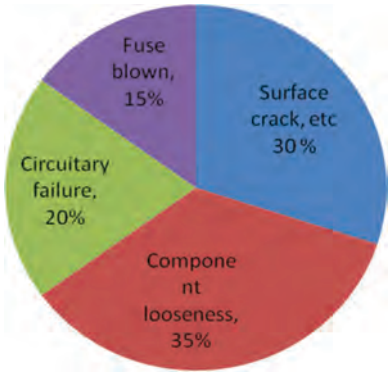

Figure 4. Percentage of important failure modes of wind turbine energy system.

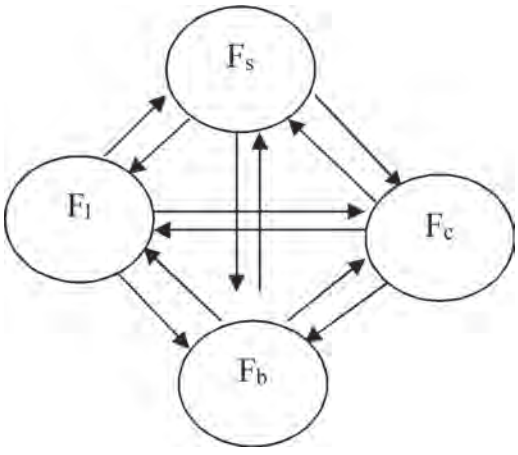

Figure 5. Causality digraph for wind turbine energy system.

5 CAUSALITY DIGRAPH

The causality digraph, $G_{CD} = (V_F, E_F)$ for wind turbine energy is developed with, nodes, 'V_F' representing the failure modes and the edges 'E_F' representing the causal relation/interdependencies among the four major failure modes indentified under Section 4. The developed causality digraph is shown in Figure 5.

The causality digraph helps to perform visual analysis. In order to carry out criticality analysis of failure modes and criticality evaluation of the units of wind turbine energy system, the causality digraph will be converted into an equivalent matrix by using matrix method. This is described in the subsequent section, i.e. Criticality Evaluation.

6 CRITICALITY EVALUATION

In this section, the criticality analysis and evaluation is performed by defining equivalent matrix for the developed causality digraph of the wind turbine energy system. As discussed under Section 5, the causality digraph represents the four major failure modes and their causal relations. If there are a large number of failure modes, then the digraph will become complex. It will be difficult to perform the visual analysis of the digraph. Moreover, the quantification of severity of failure modes and their causal relation is necessary to identify the critical element of the wind turbine system. It is, therefore, essential to convert the digraph into equivalent matrix for further processing. The equivalent matrix, which is known as 'Wind Turbine Criticality Matrix' (WTCM), E_{CM}, is written as;

$$E_{CM} = \begin{array}{c} \begin{matrix} \text{s} & \text{l} & \text{c} & \text{b} & \text{Failure mode} \end{matrix} \\ \begin{bmatrix} \text{F}_\text{s} & f_{\text{sl}} & f_{\text{sc}} & f_{\text{sb}} \\ f_{\text{ls}} & \text{F}_\text{l} & f_{\text{lc}} & f_{\text{lb}} \\ f_{\text{cs}} & f_{\text{cl}} & \text{F}_\text{c} & f_{\text{cb}} \\ f_{\text{bs}} & f_{\text{bl}} & f_{\text{bc}} & \text{F}_\text{b} \end{bmatrix} \begin{matrix} \text{s} \\ \text{l} \\ \text{c} \\ \text{b} \end{matrix} \end{array} \quad (1)$$

where the diagonal elements represent the failure modes (F_s, F_l, F_c, F_b), while the off-diagonal elements represent the causal relation/interdependency between the failure modes, *i* and *j* (fij, *i*, *j* = s, l, c, b; fij≠fji). The WTCM is analogous to permanent matrix in the graph theory. It is mentioned that the permanent is a standard function that is used in combinatorial mathematics [16]. Permanent of WTCM is criticality expression for the wind turbine energy system. The 'Wind Turbine Criticality Expression' (WTCE), which represents severity of failure modes and their causal relations/interdependencies from combinatorial consideration, is obtained from its WTCM (eqn. (1)), as;

$$\begin{aligned} &P(E_{CM}) \\ &= F_s F_l F_c F_b + f_{ls} f_{sl} F_c F_b + f_{cs} f_{sc} F_l F_b + f_{bs} f_{sb} F_l F_c \\ &\quad + f_{lc} f_{cl} F_s F_b + f_{cb} f_{bc} F_s F_l + f_{lb} f_{bl} F_s F_c + f_{lc} f_{bl} f_{cb} F_S \\ &\quad + f_{lb} f_{cl} f_{bc} F_s + f_{sl} f_{lc} f_{cs} F_b + f_{sl} f_{lb} f_{bs} F_c + f_{sc} f_{ls} f_{cl} F_b \\ &\quad + f_{cb} f_{bs} f_{sc} F_l + f_{sb} f_{ls} f_{bl} F_c + f_{bc} f_{cs} f_{sb} F_l + f_{sl} f_{ls} f_{bc} f_{cb} \\ &\quad + f_{sl} f_{lc} f_{bs} f_{cb} + f_{sl} f_{lb} f_{bc} f_{cs} + f_{sc} f_{ls} f_{bl} f_{cb} + f_{sc} f_{lb} f_{cs} f_{bl} \\ &\quad + f_{sc} f_{lb} f_{bs} f_{cl} + f_{sb} f_{ls} f_{cl} f_{bc} + f_{sb} f_{lc} f_{cs} f_{bl} + f_{sb} f_{lc} f_{bs} f_{cl} \end{aligned} \quad (2)$$

The WTCE (eqn. (2)) helps to carry out criticality analysis from combinatorial considerations as it takes care of the severity of failure modes and all possible causality relations among failure modes. The WTCE, which is the characteristic of the causal relations between failure modes of wind turbine energy system, contains number of terms. Each term in the expression has physical meaning. The first term in the expression represents the severity of the four major failure modes. Each term, from second to seventh, represents a two-failure mode causality loop and the severity of two failure modes, and each term from eighth to fifteenth represents three-failure mode causality loop and the severity of three-failure modes. Each of the last nine terms represents severity of causal relations between all major failure modes. By substituting the severity value of failure modes and their causal relations, one can carry out not only the criticality analysis of wind turbine, but also the evaluation of its criticality index.

For performing criticality analysis, each term is examined for severity. The first term in the expression contains the combination all failure modes; $F_s/F_l/F_c/F_b$, which represents the severity of

all major failure modes. By examining this term, the design or maintenance engineer will be able to identify critical failure modes or critical causal relations between failure modes. This will prompt the engineers to take appropriate corrective action. For example, if the severity of the failure mode, F_l, component looseness is higher in electrical subsystem, then an additional care must be taken to minimise its severity or remove the failure mode. In the similar way, other terms are used for criticality analysis, and appropriate preventive or corrective actions can be taken. In order to evaluate criticality index of the wind turbine energy system, the severity values of failure modes and that of failure interdependencies are substituted in WTCE, which will then be solved to obtained numerical index that represents the severity of the failure modes of the wind turbine energy system. The main objective of the work is to evaluate criticality index at subsystem level, so that the critical subsystem can be selected and ranked based on the criticality index. It is recommended that the severity value should be obtained from wind turbine shop-floor data base or experienced wind turbine service/ operational personnel. However, the severity of the failure modes and their causal relations can also be proposed based on the field experience as there is no data source that provides the severity data for the wind turbine components and no commonly accepted method available as well. The failure modes indentified in Section 4, interact with each other, making causal relations at varying degrees. Depending upon the severity of the failure modes and the degree of their interaction or influence of one failure mode on the other, appropriate severity rating may be selected for each failure mode and their causal relations. In the present work, the data of severity rating are obtained by making extensive interaction with service engineers and operational personnel of wind turbine manufacturing industries. Some of the technical report and literatures [1–10] are also useful in this regard. It is to be mentioned that obtained data is the severity ratings, which are in the form of qualitative terms, e.g. Low, Average, or High. These terms will be converted into quantitative values, i.e., severity value, for evaluating criticality index.

In order to convert the severity rating into severity values, an appropriate and accurate method needs to be selected. In this work, a fuzzy theory based approach has been chosen for converting severity rating into severity values. The severity values of the identified failure modes and their causal relation are substituted in eqn. (2), i.e., WTCE, to obtain criticality index of the wind turbine energy system, at its various subsystem level. Based on the criticality index, the critical subsystem can be selected. The following section will describe the conversion of severity rating into severity values using fuzzy theory, and the evaluation of criticality index of some selected units of wind turbine energy system.

7 FUZZY THEORY IN CRITICALITY EVALUATION

Fuzzy theory provides a tool for directly manipulating the linguistic terms that an analyst employs in making a criticality assessment for a failure modes, effects and criticality analysis (FMECA). In the proposed approach, these parameters, i.e. severity rating (linguistic term) are represented as members of a fuzzy set, fuzzified by using appropriate membership functions and are evaluated in fuzzy inference engine, which makes use of well-defined rule base and fuzzy logic operations to determine the crisp score, which represents the criticality/riskiness level of the failure. This means that the method will convert linguistic term into fuzzy numbers and the fuzzy numbers into crisp scores. The higher the value of crisp score, the greater will be the risk and lower the value of crisp score, and the lesser will be the risk.

To demonstrate the method, a 5-point scale having the linguistic terms low, below average, average, above average, and high is considered (Refer Fig. 6). The linguistic terms are converted into fuzzy number, and then to crisp score.

The crisp score of fuzzy number 'M' is obtained as follows:

$$\mu_{\max}(x) = \begin{cases} x, 0 \le x \le 1 \\ 0, otherwise \end{cases} \tag{3}$$

$$\mu_{\min}(x) = \begin{cases} 1-x, 0 \le x \le 1 \\ 0, otherwise \end{cases} \tag{4}$$

The linguistic terms with their corresponding crisp scores are chosen from Figure 6 and given in Table 1. The crisp score represent the severity value of failure modes, and that of causal relations.

The severity value is selected from Table 1, based on the degree of severity for each of the failure modes and their causal relations. By substituting these values in eqn. (2), the criticality analysis is carried out and subsequently criticality index for the wind turbine energy system is obtained at various subsystem levels. For example, let us examine the severity of the major failure modes for drive train unit for criticality analysis. From Table 1, the severity values for all major failure modes, i.e., $F_v/F_l/F_c/F_b$ of the drive train unit are taken as; 0.695/0.895/0.495/0.295 respectively, and substituted in eqn. (2) in place of the first term.

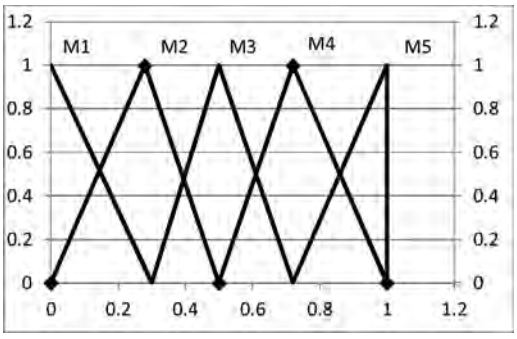

Figure 6. Linguistic terms to fuzzy numbers conversion (5-point scale).

Table 1. Conversion of linguistic terms (Severity rating) into crisp score (Severity value).

Linguistic term (Severity rating)	Fuzzy number	Crisp number (Severity value)
Low	M1	0.115
Below average	M2	0.295
Average	M3	0.495
Above average	M4	0.695
High	M5	0.895

It is observed that the failure mode, component looseness, F_l is more severe, and suitable corrective action needs to be identified and implemented to maintain or redesign the drive train keeping in mind the severity of component looseness. On the similar line, the severity values of the failure modes and their causal relations are substituted in place of remaining terms and the criticality analysis is performed for the drive train unit. Subsequently, the eqn. (2) will be solved to obtain criticality index for the drive train unit, and obtained as ***0.6741***. Similarly the criticality analysis is carried out to identify critical failure modes/critical causal relations between failure modes for the remaining units by choosing appropriate severity values from Table 1. In the example discussed here, seven units (i.e., subsystems) such as; *drive train, generator, electronic control system, yaw drive, electrical system, hydraulic system and gear box*, are considered for evaluating criticality index. The criticality index for the all subsystems are evaluated and presented in Table 2. The electrical system is identified as critical unit as it has highest value of criticality index, which is ***2.2314***; it is, therefore, obvious that the electrical system is assigned criticality rank as 1. The electrical system of wind turbine energy system requires more attention in terms of, for example, improved design, reliability, maintainability, safety, etc. The

CI – Criticality Index; CR – Criticality Rank.

design activity should be oriented towards removing the failure modes, reducing the probability of occurrence, and minising the severity of the failure. Similarly, other units of the wind turbine energy system are prioritized based on the criticality index, and suitable preventive or corrective actions are taken, be it in design or operating stage.

8 CONCLUSION

In this paper, a methodology for criticality analysis and evaluation of criticality index for wind turbine energy system at various subsystem level has been proposed. Criticality index for various units of the wind turbine energy system has been evaluated using fuzzy diagraph models. Criticality index is useful in ranking, and identifying the critical wind turbine units, which require immediate maintenance action, redesign or modification.

This method will be helpful for the system safety and reliability analysts in taking corrective action during design and operational stage of complex wind turbine energy system.

ABSTRACT: Dynamic Positioning (DP) control system is currently utilized for maintaining the position of Floating Production Storage and Offloading (FPSO) in a variety of the ocean environment conditions. However, FPSO in the Arctic region, which operates under diverse ice conditions, should be designed with an advanced mooring system together with the DP system as the FPSO needs safer system compared with the normal DP systems. A novel DP and mooring system for the FPSO operating in the Arctic region is now being developed at KRISO in Korea. A platform shape of the FPSO that has minimum resistance and maximum operation efficiency is also under development. Therefore, analyses and assessments of potential risks are required, considering that the developing system has many novelties compared to the conventional DP or mooring system. Hazard identification study (HAZID) is one of the most widely used traditional methods to identify hazards of a system, and the method is simple to use and requires limited training. System Theoretic Process Analysis (STPA), on the other hand, was recently developed for modern complex control systems and provides systematic analysis procedure based on systems theory. The main objectives of this study are to suggest an approach for hazards identification associated with the design and operation of DP and mooring system, by utilizing complementary hazard identification methods (HAZID and STPA). HAZID has been applied to the structural part of the system, while STPA has been applied to the control system. The paper also includes a comparison of the strengths and weaknesses of the selected methods and a discussion of complementary use of HAZID and STPA.

1 INTRODUCTION

1.1 *Background*

It takes almost a decade to make the first oil production since finding the oil in the Northern Alaska in 1969. Various R&D for the effective and safe operation of offshore plants were conducted under the extremely difficult environment conditions in the Arctic region such as low temperature, iceberg etc. To overcome the risk factors in Arctic sea, a variety of fixed type offshore platforms were considered so far. However, the exploitation of natural resources is taking place at deeper waters in the Arctic region, so floating type offshore plant platforms are considered.

The most important factors for design and operation of floating type offshore plant in the Arctic area is that various techniques are required to keep the stable operation and production under the condition of a verity of ice conditions, e.g. icebergs, ice floe (drift ice) etc. It is well known that the Arctic conditions are much harsher/tougher environment conditions for the safety of the operating vessel, compared to the normal sea ones when considering polar lows, sea ice, low temperature, uncertainty of metocean data etc.

The improved Dynamic Positioning (DP) system and more stable mooring system is required to keep the operation positioning in the Arctic region. The DP system will help ice management during the operations when the ice floes are approaching, and

the mooring lines make the offshore plants more stable.

The equipment with the advanced technologies are installed on the offshore plant but there are still hazards (risks) during the operation. For example, if ice management is impossible due to an extremely large iceberg, the offshore plant should be removed from the operation place to the safer place based on a prepared manual. Therefore, a variety of scenarios should be prepared considering many different risk circumstances.

To identify hazards and hazardous situations that may occur in the operation of DP and mooring systems, it is important to carry out a systematic hazards identification. Several *hazard identification methods* have been developed, see e.g. Rausand (2011). One of the most widely used hazard identification methods is HAZard IDentification (HAZID). The Preliminary Hazard Analysis (PHA), a variant of HAZID, was developed by the U.S. Army (MIL-STD-882D) to evaluate hazards early in the life of a process, and has been successfully used for safety analysis of machinery and process plants (Rausand, 2011, CCPS, 2011). HAZID is a rather simple and versatile technique that requires limited training and can cover a range of safety problems (Rausand, 2011). However, this method is a brainstorming-oriented technique, with support of checklists of known hazards, and the results are strongly dependent on knowledge and expertise of the analysts (Molland, 2011). This is a particular concern when the systems increase in complexity, and have unidentified behavior due to extensive use of ICT technologies. These are typical attributes of e.g. the DP system. Dedicated hazards identification methods have therefore been developed to handle more complex, software-intensive, sociotechnical system (Leveson, 2012). One such example is the Systems-Theoretic Process Analysis (STPA).

STPA is a further development within the framework of Systems-Theoretic Accident Model and Processes (STAMP) causality model (Leveson, 2012). STPA can identify the hazards covered by traditional hazard identification methods, but it also can identify additional hazards that are not included or poorly handled in the traditional methods, like software errors, component interactions, complex human errors, and so on (Leveson and Thomas, 2013). STPA identifies unsafe control actions, using a systematic analysis of a functional control structure of the system (Leveson and Thomas, 2013). However, STPA may not necessarily be suited for analysis of systems comprising only passive component with no control action.

1.2 *Literature study*

DP and mooring system in the Arctic Ocean are seldom applied. Therefore, the DP and mooring system which have been applied and operated in normal sea areas to keep the operating position are investigated first. The DP system is closely related with the control system, so the DP system is researched for STPA and mooring system is researched for HAZID in this study.

The most frequent accidents come from mooring line failure during the operating offshore plant (FPSO) between 2001 and 2013. That is, the number of accident cases is thirteen (13) times, and other cases are ten (10) times from the chain failure and five (5) times from wire rope disconnection. In particular, accidents from the mooring line connection was the main cause of the catastrophic disaster (Offshore Magazine, 2013).

Ma et al. (2013) and Kvitrud (2014) have researched about the accident causes of the mooring system and DP system in offshore structure and found that the top chain, wire rope terminations and connectors of mooring system are the major reasons. Several incidents have been reported for floating structure in North Sea, and the main causes of accidents are the mooring lines failures which are overloaded during extreme weathers (Kvitrud, 2014). There are several QRA techniques on DP systems during drilling operations in the Arctic or normal sea condition (Pedersen, 2015, Team Energy Resources Limited, 2002), but HAZID work applied for DP and mooring system are extremely seldom.

Only limited number of studies have applied STPA to DP systems. Abrecht (2016) conducted STPA analysis for a DP system of an offshore supply vessel. After identifying unsafe control actions (UCAs) and casual scenarios of identified UCAs, the study also conducted traditional hazard identification analyses, such as Fault Tree Analysis (FTA) and Failure Modes and Effect Analysis (FMECA), for the DP system and compared the results to discuss advantages of STPA. Rokseth et al. (2017) also analyzed a typical DP system using STPA and discussed applicability of STPA compared with FMECA. However, there is no previous study that applied STPA to DP and mooring system.

1.3 *Objectives*

The main objectives of this study are to suggest an approach for hazards identification associated with the design and operation of DP and mooring system, by utilizing complementary hazard identification methods (HAZID and STPA). HAZID has been applied to the structural part of the system (e.g. hull structure, mooring lines, turret system etc.), while STPA has been applied to the control system (e.g. DP systems etc.). The paper also includes a comparison of the strengths and weaknesses of the selected methods and a discussion of complementary use of HAZID and STPA.

1.4 *Structure of the paper*

The remainder of this paper is organized as follows: DP and mooring system is introduced in Section 2. Section 3 and 4 analyze hazards of DP and mooring system using HAZID and STPA respectively. Finally, results and discussion are presented in Section 5.

2 INTRODUCTION TO ARC7 PROJECT AND DP AND MOORING SYSTEM

Korea Research Institute of Ships and Ocean Engineering (KRISO) has initiated a five years long term research project (ARC7 project) to develop a hull form design for a year-round floating type offshore structure in the Arctic condition with DP and mooring system. In order to design an offshore structure hull form for the given operating condition in Arctic region (ARC7 condition[1]), an ice performance evaluation methodology which uses KRISO's ice tank and numerical analysis methods have been developed. In this research, Ice load estimation, hull form design, configuration design of mooring & DP systems are considered as core technologies.

The aim of the research project, ARC7 project, is design hull form for the offshore plant structure in the condition of the ice sea condition and over 200m depth. The safety of the designed system, DP and mooring system for station keeping in ice condition should be proven, which is the proper one for the requirement of the aim of the project.

The designed FPSO systems are applied for the offshore plant structure, which is a ship-type planform as shown in Figure 1. The developing systems and optimized hull form are designed for the minimized ice drag force and maximized operational efficiency.

Thrusters for the DP system and mooring lines for the mooring systems are developed for the different ice conditions based on the ice management scenarios. Concept of DP and mooring system with ice management in the Arctic ice sea is shown in Figure 2.

Design for the DP and mooring system should be considered together with the hull form of the offshore plant. The design process follows design spiral to find best compromise with in the given boundaries such as environment conditions, cost, rules (regulations) etc. Developed design spiral for the offshore plant structure with the DP and mooring system in Arctic Ocean is shown in Figure 3.

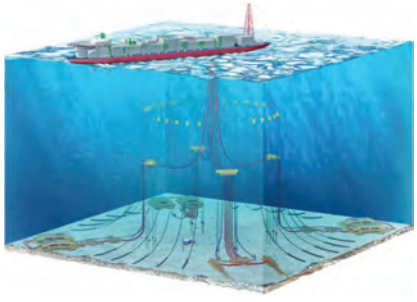

Figure 1. Configuration of offshore plant system in the Arctic region (Kim et al., 2017).

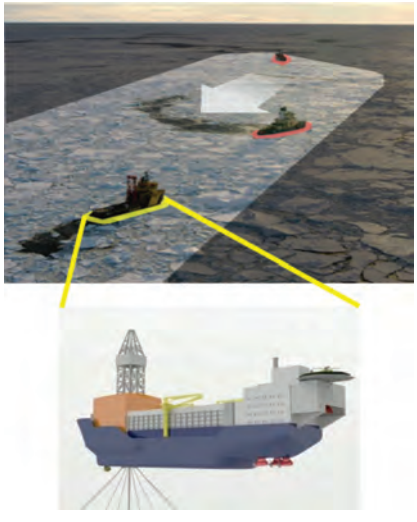

Figure 2. Concept of DP and mooring system with ice management in Arctic sea (Keinonen et al., 2006).

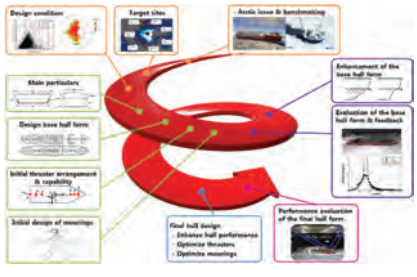

Figure 3. Design procedure (design spiral) of the offshore plant structure with the DP and mooring system in Arctic sea.

[1]ARC7: One of the ice class rule of the Russian Maritime Register of Shipping (RMRS). The ice classes are divided to non-Arctic, Arctic and icebreaker classes. The ice class notation is followed by a number which denotes the level of ice strengthening: Ice1 to Ice3 for non-Arctic ships, Arc4 to Arc9 for Arctic ships, and Icebreaker6 to Icebreaker9 for icebreakers. These ice classes can be assigned in parallel with the Finnish-Swedish ice class and/or the IACS Polar Class, provided the vessel complies with all applicable rules. The selection of ice class is based on the operating area in the Russian Arctic, time of year, ice conditions, operating tactics, and whether the vessel operates under icebreaker escort or independently (RMRS, 2017).

3 HAZID FOR THE DP AND MOORING SYSTEM

3.1 *HAZID workshop for the DP and mooring system in the arctic region*

HAZID work has been carried out for "the year-round floating offshore structure hull form development which has DP system and mooring system as the mean of the station-keeping in the condition of ARC7". The HAZID workshop was performed for the FPSO's concept design (hull form, DP system, mooring system, turret system etc.) for operating in the Barents Sea.

Hazards and risks during the installation, operation, and maintenance in the Arctic sea are identified, and the causes and consequences of the systems are discussed in the HAZID workshop.

Preventive safeguard and mitigating safeguard to prevent or minimize for the identified hazards (risks) are suggested in the workshop, and HAZID report/worksheet were prepared

3.2 *HAZID results*

The hazards (risks) in the three nodes (hull, mooring and turret systems) for the failure of structure and systems were identified in the HAZID workshop.

Main causes and consequences for the hull structural failure were identified, and the preventive/mitigating safeguard were suggested during the HAZID workshop.

Main causes of the hull structure are collision, green water, wind, wave, current, sea ice and low temperature. The mooring system failure came from improper connection between mooring lines, excessive tension, green water, wind, wave, current, sea ice, low temperature, system malfunction etc. Main causes of the turret system failure were, on the other hand, identified as collision, green water, environment (wind, wave, current), low temperature etc.

3.3 *Recommendation and guideline*

The identified hazards or risks from the HAZID workshop were classified as shown in Table 1. The hazards (risks) are mostly related to ice, temperature, and ocean environment in the Arctic region, while personal risk and downtime occurrence were the common consequences for the accident cases. Working procedure document, safety fence, rapid recovery were suggested as preventive/mitigating safeguards for the currently designed system.

Table 1. Summary of HAZID.

			Existing safeguards	
Cause		Consequence	Preventive safeguard	Mitigating safeguards
Node (1) Hull Structure	Collision	Capsizing & sinking	– Robust design – Increase S.F. – Improve damaged stability	Auto-ballast control system
	Sea ice	Ice impact	– Ice management – Ice avoidance	– Auto DP system
	Low temp.	Brittle fracture	– Winterization – Heat line – Improve material property – Mooring line upgrade	– Deicing
Node (2) Mooring/DP system	Green water	Impact on deck	– Green water protector – Proper flare angle – High freeboard – Deflector	– Safety plan
	Sea ice	Large offset	– Ice management – Ice avoidance – High DP capacity – Heading control	– Proper winch operation
	Current	DP overload	– High DP capacity – Heading control	– Proper winch operation
	Wave	Large offset	– High DP capacity – Heading control	– Proper winch operation
Node (3) Turret	Collision	Mooring disconnection	– Redundancy design – Heading control	– Heading control
	Sea ice	Fail to disconnect	– Redundancy design	– Rapid OSV support – Auto system
	Current/Wave	Risers failure and hydrocarbon release	– Redundancy design – Shut down valve	– Oil spill recovery plan

Major cause for the systems and recommendations (safeguards) from the HAZID workshop are shown in Table 1.

4 STPA FOR THE DP AND MOORING SYSTEM

The STPA focused primarily on the control system, and its interaction with ship, ship engine and sensors, environment, DP-operator, and bridge officer. The STPA was carried out in three main steps, following the STPA procedure: (1) Establish system engineering foundation, (2) Identify Unsafe Control Actions (UCAs), and (3) Identify scenarios and safety constraints.

4.1 *Establishing system engineering foundation*

The first task of STPA was to establish *system engineering foundation*, which includes defining system-level accidents, hazard and safety constraints, and establishing functional control structure.

System-level accidents of an offshore vessel with DP and mooring system are *Rupture of the riser* and *Structural damage of the vessel*. The former is caused due to unintended drift of the vessel beyond the riser disconnect limit, and collision with other vessels or icebergs can be the cause of the latter. System-level accidents, hazards, and safety constraints are summarized in Table 2.

The second task of the system engineering foundation was to establish functional control structure. A high-level control structure was developed first, as shown in Figure 4, and a detailed structure was then developed as shown in Figure 5.

The DP and mooring system is controlled by DP Operator who receives commands from Bridge Officer. DP Control System calculates vessel motion and provides control command to Power System and Thrusters for position keeping of the vessel. Responsibilities and process models of each controller in the functional control structure are defined in Table 3.

4.2 *Identifying unsafe control actions*

STPA considers that safety can be treated as a dynamic control problem, rather than a component failure problem (Leveson and Thomas, 2013), and therefore the main focus of STPA is to identify control actions that lead to unsafe situations of a system. These control actions are called Unsafe Control Actions (UCAs).

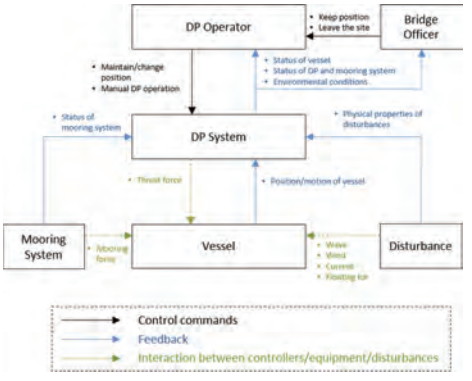

Figure 4. High-level control structure of DP and mooring system.

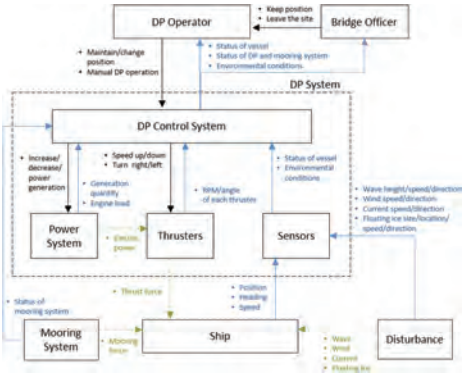

Figure 5. Detailed control structure of DP and mooring system.

Table 2. System-level accidents, hazards, safety constraints.

System-level accident	System-level hazard	System-level safety constraints
SLA1: Rupture of the riser	SLH 1: The vessel fails to maintain its position and drifts outside riser disconnect limit	SLSC 1: The vessel must never drift outside riser disconnect limit
SLA 2: Structural damage of the vessel	SLH2: The vessel fails to maintain its position and collides with other vessels	SLSC2: The vessel must never drift toward other vessels
	SLH3: The vessel fails to avoid icebergs that are beyond the structural strength	SLSC3: The vessel must avoid icebergs that are beyond the structural strength

The UCAs can be identified by examining combinations of control commands and process models that were identified from Section 4.1. Some examples of UCAs that were identified in our study are shown in Table 4.

4.3 *Identifying scenarios and safety constraint of each UCA*

The last step of STPA was to identify scenarios, casual factors, and safety constraints for each UCA. The scenarios and casual factors describe

Table 3. Responsibilities and process models.

Controller	Responsibilities	Process models
DP Operator	– Maintain or change position of the vessel depending on commands from Bridge Operator	– Command from Bridge Officer (keep/change position) – DP mode (position keeping/ moving to other site) – Status of automatic DP control system (operating/malfunction) – Status of mooring system (moored/disconnected) – Environmental conditions (thrust force required/ not required)
DP Control System	– Calculate vessel motion based on position, environmental conditions and mooring forces – Provide control commands to Power System to generate required electric power to Thrusters – Provide control commands to Thrusters to generate required thrust force to the vessel	– Command from DP Operator (maintain/ change position, manual operation) – Position of vessel – Environmental conditions – Mooring forces – Power generation quantity – Engine load – RPM of each Thruster – Angle of each Thruster

Table 4. UCAs of DP control system.

UCA.DPC01: DP Control System does not provide Speed up command to Thruster when vessel needs more thrust force		
Scenario	Associated causal factors	Safety constraints
DP Control System receives wrong measurement from reference sensors	Low accuracy of reference sensors	SC.DPC.01.01 Accuracy of reference sensors must be tested periodically SC.DPC.01.02 Reference sensors must have 2oo3 configuration
DP Control System receives no measurement from reference sensors	No power supply to reference sensors	SC.DPC.01.03 DP Control System must generate an alarm when no signal is received from reference sensors SC.DPC.01.04 Reference sensors must be connected to UPS
	Broken signal wires from reference sensors	SC.DPC.01.03 DP Control System must generate an alarm when no signal is received from reference sensors SC.DPC.01.05 Signal wires must be inspected periodically
DP Control System receives correct measurement, but DP Control System does not provide *Speed up* command	Wrong logic inside PCS	SC.DPC.01.06 Logic of DP Control System to generate *Speed up* command must be fully demonstrated during sea trial

Table 5. Scenarios, causal factors and safety constraints of UCA.DPC01.

No	Control Action	Not provided	Provided	Too early	Too late	Too short	Too long
1	Speed up Thruster no.1	UCA.DPC01 DP Control System does not provide *Speed up* command to Thruster when vessel needs more thrust force	UCA.DPC02 DP Control System provides *Speed up* command to Thruster when vessel needs to reduce or maintain thrust force	UCA.DPC03 DP Control System provides *Speed up* command to Thruster too early, before vessel needs more thrust force	UCA.DPC04 DP Control System provides *Speed up* command to Thruster too late, when vessel needs more thrust force immediately	UCA.DPC05 DP Control System provides *Speed up* command to Thruster too short, so Thruster cannot generate enough thrust force	UCA.DPC06 DP Control System provides *Speed up* command to Thruster too long, so Thruster generates excessive thrust force
2	Speed down Thruster no.1	UCA.DPC07 DP Control System does not provide *Speed down* command to Thruster when vessel needs less thrust force	UCA.DPC08 DP Control System provides *Speed down* command to Thruster when vessel needs to increase or maintain thrust force	UCA.DPC09 DP Control System provides *Speed down* command to Thruster too early, before vessel needs less thrust force	UCA.DPC10 DP Control System provides *Speed down* command to Thruster too late, when vessel needs less thrust force immediately	UCA.DPC11 DP Control System provides *Speed down* command to Thruster too short, so Thruster generates excessive thrust force	UCA.DPC12 DP Control System provides *Speed down* command to Thruster too long, so Thruster cannot generate enough thrust force

why and how UCAs occur, and safety constraints suggest requirements or guidelines to prevent scenarios from occurring, and ultimately, to prevent occurrence of UCAs.

Contrary to previous steps to identify UCAs, STPA does not provide structured guidance for this step. Identification of scenarios, causal factors, and safety constraints should therefore rely on brainstorming of analysts. Some of the results of this step is shown in Table 5.

5 RESULTS AND DISCUSSION

In this study, hazards of DP and mooring system have been analyzed using two hazard identification methods: HAZID and STPA. The scope of HAZID was limited to the hazards related to mooring system, while STPA focused on the control hazards of the DP system.

The advantages and limitations of each method, introduced in Section 1, were confirmed in the analyses of this paper. HAZID covered extensive safety problems, like hazards during installation, operation, maintenance, and so on. This method can be applied without limitation for static (passive) systems that requires no control actions, like mooring system, as well as dynamic (active) systems that requires control actions, like DP systems. However, HAZID provides less structured approach to identify hazards related with control problems compared with STPA. The results of HAZID are therefore highly affected by the knowledge and expertise of analysts. On the contrary, STPA provides well-structured systematic approach to identify hazards of a control system, and this systematic approach reduces reliance on analysts' knowledge or expertise and supports thorough hazard analysis of a system. However, STPA may encounter some problems when the method is applied to systems comprising only passive component with no control action, because STPA is a specialized analysis method for control problems. For instance, multiple mooring line failure due to heavy wind and/or wave is a critical hazardous event that can lead to rupture of the riser

or collision with other vessels, but this might not be directly identified by STPA because no control action is related with this hazardous event. This hazardous event can only be included indirectly into the analysis as a process model or as a scenario of some UCAs of the DP system.

Previous studies on STPA indicates that STPA can find wider range of safety problems than traditional hazard identification methods. In 2003, STPA was applied to U.S. Missile Defense System that had already been analyzed using traditional hazard identification methods, and STPA found so many additional flaws that the project was delayed for six months to fix the problems (Pereira et al., 2006). For an unmanned spacecraft of the Japanese Aerospace Exploration Agency (JAXA), STPA found every hazard identified by fault tree analysis and additional hazardous scenarios that were related to system design flaws, software, and so on (Ishimatsu et al., 2010). After analyzing a typical DP system, Rokseth et al. (2017) concluded that STPA can be considered as complementary to FMEA, providing a better risk picture of the DP system, and the same applies to this case study. At least for the specific case of this paper, STPA may cover a narrower scope of safety problem than a traditional hazard identification method, HAZID. The well-structured and systematic approach of STPA consequently resulted in limited applicability. This is not the only problem of STPA. HAZard and OPerability (HAZOP) study, for instance, provides specific guidewords and process parameters to identify hazards of a process system, and consequently, the application of this method is limited to process hazards (Rausand, 2011). To use HAZOP for other kinds of hazards, the guidewords and parameters should be modified for the hazards. The more a method provides guidance to identify hazards, the more restricted the scope may become.

For thorough analysis of hazards for DP and mooring system, complementary use of several hazard identification methods may be required, because each method has its own advantages and limitations, as confirmed by this study. A combined approach based on multiple hazard identification methods, to strengthen the strength and make up for the weakness of each method, would be an important further work.

Department of Mechanical Engineering, TEI of Piraeus, Egaleo Attica, Greece

ABSTRACT: The aim of this paper is to present the study elaborated through a specific risk analysis approach that highlights the potential risks and accidents in a geothermal installation in order to make the latter more reliable and environmentally friendly. The study also aims at offering a different perspective to the public benefiting from geothermal energy by influencing positively peoples 'awareness on this kind of facilities. The geothermal fluid may contain several Non-Condensable Gases (NCG), such as carbon dioxide (CO_2) and hydrogen sulfide (H_2S). Moreover, the presence of silica and boron in the geothermal brine can be hazardous both to people and to the surface environment. The safety analysis presented determines potential accidents in the storage phase and appropriate remediation actions, in the case that the geothermal fluid reinjection methodology is used.

1 INTRODUCTION

1.1 *General*

During the last years, the continuously rising energy demand worldwide is very evident. This can be explained by the sharp growth of the developing countries, as well as the improvement of living standards in the developed ones. Fossil fuels are the main energy source for most of the countries for several decades. However, the limited inventory of the former and the need for energy independence made most countries to invest gradually into renewable energy sources in order to reduce the share of technologies based on fossil fuels. Renewable resources have an unlimited availability, are usually equitably distributed around the world and are characterized as clean technologies because they produce very little waste and also have a minimal environmental impact. Moreover, they contribute not only to the reduction of CO_2 emissions but also to other pollutant gas emissions, such as sulfur, nitrogen oxides, VOCs (Volatile Organic Compounds) fostering both environmental protection, and growth sustainability. This is in line with the future socioeconomic and environmental needs of global economy according the Kyoto treaty objectives (Dincer, 2000 & deLIano-Paz et al., 2015).

Geothermal energy offers an alternative to this respect. Its utilization for electricity generation has been commercially used since 1913. As a renewable energy source, it can enhance a low carbon economy and strengthen independency from imported fuels. Geothermal power can be used as baseload renewable energy 24/7 in order to generate electricity regardless of the weather variations. Moreover, geothermal energy can fluctuate depending on the needs and can be flexible to support the intermittent renewable energy resources demands from wind and solar parks. In this context, it can be used to provide the stability of the power grid enhancing the efficiency of the entire system and increasing the security of energy supply against disruptions for geopolitical reasons and fossil fuel's price high volatility (deLIano-Paz et al., 2015).

The geothermal fluid itself may contain several Non-Condensable Gases (NCG), such as carbon dioxide (CO_2) and hydrogen sulfide (H_2S). Moreover, the presence of silica and boron in the geothermal brine can be hazardous both to people and to the surface environment. For these reasons geothermal fluid reinjection is used, a vital part of any geothermal development. The reinjection plan should be developed as early as possible in any geothermal development taking into account that the field characteristics are likely to change with time.

1.2 *Geothermal injection plants*

Few types of geothermal installations have been used so far. In 1970 on Achuapan field in El Salvador, the first injection effort has been implemented for environmental reasons, where a high Boron

content (~50 ppm) was identified and surface disposal was not admissible (Einarsson et al., 1975). Nowadays, injection seems to be the most favorable solution both environmentally and economically. Geothermal fluid injection is important to a geothermal project for a number of reasons, such as (a) to avoid surface disposal which can cause environmental impact, (b) to support the reservoir pressure, (c) to avoid any ground subsidence, and (d) to benefit from rock matrix heat.

Depending on the type of the geothermal system, reinjection can be infield, outfield or a mix of them. For vapor-dominated systems, where the water can run out, reinjection should be infield, while for hot water and liquid-dominated system a mix of infield and outfield injections is recommended. Through infield reinjection pressure support is provided and, consequently, drawdown and the potential for subsidence will be reduced. However, outfield reinjection protects the production area from the risk of cold water returns (Kaya et al., 2011).

In the present study the infield reinjection of thermal fluid is used as the technology method.

1.3 *Types of hazards*

It has been noted that the lack of planning for injection early in the development phase usually caused delays in putting power on line and reaching the planned generation level as well (Arnorsson, 2004). Thus, as it was mentioned above, the injection process is a vital part of any geothermal development, affecting directly the success or failure of any geothermal field development. Chemical pollution occurs both from gaseous components in steam that are discharged into the atmosphere and from aqueous components in spent water that may mix surface and ground waters, characterized as the most adverse environmental effect of geothermal energy utilization. Geothermal fluid may be including CH_4, CO_2, B and H_2S. The last is a noxious gas that has an unpleasant smell, when present in low and harmless concentrations and can be fatal, if inhaled in high concentrations for a longer period of time. In order to reduce chemical pollution both waste water and steam condensate should be injected into drill holes (Arnorsson, 2004).

2 TECHNOLOGY USED

2.1 *General principles*

The single-flash steam technology is adopted when the geothermal production wells indicate a mixture of steam and liquid, in order to convert the geothermal energy into electricity in a simple way. Initially, after its extraction the geothermal fluid mixture passes through a cylindrical cyclonic pressure vessel and is separated into distinct steam and liquid phases, with a minimum loss of pressure. The sitting of the separators is part of the general design of the plant and there are several possible arrangements, as shown in Figure 1 (Dipippo, 1998).

A typical 30 MW single-flash power plant includes 5–6 production and 2–3 injection wells relatively. These wells can be drilled at sites across the field or from a single pad through a directional drilling in order to intercept wider zone of the reservoir. In either case, through a piping system the geothermal fluids are transported from the production wells to the powerhouse and then to the disposal wells. Of course, the initial piping system can be modified if new power units are added later on.

2.2 *Description of problems actually connected with the injection of waste geothermal fluid*

Geothermal fluid does not necessarily require to be injected into the production geothermal reservoir; it could be injected into a different aquifer simply to avoid any environmental impact owing to surface disposal. However, in that case many problems can occur, such as ground subsidence, seismicity or leakage of the injection fluid to the surface due to the injection pressure, despite the fact that injection in a shallower aquifer than the producing reservoir saves drilling cost. On the other hand, injection into the production reservoir could be both beneficial as it was mentioned above but also risky owing to the potential cooling of the production well and the possible adverse impact on the chemistry of the extracted geothermal fluid (Sanyal et al., 1995).

The injection of waste geothermal fluid is most of the times connected with a number of problems. The suitability of injection sites is a critical choice for plant operation, production, while the injection within the same fault zone can cause serious cooling. Thus, the developer in such systems has the choice to inject in shallow ground water aquifers, if the geothermal fluid is environmentally benign and could also inject deeper within the fault zone,

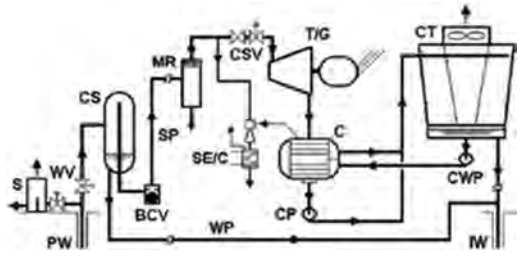

Figure 1. Simplified single-flash power plant design.

in order to be heated up before mixed again with the production line. Finally, in the case of environmentally benign fluid, the latter can be discharged on the surface.

Cooling provided by injection, seems to be the most common problem in the geothermal industry. According to Sanyal et al. (1995), there are two causes for injection—induced cooling: a) Very close distance between production and injection wells, b) "Short—circuiting" of the injected fluid to the production wells caused by a fault or fractured zone. However, the cooling problem can be identified through tracer test program conduction and could give alert to the developer.

A potential groundwater contamination can be caused by the injection of the geothermal waste on the geothermal reservoir; the main factors are the up flow of the injected water to the groundwater aquifer through a fault and the potential leakage of the injected fluid behind the casing caused by poor cement bond or probable damage due to corrosion or mechanical causes. However, through a careful geologic modeling the first cause can be avoided by locating injection wells in alternative sites.

Leakage of injection waste water to the surface can be identified in very shallow geothermal reservoirs (a few hundred meters). In order to avoid this kind of problem, injection should be deeper than the production level. Moreover, the occurrence of micro earthquakes near injection sites could be induced due to high pressure injection. More specifically, if the fluid pressure is increased beyond the original pore pressure and subsurface zones of weakness or active faults exist near the injection area, seismic activity may be induced. Thus, in order to avoid seismic activity, injections wells should be located away from known active faults, and the injection pressure should be lower than the original pore pressure of the system.

3 USE OF RISK ANALYSIS

3.1 *General*

Risk Analysis stemmed from the Major industrial accidents of the last decades involving dangerous chemicals that pose a significant threat to humans and the environment. It involves hazard identification, hazard evaluation, the development of potential risk reducing measures, and the communication of risk information to decision makers (Papazoglou et al., 1992) Risk analysis typically involves the following key steps:

- Hazard identification (HAZID)
- Frequency analysis
- Consequence analysis
- Quantification of risks using output from frequency and consequence analysis
- Investigation of potential risk reducing measures
- Development of recommendations

The common methods used in Risk Analysis are a) the hazard and Operability Analysis (HAZOP), b) the Failure Modes and Effects Analysis (FMEA), c) the "What if" scenarios, d)the Fault Tree (FT) Analysis, e) the Event Tree (ET) Analysis, f) the Risk Matrix and many other methodologies, which range from purely Qualitative to totally Quantitative and a mix of the two that are applied according to the needs and resources of the plant to be analyzed. Making assumptions about the detailed engineering of the reinjection method used, as series of accident scenarios including hydrogen sulfide (H_2S) release have been identified and are presented below.

3.2 *Accident scenarios in the geothermal plant*

The gases that exist in the geothermal re-injection fluid, namely the carbon dioxide (CO_2) and hydrogen sulfide (H_2S), also exist with the natural steam and do not condense at the condenser temperatures; these gases pass through a steam jet ejectors and, after condensers (SE/C in Figure 1) and the vacuum pumps, can removed increasing the overall pressure in the condenser and lowering the turbine power output. If a series of misfortunes happen and all protection systems (PSV, pressure control) fail to operate, the pressure will increase consequently above the normal limits and a possible break in the tank will occur. Two accidental scenarios have been analyzed together with their consequences:

a. Instantaneous failure of the tank full of H_2S
b. Failure of a pipeline carrying H_2S.

The SOCRATES toolkit has been used for these analyses; this is an in-house development of NCSR "DEMOKRITOS with gas outflow, dis-

Table 1. Outflow data for plant damage states (a) and (b).

Outflow data	Plant damage state (a)	Plant damage state (b)
Type of Installation	Tank	Tank
Storage conditions	Gas Pressurized	Gas Pressurized
Pressure in tank	$4 * 10^5$ (Pa)	$4 * 10^5$ (Pa)

persion and consequences assessment codes based on TNO's "Yellow", "Green" and "Purple" books respectively (TNO, 2017).

The initial conditions to this software for outflow calculation are presented in Table 1 below:

4 RESULTS

SOCRATES toolkit calculated the concentration of Hydrogen Sulfide over a specified time and distance on the appropriate mesh for the case studies. In both cases scenarios, the instantaneous and the continuous release, Hydrogen Sulfide had enough buoyancy owing to its temperature and dispersed in the atmosphere in accordance with the Gauss model. All the parameters considering the meteorological phenomenon such as, the velocity, the direction and the stability class of the wind as well as the environmental temperatures are the mandatory data/ input for the Gaussian model when dealing with such dispersions and uncertainty in their values has been taken into consideration. More specifically, in the SOCRATES toolkit, sixteen (16) cases regarding the various meteorological parameters were simulated and correlated with site prevailing meteorological conditions.

Individual and Group Risk are calculated for plant damage states (a) and (b) for each mesh point in the area. The isorisk curves in Figures 2 and 3 present the individual risk for plant damage states (a) and (b), respectively.

Figure 2. Isorisk curves and consequences zone for plant damage state (a), Instantaneous release.

Figure 3. Isorisk curves and consequences zone for plant damage state (b), Continuous release.

5 DISCUSSION OF RESULTS

The Risk Analysis results presented in the previous section demonstrate the minor risk of the geothermal plant activity in the surroundings of the installation, as the 10^{-6} isorisk curve remains within the battery limits of the installation. Only plant operators are likely to suffer some discomfort owing to Hydrogen Sulfide, should an accidental release of the latter happen. However, personnel members are normally well trained and have sufficient Personal Protective Equipment (PPE) to deal with this hazard. The consequences findings though the SOCRATES toolkit running and interpretation of the results give promising results towards the low-risk operation of such plants in the proximity of inhabited areas.

6 CONCLUSIONS

In this paper, the results of a Risk Analysis of a geothermal power system caused by the injection of geothermal fluid back to the origin reservoir were presented. Additionally, environmental threats specific to geothermal fluid injection sites have been also mentioned.

Specific accidental scenarios of Hydrogen Sulfide release have been studied through the SOCRATES toolkit and the consequences owing to its dispersion are considered as non-significant to nearby communities. Plant personnel are aware of possible threats and can take specific mitigation measures.

Geothermal fluid injection condensate is a solution to environmental impacts but also helps maintain reservoirs pressure, increasing both the operational lifetime of the production well and the reservoir lifetime. Waste fluid injection is favorable against surface disposal of waste water due to its constituents which may cause adverse effect on the environment and the people.

In Greece geothermal energy has been used already in the early '90s only for direct utilization. The Greek reservoirs are not in use for electricity production in the country. One of the reasons was severe technical problems. These problems seem to be faced nowadays with the new prevention and mitigation techniques.

The final conclusion is that a reinjection plan should be developed as early as possible in any conceptual study of a geothermal development taking into account the field characteristics and also preferably the Risk Analysis results.

ABSTRACT: ADS-IDAC is a discrete dynamic PRA simulation platform in which the time-dependent changes in the functional state and parameters associated with the system elements are traced to generate scenarios by branching to new sequences at various time steps following a small set of general branching rules. These model-based branching rules have been developed to obtain a more realistic and complete solution space than the traditional static PRA methods, and avoid the sequence explosion phenomenon as the number of system states increases. This paper describes a new version of the ADS-IDAC simulation platform that includes: branching based on important human operator events – e.g., information processing, decision-making, procedure-following, or action-taking type, and full implementation of Human Error Probability (HEP) quantification rules that explicitly account for HEP dependencies based on shared performance shaping factors modeled using a dynamic Bayesian network.

1 INTRODUCTION

The dynamic Probabilistic Risk Assessment (PRA) methodologies are model-based simulations used to generate risk scenarios and their associated probabilities. This is achieved through general rules of stochastic and deterministic behaviors and interactions of the system and its elements – e.g., process variables, hardware, human operators, and environmental conditions. The simulation engine of a dynamic PRA platform tracks possible changes in the functional state and parameters associated with the elements of the system as a function of time. The nature and impact of the interactions and interdependencies among the system elements are processed by the simulation engine to generate risk scenarios. Ultimately, depending on the selected method chosen for scenario generation, probabilities of individual or clusters of scenarios are calculated for the system end states of interest. Dynamic PRA methodologies are especially important when the system includes time-dependent and complex interactions between the process variables, hardware, human, and environmental conditions. They provide a natural framework to include physical models, such as thermal-hydraulic codes for Nuclear Power Plants (NPPs), mechanistic models of hardware failure, cognitive models of human behavior, and those of natural hazards. Such a dynamic PRA simulation platform is ADS-IDAC: the Accident Dynamics Simulator coupled with the Information, Decision and Action in a Crew context cognitive model, and a realistic nuclear power plant thermal-hydraulic model. It is one of the most mature discrete dynamic platforms with an evolution that spans more than 25 years (Fig. 1).

In most of the Human Reliability Analysis (HRA) methods, the Human Error Probability (HEP), defined as the probability of an operator not completing a specific task, is quantified as a function of the Performance Shaping Factors (PSFs). In ADS-IDAC, the PSFs are quantified in terms of their contextual parameters (i.e. surrogates) and their impact on the cognitive processes is implemented through manifestation nodes as is illustrated in Figure 3 (Li, 2013).

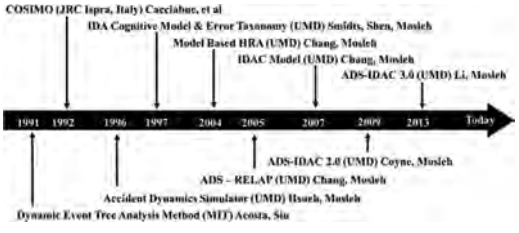

Figure 1. ADS-IDAC development history.

Although it greatly improved the explicit impact of the PSFs on the human performance, ADS-IDAC still lacks a full implementation for explicitly quantifying the HEPs based on the dynamic nature of the PSFs. For each individual or team activity, the behavioral effects of the PSFs can be accounted for through an influence diagram. Like its application in the Phoenix method (Ekanem, 2013), the Bayesian Belief Network (BBN) approach can be used to estimate the probability that a specific cognitive behavior occurs given certain conditions.

The main objective of the research reported in this paper was to introduce a set of comprehensive quantification rules to enable dynamic calculation of branch probabilities and complete risk scenario probabilities. The HFE dependencies were explicitly accounted for through the shared PSFs using a newly developed dynamic Bayesian network starting from a BBN model of PSFs developed in the Phoenix method.

2 IDAC HUMAN BEHAVIOR ADJUSTED BY CONTEXT AND OPERATOR VARIABILITY

During the simulation, the human operator behavior in IDAC is adjusted based on the context through a mechanism of surrogates—Performance Shaping Factors (PSFs) – manifestation nodes (Fig. 2). At each time step, the NPP state parameters are used to adjust the surrogate node values, the surrogates (yellow nodes) affect dependent PSFs (blue nodes) and in turn the PSFs affect manifestation (green nodes). The relationships between these nodes are based on empirical correlations found through extensive literature reviews corresponding to the appropriate human behavior mechanisms (Li, 2013).

Like all information processed by the operator model, all the dynamic PSF values are based on information perceived by the operator rather than data obtained directly from the thermal-hydraulic model or control panel. Perceived data may differ from the actual parameter value in thermal-hydraulic model or control panel due to time lags in updating perceived data and any distortions introduced by perception filtering and biasing.

The PSFs modeled in ADS-IDAC are: parameter criticality, system criticality, information load, time constraint load, cognitive task load, passive alarm load, expertise, task complexity, stress, fatigue, and problem-solving style. All of them are dynamic PSFs, except expertise and problem-solving style.

The criticality of system condition dynamic PSF represents the operator's perception of the level of degradation of key safety functions compared to normal operation. The value of the system criticality PSF corresponds to the aggregate deviation of key safety parameters from a nominal value. Each operator profile has its own parameters used to calculate this PSF: the threshold limits associated with each parameter, and the weighting factors used to aggregate the parameter contributions. The contribution from each identified parameter to the overall criticality of system condition PSF value is denoted as the parameter criticality. Given a set of high and low threshold limits, the parameter criticality corresponds to the magnitude of the parameter's deviation from a nominal safe condition.

The information loading dynamic PSF represents the operator's mental workload associated with the perception, processing, and communication of information. All information available from the NPP hydraulic model and crew communications must first pass through the operator's perception filter before it can be memorized and used. Consequently, the information flow rate through the perception filter provides an appropriate measure of each operator's information processing workload.

The time constraint load dynamic PSF represents the time available until a monitored NPP parameter exceeds a critical threshold. Because operators will normally monitor more than one important parameter, the overall PSF value is based on the most time critical parameter. The knowledge base profile for each operator includes data

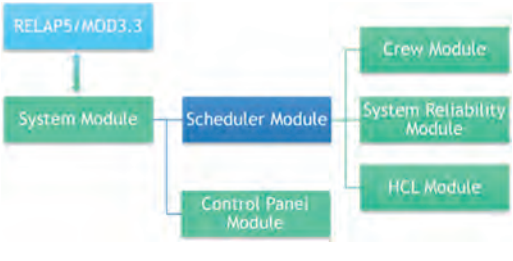

Figure 2. ADS-IDAC architecture.

Figure 3. Surrogates (yellow) – PSFs (blue) – Manifestation Nodes (green) IDAC model.

defining how the time constraint load PSF value is calculated, including a listing of NPP parameters used to calculate the time constraint PSF value along with the associated critical threshold values.

The task load dynamic PSF is indicative of the actual task demand assigned to a person quantified in terms of the number and type of tasks in a time unit. NPP control room operations do not normally involve heavy physical work, so in ADS-IDAC only the cognitive task load is of interest. Simulation HRA models possess a unique advantage of tracking each activity performed by the operator, which allows the code to count and to assess the workload specifically; therefore, the cognitive task load is also a dynamic PSF evaluated at each time step.

The passive alarm load dynamic performance factor embodies the number of salient stimuli that catch the operator's attention automatically like the alarms in the control room. Most often passive information is intrusive and grabs the operators' attention while interrupting their ongoing cognitive processes. Thus, too much passive information could be overwhelming. In addition to causing mental stress, it shifts one's attention and impedes the ability to refocus.

Operator expertise facilitates operator's coping with fast system dynamics in several ways: structuring and sorting the observations systematically, speeding the retrieval of knowledge for explaining the observation, and making connections between different pieces of information.

The task complexity dynamic PSF represents a measure of interaction among system dynamics, diagnosis confusion, and operator expertise. Amongst the system dynamics tracked at each time step are parameter trend changes, component state changes, and alarm state changes. Diagnosis confusion represents the complexity induced by inconsistent information and indicates the operator's level of understanding of the current NPP status.

The stress dynamic PSF combines various stress inducing PSFs into one factor: time constraint load, passive information load, cognitive task load, and task complexity. Each of the stressors has an equal weight on the stress value.

As the NPP control room operators' tasks do not involve heavy physical work. Thus, only the following three dimensions are considered in calculating this dynamic PSF: mental fatigue, sleepiness, lack of motivation/activity. It is evaluated based on an initial fatigue level at the beginning of their shift, a prolonged effort component due to performing tasks over a long period of time, and a sustained effort component representing the accumulation of fatigue by performing tasks. Moreover, the sustained effort component of fatigue is accelerated by the stress level.

The problem-solving style static PSF is reflected into the following of model parameters and information processing functions. In ADS-IDAC three problem solving styles have been implemented: Vagabond, Hamlet, and Garden-Path styles. They affect various parameters used to model the variation in diagnosis of operators in the reasoning module: routine monitoring time interval, maximal alarm stack length, prioritization of investigation items, investigation termination criteria, and accident awareness thresholds.

This framework performs well for adjusting the behavior of human operators based on the context. However, it is incomplete as it does not include any HFE, Crew Failure Mode (CFM), or HEP quantification that must be included in the generated Discrete Dynamic Event Tree (DDET) events for its full quantification.

3 NEW QUANTIFICATION MODEL FOR HUMAN ERROR

3.1 *Overview of HCL*

The HCL methodology (Wang, 2007) was developed for risk scenario analysis in PRAs of technological systems that considers not only the risks associated with hardware components (also called 'hard' causes), but also the risks generated by human activities, physical environment or socio-economic environment (also called 'soft' causes). This methodology offers a multi-layered modeling approach so that each individual domain of the system is modeled with the most appropriate technique. The three layers modeled in HCL are: Event Sequence Diagram (ESD) layer – it is used to model the risk context, Fault Tree (FT) layer – it is used to model the physical systems' behavior and quantify their impact on their corresponding linked events in the ESD, Bayesian Belief Network (BBN) layer – it is used to model the causal relations between events that have 'soft' root causes (Groth, Wang, Mosleh, 2010).

The HCL library was coupled with ADS-IDAC in a previous research effort for its FT-BBN quantification capabilities. The FTs were dynamically linked to the DDETs for modeling support systems and their impact on the frontline systems (Diaconeasa, 2017).

In this research only the BBN layer of the HCL architecture was necessary. Its capabilities had to be expanded to include leaky noisy OR gates that are used to reduce the conditional probability table size.

3.2 *Overview of the phoenix method*

The Phoenix method is a static HRA method that was developed out of the IDAC model. In the Phoenix method, the quantification of HFE is performed using a BBN for modeling the effect of the

PSFs on the CFMs. The construction of the BBN was made using the CFMs and PSFs as nodes and the arcs to show the relationships of influence between them through a conditional probability table. BBNs provide numerous benefits such as the ability to incorporate both qualitative and quantitative information from different sources for analysis, a causal structure for modeling interdependencies among its elements, the flexibility of updating the present state of knowledge of the model to incorporate new evidence as it becomes available, the capability of reasoning under uncertainty, and its ability to interface with existing conventional PRA models.

3.3 *HFE quantification through a dynamic Bayesian network*

The starting point for developing a quantification framework of the ADS-IDAC HFEs was the Phoenix method briefly described in the previous section. It is a natural step to include the additional elements of the Phoenix method into the IDAC model as part of the full dynamic ADS-IDAC simulation environment.

A BBN is valuable for problem domains or systems where the variables do not change over time. This assumption cannot always be assumed. For example, NPP system parameters and human operators' reasoning are clearly changing over time. In these cases, a Dynamic Bayesian Network (DBN) is necessary. A DBN is a BBN that is extended to incorporate a temporal dimension to enable the modeling of dynamic systems. The temporal extension of a BBN does not necessarily mean that the network structure or parameters changes dynamically, but it means that a dynamic system is being modeled. Hence, a DBN is a directed, acyclic graphical model of a stochastic process. It consists of time steps, with each time step containing its own variable values. The basic idea in a DBN is to specify how variables at time t influence variables at time t + 1 and replicating the structure of a model for each time step (Fig. 4). This concept of the dynamic Bayesian network was used to model the dependencies between the HFEs by replicating the network structure to represent the dynamic system and ultimately estimate the conditional HEP at each time step. This structured, causal model integrated into ADS-IDAC also helps improve the reproducibility and transparency of results produced by different HRA analysts for the same scenario.

Construction of the DBN involves building the structure of the network and defining the data describing the causal relationships between the network's nodes, and the nodes that will change in time. Unfortunately, the Phoenix method BBN cannot be adopted without modifications as some of its nodes

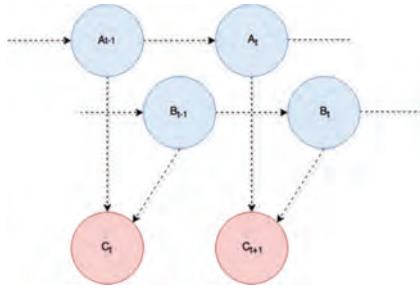

Figure 4. Simplified dynamic Bayesian network with developed on one time step with two dynamic nodes A and B influencing node C at every time step.

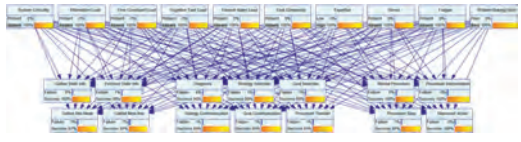

Figure 5. DBN of PSFs and HFEs.

Table 1. Mapping between the PSFs of ADS-IDAC and Phoenix.

ADS-IDAC	Phoenix
System criticality	Time constraint
Information load	Resources
Time constraint load	Time constraint
Cognitive task load	Task load
Passive alarm load	HSI
Expertise	Knowledge/Abilities
Task complexity	Procedures
Stress	Stress
Fatigue	Stress
Problem-solving style	Team effectiveness

do not have an ADS-IDAC equivalent and they do not cover all the HFEs modeled by ADS-IDAC.

The structure of the dynamic Bayesian network contains two layers in which all the top layer nodes influence all the bottom layer nodes (Fig. 5). Since the primary purpose of this dynamic Bayesian network is to model the effect of the PSFs on the crew failure modes, the top layer contains the PSF and the bottom layer contains crew failure modes. The top layer contains the PSFs described in the previous section: system criticality, information load, time constraint load, cognitive task load, passive alarm load, expertise, task complexity, stress, fatigue, and problem-solving style. As the Phoenix method does not have the same PSFs, based on their definition and purpose an equivalence relationships table was created to match the PSF used in ADS-IDAC and Phoenix (Table 1). All the PSFs except the expertise

and problem-solving style are dynamic; therefore, their value will change as the simulation progresses depending on the context. The PSFs have also been normalized to have values between 0 and 1.

The bottom layer of the dynamic Bayesian network in Figure 5 is made of crew failure modes. As in the Phoenix method, the crew failures modes specify the possible forms of human error in each of the information pre-processing, decision-making, and action execution phases.

The crew failure modes are also the generic functional modes of failure of the crew in its interactions with the NPP and represent the manifestation of the crew failure mechanisms and proximate causes of failure. They are selected to cover the various modes of crew response including procedure driven, knowledge driven, or a hybrid of both. To avoid double counting crew failure scenarios during the estimation of HEPs, the crew failure modes are defined as being mutually exclusive.

The crew failure modes within the information phase assume that the crew has failed in detecting, noticing and understanding the plant function they are supposed to be handling. Human failure in this phase can be divided into two major groups namely: failure to perceive passive information and failure to actively gather information. The crew failure mode that would occur during the perceiving of passive information is "Perceive State Info" – the crew fails to perceive the plant parameters or states from the control panel. The crew failure modes that would occur during the active gathering of information are: "Gather State Info" – the crew unintentionally try to collect the information from the wrong source, "Gather Info Mode" – the crew decide to use the old memorized information instead of collecting updated information, and "Gather New Info" – the crew failure in gathering new information. The equivalence table between the ADS-IDAC and Phoenix crew failure modes in the information phase is given in Table 2.

The crew failure modes within the decision-making phase assume that there is failure in situation assessment, problem solving and decision-making given correct information pre-processing. Therefore, the assumption is made that the crew has detected, noticed and understood the plant functions they are supposed to be handling. However, they have failed to make a correct assessment of the plant condition, diagnose, decide and plan the adequate response needed to solve the problem at hand. Moreover, the decision-making operator has the responsibility to communicate the action-taking operators the appropriate strategy. Ultimately, failures in this phase result in implementing an incorrect recovery strategy, hence failing the required function. Therefore, the following crew failure modes have been included: "Diagnosis" – decision-maker reaches the wrong assessment of the plant, "Strategy Selection" – decision-maker takes the wrong strategy given the correct situational assessment, "Strategy Communication" – decision-maker fails to communicate the correct strategy selected to the action-taker, "Goal Selection" – decision-maker selects the wrong immediate goal given the correct situational assessment, "Goal Communication" – decision-maker fails to communicate the correct goal selected to the action-taker, and "Procedure Transfer" – decision-maker switches to the wrong procedure. The equivalence table between the ADS-IDAC and Phoenix crew failure modes in the decision-making phase is given in Table 3.

The crew failure modes within the action execution phase involve failure in action execution given correct information pre-processing, situational assessment, and decision-making. It is assumed that the crew has detected, noticed and understood the NPP function they are supposed to be handling. Also, it is assumed they have made a correct assessment of the NPP condition, diagnosed, decided and planned the adequate response needed to solve the problem. However, they fail in executing the response or required action. It is assumed that the crew failure modes in the action execution phase are unintentional errors, that is the operators are always acting in the interest of recovering the NPP. The following crew failure modes have been included: "Mental Procedure" where the crew fails to adapt the instinctive response procedure to the current situation, "Procedure Step" where the crew skip or pause a procedure step in order to rely of their knowledge,

Table 2. Mapping between the CFMs in the information pre-processing phase of ADS-IDAC and Phoenix.

ADS-IDAC activity	Phoenix CFM
Perceive state info	Reading error
Gather state info	Wrong data source attended to
Gather info mode	Decision to stop gathering data
Gather new info	Team effectiveness

Table 3. Mapping between the CFMs in the decision-making phase of ADS-IDAC and Phoenix.

ADS-IDAC activity	Phoenix CFM
Diagnosis	Plant/system state misdiagnosed
Strategy selection	Inappropriate strategy chosen
Strategy communication	Information miscommunicated
Goal selection	Inappropriate strategy chosen
Goal communication	Information miscommunicated
Procedure Transfer	Inappropriate transfer to a procedure

"Procedure Interpretation" where the crew misinterpret the procedure step expectation, and "Maneuver Action" where the action-taker does not perform the requested action. The equivalence table between the ADS-IDAC and Phoenix crew failure modes in the action execution phase is given in Table 4.

Some of the crew failure modes fall into the category of errors of commission, that is they are the result of their intent given the wrong situational assessment of the NPP conditions.

The DBN structure defined by the PSFs and CFMs given above was integrated into ADS-IDAC by linking the all the human events types simulated into ADS-IDAC to the appropriate CFMs.

In the information pre-processing phase, the CFMs are linked to the human event types as follows. The "Perceive State Info" crew failure mode is used to estimate the probability of the action-taker to correctly register the perceived information for an alarm state, a frontline system state, a support system state, a parameter value, and a parameter trend value from the control panel. The "Gather State Info" crew failure mode is used to estimate the probability of any of the human operators to collect the information from the correct source on the control panel: alarm state, frontline system state, support system state, or parameter value. The "Gather Info Mode" crew failure mode is used to estimate the probability any of the crew members succeeds in collecting updated information instead of using old memorized information. The "Gather New Info" crew failure mode is used to estimate the action-taker's or decision-maker's probability of adding a parameter to the scan queue for gathering updated information.

In the decision-making phase, the CFMs are linked to the human event types as follows. The "Diagnosis" crew failure mode is used to estimate the decision-maker's probability of reaching the correct assessment of the NPP given their understanding of the NPP conditions. Note that if the operators do not correctly understand the NPP conditions, they will still reach a diagnosis, even if it's the wrong one. The "Strategy Selection" crew failure mode informs the decision-maker's probability of selecting the appropriate strategy given the correct situational assessment. The supported strategy selections in ADS-IDAC are wait and monitor, procedure following, hardwired diagnosis, and knowledge-based reasoning. The "Strategy Communication" crew failure mode is used to estimate the decision-maker's probability of communicating to the action-taker the selected strategy. Moreover, if the action-taker is in the follow instruction strategy mode, the same crew failure mode is used to estimate the decision-maker's probability of communicating to the action-taker the appropriate instruction. The type of instruction can be to obtain information about an alarm state, a frontline system state, a support system state, a parameter value, and a parameter trend value from the control panel or change their values. The "Goal Selection" crew failure mode is used to estimate the decision-maker's probability of selects the appropriate immediate goal given the correct situational assessment. Selecting the inappropriate goals can lead a delay in the appropriate recovery actions. The "Goal Communication" crew failure mode is used to estimate the decision-maker's probability to communicate the correct goal selected to the action-taker and consultant. The "Procedure Transfer" crew failure mode is used to estimate the crew's probability to switch to the correct written or mental procedure. The "Mental Procedure" crew failure mode is used to estimate the crew's ability to perform the appropriate instinctive response procedure based on the correct situational assessment. The "Procedure Step" crew failure mode is used to estimate the crew's probability of correctly skipping or pausing a procedure step in order to rely of their knowledge. The "Procedure Interpretation" crew failure mode informs the crew's probability to correctly interpret the procedure step expectation. As in the case of perceiving information, the expectations can be related to an alarm state, a frontline system state, a support system state, a parameter value, or a parameter trend value from the control panel.

In the action-taking phase, only one CFM is modeled as follows. The "Maneuver Action" crew failure mode is used to estimate the action-taker's probability to complete an action communicated by the decision-maker or from procedures.

After defining the PSFs, the CFMs with their mapping to the existing human events in ADS-IDAC, the next step was to obtain the data necessary to quantify the DBN. In order to achieve this, the estimated and calibrated parameters from the Phoenix method were adopted. The data sources used in the Phoenix method include German NPP operating experience data, other HRA methods (e.g. SPAR-H), and expert judgement. The advantage of the Bayesian network is that when new human performance data becomes available, be

Table 4. Mapping between the CFMs in the action execution phase of ADS-IDAC and Phoenix.

ADS-IDAC activity	Phoenix CFM
Mental procedure	Failure to adapt procedures
Procedure step	Procedure step omitted (intentional)
Procedure interpretation	Procedure misinterpreted
Maneuver action	Incorrect operation on component

it qualitative or quantitative, it can be easily integrated into the model parameter estimation process using Bayesian inference. Common sources of information that can be used are experimental data (e.g. control room simulator data), operating experience (e.g., licensee event reports), HRA databases, like the US NRC sponsored database project called the Scenario Authoring, Characterization, and Debriefing Application (SACADA), in addition to expert judgement.

The conditional probability table for each crew failure mode node in the Bayesian network is used to capture the strength of influence between each crew failure mode and its parent PSF nodes. This implies that the probability of the crew failure mode given all its possible combinations of the PSFs needs to be defined. This is challenging problem as the number of conditional probabilities in the conditional probability table grows exponentially with the number of nodes and states.

To reduce the conditional probability table size, the noisy OR gates can be used to specify the DBN and to build the conditional probability table for the crew failure modes nodes. In relation to the DBN quantification model included in ADS-IDAC, the leaky noisy OR gate also give the advantage of representing the probability that a crew failure can occur even when there is no influence from any of the PSFs. In other words, the leak factor provides a way to include other PSFs that are not explicitly represented in the DBN model as individual PSF nodes.

Using the HAMMLAB empirical data and the HRA results from the international empirical study (Lois, 2009), the conditional probability table has been normalized. The normalization procedure was the following: HFE 1A, failure to isolate the steam generator in the simple SGTR scenario, has been quantified using the original conditional probability table. The probability obtained has been scaled down two orders of magnitude such that the simulated HFE 1A falls inside the band of results obtained in the international empirical study.

The quantification of the successful human events captured by ADS-IDAC is a very critical aspect of the full DDET quantification. Now all the successful human events have a probability covering the full unit interval instead of an assumed fixed probability of one.

Compared to the conventional HRA methods, ADS-IDAC is able to quantify each individual activity that can lead to a particular HFE. Therefore, it is not only able to transparently predict the system and crew behavior, but quantify the probability of succeeding or failing at each time step for each activity the crew is undertaking based on the actual context through the linked DBN as is illustrated in Figure 6.

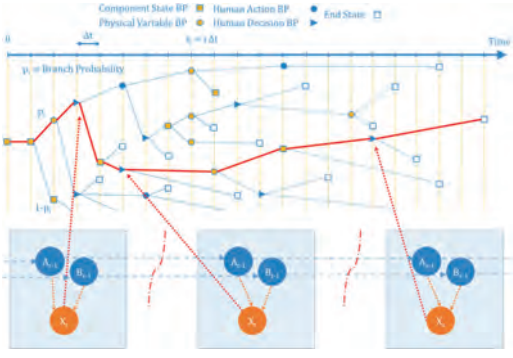

Figure 6. Graphical representation of an ADS-IDAC generated DDET where human events quantified with a simplified DBN are highlighted.

4 EXTENDED BRANCHING OF EVENTS IN GENERATION OF DDETS

The ADS-IDAC simulation engine generates a DDET by activating success, failure or partial failure branching points when certain conditions are met. The construction of the DDET is driven by a rich contextual environment simulated by ADS-IDAC and guided by the branching rules, which allow the modeling of variability in system and human operator.

The DBN covering the effect of PSFs on the CFMs at each time step was integrated into ADS-IDAC by linking all the human events types simulated in ADS-IDAC to the appropriate CFMs. That is, all the human events are assigned a success probability at each time step based on the current state of the DBN. One consequence of this framework can be seen with the following simple example. During a diagnosis, the crew may need to check the status of a component multiple times. Depending on the context, and implicitly on the value of the PSFs, the probability of the crew to correctly perceiving the status of that same component may be different. Therefore, new branching rules have been added to capture human performance variability, and to quantify the human failure events.

The branching points that were linked to be quantified with the DBN are described below:

- When a strategy is changed, based on the "Strategy Selection" crew failure mode two branches are generated: one in which the crew continue the current strategy, and another in which they switch to the new strategy.
- When a procedure step indicates a transfer to another procedure, two branches are generated: one in which the crew switches to the new procedure, and another in which they continue the current procedure.

- When an accident diagnosis threshold is exceeded based on the knowledge-based reasoning, two branches are generated: one in which the crew take recovery actions based on their reasoning, and another in which they transfer to the appropriate procedure.
- When a mental belief activation threshold is exceeded based on the heuristic reasoning two branches are generated: one in which the crew transfer to the mental belief, and another in which the crew bypass the mental belief and continue their activity.

These rules together with the newly developed quantification models help to keep the simulation space expansion under control, yet it also allows sufficient degrees of freedom for the system and crew to evolve into unexpected behaviors. For example, given the procedure step skipping probability is quantified at each time step containing written procedure steps or mental procedures either deterministically or stochastically, the skipping of procedure steps could be simulated and their impact analyzed in a consistent and transparent way.

5 CONCLUSIONS

A set of comprehensive quantification rules to enable dynamic calculation of branch probabilities and complete risk scenario probabilities was developed and implemented using a DBN. The HFE dependencies were explicitly accounted for through the shared PSFs by adapting the BBN model of PSFs developed in the Phoenix method to the dynamic environment of ADS-IDAC.

ABSTRACT: Conventional Probabilistic Risk Assessment (PRA) methodologies and software tools developed for a variety of risk-informed applications are also characterized as 'static', referring to the fact that temporal and phenomenological aspects of risk scenarios are at best implicit in the models and results. For instance, typical core melt cut sets are essentially logical combinations of contributing events, without consideration of possible effects of different time ordering of the constituent events, and timing of event initiation or termination. Over the past three decades a small community of researchers have directed toward developing and exploring possible benefits of dynamic PRA methods and tools. Dynamic methodologies provide a natural framework to include physical models, mechanistic models of hardware failure or human operator behavior models. In this paper, the capabilities to link conventional PRA platforms with dynamic PRA tools are described and the concept of cut set diffraction is introduced. This facilitates the use of newer risk analysis methods while still using the existing probabilistic information that, at least in the U.S., is available for every Nuclear Power Plant (NPP).

1 INTRODUCTION

Conventional Probabilistic Risk Assessment (PRA) methodologies and software tools developed for a variety of risk-informed applications are also characterized as 'static', referring to the fact that temporal and phenomenological aspects of risk scenarios are at best implicit in the models and results. For instance, typical core melt cut sets are essentially logical combinations of contributing events, without consideration of possible effects of different time ordering of the constituent events, and timing of event initiation or termination. Additionally, the basic events in classical PRAs are typically binary, a situation that can mask the impact of such thing as degraded component states. Furthermore, conventional PRAs have come under attack in terms of adequacy in providing important contextual information for proper modeling and analysis of operator errors.

These are some of the reasons stated in support of the need for simulation based PRA, generally known a dynamic PRA. Over the past three decades a small community of researchers have directed toward developing and exploring possible benefits of dynamic PRA methods and tools. These efforts show a significant diversity of objectives and methodology. Among the stated objectives are: study of impact of timing and sequencing of events, understanding the effects of variations in the underlying physical processes, and study of operator error, particularly errors of commission. Methodological and computational works cover the computational efficiency of generating dynamic event trees (discrete and continuous versions), scalability and convergence, post-processing of generated results, software platform generality, and user interface features.

With significant advancement of dynamic methodologies and computer power and storage capacity, the prospects of using dynamic PRA tools to answer risk questions is more real now than ever before. Despite the progress in the development of dynamic PRA methods and tools, the conventional PRA method and software platforms are expected to remain the method of choice for the current generation of NPPs. However, a strong case can be made that conventional PRAs can be augmented by dynamic approaches, especially for scenarios where dynamic characteristics are anticipated to be important.

An efficient path to enable such augmentation is to develop protocols and capabilities to link conventional PRA platforms with dynamic PRA tools. This will facilitate the use of newer risk analysis methods while still using the existing probabilistic information that, at least in the U.S., is available for every NPP.

2 CONVENTIONAL AND DYNAMIC PRA

2.1 *Conventional PRA*

In the application of the defense in depth concept, Probabilistic Risk Assessment (PRA) is used to determine the probability for breaching each barrier. In general, PRA methods are employed to identify failure scenarios and to estimate their associated risk by answering to three fundamental questions (Kaplan and Garrick 1981): 1) "What can happen?", 2) "How likely it is that it will happen?", and 3) "If it does happen, what are the consequences?" System performance reliability, uncertainty analysis, and human reliability analysis methods are explicitly integrated into the PRA framework, thereby enabling the application of defense in depth, which would be impossible to do using deterministic analysis methods alone.

PRA is a matter of scenarios and their likelihoods as illustrated in Figure 1 showing an event tree with the system actuation failure event represented through a fault tree (Garrick, 2008). The theory of structuring scenarios is rooted in field of reliability engineering and systems analysis. Reliability engineering produced graphical representations that were very useful in describing how systems perform. Fault tree analysis is a deductive reasoning process for building failure models. Its roots are switching algebra and circuit theory coming out of the Bell Labs. The inductive reasoning process of the event tree concept has its roots in decision theory and was developed into a systems performance tool in the reactor safety study WASH 1400 (Rasmussen, 1975). The theory of probability as a measure of likelihood evolved in the fields of mathematics over hundreds of years. For events that occur frequently, a frequency can be quantified to reflect the number of occurrences per unit of time. However, for events that rarely occur, or may not occur at all, the concept of probability is quantified. Probability is synonymous with 'credibility' as in the credibility of a hypothesis based on all of the available evidence. Ultimately, for any defined undesirable event frequencies, such as fatalities, in the form on probability of frequency are the main measure of safety risk for engineering systems.

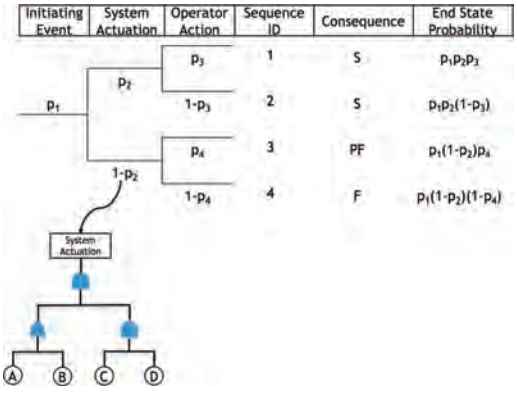

Figure 1. Conventional PRA.

A full score PRA involve the following well established steps (Garrick, 2008):

- define the system and its success state—usually involves linearizing the system into logically progressive operating states, that is fixing in time the top events based on the analyst's understanding of the system operation,
- identify and characterize the hazards also called threat assessment,
- develop and structure the 'what can go wrong' scenarios that lead to undesired outcomes or vulnerability assessment—creative exercise analyst dependent
- quantify the scenarios—the uncertainties associated with the scenarios must be part of the answer
- assemble results into measures of risk, and importance measures,
- interpret the result for meaningful risk management.

Each sequence is a path to either type of consequence: success (S), failure (F), or partial failure (PF) state. Each probability is a conditional probability. The sequences are quantified by propagating the probability density functions representing the split fractions of the top events through their corresponding paths up to their end states. One of the end results is a probability of frequency curve for each sequence end state consequence or in the form of a mean and median with its confidence interval. However, the quantification results are as important as the scenarios generated by the analysts and their relative importance to the NPP safety.

Multiple conventional PRA software platform are readily available in academia, industry, or regulatory agencies. The most common ones are IRIS (Fig. 2), RISKMAN, CAFTA, RiskSpectrum Suite, SAPHIRE. In this work, the IRIS tool was selected as the conventional PRA platform of choice, however the generic architecture used is applicable to the other software platforms.

2.2 *Dynamic PRA*

Dynamic PRA methodologies are generally those that use a time-dependent phenomenological model of system evolution and take into account its stochastic behavior to estimate the risk associated with the system response to an initiating event (Aldemir, 2013). The system evolution model

Figure 2. IRIS platform for modeling ESDs, FTs, and BBNs.

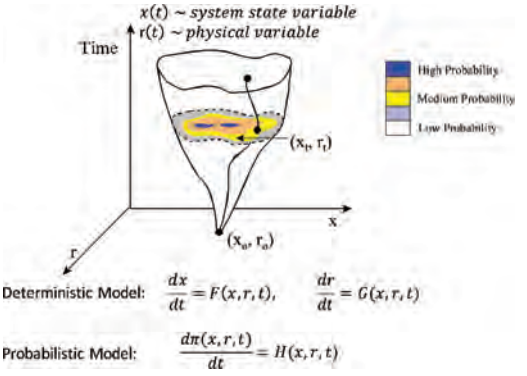

Figure 3. Dynamic PRA (Mosleh, 2015).

keeps track of the current hardware status, current level of processes variables, current operator assessment, scenario history, and time (Siu, 1990). A graphical representation of the system evolution space with its probabilities of occurrence is shown in Figure 3.

Dynamic PRA has been grouped in two main categories: continuous-time (e.g. Continuous Event Tree (CET)) and discrete-time (e.g. Dynamic Event Tree Analysis Method (DETAM), Accident Dynamic Simulator (ADS), Analysis of Dynamic Accident Progression Trees (ADAPT), and Risk Analysis Virtual Environment (RAVEN)).

The discrete dynamic PRA methodologies use Discrete Dynamic Event Trees (DDETs) that are computationally generated based on a time-dependent model of system evolution and various branching conditions.

Essentially, all discrete dynamic PRA methodologies employ a simulation engine that generates branches at each user-specified time step or conditions with their associated probabilities and computes the probability of each scenario. As can be seen in Figure 4, branching points can include system hardware states, physical variable changes, human actions, software failures or an end state if one of the stopping criteria is met.

ADS-IDAC, the Accident Dynamics Simulator with its operating crew simulation model (Identification, Decision and Action in a Crew cognitive context) and thermal-hydraulic code RELAP5/Mod 3.3 was selected as the dynamic PRA platform for scenarios that would require more extensive operator response modeling. ADS-IDAC is a simulation engine that includes a scheduler module, a hardware reliability model, an indicator module (the control panel), and the IDAC operator response model coupled with the RELAP5/MOD3.3 thermal-hydraulic code (the system model) to generate DDETs containing contextually rich scenarios that could occur given an initiating

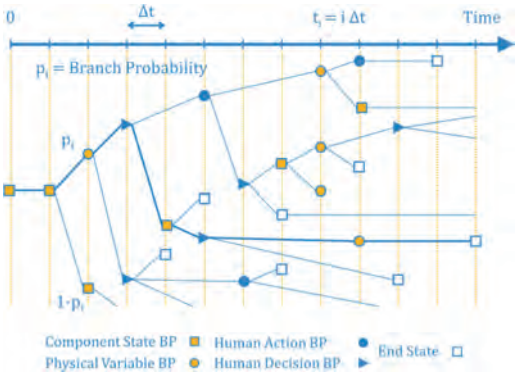

Figure 4. Discrete dynamic PRA methodology.

event. Its modular structure and the flow of information between modules are shown in Figure 5.

A scheduler module coordinates the interactions between all the other modules and generates the DDETs. As is the case for traditional ETs, the probability of each scenario or sequence is the product of conditional probabilities of its constituent branches. The indicator module simulates the control panel indicators' states driven by information from the system module. The HCL module models and quantifies the probability of Human Failure Events (HFEs) based on a Dynamic Bayesian Network (DBN) of a range of Crew Failure Modes (CFMs) and Performance Shaping Factors (PSFs) that reflect the context conditions in which the operators create situational assessments and devise recovery strategies (Diaconeasa, 2017a). The hardware reliability module simulates the failure probabilities of the system's and control panel's components, but coupled with the HCL module can model the impact of support systems on the frontline systems through dynamically linked FTs (Diaconeasa, 2017b).

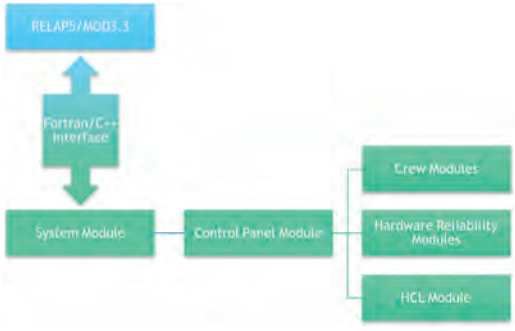

Figure 5. ADS-IDAC architecture.

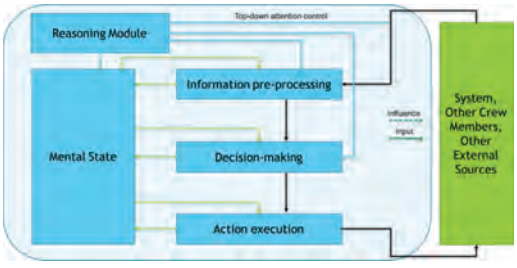

Figure 6. IDAC cognitive model for one human operator.

The IDAC model serves as underlying framework for operator behavior. IDAC decomposes the operator's cognitive flow into three main process: information processing, decision-making, and action execution (Fig. 6). The domain of applicability of IDAC is constrained to environments characterized by high levels of training and explicit requirements to follow procedures. These constraints simplify the modeling by limiting the degrees of freedom from the broader human response spectrum. In IDAC, the crew is modeled as a team of individuals working on different assigned tasks and communicating with one another. The individuals differ by the content of their memory, by their mental state, and by the goals and strategies they employ. IDAC can simulate several decision-making and problem-solving strategies, including passive and active information gathering, diagnosis, skill-, rule-, and knowledge-based actions, and procedure-following. The model includes several dynamic and static PSFs as part of the set of factors and rules that simulate the Senior Reactor Operator (SRO) and Reactor Operator (RO) responses. Each operator also has a unique knowledge base that defines his or her knowledge about nuclear plant systems and operations.

Previous research efforts in developing ADS-IDAC have shown that a small set of generic branching rules are sufficient to capture complex variations in system and crew-to-crew performance (Coyne, 2009).

3 HYBRID PLATFORM ARCHITECTURE

The hybrid static-dynamic PRA platform was designed to selectively feed conventional PRA results (e.g. cut-sets) from IRIS into the ADS-IDAC dynamic PRA platform for dynamic analysis.

The typical ET/FT/BBN analysis of conventional PRAs is used to generate a list of cut sets. Each cut set is used in the dynamic PRA analysis to constrain the branching at every time step in creating the DDET driven by the system and crew evolutions. This is graphically illustrated in Figure 7.

The optimum strategy that provides the broadest range of applications and highest compatibility with present conventional and dynamic platforms (not only IRIS and ADS-IDAC) is by creating an interface between the platforms for selectively passing information that complies with the Open-PSA model exchange format. Given that the Open-PSA model exchange format covers only ETs and FTs, the standard will be extended to cover BBNs in order to provide compatibility to all the layers of the IRIS platform. In Figure 8, the hybrid static-dynamic PRA platform is shown where the typical inputs and outputs are listed for each module.

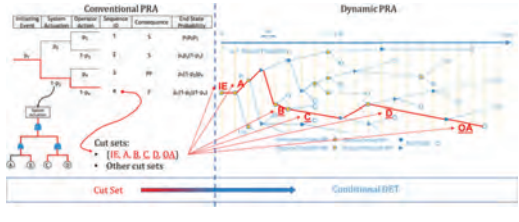

Figure 7. Hybrid static-dynamic framework.

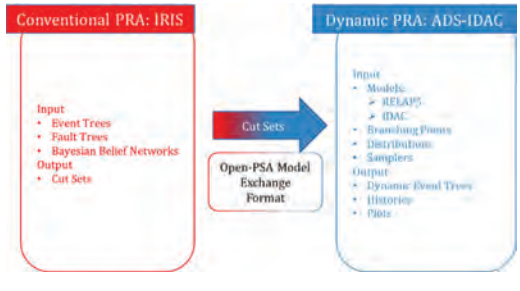

Figure 8. Hybrid static-dynamic PRA platform.

The interface acts as a gate for passing information from cut set to branching conditions in ADS-IDAC. Thus, in the ADS-IDAC model boundary conditions need to be set based on both the cut set information and the available components available in the system model either captured in the RELAP5 thermal-hydraulic model or through dynamically linked FTs.

Overall, all the branching points and the intermediate events associated with an initiating event make up the DDET during accident scenarios. The set of generic branching rules cannot create the DDET without modeling in parallel the dynamic system and human operator behaviors. Therefore, the construction of the DDET is driven by a rich contextual environment simulated by ADS-IDAC and guided by the branching rules, which allow the modeling of variability in system and human operator.

The necessity for branching rules in a dynamic PRA simulation platform like ADS-IDAC is the sequence explosion phenomenon. If the simulation engine would allow branching at every time step the number of sequences needed to be explored would grow exponentially and the simulation time would become unrealistically long with the current computational models and resources. For the same computational reasons, sequence termination conditions have been implemented to stop the engine from exploring sequences after a time period of interest, when certain physical limits have been exceeded, or when the operators enter certain procedures. For example, if the interest of the simulation is the exploration of crew variability in diagnosing a SGTR, two sequence termination conditions could be set to stop the simulation. One of them could be placed when the operators transfer to procedure E-2 "Isolation of steam generator with secondary break" or E-3 "Tube rupture in one or several steam generators." Another could be set when the simulation time exceeds a certain time period set based on previous crew performance.

At the same time, sequence termination conditions can be set to calculate an overall failure probability for an event of interest. For example, a sequence termination condition for the fuel element cladding temperature exceeding the acceptance criteria for emergency core cooling systems for light water nuclear power reactors (10 CFR Part 50.46) of 2200°F. The summation of the end state probability for all sequences that were terminated by this condition would essentially estimate an overall measure of core damage probability.

Overall, the branching rules and the sequence termination conditions do not cover all the models included in ADS-IDAC their variability is not included in the generated DDET and, ultimately, the solution space is not complete.

Branching rules that cover the failure of either frontline or support system components have been implemented. Nonetheless, by implementing branching rules alone does not mean the sequence end state probability can be quantified. Each branching point requires either a success or failure probability. The ADS-IDAC hardware reliability module covers modeling of both frontline and support system failures during operation by considering the failure rate, the number of failures desired and the time interval between them. DDET branching is modeled such that failures during operation generate two branches: success and failure branch. For a specific equipment, if more than one failure during operation is modeled, only the subsequent success branches will further allow more failures as on the failure branches this equipment had already failed. This feature further extends ADS-IDAC's capability to dynamically predict the timing importance of component failures during operation for the overall safety of the design in question is. For example, small-break LOCA scenarios in a PWR could be set up to simulate the timing of the pressurizer power operated relief valves (PORVs) stuck-open failure events and their impact on the available time for recovery actions.

The crew's recovery of frontline and support system's component failures can also be modeled (Diaconeasa, 2017b). When the crew attempt to recover a component, two additional branches are generated: a recovery branch, in which the component is successfully recovered, and a permanent failure branch, in which the component remains failed.

The branching points that were quantified with the dynamically linked FTs (Fig. 9), out of which a success and a failure branch are created, are given below:

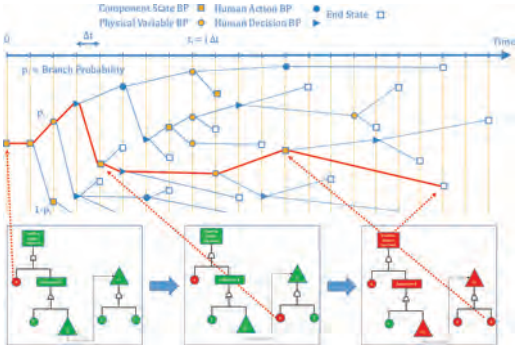

Figure 9. DDET with quantified frontline and support system branching points based on dynamically linked FTs.

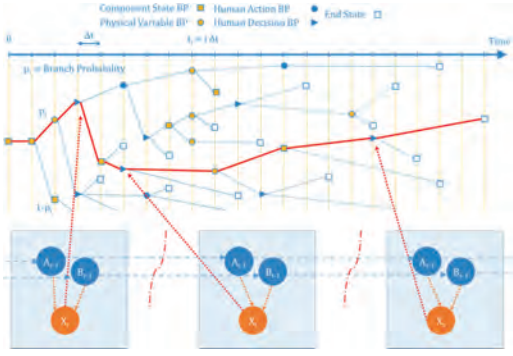

Figure 10. DDET with quantified human events branching points based on a DBN of PSFs and CFMs.

- Components of frontline systems failures at fixed time.
- Components of frontline systems failures on demand.
- Components of frontline systems failures during operation.
- Components of support systems failures at fixed time.
- Components of support systems failures on demand.
- Components of support systems failures during operation.

Using the DBN of PSFs and CFMs, a range of branching points for HFEs are implemented to model the crew's variability (Diaconeasa, 2017a). The HFEs covered in the branching rules (Fig. 10) can be of type strategy selection, procedure transfers, diagnosis of accident conditions based on either the knowledge-based reasoning or procedure following.

4 CUT SET DIFFRACTION PHENOMENON

The hardware and human operator behavior variations can act as a diffraction grating to create new scenarios starting from a single cut set, a process analogous to light diffraction in optics. This phenomenon is illustrated in Figure 11.

The number of sequences obtained from the single cut set would depend on the number of events in the cut set, but also by considering the following variations: timing and order of failures, degree of component degradation, time and degree of recovery, human decisions and actions, human dependencies, or physical variable thresholds.

The timing and order of failures are important in Fukushima-like scenarios, or hurricane

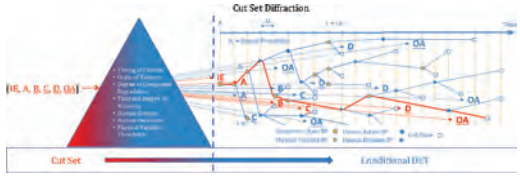

Figure 11. Graphical representation of the cut set diffraction where the input cut set is highlighted in the DDET.

scenarios, where the reactor is tripped at some time prior to the more severe plant response. How can initially smaller decay heat levels complicate the sequence of events operators are trained on? How can the order of events be shifted and how does this impact the crew response? There are scenarios where it is necessary to consider the timing of failures. For example, the failure of containment spray at some time after they successfully start will prolong the capacity of the Refueling Water Storage Tank (RWST) to supply suction before recirculation. On the other hand, the failure to secure running trains of spray per procedure would lessen the time to suction switchover.

The degree of component degradation is important in cases similar to the Beaver Valley PRA sequences initiated by a loss of an instrument bus. When can an initially benign sequence degrade and become more of a challenge? Loss of this bus fails makeup to the volume control tank, but normal charging continues. If not recovered (by switching to an alternative instrument bus), suction is shifted to the RWST. Failure to recover makeup prior to switchover to RWST could make successful termination dependent on a single check valve (in a borated environment).

The time and degree of recovery was seen to be important in the TMI-3 Loss Of Coolant Accident (LOCA). Auxiliary Feedwater (AFW) was failed, and then subsequently recovered. Once recovered, High Pressure Injection (HPI) was secured. What was not appreciated was that AFW recovery came too late, as a LOCA had already occurred.

The importance of decisions and actions of the crew can be illustrated by looking at scenarios involving the failure of Main Feedwater (MFW) and AFW. Procedures instruct the crew to recover MFW or AFW and after failure to do so, go to feed-and-bleed (F&B). Observation of different crews at simulators suggest different crews will devote different amounts of time focusing on the recovery of MFW or AFW. When would the delay result in loss of a potential success path? Also, recovery that requires steam generator depressurization (e.g., using condensate) may influence recovery characteristics. This assessment will likely

be plant-specific due to differing shutoff head capacities of the HPI pumps.

The hardware dependencies can have risk implications as is the case for shared equipment during a multi-unit initiator. Examples might be Loss of Off-Site Power (LOSP) in a NPP with shared diesels and shared equipment. Initial plant states and equipment failure conditions may be underappreciated as they could complicate plant recovery.

A consequence of the cut set diffraction phenomenon in the hybrid static-dynamic PRA platform is the consideration of non-core damage end states. PRAs are typically developed to trace the sequence of events that lead to core damage or fission products release. The frequency of such scenarios is one metric of interest in regulatory risk, as it is one common surrogate measure for public health risk. However, restricting the logic models to only determine core damage frequency, or large early release frequency, limits the breadth of information potentially available to decision makers.

5 CONCLUSIONS

A hybrid static-dynamic PRA platform was developed to leverage the newer risk analysis methods available while still using the existing probabilistic information that, at least in the U.S., is available for every NPP. The IRIS and ADS-IDAC tools make up the main elements of this platform, nevertheless similar PRA tools could be used that conform to the Open-PSA model exchange format. Finally, the cut set diffraction phenomenon was introduced and illustrated with short examples.

A framework for assessment of Technological Readiness Level (TRL) and Commercial Readiness Index (CRI) of asset end-of-life strategies

I. Animah & M. Shafiee
Cranfield University, Bedford, Bedfordshire, UK

ABSTRACT: A substantial number of industrial assets within the manufacturing, power generation, transportation, oil and gas, petrochemical processing, mining and construction sectors are facing operation beyond their anticipated design life and will be in need of intensive maintenance services in the coming years. At the end of an asset's design lifetime, the operators must make a decision on either rejuvenating the components through life-extension solutions or decommissioning the asset. This means that life extension policies (e.g. remanufacturing, reconditioning, repurpose, retrofitting) and decommissioning strategies (e.g. recycling and disposal) will continue to play a crucial role in the future management of industrial assets. However, some of the End-of-Life Management Strategies (ELMS) or their emerging technologies may not be mature yet, and therefore application of such strategies can cause extensive uncertainties. A well-documented Technological Readiness Level (TRL) and Commercial Readiness Index (CRI) for these strategies and related technologies will be a key in reducing the uncertainties involved in implementing ELMS in various industries. This paper aims to propose a systematic framework consisting of six different processes to help asset managers evaluate the TRL and CRI of different ELMS and their corresponding technologies. An essential part of developing this framework is the strong collaboration among academics and industrial experts with several years of experience in undertaking life extension and decommissioning projects. For purpose of illustrating the model, a case study involving end-of-life strategies of wind turbines is provided and the results are further discussed. The data required for this study is collected from various sources, including the published literature and industrial reports as well as by surveying academic and industrial experts. The results of this study indicate that TRL and CRI assessments are not only an effective means of evaluating the technological status of different ELMS but also a means for risk management decision making.

1 INTRODUCTION

Over the past several decades, asset owners in the manufacturing, power generation, transportation, oil and gas, petrochemical processing, mining and construction industries have focused on optimizing the design of their systems, enhancing installation techniques and improving production. However, in recent years, many of the assets operating in the above-mentioned industries are entering a new phase of development where assets are expected to reach their anticipated design lifetime. Hence, the attention of industries is now shifting towards how these ageing assets can be managed, to ensure that they continue to deliver high level of service beyond their original design lifetime.

The two most popular end-of-life management strategies (ELMS) include asset life extension and decommissioning. Asset life extension involves the application of technical and administrative procedures to extend the useful life of engineering structures, systems and components at the end of their design lives, provided they are technically and economically qualified. The benefits of extending the service life of ageing assets are enormous. For instance, extending the service life of a multi-million pound system could result in substantial return on investment. It also has the tendency to increase production volume and reduce CO_2 emissions due to slow down in the manufacturing of new products.

On the other side, decommissioning represents the last stage of the asset life cycle. It involves the total or partial removal of assets, which ensures the restoration of a site (land or seabed) to suitable condition for other uses and also maximizes material recovery from removed assets through waste management. Despite the huge potential of life extension and decommissioning to asset owners, the life extension policies and decommissioning strategies as well as their emerging technologies are not yet matured. Therefore, the application of these ELMS in many sectors often result in huge technological and commercial uncertainties.

In order to minimize the technological and commercial uncertainties involved in implement-

ing ELMS in various industries, it is important for asset owners to explore, assess and evaluate the maturity level of life extension policies and decommissioning strategies for different systems and components, taking into account technological readiness level (TRL) and commercial readiness index (CRI) of related technologies.

The TRL was first developed by NASA in 1974 as a benchmarking tool to assess and communicate the maturity levels of new technologies (Mankins, 2009). Since then, it has been applied in various industries to provide a measurement of technology maturity. Although the TRL concept is appropriate to help minimize technological uncertainties, there are often commercial or financial uncertainties characterising new programmes and technologies entering the market. Another accepted process that can be used for benchmarking the commercial maturity of new technologies is the commercial readiness index (CRI). The CRI was developed by the Australian Renewable Energy Agency (ARENA) to evaluate the commercial readiness level of renewable energy technologies.

Understanding and communicating the TRL and CRI for life extension policies and decommissioning strategies as well as their related technologies will not only enable asset owners to reduce the uncertainties involved in implementing ELMS in various industries but also can help them to determine how key assets could be competitive beyond their original design life.

The aim of this paper is to propose a framework to evaluate the maturity level of different life extension policies and decommissioning strategies by taking into account the TRL and CRI of related technologies. The proposed framework is tested with a case study involving offshore wind turbine blades that have reached the end of their original design lives. Our results indicate that the proposed framework provides a powerful decision-making tool to support asset owners to efficiently manage engineering structures, systems and components when they reach the end of their original design life.

The rest of the paper is organized as follows. Section 2 presents the conceptual framework and the steps required to aid in assessing the maturity levels of life extension policies, decommissioning strategies and the related technologies. In Section 3, the model is applied to a case study involving wind turbine blades and the results are analyzed in Section 4. Finally, the conclusions and future research directions are outlined in Section 5.

2 THE PROPOSED FRAMEWORK

The proposed framework for evaluating the maturity level of life extension policies, decommission strategies and emerging technologies is shown in Figure 1, which includes five steps. These steps are explained in details as follows:

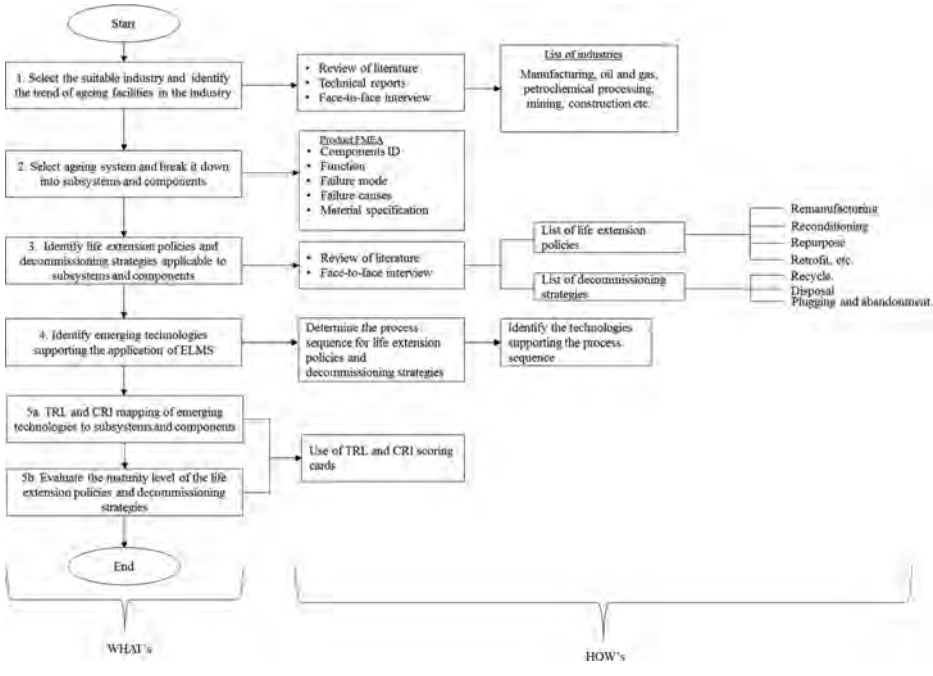

Figure 1. Steps for applying the proposed framework.

Step 1. Select the suitable industry and identify the trend of ageing facilities: As the purpose of this study is to evaluate the maturity level of different life extension and decommissioning policies as well as their related technologies to support end-of-life management of structures, systems and components within different industries, it is key to investigate the trends in the number of facilities approaching, have reached or exceeded the end of their original design life within a specific industry or company. This task can be achieved by reviewing journal articles, conference papers, technical reports, company's dossier and face-to-face interview with industrial experts. The industries/companies that can apply the proposed framework to support end of life management of ageing assets include (but not limited to) the following: power generating (nuclear energy, renewable energy and power transmission and distributions), manufacturing, transportation, oil and gas, petrochemical processing, mining, construction, etc.

Step 2. Select an ageing facility and break it down into subsystems and components: In this stage, an ageing facility is selected and decomposed into manageable units. Decomposition of ageing facility into manageable units is to facilitate the mapping of applicable life extension policies or decommissioning strategies for high-risk subsystems and components of the facility. The task of breaking down a facility into manageable units can be achieved through the use of product failure mode and effect analysis (FMEA).

Step 3. Map applicable life extension policies and decommissioning strategies to subsystems and components: At this stage, all applicable life extension policies and decommissioning strategies are identified and mapped to critical subsystems and components of the facility. The life extension policies and decommissioning strategies can be identified though literature review as well as consultations with industry experts. Examples of life extension policies include remanufacturing, reconditioning, repurpose, retrofitting, etc. while recycling, disposal and plugging and abandonment are examples of decommissioning strategies. For more comprehensive description of different life extension policies, readers can refer to Shafiee and Animah (2017).

Step 4. Identify emerging technologies for implementing life extension policies and decommissioning strategies: The goal of this stage is to identify the technologies related to the implementation of the applicable life extension policies and decommissioning strategies for the critical subsystems and components. In order to identify the related technologies, one must understand the process sequence for each life extension policy or decommissioning strategy. Understanding the process sequence for different life extension policies and decommissioning strategies will help in identifying the appropriate technologies and their features and provide specific information that allows for the allocation of TRL and CRI respectively.

The process sequences involved in extending the useful life of an engineering structure, system or component include cleaning, disassembling and inspection, repair, reassembling and testing. Whereas cutting, lifting, removal and material recovery/disposal may constitute decommissioning process sequences for systems and components, especially within the offshore oil and gas and offshore wind power industries.

Step 5. Evaluate the maturity level of the life extension policies and decommissioning strategies: This task of the proposed framework is performed by utilizing the TRL and CRI assessment scales, shown in Figure 2. The TRL scale helps to assess the technical maturity of the life extension policies and decommissioning strategies as well as their related technologies whereas the CRI scale assists in evaluating the commercial readiness of the strategies and the related technologies.

There are two rounds of activities at this stage. In the first activity, the TRL and CRI of the emerging technologies supporting the implementation of life extension policies and decommissioning strategies for subsystems and components are determined using Eq. (1) and (3) below:

$$TRL_i = \sum_{j=1}^{n} w_{ij} TRL_{ij} \tag{1}$$

$$\sum_{j=1}^{n} w_{ij} = 1; for \forall_i \tag{2}$$

where w_{ij} is the relative importance (weight) of technology j for policy/strategy i, and

$$CRI_i = \sum_{j=1}^{n} v_{ij} CRI_{ij} \tag{3}$$

$$\sum_{j=1}^{n} v_{ij} = 1; for \forall_i \tag{4}$$

where v_{ij} is the relative importance (weight) of technology j for the policy/strategy i. The weights w_{ij} and v_{ij} can be allocated by experts or estimated

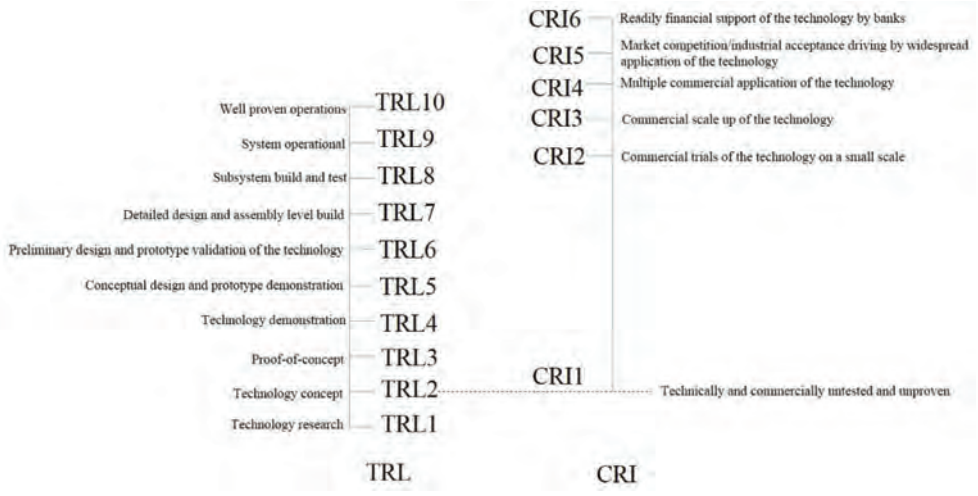

Figure 2. Technology readiness level (TRL) and commercial readiness index (CRI) scale (ARENA, 2014 and Straub, 2015).

using the Delphi-analytical hierarchy process. The second activity involves evaluating the maturity level of each life extension policy and decommissioning strategy (M) using Eq. (5):

$$M = \sum \alpha TRL_i + (1-\alpha)CRI_i, 0 < \alpha < 1 \quad (5)$$

where α and $1-\alpha$ represent the relative importance (weight) of TRL and CRI in relation to each other.

3 APPLICATION TO WIND TURBINE BLADES

The number of wind turbines reaching the end of their original design life of 20–25 years has been increasing in recent years, hence repowering, life extension and decommissioning activities are attracting the attention of both practitioners and scholars in the wind power industry. In order to illustrate the efficacy of the proposed framework, it is applied to offshore wind turbine blades which have reached the end of their original design lifetime. The data used in this study was collected from literature, academics with expertise in wind energy industry as well as blade manufacturers. In this Section, the results of the application case are presented and discussed.

Step 1. The wind power industry is the focus of this case study.

Step 2. From the product FMEA of the wind turbine provided by the operator, the proposed framework is applied to the blades, which are made of composites.

Step 3. The life extension policies and decommissioning strategies considered for the blades are briefly explained below.

- Remanufacturing: It involves the use of modern technologies and procedures to break assets down into core parts, and then engineering changes are made to the core parts in order to meet Original Equipment Manufacturers (OEM) specifications and performance. In most cases, the cost of a remanufactured system is less than that of a brand new system but with an equivalent warranty to that of a brand new system (Animah *et al.*, 2017).
- Reconditioning: According to Shafiee and Animah (2017) reconditioning involves taking appropriate actions to restore a defective system to between "as good as new (AGAN)" and "as bad as old (ABAO)" condition, hence the output is less than that of OEM's stated output.
- Repurpose: It involves taking the necessary steps to create a new use or purpose for an existing system which was originally designed for a different purpose (Aguirre, 2010; Coughlan *et al.*, 2015). With this life extension policy, engineering actions and processes are applied to make transformation to key parts of a system. The transformation is based on the technical feasibility of the engineering processes, environmental performance and economic viability of the system for future operations (Bauer *et al.*, 2017).
- Retrofitting: It involves the process of replacing old components of a system with modern

Table 1. Overview of technologies used to support remanufacturing, reconditioning, repurpose and retrofitting process for blades.

Process sequence	Technologies	Technology features
Cleaning	Jet cleaning (water jet, abrasive (sand) blasting cleaning, dry ice cleaning etc.).	With this technology, rust, grease, oil and other contaminants are removed from surfaces of components through physical interaction of the accelerated medium (sand, water, dry ice etc.) by compressed air or high pressured water (Liu et al., 2013).
	Organic solvent cleaning	This method of cleaning is performed by drenching/soaking components in organic solvent or spraying the organic solvent on component surfaces while cleaning takes place as a result of dissolution and chemical reaction (Kikuchi et al., 2011).
	Ultrasonic cleaning	Ultrasonic cleaning involves the use of high frequency (20–400 KHz) sound waves to generate agitation in a liquid (Niemczewski, 2007). The cavitation bubbles produced as a result of the agitation acts on contaminants on the surfaces for cleaning.
Disassembly	Disassembly embedded design	Disassembly embedded design integrates a disassembly mechanism into a system during design, e.g. Snap fits to dislodge locked out of position (Soh et al., 2014).
	Active disassembly	This technique makes use of external triggers such as temperature, magnetic force or pressure, for the release of fasteners. It include utilizing smart materials, freezing elements, soluble elements, pneumo-elements and hydrogen storage alloy elements as a fastening technique (Duflou et al., 2006).
Repair/ Modification/ Retrofitting process	Laser repair technology (LRT)	LRT is suitable for the repair/rebuilding of worn out metallic parts, which are considered non-repairable using traditional welding or plating techniques. The process involves injection of metal powder into a focused beam of a high powered laser in a tightly controlled atmospheric condition.
	Advanced mechanical machining processes	This technology is needed when the repair of existing components require CNC milling, turning, drilling, tapping, cutting and other machining operations.
	Industrial 3D printing	This is an additive manufacturing process which uses high powered laser fusion to produce components by building layer upon layer from a predefined 3D digital design.
	Tubercle technology	This technology mimics the bumps on humpback-whale fins to develop a more efficient wind turbine blades.
	Plastic surgery	This the use of plastic surgery to make old, smaller and less efficient wind turbine blades into bigger and efficient ones without replacing them at the end of life.
Testing	Shearography system	This is the use of optimal measurement technology or shearorgraphy sensor to detect defects such as wrinkles, delaminations, debondings and kissing bondings in wind turbine blades.

Table 2. Overview of technologies used to support recycling and disposal of wind turbine blades.

Process sequence	Technology	Technology features
Material recovery	Pyrolysis	This is the use of pyrolysis recycling technology (i.e. burning of the resin matrix with limited oxygen).
	Mechanical grinding	This is the reduction of composite materials into suitable sizes and grounding them into different grades using mechanical processes such as hammer mill.
	Solvolysis	This technology makes use of physico-chemical separation process for full material recovery of thermosets. The process uses water at sub-supercritical temperature to breakdown thermoset resin, in order to remove it from the fibre.
	Incineration	This is the burning of end of life product for energy generation.
Disposal	Landfill	Burying the materials used in the manufacturing of the system in the ground.

equivalent in order to achieve higher functionality and availability. An example of retrofitting is the blade extension program for wind turbines, in order to increase the swept area of the rotor to increase power generation at low speed.

– Recycle: Complex industrial equipment are made of different materials. In post-decommissioning, scraps from these infrastructure in the form of metals and non-metals are generated, recycling processes are then used to recover high grade materials from these scraps for other uses, thereby limiting the amount of waste generated at the end of life (Yang *et al.*, 2012). However, recycling of the products can reduce the exploitation of natural resources and protect the environment.
– Disposal: Open burning and landfills are examples of the popular disposal options for components and materials from industrial systems. However, the economic value of reusing the system or recovering materials through recycling is lost when this strategy is implemented at the end of original design life.

Step 4. A number of technologies have been proposed by both researchers and practitioners to support the process sequence for implementing life extension policies and decommissioning strategies across different industries. The technologies that can support the process sequence of remanufacturing, reconditioning, repurpose and retrofitting of wind turbine blades are shown in Table 1. On the other hand, Table 2 shows the overview of the related technologies that can support the material recovery/disposal process sequence of recycle and disposal of wind turbine blades.

Step 5. The maturity level of the life extension policies and decommissioning strategies applicable to wind turbine blades using the TRL and CRI scales in Figure 2 is evaluated. The TRL and CRI of each technology was evaluated through experts' elicitation. First, the experts were asked to allocate TRL and CRI to the emerging technologies supporting the implementation of the life extension policies and decommissioning strategies obtained from the literature. Table 3 shows the TRL and CRI of the emerging technologies supporting the implementation of life extension policies and decommissioning strategies for wind turbine blades using Eqs. (1) and (3). The weights assigned to evaluate *TRL* and *CRI* for each technology were achieved through a consensus reached by a panel of experts. Second, the maturity level of each life extension policy and decommissioning strategy has been evaluated using Eq. (5) and are ranked in Table 4.

As shown in Table 4, disposal was chosen as the most appropriate ELMS for wind turbine blades. This is because the maturity level of landfill as a technology for disposing the blades made of composites are technically well proven, commercially available and relatively cheap in many parts of the world. The second and third most suitable ELMS for the wind turbine blades are remanufacturing and reconditioning. Retrofitting, repurposing and recycling were identified as the fourth, fifth and sixth preferred ELMS for the blades. This is because the key technologies needed to support the implementation of these ELMS for products made of composite materials are still in the experimental phase. This means that the technologies are not technically matured for large scale commercial applications. For instance, pyrolysis, mechanical

grinding and Solvolysis which are considered as the most suitable recycling technologies for composite products such as wind turbine blades are at the laboratory scale in terms of technological development (Rybicka *et al.*, 2016). Thus, making landfill and incineration the most widely used technologies to support end of life management of wind turbine blades when they reached the end of their original design life.

5 CONCLUSION

In this study, a methodology was proposed to assist in understanding and communicating the maturity level of life extension policies and decommissioning strategies for industrial assets reaching the end of their original design lives. The proposed methodology considered TRL and CRI of emerging technologies supporting the implementation of different life extension policies and decommissioning strategies, in order to rank the best ELMS. To the best of our knowledge, this was the first time the TRL and CRI scales were integrated to communicate the maturity level of different life extension policies and decommissioning strategies for products reaching their end of life. For the purpose of clearly illustrating the efficacy of the proposed framework, it was applied to determine the maturity level of different life extension polices and decommissioning strategies for wind turbine blades. The findings from the case study indicated that disposal of wind turbine blades through landfilling was considered as the most appropriate strategy for managing wind turbine blades when they reached the end of their original design life. This was followed by remanufacturing, reconditioning, retrofitting, repurpose and recycle.

Engineering safety recommendations: Results from a survey in aviation

N. Karanikas
Aviation Academy, Faculty of Technology, Amsterdam University of Applied Sciences, The Netherlands

ABSTRACT: Taking into account the lack of uniform guidelines for the design and classification of safety recommendations, a relevant framework was developed according to academic and professional literature. The framework includes nine design criteria for recommendations, it incorporates classifications of their scope and expected effectiveness, and it was used to perform a questionnaire survey across aviation professionals involved in the generation of safety recommendations. The goal of the survey was to capture (1) whether practitioners are knowledgeable about the design criteria, (2) the degree to which they apply those criteria along with corresponding reasons, (3) perceptions of the expected effectiveness of types of controls introduced through recommendations, (4) the frequency of generating each control type and respective explanations, and (5) the extent to which practitioners focus on each of the categories of recommendations' scope and the relevant reasons. Overall, the results showed: an adequate level of knowledge of the design criteria; a strong positive association of the knowledge on a particular criterion with the degree of its implementation; a variety of frequencies the recommendations are addressed to each of the scope areas; a reverse order of perception of the expected effectiveness of control types compared to the literature suggestions. A thematic analysis revealed a broad spectrum of reasons about the degree to which the design criteria are applied, and the extent to which the various types of recommendations are generated. The results of the survey can be exploited by the aviation sector to steer its relevant education and training efforts and assess the need for influencing the direction safety recommendations are addressed. Similar research is suggested to be conducted by organizations and regional and international agencies of any industry sector by ensuring a larger sample.

1 INTRODUCTION

Safety investigations play a crucial role in safety improvements especially because they lead to the formulation of recommendations to eliminate or mitigate identified problems with the scope to prevent similar occurrences in the future. To date, although in aviation there are established guidelines for the conduction of a safety investigation (ICAO, 2003, 2008, 2011, 2015), there is yet little guidance about the design of safety recommendations (Pooley, 2013).

To fill this gap, researchers and students from the Aviation Academy of the Amsterdam University of Applied Sciences (Zonneveld, 2016, De Vos, 2016, Kiefer, 2016) reviewed academic and professional literature and proposed a relevant framework that includes design criteria (Table 1), their scope (Table 2) and expected effectiveness (Table 3).

The particular framework was used to perform a questionnaire survey across safety practitioners to explore the extent to which the framework aspects are known and applied, and reveal any underlying reasons.

Table 1. Design criteria for safety recommendations.

Criterion	Brief explanation	Literature*
Specific	Addresses a particular problem	(Haughey, 2014, Gregson, 2017)
Measurable	Allows monitoring of its implementation	(Haughey, 2014)
Assigned	Addressed to specific responsible agent(s)	(Haughey, 2014, Gregson, 2017)
Realistic	Achievable within current boundaries	(Haughey, 2014, Gregson, 2017)
Time-bound	End dates defined	(Haughey, 2014)
Review	Review dates defined	(Haughey, 2014)
Objectives	What and not how to achieve	(Johnson, 2003, Gregson, 2017)
Action-oriented	Actionable items are preferred over studies	(Johnson, 2003)
Non-blaming	Focus on problems, not individuals	(Johnson, 2003, Dekker, 2016)

*Indicative literature references.

Table 2. Scope of safety recommendations*.

Dimension	Category	Brief explanation
Aspect of operations	Process structure	Oriented to low-level tasks (Re)design of system's architecture and functionality
	Culture context	Change of norms and behaviours
		Focus on politics and the society
Stakeholders affected	Macro-level	Governments, associations etc.
	Meso-level	Industry sector(s)
	Micro-level	Organizations and individuals
Degree of renewal	Repair	Short fixes of local problems
	Adaptation	Improvement of larger systems
	Innovation	Creation of new solutions

*Adapted from ESREDA (2015).

Table 3. Expected effectiveness of safety recommendations.

Type of control introduced*	Brief explanation
Physical	Prevent completely actions or access
Functional	Use of technology to limit actions
Symbolic	Means to alert for hazards or remind/train rules, procedures etc.
Incorporeal	Strategies, general policies, legislation

*In descending order of robustness (Hollnagel, 1999).

2 METHODOLOGY

Following the establishment of the theoretical framework about the design and classification of safety recommendations as presented above, the researcher aimed at assessing the degree to which the aspects of the framework are known and/or applied by safety investigators and professionals involved in the formulation of safety recommendations in general (e.g., safety and risk managers). The aspects of the framework comprised the topics of a questionnaire that was administered to safety managers, investigators and professionals. The data collected from the analysis with the tool and the questionnaire responses were statistically processed to obtain an overall picture and examine differences across various variables.

2.1 *Survey questionnaire*

The survey instrument was designed with the goal to capture the following information from practitioners involved in the generation of safety recommendations: whether they are knowledgeable of the design criteria and the degree to which they apply those in daily practice along with possible reasons; perceptions about the order of effectiveness of the control types referred in literature, frequency of proposing each control type as part of their role, and explanations about the latter; extent to which they focus on each of the categories included in the three dimensions of recommendations' scope and respective reasons.

The questionnaire included an introductory section where the background and aims of the study were stated along with the voluntary character and anonymity of participation. Also, the particular section referred to the estimated time investment (i.e. up to 15 minutes) and the contact details in the case that the respondents wanted to provide feedback on the questionnaire, get informed about the results of the study or raise any other inquiry.

To examine possible variations of the responses against characteristics of the sample, the subjects were asked to fill in their main job role at the time of participation (i.e. safety manager/officer, safety investigator, or other), the year they started getting involved actively in the generation of safety recommendations, the country they were practicing their vocation at the time of participation, and their highest level of education (i.e. High School, Associate Degree, Bachelor degree, Master degree, Doctoral level, and other).

For each of the design criteria for safety recommendations, the respondents were asked to state whether they know the criterion (possible choices: YES or NO), the extent to which they apply the criterion when creating safety recommendations (possible choices: 0–20%, 21–40%, 41–60%, 61–80%, and 81–100%), and explanations about their latter. Regarding the expected effectiveness of recommendations, the corresponding section provided a brief description and a few examples for each of the control types (i.e. physical, functional, symbolic and incorporeal) and asked the participants to rank the controls in the order of their effectiveness, state which control type they most frequently introduce in their safety recommendations, and justify their last answer. It is noted, that the control types were presented to the participants in a random order of effectiveness outlined in the literature (Hollnagel, 1999). The last section of the instrument referred to the scope of recommendations and included a short description for each of the dimensions (i.e. aspects of operations, stakeholders affected and degree of renewal) and their values (see Table 2). The subjects were prompted to choose the frequency to which their recommendations focus on each of the categories of the three dimensions (possible choices: 0–20%, 21–40%, 41–60%, 61–80%, and 81–100%) and state respective reasons.

It is clarified that there were no obligatory questions to be answered. The respondents could omit any demographic or safety recommendation related question. The draft version of the survey instrument was sent to four persons with relevant academic and professional background for their review. Following the revision of the questionnaire according to the remarks collected, its final version was designed online with the use of the Qualtrics platform. The functionality of the online questionnaire was tested with the participation of the same four reviewers. The survey instrument was administered through two main channels: (1) personal emails to contact persons of the network of the Aviation Academy of the Amsterdam University of Applied Sciences that covers various aviation organizations worldwide; (2) online messages to practitioners found on the LinkedIn platform and holding relevant positions (e.g., safety managers, safety investigators). Due to time constraints, three working days were devoted to the administration of the questionnaire and a three weeks period was set for the collection of responses.

2.2 *Sample and analysis of questionnaire responses*

In total, 42 questionnaires were filled. Because of the snowball sampling strategy, the author could not have any information about the number of persons whom the instrument finally reached (e.g., unmonitored or unread emails and messages). Therefore, the response rate could not be estimated. Nevertheless, since the scope of the whole study was an initial assessment of the situation around safety recommendations, the number of responses was deemed as sufficient. Table 4 presents the distribution of the sample across its demographic characteristics. It is clarified that the apart from the main job role, the rest of the demographics were grouped due to the small number of responses in some of the categories.

Table 4. Distribution of the sample.

Demographic variable	Values	Sample size	Valid percentage*
Main job role	Safety staff	18	42.9
	Safety investigator	13	31.0
	Other	11	26.1
Years involved in generation of recommendations	< = 4	10	25.0
	5–11	11	27.5
	12–18	10	25.0
	> = 19	9	22.5
Geographical region	Europe	30	71.4
	Other	12	28.6
Highest level of education received	< = Bachelor	18	43.9
	> = Master	23	56.1

*Some demographic questions were not answered.

Regarding the analysis of data, the frequencies for each the closed questions were calculated to offer an overall view of the responses. Fisher's exact tests were performed to reveal any associations of the knowledge of design criteria with the variables of Table 4. The same variables were also used to conduct Kruskal-Wallis or Mann-Whitney tests (i.e. depending on the number of categories of each variable) for the closed questions which corresponded to ordinal data (i.e. frequency of application of design criteria, frequency of focus of recommendations on the areas defined, and level of effectiveness of controls the recommendations introduce).

It is noted that, to allow the execution of statistical tests, the frequency choices were translated to ordinal figures as follows: 1: 0–20%, 2: 21–40%, 3: 41–60%, 4: 61–80%, and 5: 81–100%. The tests were run with the SPSS software version 22 (IBM, 2013). The function of Monte Carlo Exact Test under the settings Confidence Level: 99% and Number of Samples: 10.0000 was chosen to strengthen the validity of the results. The level of statistical significance was set to 0.05.

The open-ended questions concerned, a thematic analysis was performed. The researcher individually performed a coding of the answers, which was afterwards tested for reliability with two other colleagues who were not involved in the study. The comments of the raters indicated areas of disagreement as well as cases that the content of the answers had not been captured by the initial codes. Based on these remarks, the coding was revised and retested, resulting in agreement levels ranging from 77% to 92% between the researcher and each of the participants as calculated with Cronbach Alpha tests. The finalization of the list of coding themes was followed by the calculation of frequencies per code for each of the questionnaire topics.

It is clarified that in several qualitative responses the subjects did not provide explanations about their choices in the closed questions, but they restated the latter or made general comments not applicable to the particular question. These cases were excluded from the analysis. Due to the small number of valid responses, no statistical tests were conducted between the responses and the demographic characteristics of the participants.

3 RESULTS

3.1 *Results from analysis of closed questions*

The frequencies that the design criteria of safety recommendations are known and the extent to which are applied by the survey participants are shown in Table 5. The Non-blaming, Assigned and Realistic criteria were the ones most known, whereas the Review date and Actions criteria were

Table 5. Design criteria for safety recommendations.

Criterion	Median rank (application)	Frequency (%) the criterion is known
Specific	4.5	90.5
Measurable	4.0	87.8
Assigned	5.0	97.6
Realistic	5.0	95.2
Time-bound	4.0	90.5
Review	4.0	73.8
Objectives	4.0	85.4
Actions-oriented	4.0	75.6
Non-blaming	5.0	100.0

the ones that were least known by the respondents. Also, Spearman's bivariate correlations were performed between the figures of knowledge percentage and the medians. The results of the particular statistical test showed a significant and strong association ($N = 9$, $rs = 0.870$, $p = 0.002$), meaning that the higher the knowledge on a specific criterion, the higher the degree of its implementation.

The Fisher Exact tests between the design criteria and the demographics of the population resulted in significant results only for the association of years of experience in the generation of safety recommendations with the knowledge of the criteria Realistic ($N = 40$, $p = 0.046$) and Time-bound ($N = 40$, $p = 0.008$). The participants with 19 or more years of experience in safety recommendations declared less frequently that they knew about both criteria compared to participants having fewer years of experience. Regarding the frequency of application, the Objectives criterion was applied less frequently by safety managers/officers than the rest of the job roles ($p = 0.039$) and it was utilized more by the participants with increased years of involvement in safety recommendations generation ($p = 0.025$).

Regarding the scope of recommendations, the respective medians are reported in Table 6. The statistics revealed that culture-focused recommendations were applied more frequently by participants with roles other than safety staff and investigators ($p = 0.046$). Recommendations addressed to industry sectors (i.e. meso level) were generated by safety investigators more than other job holders ($p = 0.002$). Meso—and macro-level types of recommendations were made more frequently by subjects working in Europe ($p = 0.044$ and $p = 0.021$ respectively) or having a high educational background ($p = 0.008$ and $p = 0.004$ correspondingly).

The expected effectiveness of safety recommendations concerned, Table 7 presents the survey findings with regard to the perceived degree of effectiveness for each type of control introduced through recommendations. The statistics showed

Table 6. Distribution of scope areas of generated recommendations.

Dimension	Category	Median rank (application)
Aspect of operations	Process	4.0
	Structure	3.0
	Culture	2.0
	Context	2.0
Stakeholders affected	Macro level	2.0
	Meso level	3.0
	Micro level	4.5
Degree of renewal	Repair	4.0
	Adaptation	4.0
	Innovation	2.0

Table 7. Perceived effectiveness of safety recommendations.

Type of control introduced	Median rank
Physical	2.0
Functional	2.0
Symbolic	3.0
Incorporeal	3.0

no associations of the perceived effectiveness with the demographic characteristics of the sample.

3.2 *Results from analysis of open-ended questions*

The codes derived from the thematic analysis and their frequencies showed that in many cases the subjects applied the design criteria because they were mentioned in internal or external documentation or had been seen as best practice. It was widely recognized that the Specific criterion minimizes ambiguity in the implementation of safety recommendations, which according to a few respondents is expected at some degree. However, 3 out of the 20 participants declared that some flexibility is required and recommendations should not be always too specific.

The Measurable criterion was seen by most of the subjects as often unfeasible and a few respondents stated that the effect of changes is more important than their measurement, monitoring does not apply to simple recommendations, and a customization of relevant metrics to each organizational level/function is necessary. About the Assigned criterion, 3 out of the 18 participants argued that recommendations might require the engagement of more than one responsible persons, departments, agencies etc. The comments made about the Realistic criterion showed that this helps in increasing the credibility and feasibility of the recommendation and demonstrating an achieve-

ment of a balance between the resources required for its realization and the anticipated benefits. However, 5 out of the 23 answers pointed that the Realistic criterion might be difficult to meet due to the diversity of perspectives and interests of the stakeholders involved.

The Time-bound criterion concerned, the participants expressed a variety of views. Four persons recognized that the specific criterion would ensure the implementation of a recommendation, whereas three persons stated their reservations about the feasibility of the criterion. Also, two persons did not know the particular criterion and one person did not contemplate it as important. A similar picture was observed in the answers regarding the knowledge and feasibility of the Review date and Objectives criteria. The latter criterion was appreciated by three respondents because it allows flexibility in the operationalization of the recommendation.

A combination of actions and studies depending on the type of the problem to be solved was proposed by most of the participants. Four out of the 17 subjects argued that the Action criterion increases the feasibility of a recommendation. The application of the Non-blaming criterion was seen as positive by most of the participants regarding the effects on the overall culture and increase of the effectiveness of safety recommendations. Only 1 out of the 23 answers suggested that a focus on individuals/teams might be appropriate in cases of repeated unsafe behaviors.

The answers regarding the type of control most frequently introduced by the survey respondents showed a preference in symbolic controls, followed by incorporeal, functional and physical ones. The explanations given emphasize on the decreased feasibility of controls of technical nature (i.e. physical and functional) due to the demands for more resources for their realization. The views about the effectiveness of technical or non-technical controls (i.e. symbolic and incorporeal) were almost evenly distributed. In three cases, the respondents argued that symbolic and incorporeal controls are more vulnerable and require more frequent repairs. One respondent claimed that the focus on symbolic controls sources from the pressure of authorities who ask for more and better procedures.

Regarding the focus of recommendations on specific aspects of operations, 4 out of the 17 answers addressed that the decision depends on the context of the problem identified and four of the respondents answered that is a matter of organizational focus. The views about the process and culture aspects of operations were divided into two equal parts. Four subjects claimed that those aspects are difficult to change whereas other four subjects stated that the specific aspects are easier and faster to change. Concerning the degree of renewal, repairs and adaptations were seen as equally sufficient to deal with problems, partly because of the lower associated costs. Innovations were contemplated by 4 out of the 14 participants as either expensive or not appropriate to be introduced through recommendations, and two participants suggested that the required degree of renewal depends on the problem under examination.

Lastly, regarding the level of affected stakeholders, 8 out of the 17 subjects stated that their focus on the micro level is dictated by the organizational priority to deal with local problems and the difficulty to affect the meso and macro levels. One respondent recognized that micro level interventions are cheap and another respondent stated that interventions at the lowest level could lead to changes to the rest of the levels. Once more, many subjects declared that the type of each problem is as a parameter to decide which stakeholders will be addressed in a recommendation.

4 DISCUSSION

The overall results regarding the design of safety recommendations suggest that most of the participants are knowledgeable about the criteria identified in the academic and professional literature and apply these criteria to at least 60% of the recommendations but with different extents. Rather expectedly, the knowledge of a specific criterion was positively associated with the degree of its application when generating safety recommendations. However, such knowledge was obtained more through experience, best practice or organizational documentation rather than international and regional standards. The lack of guidelines in industry standards might explain partially the fact that some of the criteria were not known and consistently applied by a fraction of the survey participants. The statistical tests showed a few differences across some criteria, mainly linked to the years of experience in generating recommendations. Two of the criteria were less known and another criterion was more frequently applied by participants with higher experience.

The Non-blaming criterion was known and applied by all participants, thus indicating that the necessity for a just culture in aviation (Humpreys, 2014, Michaelides-Mateou and Mateou, 2016, Quinn, 2007) and the role that recommendations can play in realizing a culture of fairness have been well communicated across the particular industry sector. The criteria of Assigned and Realistic also scored very high regarding the level of familiarity of the respondents and the degree of their application, this partially attributed by the participants to the contribution of these criteria to increased credibility of recommendations. On the other hand, the Review and Actions criteria were not

known by about one-quarter of the survey participants. These criteria were seen as important but sometimes not feasible or binary regarding their application. In general, the respondents expressed concerns about the strict satisfaction of the whole set of criteria for every single recommendation and argued that each case must be handled differently.

Concerning the type of controls introduced through safety recommendations, interestingly, their effectiveness as perceived by the participants is not aligned with the literature suggestions, the results showing a reverse order. Whereas the work of Hollnagel (1999) implies that physical and functional controls are more robust and effective, the respondents viewed the symbolic and incorporeal controls as such. The comments collected showed that the viewpoints about the effectiveness of technology and non-technology based controls were evenly divided. According to the participants, the main factors driving the recommendation of a specific control type are the resources available and the expectations of the authorities for improved procedures. Hence, the author contemplates that the responses about the effectiveness of controls were affected by current practice and not a consideration of their technical characteristics or potential to deal with a hazard or risk more successfully.

Nevertheless, the positions of the participants regarding the types of controls preferred are in tandem with literature suggesting that the amendment of rules or introduction of new ones are favored due to the low costs involved and the timeliness and easiness of implementation (Bourrier and Bieder, 2013). Moreover, the viewpoints of the respondents seem to confirm their efforts to generate recommendations that are realistic by taking into account the existing boundaries (e.g., resources, operational needs).

The findings regarding the scope of recommendations showed that the higher and wider the level of operations, stakeholder and renewal, the less frequency corresponding changes are suggested. Recommendations that focus on the physical processes and the work floor, specific organizations and repair of problems had been more frequently introduced by the participants. On the other hand, interventions at the culture and context aspects of the operational area, suggestions to the regulatory and standardization levels and recommendations for innovative solutions were least frequently generated. The comments of the respondents seemed to agree about the effects of cost and time limitations along with political factors that can discourage the formulation of recommendations addressing wider and deeper systemic flaws. A few conflicting statements were observed regarding the easiness to make process or cultural changes, this indicating somehow misaligned perceptions.

The statistics regarding differences of the recommendations' scope across the demographics included in the study showed that meso-levels of stakeholders (i.e., whole industry sectors) were addressed more frequently by safety investigators. This finding can be explained by the fact that aviation safety investigation standards (e.g., ICAO, 2003, 2011) prompt the examination of latent factors which in turn allows the formulation of recommendations targeted beyond organizational boundaries. Furthermore, recommendations for stakeholders other than specific organizations and individuals were generated more frequently by respondents working mainly in Europe and having a higher level of education. These findings might reflect the effects of different regional and national cultures (e.g., ICAO, 2013, Stolzer et al. 2008) as well as an influence of educational breadth and depth on the tendency to adopt systemic views and address deficiencies at higher system levels.

5 CONCLUSIONS

The current study was a first initiative to map the situation in the aviation industry around the engineering of safety recommendations. Regarding the degree to which professionals are knowledgeable about the design criteria that can increase the quality and effectiveness of recommendations and the extent to which apply these criteria in practice, the results suggested an adequate level of knowledge and a satisfactory frequency of application of the nine design criteria included in the research. However, the findings were attributed more to the employment of best practice and the reference of such criteria in organizational documentation, rather than to guidelines from regional or international guidelines or topics of training. Hence, the inclusion of respective material in standards and safety management/investigation courses is highly recommended to achieve consistency in the generation of safety recommendations and establish a commonly referred framework for their design. Nonetheless, such a framework must be viewed as a guide and not a compliance-check reference. As the study participants stated, each case has a different context and the satisfaction of all design criteria might not be feasible or proper for all recommendations.

The findings concerning the classification of recommendations based on the types of controls they introduce showed a gap between perceptions of the practitioners and the suggestions of the literature. The former viewed "soft" control types as more effective than "hard" ones, whereas literature implies the opposite. It is noted that the categorization of controls does not aim at stating a preference of any type over another but rendering the industry

aware of the weaknesses and strengths of each control type. Nonetheless, the conduction of further studies is suggested as a means to provide empirical evidence about the actual level of effectiveness of each type of control and indicate any optimum combinations of those.

When considering the focus areas of recommendations, the findings suggested an emphasis on the repair of lowest activity levels rather than systemic interventions and innovative solutions. A common characteristic of all topics examined in this study was the influence of resource and political boundaries on the generation of safety recommendations, which usually lead practitioners in suggesting cheap and easy to implement fixes. From a pragmatic viewpoint, the situation mentioned above is somewhat unavoidable, but this should not exclude the visible and explicit justification of choices when engineering safety recommendations. The recognition and documentation of the boundaries imposed on each case can support the aggregation of data and their monitoring to inform stakeholders accordingly and possibly lift existing limitations when situations allow.

The researcher would like to point out that the small sample of the current study does not allow to claim generalization of the results. However, the finding of this research can trigger the execution of similar studies at larger scales at regional or international levels regardless of industry sector.

Problems of mobile risks in territory

J. Prochazka & D. Procházková
Faculty of Transportation Sciences, Czech Technical University in Prague, Czech Republic

ABSTRACT: The issue of transportation of dangerous goods is addressed in international law since 1957, when international agreements on transport of dangerous goods by road ADR was created in Geneva. Directive SEVESO was put into practice in 1982, because occurrence of severe accidents involving dangerous substances in 70 s. Directive SEVESO was step by step more particularized according to practice and regulation REACH was added in 2007. Both legislation lays down requirements for handling with hazardous substances from the manufacture, transportation and storage through to their use. Series of agreements on the transport of dangerous goods to another means of transport followed. All agreements dealing with carriage of hazardous substance have one thing in common. Dangerous substances are treated as goods and all responsibility is bear by carrier. Critical evaluation of the existing rules and traffic accidents with hazardous substances shows that in practice there are missing tools, which would: effectively reduce the distortions of security measures that arise on the part of carriers; to ensure rapid response and the protection of other road users on the roads and railways; protecting people and environment around the place of traffic accident; and the recovery of the territory afflicted by impact of road traffic accidents with hazardous substance. Analysis of a database of accidents involving dangerous substances shows number of examples where the recovery of territory after accident with hazardous goods carried more than 10 years. Therefore, we must create system tools for coping with those risks. Basic strategy in response has to be prepared at national level for major accident during the transport of dangerous substances. Local governments need to determine critical points, places with protected assets and dangerous goods transportation. Risk management and response plans need to be prepared for critical points. The article shows tools, which is being tested in practice.

1 INTRODUCTION

The issue of manipulation of dangerous substances is studied from 50 s of the 20th century. The development and wider support, however, received up to the beginning of the 80 s after a series of accidents in the industry. In practice, it is addressed separately the risks management associated with the production, storage, and processing of large quantities of dangerous substances and risk management during transport by different type of transportation.

Prevention of accidents involved dangerous substances and their impacts is addressed in the case of industrial objects by technical, human and procedural measures in accordance with the relevant standards laid down in international treaties. Emergency plans are prepared for case of measures failure by industrial plant operators for the factory side and near surroundings (on-site emergency plan) and by public administrative to the broad surroundings (off-site emergency plan).

Prevention of accidents in case of dangerous substances transportation or dangerous goods, how carriers company call such trade commodity, also include technical, human and procedural measures based on international standards. The methodology of emergency planning is, however, mostly missing. Failure of measures, similar to industrial plans, occurs because human factor, a failure of technology or natural disaster, and it can occur also in areas with high population density. The article, therefore, will be deal with the phenomena.

The second chapter describes the nature of the accidents occurrence with presence of dangerous substances on basis of an analysis of the database of accidents involving dangerous substances and statistical approaches. The third chapter will be devoted to the assessment of the criticality of infrastructure from the perspective of their technical parameters and common accidents on one side and the amount and type of protected interests in the surrounding area on other side.

2 NATURE OF MOBILE RISK OCCURENCE

The logarithmic dependence of the number of realizations of certain phenomena N on the phenomena intensity I is observed in the case of statistics of occurrence of all known disasters, $N(I) \sim a^{bI}$,

Figure 1 in general. The prediction of the threat is based on the distribution of extreme values (Gumbel 1941) in the case of natural disasters.

The logarithmic character of ***F-N*** curves (fatalities-number) is observed even in the case of technological accidents, when the intensity of phenomenon is expressed in the number of human victims. Observed dependencies lose the logarithmic character just at the range of low and high intensities, where the differences between incidents reported and occurring are (Hirschberg 1998) due to the data set non-homogeneity in low intensities range and too short observation period in high intensity range. Results of mathematical models such as the distribution of extreme phenomena and so on can only be taken as a guide.

The causes and circumstances of accidents in the shipping domain are similar to those in technological domain (insufficient technical standards, faults in vehicle construction, bad maintenance, human factor, etc.). Therefore, we can also see the logarithmic character of the F-N curve (Boot 2013). However, we observe two differences. First, our control over the entire transport network is less than our control over the surrounding of industrial area. From that reason, the nature of this risk changes dynamically, e.g. the market with dangerous goods may steeply increase or decrease, which influences the transport of this goods; shipping the new dangerous goods may also start. The other problem is the risk mobility. An accident that occurs at one point on the transport route may happen at any other point of transport road. As example, we show three similar accidents in North America on rail route:

1. June 19, 2009 Cherry Valley (Illinois, USA) Canadian train with more than 2 million gallons of ethanol derailed to cross with the road, 1 dead (NTSB 2012).
2. July 6., 2013 Lac-Mégantic (Quebec, Canada) A train with 72 oil tanker cars derailed in a small town with about 6,000 inhabitants, about 50 dead, a large part of the city destroyed (NTSB 2014).
3. December 30, 2013 Casselton (North Dakota, USA) A train carrying a large amount of crude oil derailed, the need to evacuate over 2,000 people, but fortunately no losses to life (NTSB 2017).

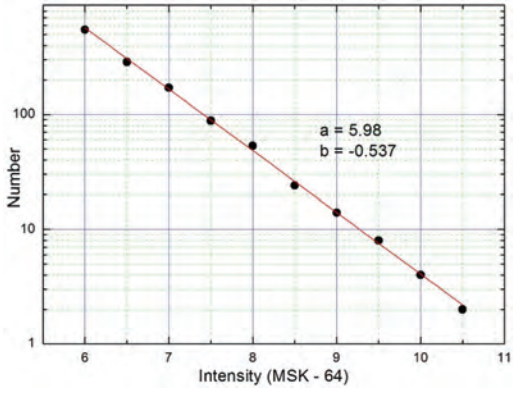

Figure 1. Logarithmic dependence of earthquake occurrences on intensity in Central Europe, circuit with a radius of 400 km (Prochazkova 2017).

The three above-mentioned accidents have common features, in addition to the region, the large-scale fires of large amounts of flammable substances. However, the impacts of individual accidents were diametrically different due to the varying population density and different protected interest concentration in the immediate vicinity of accident place.

The nature of mobile risks does not allow us to determine the real threats based only on site specific events. We need to extrapolate a wide range of information on accidents with the dangerous substances presence across the entire transport route where the accident occurred or whitherward the followed substance is transported under similar conditions. Procuration and lessons learned only from the accident site are not sufficient.

In the case of mobile risks, it needs to be taken into account that it is only a matter of time when a major accident occurs, namely even in densely populated area or even containing the high concentration of other protected interests, such as the sources of drinking water, power stations, and the like. Under certain circumstances, the transport of dangerous substances can be excluded in places with very high criticality as they present the places with big concentration of public assets; the mark "Forbidden for vehicles carrying the dangerous goods" is possible to use only exceptionally from economic reasons. In the Czech Republic, the transport of dangerous goods is, for example, excluded on the highway between Praha and Brno, between 49 and 90 km due to a drinking water source for the Praha.

However, a similar solution cannot always be used or it is connected with a lot of problems, and therefore, its application is justified only in places with especially high criticality. For less but still critical sites, it is still necessary to carry forward the lessons learned from all accidents with the presence of transported dangerous substances and to establish the plans for possible response at least on the basis of the requirements of crisis management, population protection and critical infrastructure protection.

It is necessary to introduce the role of local government in the transport of dangerous substances on the emergency management level or at least on the level of crisis management in addition to the already established obligations of dangerous goods carriers. The first step of local government is to set up the team of experts which proposes the professional solution of problem under account.

Head of the team need to be the safety management expert. He/she can be from municipality or regional Security Council, who is responsible for crisis management, Act No. 240/2010 Coll., on crisis management in the Czech Republic, or some external professional from Technical Support organization. Members from police force and firefighter force are also important. The nature of the problem also requires expert from the chemical industry. Czech chemical industry provides consulting services (TRINS 2015) for accidents with dangerous substances. Team can also be extended on transport expert and health care expert.

The team then needs to know the nature of accidents that can occur in the followed territory and it needs to determine the distribution of risks that can realized here and to characterize the possible emergency situations. Special attention should be paid to dangerous substances that are transported in large quantities through the roads at territory of given municipality. This especially involves the vicinity of chemical plants and long-distance transit corridors important for operation of specific industries.

Larger quantities of hazardous substances are transported by rail (Becherova 2017), so it is necessary to consider in this case the larger affected area than at the road transport. Responses plans need to be also prepared for pipeline transitions, especially at locations, where pipeline are placed above the surface (Hansler 2012). Pipelines surrounding can be better monitored and it is not so associated with mobile risk issues.

The municipality, in cooperation with the regional industry, can identify the specific substances that are transported on regional roads. It is obvious that fuel transports have a special position, because the transport of fuels is presented always and everywhere. The accidents with presence of fuels dominate to all transport accident statistics for dangerous substances (Procházková 2015a).

Local government needs to take into account also the transit traffic, at which the type of hazardous substances is heavily to predict. From the professional viewpoint, the response plan types would be prepared with regard to properties and hazards of substances associated with the individual hazard classes, fire hazards, explosion hazards, hazards of leakage to the environment, and also with combination of these three factors mentioned above, Figure 2.

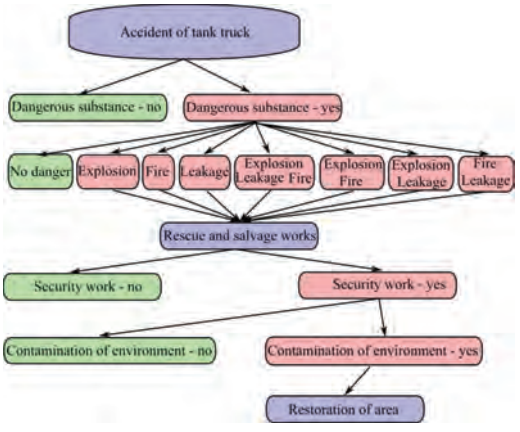

Figure 2. Process model of a crash accident response for the transport of dangerous goods.

It is necessary to determine the nature and extent of the threat, for both, the fuels and the hazardous substances that have been transported in followed location. The character of accident scenario is given by chemical, physical and other properties of transported substances, and also by site and meteorological conditions in time of accident origin. The extent of threat is based not only on the properties of dangerous substance, but especially by its amount. The amount is usually limited by relevant legal and technical standards for every shipping type.

The properties of substance, which predetermine the extent and nature of threat, are given in the safety data sheet. Everybody, who works with the hazardous substances during the shipping, has responsibility to respect the instructions in the safety data sheet. The issue of shipping the below-limit amounts of hazardous substances is solved by the REACH order in separate chapter. The Safety Data Sheet needs to be always available at substance handling site. In the case of transport, however, this is a common problem, e.g. this document is not in all languages of countries through them the shipment goes over.

The experiences from daily practice show that people often underestimate the hazards that are given in the safety data sheet. They do not consider that properties of each hazardous substance vary in dependence on local conditions that are in site of transportation. For example, the ignition temperature of unleaded petrol in the liquid state can be more than 250°C, the ignition temperature of the vapour/air mixture is substantially lower (Česká rafinérská 2012). The findings from the safety data sheet, therefore, need to be supplemented by lessons learned from studies of real-world accidents or by the results of practical experiments.

At present, many databases contain the accidents with hazardous substances. For example, it can be mentioned the energy accident database ENSAD, which include also fuel transportation. This database itself comes out from many other databases (Burgherr 2017). Compilation of databases is very expensive, and therefore, the availability of some databases is very limited. For many organizations, it is then necessary to carry out their own investigations across relevant case studies (Prochazkova 2014).

Complete statistics of traffic accidents enable to determine the most common causes of accidents. Detail study of major accidents shows the great number of combinations of phenomena that can occur at accidents, i.e. the prediction of accident scenario is not easy. Lessons learned from both, the statistics and the case studies allow us to evaluate only the general data for probability of accident and expected impacts at the sites under consideration; the real scenario will be always determined by momentary local conditions in the given site.

3 MOBILE RISK AND EXPERT METHODS

For compilation of groundwork for determination and mastering the risks, it is necessary to put together: the team of experts who well know the behaviour of hazardous substances under different conditions that can be expected during the transport; and to collect data on dangerous substances and common amounts that are transported. Then, it is necessary to use suitable tools for risk analysis, namely the Checklist and What, if analysis. In practice, a lot of software tools are used. Therefore, we take a short comment on the widely used computing software for the dispersion of dangerous substances.

Determination of the affected area is a key step for subsequently identification of impacts and compilation of response plans. The form and size of affected area are calculated using the dispersion models. These models need to take into account the properties of substances (lighter or heavier than air), atmospheric conditions (wind speed, temperature, humidity, inversion) or local relief topography (buildings, forest, terrain slope). The factors that affect the dispersion are many, so mathematical models have to use certain approximations in many cases, which reduce the accuracy of outputs. Therefore, it is suitable to apply experts´ experiences before their use in practice.

At present, the models convert from analytical calculations to calculations using the computer technology. Computer technology can combine analytical and numerical calculations, but essentially is based on the same formulas (Leksin 2015). The advantage of computer models is the accuracy, the model can take into account a larger number of input parameters, and the accessibility, the model can be used by broad public; the knowledge of model mathematical background is not necessary. The disadvantage is non-transparency of computation, because the user does not often know what omissions at calculation are performed (the omissions are hidden in software model concept).

Although computer computations allow us to use more complex models, it is necessary as it was given above to use the expert judgement at transfer to practice. It is fact, that each result, in addition, is greatly affected by the interface at the input, where we cannot include a number of geographic data in the calculation. In some cases, geographic conditions are deciding (Pontiggia 2010). The dispersion models can provide us with a lot of information still, despite all the uncertainties and unsureness. Figure 3 shows the dispersion behaviour for the chlorine tank in normal atmospheric conditions.

The example at Figure 3 suits for preliminary identification of the belt width around the considered ground road where we follow the impacts on protected interests. Common atmospheric conditions are sufficient to response at normal and may be emergency situations. For very extreme meteorological conditions it is necessary to use the principals of crisis management and for it success it is necessary to prepare both, the scenarios for unfavourable up to extremely conditions and the response plans. For real accident site it is necessary to consider the properties of affected area and local conditions. Detail investigation of critical sites, e.g. the sites on roads with frequent traffic accident, very improves the model results.

The densely populated areas or areas with high density of other public protected interests are fac-

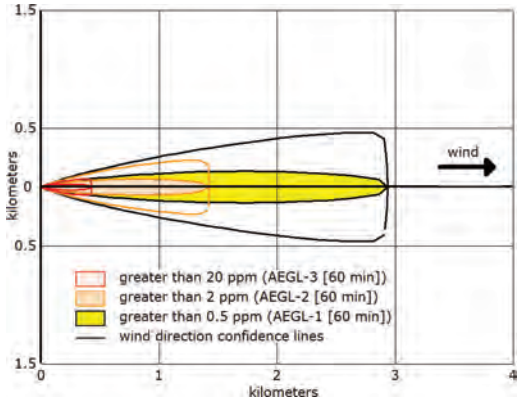

Figure 3. Dispersion of chlorine from the tank according to the ALOHA dispersion model under normal atmospheric conditions.

tors that would be taken into account when we select the critical sites, for which from safety reasons there are necessary the preventive actions and the preparation of response plans. The occurrence probability of traffic accident in critical site is further important. The local territory investigation is very important road parameter. Such investigation can be executed using the special Checklist.

The Checklist needs to take into account the physical parameters of the road (horizontal profile, vertical profile, surface properties), environmental characteristics (weather, climate), utilization of road (traffic density, purpose of traffic) and other complications (tunnel, bridge, canyon) (CSA 2002). It is appropriate to add accident statistics to the overall criticality assessment, if it is monitored for a given section. Assessment of criticality can be done in the selected sites of road only if it is performed cumulatively for road sections. The example of such a Checklist is in Table 1, where it is judged the section of highway in Central Bohemia, where transport Praha-Vienna (south-east) and Praha-Linz (south), E50, E55, E65 is located.

For identification of critical highway spots, it is necessary to determine the size of risk in a given place for possible traffic accidents with presence of hazardous substances. Assessment of risk size at real location for the fixed event is influenced by density of protected interest and by likelihood of accident. Methods for impact assessments are several, but most of them have a relatively narrow focus on the situation (input data) or the protected assets. For the public administration, as the legal guardian of territory, it is the most appropriate the method "What-If analysis" performed by brainstorming with a team of experts, and the following judgement of losses at protected interests following from the determined impacts.

The team of experts needs in the first to collect information on possible events, i.e. the characteristics of hazard connected with leaked substances. Then, it needs to determine the scenarios of affected areas at different meteorological conditions for individual hazardous substances. Next, it is necessary to determine the acceptability of impacts in individual scenarios at different meteorological conditions.

The experts can execute assessment by brainstorming. The identified impacts are best structured by the area of protected assets:

- human lives, health and security,
- property and welfare,
- environment,
- critical infrastructure and technologies.

It is also suitable to consider the development of impacts with time, how they occur apart from the structure by type of protected interests. Such data enables to build more accurate response plan. It is also necessary to identify the primary accident

Table 1. Checklist for critical assessment of the first 21 km of the D1 motorway in Central Bohemia.

D1-km	Horizontal profile	Vertical profile	Complication (tunnel, bridge, canyon)	Technical condition of communication	Traffic intensity 50000/hour	Average of accident/ 1 month	Climate condition	Total

impacts, the secondary impacts to which it belongs e.g. the loss of supply of affected area, damage of drinking water sources etc. An example of such analysis can be found in article (Prochazkova 2015b). According to performed tests such analysis takes about 3 hours. In the case of team composed from 5 experts, it is 15 man hours. As a rule, such analysis is necessary to perform for several different places. The result of such work is good preparation for mitigation of impacts of traffic accidents and precise response plan that reduces losses on protected interests.

4 RISK ASSESSMENT

Under the risk assessment the losses need to be quantified in adequate values. For public administration and managers, the most comprehensible formulation of losses is in finances. In the case of property and infrastructure, it is not the problem to determine financial value of losses and damages. In the case of the environment, however, there are a number of methodologies, most of which only focuses on the production effect of environment and ignores the whole area of its importance for humans.

Financial evaluation of losses on human lives and damages of health in EURs includes a certain point of cynicism; in some countries it misses the appropriate legal rule for its determination. Therefore, it is important, so the public administration may determine the clear instructions and methodologies for this case. These procedures are mostly based on local culture, legislation, and the society tolerance for different risks.

The appropriate risk is possible to assess as soon as we know the extent of the damage and the probability of its realization. The risk can be expressed in the form of value of damage per unit of time, for example, by the equation

$$R = D \cdot P = D \cdot A_r T_{ds} \quad (1)$$

where R is the risk, D is the impact (damage), P is the probability, A_r stands for accident and T_{ds} the intensity of transport of dangerous substances.

The critical matrix can be also used to express the risk. It shows much more information and allows sophisticated access to risk; especially, in the ALARP (As Low As Reasonable) approach, for hazardous substances. Figure 4 shows the combined form of the Critical Matrix (Impacts versus Probability) and the F-N Curve (Number of Death vs. Frequency), (Det Norske Veritas 2014). It determines which situations are acceptable, conditionally acceptable (ALARP), or unacceptable. Decisions on preventive measures and on response

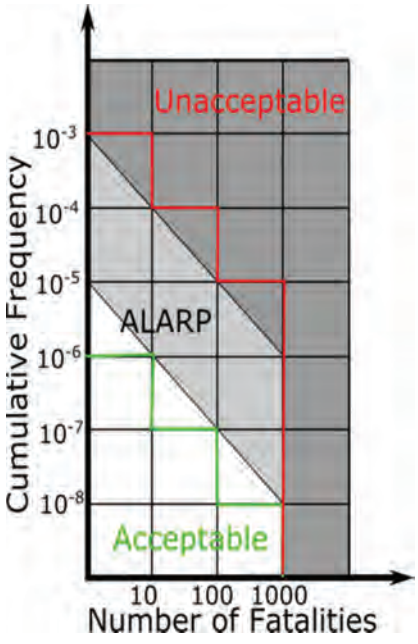

Figure 4. Criticality matrix and F-N curve for accident with dangerous substances involved (Det Norske Veritas).

Figure 5. Risk Management in public space, expert do Risk Assessment, Risk Decisions is executed by elected representatives, and Risk Mitigation is applied by technical experts.

plans are subsequently made according to position of our judgement result in the criticality matrix. The matrix given in Figure 4 only counts the human lives, but it can be transformed to other protected interests.

Establishing the position of analysed situation in the criticality matrix in Figure 4, is the final part of the risk assessment. The team of experts passes the results of risk assessment to responsible office for the territory governance that is responsible for territory safety management and for correct decision-making. The risk management issue moves to the next stage, Risk Decision, Figure 5. The decision on further approach to revealed risks and on measures for coping with identified risks belongs to the responsibility of elected representatives, who are not experts, which often influence the quality of decisions.

The roles of experts return at the final stage of Risk Management, i.e. at Risk Mitigation, but real measures are influenced by limits given by public administration decision-making (e.g., it very influences amount of finances that can be used for risk mitigation).

5 CONCLUSION

Critical judgement of present situation shows that in practice, there are missing the tools that: effectively reduce breaking the security measures on the carrier side; enable fast reaction to accident; enable protection of all road / railroad users including the humans and environment in traffic accident vicinity; and prop up the renovation of affected area so it can be used for human needs.

The article demonstrates a methodology for the risks assessment associated with the transport of dangerous goods by road or rail. The main problem is the nature of mobile risks associated with transport. Another problem is the risk dynamics. This methodology is primarily targeted to public administration, and it well supplemented the measures of legal rules that are primarily targeted on the carriers of dangerous goods. This methodology consists of three steps: risk analysis, risk judgement; and risk mitigating.

Identification and awareness with the nature of mobile risk phenomena in the reporting area is the first step. The main problem during the risk identification is neglecting the mobility and dynamics of the risk. The often error in practice is that it is not considered the experiences from accident sites in other regions. The analysis and judgement of emergency situations, which may arise as consequence of accident with dangerous substances, is the second step.

The recommended methodology seeks to combine practices using the computational models with investigation of experts based on knowledge of real territory. The final step is the risk mitigation and early response; the combination of criticality matrix with the F-N curve is used. The methodology calculates the significance only with life-threatening impacts and needs to be adjusted to include other fatal impacts, such as groundwater contamination, or the destroying of other critical infrastructure elements.

The above described methodology includes procedures and tools for risk assessment by team of experts. In co-operation with real local experts we step by step determine real results for individual real public administration (selection of appropriate preventive measures, processing the response plans for very hazardous substances at the level of emergency and crisis management).

Risk-based regulation and certification of autonomous transport systems

S.O. Johnsen, Å. Hoem & T. Stålhane
Faculty of Information Technology, NTNU, Trondheim, Norway

G. Jenssen & T. Moen
SINTEF Technology and Society, Trondheim, Norway

ABSTRACT: Autonomous transport systems in all modes—road (i.e. autonomous cars), aviation (i.e. drones), shipping and rail are coming. Regulation and testing are on-going in Norway. Risks of autonomous systems are uncertain due to missing data, emerging technology and variation in framework conditions. However, accidents of autonomous cars seem to be 1/3 or 1/2 of current levels. Incidents are different, needing outside interventions sometimes. Based on review of experiences across the modes and regulations, we suggest agile and transparent learning in the whole autonomous ecosystem, between all modes. System certification are needed, and system responsibilities must be clarified. Structures for orchestrating transport (i.e. control of many autonomous vehicles with possible common failures) and marking autonomous transport, should be established. In the interfaces between humans and systems there are differences in autonomy as imagined vs. performed, leading to new incidents and accidents. Emerging safety/security issues must be explored.

1 INTRODUCTION

This paper discusses experiences of autonomous transport systems, to establish a framework for risk based governance. Risk and risk governance are based on the process described by Renn (2005), starting with problem framing; risk appraisal (hazards and vulnerabilities); risk judgment; risk communication and risk management. The implementation of autonomy can reduce transport risks but it can also introduce new risks in the interfaces between the autonomous system and the environment (such as humans). As discussed in Lund and Aarø (2004), risk reduction must be based on a broad set of actions such as regulation, technical design, training and awareness.

Based on involvement in the regulatory process in Norway and experiences of autonomous transport systems we have discussed new emerging risks and threats. We see the need for establishing framework such as regulatory actions and clarification of responsibilities as autonomy is being implemented.

In the following we have defined autonomous systems and concepts such as Levels of Automation (LOA) used to specify degree of automation.

1.1 *Definitions and terminology*

Safety is related to accidental harm, while security is related to intentional harm. Safety is defined as: "*the degree to which accidental harm is prevented, reduced and properly reacted to*", Firesmith (2003). Security: "*the degree to which malicious harm is prevented, reduced and properly reacted to*".

In Parasuman and Riley (1997) automation and autonomy is described as "*The execution by a machine agent (usually a computer) of a function that was previously carried out by a human*". Automation can be done by various means i.e. 1: Remote controlled (Surveyed and/or externally controlled); 2: Autonomous (based on own sensors and systems); 3: Cooperative and connected (based on own sensors and other traffic information) or 4: A combination of 1–3. The terms autonomous and automated has been used interchangeably in some papers. We have made a distinction. By *autonomy* we mean a system that is non-deterministic in that it has a freedom to make choices, and by *automated* we mean a system that is more deterministic in that it will do exactly what it is programmed to do. This is based on the taxonomy and discussion of autonomy from Vagia et al. (2016).

When trying to scope risks of autonomous systems we must include the regulation, risk governance, organizational framework, interfaces to humans and the autonomous system (a combination of software components and cyber physical systems). The system is often a collection of systems being developed by different stakeholders. Thus, we have used the concept of autonomous

ecosystem, AEC. This is inspired by the concept Software Ecosystems (SEC). SEC consists of components developed by actors both internally and externally of the company, i.e. outside the traditional borders to a group of private persons and actors. Manikas et al. (2013) defined a software ecosystem as: "*the interaction of a set of actors on top of a common technological platform that results in a number of software solutions or services. Each actor is motivated by a set of interests or business models and connected to the rest of the actors and the ecosystem as a whole with symbiotic relationships, while, the technological platform is structured in a way that allows the involvement and contribution of the different actors...*". Arguments for using such a concept is the realization that development increasingly is taking place outside of organisational silos due to the need for speed of development, need for supporting applications, reduction of development costs, competition. This is creating the need to address governance challenges in an ecosystem framework.

An example of an autonomous ecosystem is Intelligent Transport Systems (ITS) consisting of autonomous vehicles, integrated with traffic control, electronic payments and other systems. Autonomous ecosystems handle information, but also actual critical processes such as transport (via automobiles, boats, drones and trams). These ecosystems must be safe and secure. The systems must be able to handle unanticipated events, breakdowns and be able to go to a safe and secure (end-)state.

To explore the main risks of autonomous systems, we need to clarify responsibilities i.e. LOA in task execution. LOA is described by steps going from no automation where the humans are fully in control to a fully automated system with no human interaction. Sheridan and Verplank (1978) introduced 10 steps of automation, going from LOA1: Fully Manual Control to LOA10: Fully Autonomous Control. The LOA has been adapted to the car industry by the Society of Automotive Engineers (SAE), describing six levels of autonomy in driving, SAE (2016). Going from no autonomy (level 0), through driver assistance, partial automation, conditional automation, high automation, to full automation (level 5). The design of the autonomous transport system must ensure that the system maintains an accepted level of performance despite disturbances, including threats of an unexpected and malicious nature. Our approach is to speed up learning and knowledge sharing between modes, since the autonomous systems have different maturity and experiences in aviation, rail, road and sea.

The concept of resilience engineering is an important strategy to handle unanticipated incidents. Hollnagel, Woods and Leveson (2006) define resilience as "*the intrinsic ability of a system to adjust its functioning prior to or following changes and disturbances, so that it can sustain operations even after a major mishap or in the presence of continuous stress*". Handling of unanticipated incidents and continue to operate safe is a key ability of autonomous transport systems.

Based on the preceding introduction, the research questions (RQ) we want to explore are:

- RQ1: What are the major risks introduced by autonomous transport systems?
- RQ2: What regulatory issues should be prioritized to handle these risks?
- RQ3: What are the way forward, i.e. main approaches and issues needed to mitigate major risks of autonomous transport systems?

2 SCOPE, CHALLENGES AND METHODS

When discussing autonomous ecosystems, we include the organisational framework, regulation, human interactions and understanding in addition to the actual systems in autonomous systems and the infrastructure. This is described in Figure 1.

2.1 *Challenges and problems*

When introducing new technology such as autonomous systems, one of the basic challenges is to understand emerging risks. Safety, security and resilience have often been identified late when vulnerabilities have been exploited and unwanted incidents have been published. There has been a tradition in the software industry that vendors seldom have to pay for these unwanted incidents even if they are due to poor quality, poor focus on safety, security or resilience. The consequences and costs have been given to users, organisations and society. In autonomous transport, the consequences can be loss of lives and/or environmental damage. In addition, when discussing vulnerabilities in autonomous ecosystem, one challenge is that there is not one single supplier, but a set of suppliers involved. It can be difficult to identify responsibilities and manage competencies, if framework conditions (regulation/responsibilities) are missing.

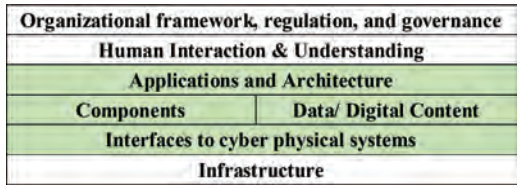

Figure 1. Scope of autonomous ecosystems—AEC.

2.2 *Methodology and approach*

We have based this paper on empirical data from users of autonomous transport systems, a targeted literature review of autonomy and safety in addition to discussion of suggested regulation of autonomous road transport in Norway.

We have explored experiences of autonomous transport systems from St. Olav Hospital in Norway, where autonomous systems have been used from 2006 to 2017. St. Olav has 10,500 employees, and covers an area of 200,000 M^2. We are involved in pilot projects with self—driving shuttle busses in three Norwegian cities. Trials addressing feasibility of Mobility as a service (MAAS) linking up to public transport (first and last mile). We are involved in trials with eco-friendly autonomous ships/vessels for cargo and passenger travel along the Norwegian coastline.

We have performed a literature review based on a keyword search of autonomy, safety, security and resilience using SCOPUS, ACM Digital Library, IEEE Explore, Springer Link and Science Direct.

We have been involved in a hearing of regulation related to testing of autonomous vehicles in Norway from the Ministry of Transport and Communications—MTC (2016). The suggested regulation was distributed in December 2016, comments to be given within March 2017 and the regulation were proposed to be approved as law in December 2017. Our comments were based on the literature review, experiences from St. Olav's and other public comments.

The taxonomy used to register incidents has been based on Blanco et al. (2016). They collected a broad set of naturalistic accident data from autonomous driving, using a taxonomy of crash seriousness going from most serious at C1 to negligent at C4.

C1: Crashes with airbag deployment, injury (needing doctor visit), rollover, more damage than $1,500, require towing, police reportable.
C2: Minimum of $1,500 worth of damage, crashes such as large animal strikes and sign strikes.
C3: Crashes involving physical conflict with another object, but with minimal damage. Includes most road departures, small animal strikes, all curb and tire strikes potentially in conflict with oncoming traffic and with higher risk potential if no curb.
C4: Tire strike only with little or no risk element (e.g., clipping a curb during a tight turn), considered to be of such minimal risk that most drivers would not consider these incidents to be crashes.

3 RESULTS AND DISCUSSIONS

In the following section, we have documented experiences from autonomous systems at St. Olav Hospital; some selected findings from our literature review; and key issues discussed during regulation of testing of autonomous transport systems.

3.1 *Findings from autonomous systems at St. Olav*

St. Olav Hospital has installed an automated transport system called Transcar LTC2 Automated Guided Vehicle System (AGV) from Swisslog. They installed seven AGVs in 2006, and additional 14 AGVs at the end of 2009. From 2010 to 2017 they have had 21 AGVs in operations. Each week the 21 AGVs transport medicine, food, clothes and garbage, in total 70–80 tonnes. (Each AGV can transport a load of 500 kg, and is transporting 3.6 tonnes each week). The speed is slow, moving at approximately 2 km/hour (maximum speed is 5 km/h). The AGVs can send signals, open doors, and reserve elevators to deliver goods. There are different suppliers of door and elevator automation. When there are conflicts that cannot be resolved, a signal is given to the operational centre. The centre is manned by an operator that can intervene through the system, or go to the place where there is a conflict.

The AGVs can communicate (i.e. deliver pre-programmed messages) such as "Please move—you are in my way", or "Elevator is reserved—please move out of elevator". A key issue related to the awareness building between automated transport systems and humans are the above-mentioned communication from the AGVs, supporting the understanding that the automated system need to inform the bystanders about their perceptions and what they are going to do next, that helps staff, patients and visitors to learn to interact with the AGV's and to anticipate their behaviour.

In the Transcar LTC2 Operations and Maintenance manual it is written "*Always maintain a distance of 1.5 meters between the vehicles and people or objects.*" This safety guideline is not possible to implement at St. Olav due to space limitations.

There are traces on the floor indicating that the AGVs are always following the same pathway, thus (new) common failures may happen.

There has been a total of 100–130 minor incidents per year (5–6 per AGV) categorised as C4 by us. Minor repairs are done on the AGVs, changing around 50 components per year. There are around 15 emergency stops each year, categorized as C3, where components must be changed. We do not have data indicating that there has been any incidents of category C2 or C1. Reported incidents are minor crashes due to faulty navigation, for example due to objects placed in the route travelled that is not detected.

When interviewing the users some incidents that can be generalized were reported:

- The AGVs have problems with pallets close to the walls. The AGV uses the wall as reference in steering. A misplaced pallet results in a lateral shift of the AGV position and may sometime end up with a collision. Initially the operators used a great deal of time to clear the transport road area (in the basement) from clutter (i.e. parked bicycles, pallets with supplies); this work has been reduced now—but maintenance and design should take into accord these limits of AVGs.
- The AGV collided several times with the forklifts, since the LiDAR sensor (light detection and ranging) had a limited vertical field of view and was seeing a free zone (space) under the forklift. This was mitigated by placing a black rubber skirt under the forklift. The same kind of collisions happened when using stepladders on the floor in the AGVs pathway, since the LiDAR did not detect the object. Thus, one issue has been the ability to see and identify objects in relation to the AGVs sense of its own size and position. This may be a general challenge with autonomous transport systems. The death accident of Joshua Brown, described by NTSB (2017) and NHTSA (2017), was between a Tesla and a trailer crossing the road—a white trailer giving poor contrast and with substantial height above the ground. Some similarity with the forklift problems at St. Olav. A rubber skirt under the trailer may have increased visibility/visual signal of the trailer.
- The AGVs can open doors, reserve and use elevators. Sometimes there has been conflicts between the AGVs and the users, needing human intervention through a central control.
- Software updates of AVGs, elevators and doors has led to interface problems, thus there is a need to look at the AVGs as a part of an ecosystem.

During the 11 years' operating the AGVs there has been no reporting of human injuries at St. Olav. However, at the AHUS hospital (AHUS, 2009), with the same system—one incident happened in 2009, where a nurse sustained a minor injury when colliding with the AGV (i.e. category C3 or C4).

In summary, the AGV system has had an impressive safety record at St. Olav's Hospital. Key issues of safe operations are related to an ecosystem approach planning the interaction between technology, organisation and humans. Based on preparation trough pilots; low speed; communication between automated systems and humans to inform surrounding people of the AGV's intended behaviour. The unexpected may happen, thus there was a need to establish a manned control centre that can intervene during operations.

3.2 *Key findings from literature review*

In Axelrod (2014) the focus is on software assurance of safety-critical and security-critical systems. The perception is that use of the current methods has not achieved the wished-for level of protection, and that there are missing security principles and standards. There seems a need for incentives or regulations to implement protective and immunizing measures in software. A requirement could be that these measures are included in a certification process. On governance, it is suggested to establish software assurance standards at the United Nation (UN) level; to have a risk based approach; to share best of breed methods; and the need to discuss liabilities for damages occurring because of an attack or security-related errors.

International governance of security of the infrastructure is addressed through several channels such as standard bodies (i.e. ISO, IEC) and international bodies such as OECD, EU, NATO and UN. Autonomous systems are international—involving many actors with different agendas. In GCIG (2016) there is a discussion of governance of emerging technology as it is integrated into critical infrastructure, such as transport systems. It is suggested that manufacturers should follow the principle of privacy and security by design, when developing new products. They must be prepared to accept legal liability for the quality of the technology they produce. Buyers should collectively demand that manufacturers respond effectively to concerns about privacy and security. Governments can play a positive role by incorporating minimum security standards in their procurement. It is suggested that government regulations should require routine, transparent reporting of technological problems to provide the data required for a transparent market-based cyber-insurance industry. It is suggested to establish an agreement (a compact) based on collaboration between government, industry and private society supporting this evidence based decision making.

In Koscher et al. (2010) vulnerabilities in cars are pointed out, such as the possibility to control a wide range of automotive functions and completely ignore driver input from dashboard, including disabling the brakes, selectively braking individual wheels on demand, stopping the engine, and so on. Attacks were easy to perform and the effects were significant. It is possible to bypass rudimentary network security protections within the car, and perform attack that embeds malicious code in the car that will completely erase any evidence of its presence (after a crash). There is a discussion of the challenges in addressing these vulnerabilities in the existing ecosystem.

In Lima, et al. (2016) semi-autonomous and fully autonomous cars are described as coming

from the development stage to operations. The autonomous systems are creating safety and security challenges. These challenges require a holistic analysis, under the perspective of ecosystems of autonomous vehicles. These systems will become important critical information infrastructures, simultaneously featuring connectivity, autonomy and cooperation. Threat analyses and safety cases should include both (random) faults and (purposeful) attacks.

In DHS (2015), there is a discussion of Cyber-Physical infrastructure risks in the future smart cities. Several examples of unwanted incidents are described in transportation systems (i.e. autonomous vehicles; trains) in electricity distribution and management and in water and wastewater systems sector. It is suggested to the regulator to work with standards and regulations in addition to communication and increased engagement by giving direct assistance. Challenges mentioned are the need to establish goal based standards and regulations as new technology is implemented and to focus on dissemination of best practices and systematic education.

In (Cerrudo, 2015) there is an empirical evaluation of "smart cities" looking at a broad set of technologies of traffic control, management of energy/water/waste and security. Known vulnerabilities are in traffic control systems, mobile applications used by citizens, smart grids/smart meters and video cameras. The issues are lack of cyber security testing and approval, lack of encryption, lack of City Computer Emergency Response Teams (CERT), and lack of cyber-attack emergency plans. There are reasons to anticipate that we establish potential for serious incidents, if these issues are not addressed and mitigated.

In Frei (2010) there is a discussion of the security dynamics of general software ecosystem (SEC), applicable to autonomous ecosystems. They examine 27000 vulnerabilities in the decade (1996–2008). The paper explores several policies such as security through obscurity, responsible disclosure of vulnerabilities (a suggested policy) or security through transparency. One key insight is that secrecy prevents people from assessing their own risks, which contributes to a false sense of security. Responsible disclosure means that the researcher discloses full information to the vendor, expecting that mitigation is developed within a reasonable timeframe. An increasing number of organizations has adopted some form of responsible disclosure. A risk based regulatory regime are dependent on such an open discussion of the risks.

In summary, if we want systems that are safe, secure and reliable, both safety, security and reliability must be built together. There has been documented several vulnerabilities and responsible disclosure of vulnerabilities to the vendors, seems to be a beneficial policy. Some sort of communities of practices, and a CERT of autonomous systems should be established. There is missing international regulation or compacts based on private public partnerships to ensure privacy, safety, security and resilience. Vendors must ensure this quality by design, and must be prepared to accept legal liability of the technology they produce. Regulations should require routine, transparent reporting of technological problems to provide data for a transparent market-based cyber-insurance industry, and a risk based regulatory regime.

3.3 *Key issues when discussing regulation*

3.3.1 *Selected issues from all forms of transport*

Risks of autonomous transport are not well known at present. To increase knowledge and learning, experiences, taxonomies, regulations and relevant incidents should be gathered and disseminated from all modes—autonomous road systems (vehicles), air transport (i.e. drones), rail (unmanned metro and rail systems) and shipping. Accident investigators and rule-makers (such as "The Accident Investigation Board in Norway") should develop methods for investigation of accidents of autonomy and report their findings.

Shipping: Completely unmanned ships seem to give large benefits and enables new transport systems, some of these issues are documented in Rødseth (2017). There is a need for onshore control centres to manage autonomous shipping operations. Norway has focused on autonomy in sea transport. A network, Norwegian Forum for Autonomous Ships (NFAS) at nfas.autonomous-ship.org, has been established. A more general research program called Centre for Autonomous Marine Operations and Systems (AMOS) has been initiated at the Norwegian University of Technology and Science, ref www.ntnu.edu/amos. The Trondheimsfjord has been selected as a national testing area in collaboration with The Norwegian Maritime Authority and The Norwegian Coastal Administration. At the end of 2017 three testing areas has been established in Norway (Trondheimsfjord, Storfjord and Horten). Test areas has also been established in Finland and China. Risk levels of autonomous ships are influenced by existing incidents and new incidents (i.e. caused by new automation, and former incidents mitigated by crew now being removed). Work is ongoing to explore safety of autonomous sea transport, and to explore a taxonomy of LOA for shipping, Rødseth et al. (2017). In Trondheimsfjord an autonomous passenger ferry is going to be tested in 2018–2019. The authorities need to set rules and requirements based on acceptable risk levels. There

is an increased need for Human Factors knowledge to improve the quality of interfaces (i.e. "human in the loop" control when needed) between humans and the autonomous systems.

Aviation: To govern the use of Remotely Piloted Aircraft Systems (i.e., drones) in Norway, regulation has been established, Civil Aviation Authority—CAA (2016). The operator must be certified through an exam, CAA (2017). Experiences of remotely piloted aircraft Systems, Waraich et al. (2013), documents that mishaps may happen (i.e. 50 mishaps occur every 100,000 flight hours' vs human-operated aircraft where there is one mishap per 100,000 flight hours). The high mishap rate is related to poor attention to human factors science and design in ground control centres, Waraich et al. (2013). Several pilot projects with drones are planned, transporting goods/persons.

Rail/Metro systems: By automated metros (rail systems) we mean systems where there is no driver in the front cabin, nor accompanying staff, also called Unattended Train Operation (UTO). UTO have been in operations from 1980. In UITP (2013), there are listed 674 km of automated metros consisting of 48 lines in 32 cities. UTO´s are found in Barcelona, Copenhagen, Dubai, Kobe, Lille, Nuremberg, Paris, Singapore, Taipei, Tokyo, Toulouse and Vancouver. Wang et al. (2016), list the arguments for UTO as increased reliability, lower operation costs, increased capacity, energy efficiency and an impressive safety record. There is substantial infrastructure cost to ensure safe on and offloading of passengers and that the track is safe and isolated from other traffic. Four distinct Levels of automation are defined: GoA1: *Non-automated train operation, with a driver in the cabin*. GoA2: *Automatic train operation system controls train movements, but a driver in the cabin observes and stops the train in case of a hazardous situation.* GoA3: *No driver in the cabin but an operation staff on board.* GoA4: *Unattended train operation, with no operation staff on board*. We have at present not found normalized accident data for UTO (incidents based on person km), but no accidents have been reported. It seems that the UTO has exceptionally high safety. However more systematic analysis and normalization of all international UTO transport incidents are needed.

Road Transportation: Google's self-driving cars, where the vehicle systems control all aspects of the driving, have been on public roads in the US since 2009. The safety record has been impressive. However Google engineers are supervising and re-taking vehicle control if necessary. The death accident in 2016 (Joshua Brown) by Tesla in Autonomous driving condition was caused by a tractor-trailer that made a left turn in front of the Tesla, and the car failed to apply the brakes. The Tesla did not "see" the trailer—it was all white and had poor contrast with the surrounding bright white sky. In addition, there was a high gap between the road and the trailer. The National Transportation Safety Board (NTSB, 2017) found that the system's "operational design" was a contributing factor to the crash because it allows drivers to avoid steering/watching the road for periods of time that were "inconsistent" with warnings. Tesla could have taken further steps to prevent the system's misuse. In addition, NTSB faulted the driver for not paying attention and "over-reliance on vehicle automation". It also seems there is a need for better training of drivers related to autonomous systems—a part of driver education and driver license requirements.

There are scarce safety data so far, but data from the period 2009 to end of 2015 has been collected from Googles cars, in Teoh et al. (2017). There were three police reportable accidents (denoted as level C1) in California while driving 2,208,199 km, giving an accident rate of 1,36 police reportable incident pr. million km. This is 1/3 of reportable accidents of human-driven passenger vehicles in the same area. Car accidents involving autonomous cars are different from human driven. Google cars get more rear-ended by other vehicles while stopped or barely moving. There is an element of risk negligence in that the human driver does not fully anticipate the action of the self-driving car. There are also challenges of sustained human attention during lengthy period of autonomous driving, making it difficult for the human operator to intervene i.e. "Human in the loop" challenges. Huffington (2017) documented that Waymo's human drivers had to take control from the automated system (i.e. "disengagement") once for every 5,000 miles in 2016. "Backup" human drivers in Uber's self-driving cars had to take over about once every mile as of March 8, ref Recode (2017). It is a challenge to get situational awareness after having been out of the driving control loop for 5,000 miles. The takeover time of the human driver varies from 2 to 26 seconds, ref Eriksson et al. (2017), challenging the design of autonomous systems to enable human intervention.

Analysing all car accidents, it is suggested that 80–90% of accidents are due to "human errors", thus autonomous cars could reduce the level of accidents substantially. However, autonomy could introduce new types of accidents, due to automation itself or due to human drivers not predicting action from the automation. In Blanco, et al. (2016) it is suggested that accident rates are reduced to ¾ of present, while Teoh et al. (2017) documents accident levels of autonomous systems as 1/3 of human driver systems. The National Highway Traffic Safety Administration (NHTSA, 2017) reported a reduction in vehicle crash-rate

by almost 40% with Autosteer activated in Tesla Model S and Model X, compared to before. In Cummings et al. (2014) it is suggested that the level of accidents could be reduced by 50%. More experiences must be gathered, but significant reduction of accidents is expected.

3.3.2 *Need for systematic open data reporting*
At present there are missing data of incidents (accidents and successful recoveries) related to autonomous systems. Open reporting must be established covering systematic safety records and security stories, being available to researchers and industry actors, such as insurance. The scope must cover actions from the autonomous system but also document perceptions and understanding from the involved human actors. The differences between espoused values (rule based actions/work as programmed in autonomous systems) and actual values (actions/work as being done by humans in interaction with autonomy) can create the basis for errors and accidents. It should be a key area of research to explore accidents because of poor design vs. blaming the human actors. Use of video recording could help, based on regulation protecting personal data; (EU 2016:679). There must be a combination of data gathering in combination with in-depth accident investigation. Accident investigation boards should explore accidents of autonomy, to support rapid learning and changes in addition to improve their methods to analyse autonomy incidents.

3.3.3 *System perspective and human factors*
Safety of autonomous systems are dependent on new designed technology, human factors and organisational issues as discussed by Cummings et al. (2014). The perception should be that most accidents in autonomous systems are a consequence of poor design and poor testing, and that "human errors" are a consequence and not a cause as described by Dekker (2002). Moving trivial functions (that can be programmed) to an autonomous system, means that tough decisions and deviations must be handled by humans. Thus, the science of Human Factors, knowing strengths and weaknesses in cognition and ergonomics, must get a significant position when automation is designed and implemented.

3.3.4 *Responsibilities and certification*
The autonomous system decides based on design approved by the manufacturer. Thus, product responsibilities of accidents and incidents must be placed at the manufacturer (OEM). This is in line with the view of the car OEMs Volvo, Google and Mercedes-Benz (Iozzio, 2016). This is also in line with the supervisory responsibility demanded in the Oil and Gas industry (i.e. where the operator is responsible for the chain of suppliers employed). This supervisor responsibility must be placed on the car OEMs, including the continued updating and adaptation of software in use. Certification is needed, such as the ISA/IEC-62443 scheme of industrial control systems used since 2010. However, certification is still being developed, a survey documenting key issues are found in Martin, et al. (2015).

3.3.5 *Security and risk-based regulation*
Security (for safety) must be included in the development of autonomous systems, and systematic testing (including penetration testing) must be done as a part of certification prior to product release. The precautionary principle must be established as a condition for autonomous transport systems, COMEST (2005).

4 CONCLUSIONS

Related to the research question RQ1 (major risks): The sensors and systems used in autonomous systems, does not have a perfect view of the surroundings, and may also act uncoordinated with their surroundings, thus new type of accidents may happen. There is a need to speed up learning from these incidents and to be aware of communication and information challenges in operations.

Human control and assistance through control centres and via human machine interactions must be designed based on the science of Human Factors in order to avoid higher levels of accidents as documented by Waraich et al. (2013).

We continue to see vulnerabilities and exploitation of software in the public and private sectors. Different perspectives are used in security and safety, due to different adversity models. The security community are addressing threats (directed, deliberate, hostile acts) and the safety community are addressing hazards (undirected events). AEC are so pervasive across all sectors that a silo approach can no longer be acceptable. To ensure that all actors in the value-chain understands this, a silo-based "need to know" principle must be replaced by transparent and open reporting. This can also support a market based cyber-insurance industry.

Related to the research question RQ2 (regulation): There is a need for regulatory action from government to set minimum standards, establish responsibility, and follow up of incidents/accidents. Prescriptive and detailed rulemaking on a national level is wanting, but should be replaced by functional approach demanding the same level of risk in automated systems as in existing systems.

Vendors must have responsibility to ensure safety, security and resilience by design, and must be prepared to accept legal liability for the quality of the technology they produce. Ideally, a formal process of product acceptance and certification (i.e. safety case) should be established before a product can be sold. The manufacturers should establish a proactive focus on (best practice) safety/security standards. There is a need to ensure that there is some sort of a structured learning process (among all relevant actors) when incidents happen.

Related to the research question RQ3 (way forward): Innovative approaches, such as the perspective of Autonomous Ecosystems (AEC) are needed to handle the challenges of autonomous transport systems. The science of Human Factors need to be prioritized to ensure that human intervention can be designed in the system and can be performed in actual operations based on actual human limitations and human strengths to improvise and handle unanticipated events.

Safety has been dependent on publicised accidents and a systematic learning loop between users, the regulator and industry. One component in the learning loop of complex software systems has been reporting and analysis of incidents through computer incident response teams (CERTS). There is a need to establish CERTS of AEC to help coordinate actions.

Rules and mechanisms for updating software in autonomous systems will become more urgent as failures can lead to accidents, thus handling of updates must be addressed in a systematic manner.

Communication between autonomous transport systems and drivers and bystanders must be improved. Autonomous systems are rule based while humans are not, thus there may be misunderstandings and common failures, creating need for interventions through transport centres controlling the flow of transport.

These AEC will be exposed to new strains—thus there must be a focus on how to handle surprises by resilience, to ensure that new demands/ stress/ failures are not impacting transportation in a catastrophic way.

ABSTRACT: Risk communication and information exchange have become more challenging in today's complex projects, which involves different stakeholders in different roles. Unstructured data communication and flaws in knowledge exchange may lead to erroneous risk perception and evaluation. The role of risk analysis has become more critical in this perspective. This paper proposes a new way to enrich risk analysis with the help of knowledge of systems engineering. Focus is given to establish a Failure Mode, Effect and Criticality Analysis (FMECA) model using models from systems engineering which are more systematic compared to models used in tradition approach. A reference case study is analyzed, which is inspired from the subsea laboratory at the Department of Mechanical and Industrial Engineering (MTP) at the Norwegian University of Science and Technology (NTNU). The investigation focuses on the series of relevant risks for the subsea gas boosting section in offshore Oil & Gas installations. Results from the present study are discussed with emphasize on three aspects: (1) cross-system effects, (2) reasonable and reachable risk reduction measures and (3) multiple system dimension. We acknowledge that the proposed method based on system thinking can be used to construct system behavior model, which in turn could be used in FMECA development to gain better understanding of risks and to improve the overall performance of system.

1 INTRODUCTION

In the last decades, the industry, from manufacturing to chemical and Oil & Gas (O&G) sector, has become more and more complex, notably by incorporating innovative technologies requiring new stakeholders. Risk analysts are responsible for the identification and the analysis of potential risks arising from the performed activities and for treating these risks, according to established acceptance criteria (ISO 31000, 2009). Many factors affect the actual risk level in different ways. For instance, a new human machine interface may cause stress and therefore influence operator performance. The risk posed by these factors raises the importance of both the risk analyst and the communication network with the other professionals, consequently, the focus moved to risk management.

Risk management involves different disciplines at different levels across the entire enterprise. However, nowadays in the industry, the coordination between the different parties is not stressed enough when instead it should be properly maintained (Rice & Spence, 2016). Bringing different areas of expertise together in analyzing the potential risks and identify threshold criteria is still challenging. Moreover, the methods adopted for information collection and analysis are often unstructured (Kirsch, Hineb, & Maybury, 2015). The inconsistence in jargon used and the difference in the theoretical background of the different stakeholders may lead to erroneous decision-making and costly correction for inadequate and inappropriate actions.

Failure Mode, Effect and Criticality Analysis (FMECA) has been widely accepted as the risk identification and the characterization tool for

hardware components since the late 1960s. However, today's industry involves fast-moving technology innovations and faces challenging operating conditions. There is no formal procedure in constructing FMECA for such complex system and then the quality and content of FMECA depend on the competence and experience of risk analysts. In some practices, analysts start FMECA without establishing a baseline system concept. Based on this scenario, the solution is to structure coordinated and distributed system information about what is taking place and what is needed for proper risk mitigation.

The existing frameworks for risk management in Oil and Gas industry (ISO 31000, 2009; NORSOK Z-013, 2010) also highlight the needs of establishing the system concept before starting risk analysis, and maintaining and updating the system concept based on given indications, however, no detailed methods and approaches are prompted. This paper suggests the use of often-cited approaches in Systems Engineering (SE) to fulfil such needs, to prevent excessive resource for reaching the agreement on the system concept.

The main objective of this contribution is to investigate how FMECA can get advantages from SE. Many companies have adopted SE as the systematic approach for the design of complex systems (Asbjørnsen, 1992; Haskins, 2008). In fact, SE may help in mediating information exchange among professionals in a simple and concrete way by means of different analyses and models at different detail levels. In this sense, it allows the right person to access the right information at the right time and use it. The adaptation and exploitation of SE approaches and models can assist in maintaining the unified context of the system and ensuring that the interests of different stakeholders are properly understood and considered.

This paper provides a notion through a practical case on to what extent and in which ways the risk analysts think SE methods as effective for supporting FMECA. The following of this paper is organized as follows: Section 2 describes the basis of the subsea gas boosting laboratory that still demands further improvements from a risk perspective. Section 3 discusses the key features of linking and coupling systems engineering and risk analysis models. In Section 4, the proposed model is executed with the practical case and the results are presented in section 5, discussed in section 6 consecutively. Sections 7 presents conclusions.

2 A PRACTICAL CASE

The paper tactically selects an accessible subsea laboratory located at the Department of Mechanical and Industrial Engineering (MTP) at the Norwegian University of Science and Technology (NTNU) to investigate a larger spectrum of risks relevant to subsea gas boosting, as shown in Figure 1. As of today, one challenge for subsea boosting is the compression of wet gas (within

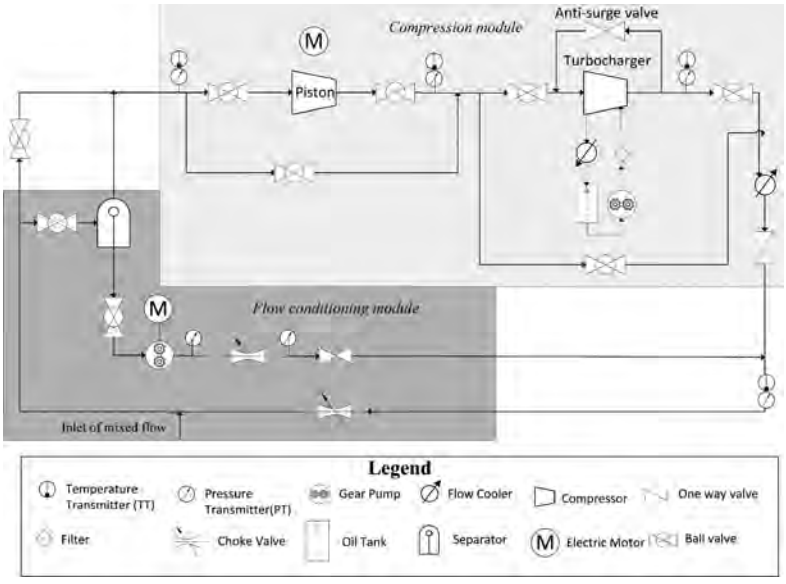

Figure 1. Subsea compression laboratory.

water fraction of 2–20%) since the stratified gas-liquid flow may run the high risk of damaging the traditional compressor. The laboratory is constructed as the pre-testing facility to emulate the different existing solutions for subsea wet gas compression in the Norwegian Continent Shelf, i.e. Ormen Lange and Åsgard (within pre-separation) and Gullfaks (without pre-separation).

This laboratory includes two major modules to test different characteristics of wet gas: the separation module (i.e. the left-bottom) and the compression module (i.e. the right-top). The mixed flow within water fraction (ranged from 0–20%) is emulated by controlling the inlet flow. The implementation of a separation module can separate the water from mixed flow before entering the compression module, and allow studying how the working efficiency and robustness of a separator can influence the whole compression process. The compression module involves a compressor driven by a piston and a compressor driven by the turbocharger, where the piston compressor is very vulnerable by particles and water. Three test scenarios are therefore formulated by the manual close/open of ball valves:

- Wet gas compression with the separation module, where the piston is bypassed
- Wet gas compression without the separation module, where the piston is bypassed
- Dry gas compression, where the piston and turbocharger can compress in the series

The laboratory is almost completed in late 2016, but still demands many improvements in respect to different aspects. This paper exclusively focuses on managing emerged risks of the current structure of the laboratory and devotes to present the obtained results and knowledge for the new development in the industry-size gas boosting system.

3 METHOD

This paper aims to suggest a structured method to enrich the scope of validity of risk assessment by taking advantage from SE. The proposed method propagates SE activities toward risk assessment activities such as FMECA, as shown in Figure 2. SE workshop and FMECA workshop that focus on very different objectives are as the heart of this method. This collaborative method of knowledge transfer enables effective risk management with an objective of dispersing expert knowledge into available tacit knowledge (Alavi & Leidner, 2001).

The starting part of the model is preliminary analysis, which includes defining process goal, defining system along with its boundary, environment and interactions. This facilitates having an overview of the process and to be informed about what is included and what isn't included. SE workshop involves experts (e.g. Designers, operators, managers) to create the static vision of the structure of the system from operational, functional and physical perspectives. SE workshop covers the

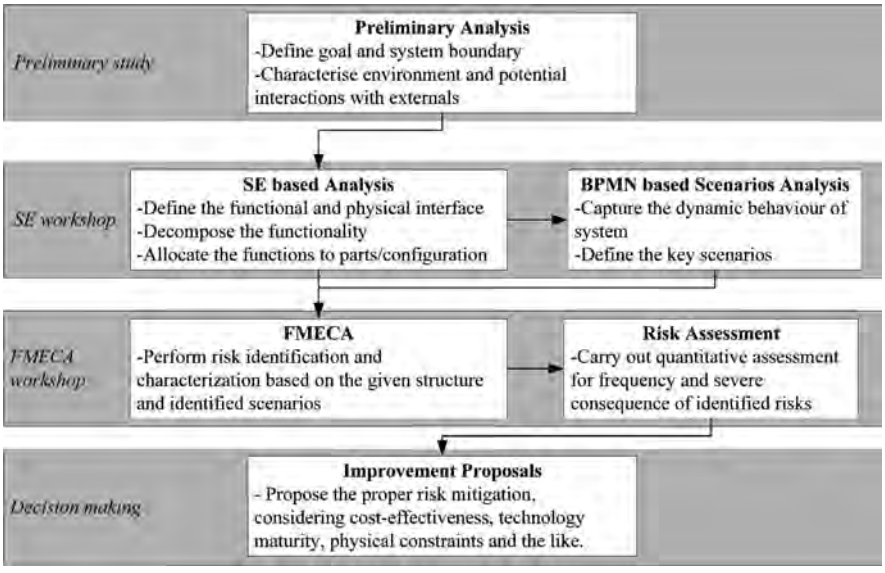

Figure 2. The conceptual map for the proposed method.

interests and the expertise of each contributing stakeholders.SE workshop consists of two concurrent analyses: SE based analysis that covers the operational, functional and physical aspects and the scenario approach that borrows Business Process Model and Notation (BPMN) (White & Miers, 2008). Operational analysis introduces behavior of the system that helps performance based assessment. We can introduce conflict among different component behavior. For example, component C will go off if the component A shuts down or one specific pump may trigger electric supply failure. It solves the conflicts by considering the system function in an ordered sequence of declarations. Functional decomposition specifies how the component functions realize the module functions and how the module functions realize the overall function. Functions that make up another function are grouped together in sets based on ways of achievement. Material, energy and signal flows are viewed as the attributes of these interactions. The functionality is allocated to the preferred parts and layouts. Physical decomposition is made based on the layout of components provided by supplier to show connections between components. This enables us to check interdependency among system components. The availability of the system, including reparable elements can be determined. If one component is out of order, the effect of that on the system or other components can be realized by following the connections. Management personnel can set their work order easily by following the connection.

Designing the scenarios is always an effective way of correctly abstracting the concerns in design. The scenario analysis of a given system is completed on the basis of static vision of its structural decomposition. BPMN can be considered as procedural knowledge representation which represents a set of interconnected procedures (Ligęza & Potempa, 2012). BPMN is therefore considered as a feasible approach to study some scenarios generated from the combination of critical failure, near-miss and even safe states on each interconnected procedure. Both business experts and process experts can easily understand the semantics of BPMN, so this tool is considered feasible to graphically represent the interested scenarios.

The result of SE work is used to conduct FMECA. To carry out the FMECA, multidisciplinary experts are invited to form the team. The team, analyses system components for failure modes. Then potential causes and effects are determined, but forgetting the internal-related or external-related failure modes (DNV-RP-D102, 2012). Involving the scenario-based approach (e.g. BPMN) offers the opportunity to enrich the traditional FMECA. SE workshop combines various discipline knowledge in one common platform and captures multidimensional knowledge into one frame. Different discipline experts analyses the same issue from different angle and may find a different solution (Su & Dou, 2013). It assures universal agreement on a conflicting issue, eliminates bias toward severity rankings, and carry out a detailed analysis of the system structure as well as its process. In addition, generic FMECA contains no dynamic features of the system being analyzed. Using scenario-based analysis as the baseline can assist the risk engineers to clarify the context of each failure modes. The similar approach, called as the scenario-based FMEA was discussed in (Issad, Kloul, & Rauzy, 2017).

After completing FMECA, one can carry out the well-round risk assessment on a basis of FMECA to provide indications for further improvements regarding risk mitigation, recourses and modifications on its structure.

The proposed method is vividly illustrated by the following analysis of the presented case.

4 ANALYSIS

4.1 *Preliminary analysis*

The preliminary analysis defines the preliminary system concept to describe what the system should do, without specifying any functionality and embodies. The analysis covers all the elements that are unmodifiable from engineering perspective, like the external environment of the system, users, legal and regulatory framework and the like. The analysis paves the ground for all the possible technical solutions for the stated problem.

Figure 3 illustrates the operational context within the subsea compressor laboratory, which only indicates what the system do without specifying how to achieve the goal. Different models can be developed on basis of defining operational context of subsea compressor laboratory. For instance, state diagram can be made to check the operational constraints by combining the states of laboratory and those of its external systems, like the energy supply system. The complete preliminary analysis can lay a solid foundation towards the SE workshop that complete the system concept.

4.2 *SE workshop*

The SE workshop executes the analysis stated and discussed above in Section 3, including the functional decomposition and physical decomposition. Functional decomposition is to define the different levels of functionality based on the system mission. Physical decomposition is based on the Process & Instrumentation Diagrams (P&ID) and layout of each component to check physical interactions among subcomponents and allocations. Figure 4 illustrates the physical decomposition of

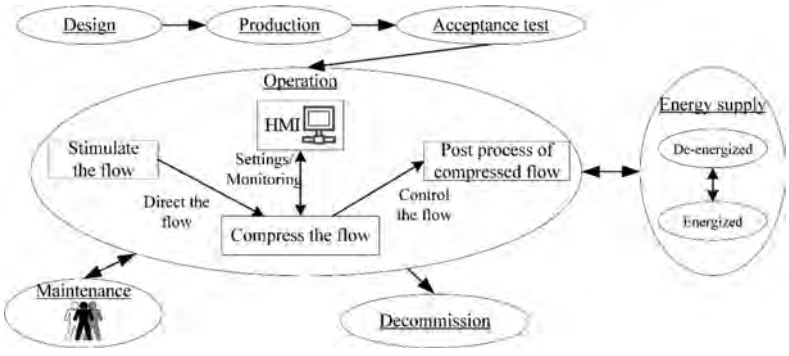

Figure 3. Operational contexts of subsea compressor laboratory.

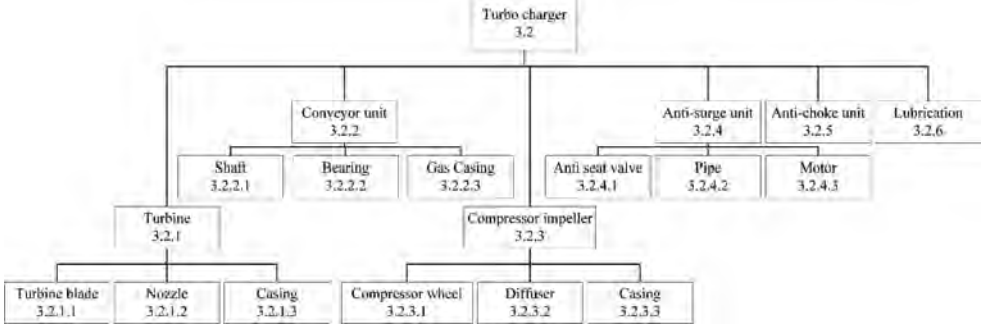

Figure 4. Physical decomposition.

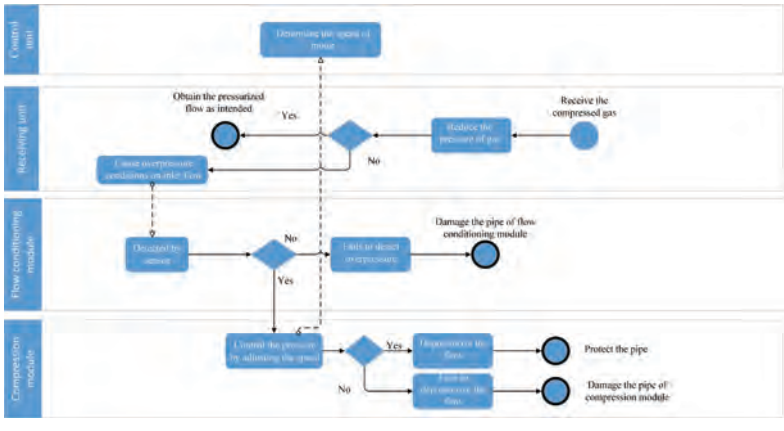

Figure 5. Simplified BPMN for overpressure scenario.

the selected system, the turbo charger to exemplify some key activities in SE workshop.

The decomposition is rather easy to apply for analyzing the functionality and physical structure of the system. One can refine all the operational contexts with sufficient details and trace the changes of functionality and structure through such method. However, this method only describes the system concept statically. Indeed, to complete the well-round risk analysis, we have to carry out the scenario analysis that dynamically describe the events that trigger the transitions between each operational context.

As discussed before, BPMN models are convenient to visualize practical scenarios. Figure 5 presents one selected accident scenario. In Figure 5, the laboratory is tactically divided into

four lanes, including a control unit that is not illustrated in Figure 1. The interfaces (information exchange) between control unit and other lane are indicated by the message flow, i.e. the dashed line. Three decision points are presented to accommodate different missions. The identified operational contexts are also reflected in BPMN model. One can explicitly observe how the control unit influences the whole process of subsea gas compression, and connects each object within distinct activities through BPMN. Here, focus is given to the overall process, system interactions, interface and sequence to work flow, where no time/temporal aspects are considered. Different consequences are specified upon the success of activities, i.e. the availability of corresponding objects. Through generating the accidental scenarios, designers are able to identify the additional needs and carry out complementary analysis to improve the design proposal, see also the summarized result in Section 5.

4.3 *FMECA workshop*

The results from SE workshop are integrated in the FMECA. One advantage is the explicit identification and evaluation of the potential failure modes across physical boundaries. The effect of failure on the subsystems can be studied by analyzing the sequence flow. For instance, the turbocharger compressor receives the flow from the gas intake under the test scenario 2. Once there is a failure or malfunction of the gas intake component, (e.g. Leakage in pipeline or contaminated with liquid from the surroundings), the compressor can be damaged or experience the temporary loss of efficiency. Such risk can be immediately registered when developing FMECA. Another advantage is that BPMN highlights major tasks within the block instead of a corpus of components. In some practices, analysts produce FMECA based on the checklists of physical components (for example Figure 4) as they did not analyze the entirety of the given system concept. By adopting the BPMN model in SE workshop, risk analysts are able to create the FMECA that covers the most significant accident scenarios, which saves a large amount of repetitive and unbalanced works when coordinating the contributions from different design teams.

5 RESULT

Table 1 summarizes some key implications raised after conducting two workshops. The differences between laboratory environment and subsea environment are considered and discussed in the last column of Table 1.

Table 1. Improvement proposal for subsea gas boosting laboratory.

Key issues	Description	Decisions	Relevance for industry-size case
Installation of additional valves, sensors or transmitter	Flow sensor in the water inlet	Must do. The humidity must be controlled to map the characteristics of flow	Not relevant for the flow from the real gas field.
	Pressure sensor in the oil loop	Should do. High pressure may blow the pipe.	Relevant.
	Level transmitter in the oil reservoir	Should do. The implementation can assist in the maintenance (oil refill). Especially when the laboratory is continuously run or stop using for a long time (volatilization of oil)	Highly relevant.
	Flow meter before compressor	Can consider for smooth operation Compressor efficiency decreases with increased mass flow.	Highly relevant.
	Flow mixer	Can consider. The stratified flow runs a higher risk of damaging the compressor than a dispersed homogenous flow.	Not relevant, stratified flows are fairly common even in the real gas field.
	Pressure relief valve in the separator	Should do. The implementation will reduce the risk of separator blow.	The relevance depends on the type and size of separator.

(*Continued*)

Table 1. (*Continued*).

Key issues	Description	Decisions	Relevance for industry-size case
Installation of additional components	Logic control unit connected to all sensors and controllers	Must do, to control the process easily and from a remote location.	Highly relevant.
	Additional filters in the inlet water line	Not necessary if have confidence that supply water is clean	The relevance depends on the needs of removing sands or other particles, requiring expertise from reservoir management.
	A Protective wall around the whole lab	Should do, which will prevent smoke dispersion and reduce fire spread	Highly relevant.
	Protective housing for piston compressor, turbocharger, water pump after the separator	Can consider, as it will prevent from damage in case of water flooding. The cost analysis is needed.	Highly relevant.
Maintenance strategy	Leakage test before the operation	Must do, as it is the most cost-efficient mean to check the integrity of the system.	Only relevant for the site-acceptance test. The leakage sensors are implemented for this purpose.
	Periodic dust cleaning	Must do, as it will reduce the blockage of valves and pipe network.	Not relevant.
	Documentation of operation strategy of system and valves	Must do, as it will reduce human error in operation.	Mostly important.

The results are obtained by considering the major risks within the existing design. One limitation of the current analysis is that the engineering efforts behind each decision are not included. The remaining works are the complementary analysis such as life cycle cost analysis to support the decision-making in the real practice.

6 DISCUSSION

This collaborative model of SE workshop and FMECA workshop makes access to a comprehensive knowledge network of practical experience and expert understanding. This enables identification of potential hazards and implementation of appropriate measures for prevention of accidents. The proposed method enables expert to capture and document the experience they have gained throughout different projects. This can be implemented both in the design phase and in modification phase.

In the traditional approach of FMECA, a failure analysis is mainly carried out on the component level, functional interactions between observed components are not included (Bertsche, 2008). Failure analysis is carried out for the individual process steps. The entire production process is not thoroughly analyzed, for example, the layout of individual component is not considered (Bertsche, 2008). The benefits of developing the FMECA through the identification of key scenarios are listed in the following, based on experiences from practical cases:

- Cross-system effects

It is possible to achieve a holistic and systematic view of the system through SE workshop. The functional analysis assists in comprehending

the effect of failure on subsystem functions and system functions.

- Reasonable and reachable risk reduction measures
Risk reduction measures cover several factors, e.g. maintenance scheduling, decision-making support and barrier management. The architectural analysis can clarify the main constraints that limit in choosing these factors. The coordination between FMECA workshop and SE workshop is therefore concerned with whether the selected structure offers the best balance of these factors.

- More than one single dimension
SE workshop involves experts (e.g. designers, operators, managers) in performing BPMN; operational, functional and physical analysis. This allows to include the interests, expertise and the needs of each stakeholder in the very beginning phase of risk analysis and reflects in the development of FMECA.

In the proposed method, important aspects like interaction between components and environmental effects are considered which gives more confidence in risk analysis and in decision making. An abstruse idea of a system introduces uncertainty in the risk assessment process. The consistent representation of knowledge and system assures that results of risk estimates can be integrated in decision making without less doubt. Only system related uncertainties are being dealt here, which can be mitigated with system knowledge based on experience and expertise.

To present the whole system on like only like P&ID will create a blur on communicating the message. This paper proposes structural breakdown type diagram to represent the physical and functional behavior of the system. The analyses include state in the behavior attribute of a system in the model that describes interdependency and helps performance based assessment.

When the system is complex enough, and one component is serving different functions of the system, it can never be edited as a whole or only through physical or functional dissection. Application of both functional and physical analysis gives a hierarchical breakdown with branches to show connections between components. When one component is out of order, the effect on other components or on the whole system can be observed easily by following the connections, so management personnel can set their work order easily.

If any new component is added to or reduced from the system, editing decomposition diagram is easy which helps to modify FMECA easily. It is often found that in traditional approaches for a change of system, risk assessors have to go through FMECA fully. Prior establishment of physical and functional analysis allows users to modify knowledge easily in case of a change of system.

Effective knowledge transfer and integrated knowledge management help to make a more resilient and reliable system by reducing vulnerability. It helps to develop a better plan for proactive measure to cope with the emergency. These workshops include models for performance and reliability, previous experience, realism of assumptions, representativeness of scenarios along with most critical issues, thoroughness of analysis and first class deliverable.

Effective maintenance also requires integrated information and knowledge system from which maintenance team can get output from other disciplines to make proper maintenance record and work order. Capturing system knowledge effectively facilitates full retrieval of information to implement preventive maintenance on a contrary to corrective maintenance. Failing to do so, increases cost significantly (Motawa & Almarshad, 2013).

Risk engineers often do the risk analysis to compare the risk level to check whether the specified activity is to be complied with the standard. In this prospect, a greater chance for improvement remains out of scope and behind the paperwork. By the arrangement of thinking around systematic activities described earlier, risk can be communicated effectively and efficiently. The quality of risk assessment can be improved by capturing and identification of all possible issues systematically. By sharing with one another's information, it is possible to get a better risk picture in more than one single dimension (Su & Dou, 2013).

However, going through all details is time consuming as there remains a lot of overlaps and repetitions among functions. It is difficult to define the scope of subsystem when one single component performs two functions. It is also questionable whether to assume the previous work as reliable enough or not. Finding necessary expert and shareholders' opinion on a timely manner need proper planning. The execution of the proposed method needs a high management capability of the organization. An organization should have a commitment to provide resources, freedom and time needed to acquire information. Implementing the analysis in development phase makes it possible to identify weak spots and comparative tests can be carried out.

7 CONCLUSION

Modern society deals with a larger spectrum of risk and a larger spectrum of stakeholders, of interest, value and knowledge. Recognizing the wider scope of risk leads to a positive evolution in managing risk. A structured communication model can help in this respect. In this paper, we

presented how SE may help in capturing different nodes of a system for effective risk evaluation, through the basic analysis technique like FMECA. The proposed method is checked with a subsea gas boosting laboratory where the case study assures more confidence in making development proposal and risk mitigation. By doing this type of analyses in the development phase, it is possible to identify weak spots and comparative tests can be carried out. Modifications in the design phase saves cost and preventive measures can be taken.

As a future improvement, a consequence study can be included in detail and should be checked with other applications. The paper also suggests AltaRica 3.0 to encode the FMECA for quantitative risk assessment. This recent achievement has been brought to the forefront in the risk analysis community, see also more details about this modelling language in (Prosvirnova, 2014). This modelling formalism suggests taking the advantages from a structuring paradigm, i.e. S2ML (Batteux, Prosvirnova, & Rauzy, 2015), and a sufficient mathematical framework, i.e. GTS (Rauzy, 2008). With the support of this modelling language, the analysts can provide indications of the system structure as well as the operational process.

ACKNOWLEDGEMENTS

The authors would gratefully thank Christian Holden, for kindly sharing his knowledge and design experience about the subsea laboratory at the Department of Mechanical and Industrial Engineering at the Norwegian University of Science and Technology (NTNU) and for patiently answering technical questions.

Study on the flight landing quality evaluation model with analytical network process and matter element analysis method

Jingsong Lei, Wenbing Chang, Lei Li, Shenghan Zhou & Yiyong Xiao
School of Reliability and Systems Engineering, Beihang University, Beijing, China

ABSTRACT: This study firstly proposes an evaluation model for evaluating flight landing quality based on Analytical Network Process (ANP) and Matter Element Analysis Method (MEAM). Focus on the complexity of flight landing quality synthetic evaluation and incompatibility between single factor identification and hierarchical classification, building element matrics, using ANP to calculate the weight of each parameter and calculating correlation degree to evaluate the flight landing quality. The results of case study show that the model with ANP and matter element analysis model can be applied to evaluate the quality of landing, and compared with the classic Comprehensive Weighting Method (CWM), this evaluation result is more objective, accurate and reasonable.

1 INTRODUCTION

Aircraft landing is one of the most important stages in the whole flight phase, which is seriously affected by the environment and human factors, and the potential failure rate is the highest (Feng Yachang et al.1993). Data of fatal accidents makes it clear that about 23 percent of all fatal accidents take place in the landing phase from 2003 to 2012, though this phase just accounts for about 1% proportion in whole flight phase (X. H. Wang et al. 2009). So it is important to analyze the landing quality so as to find out the way to improve landing quality and make landing safer.

Nowadays, the Quick Access Recorder (QAR) is widely used for aircraft health status monitoring. The QAR data contains variety of flight information. It is used in many methods to analyze landing status and aid decision-making in landing process.

There are few studies studying landing quality, Zhang Rongjia analyze and discuss heavy landing of A321 flight based on QAR data (2012), Feng Yachang et al (1993) used loop separation parameter method to evaluate landing quality. Although there are few studies on landing quality, there are a number of literatures on the study of landing. Landing quality is a part of the landing. In condition of lacking studies on landing quality, it is necessary to study the literatures of landing. Julia A. Bennell et al (2017) considered the scheduling of aircraft landings on a single runway, built algorithms for creating landing schedules and verified the algorithms by random test data and real data from London Heathrow airport. B.S. Girish (2016) proposed a hybrid particle swarm optimization algorithm in a rolling horizon framework to solve the Aircraft Landing Problem (ALP).

Both Analytical Network Process (ANP) and Matter Element Analysis Method (MEAM) are common methods. ANP describes the relationship of elements in the system by network structure rather than hierarchy structure. The indexes in system may have mutual influence on each other. ANP is able to find out the correlation among indexes. Zhou Lisha (2009) used ANP to evaluate power customer satisfaction. Wang Haolun et al (2014) applied ANP to analyze SWOT for strategy decision of enterprise. Xiang Yong & Ren Hong (2014) evaluated the smart city based on the ANP-TOPSIS method. MEAM is widely used in evaluation. Huang Huiling et al (2010) used MEAM to evaluate land eco-security, Huang Jian et al (2007) used MEAM to evaluate power quality. ANP and MEAM are widely applied, yet they have not been applied together. This paper will firstly integrate ANP and MEAM. Specifically, this paper will apply ANP to calculate the weight of each index and apply MEAM to evaluate landing quality. 5 flights with their respectively flight data are studied for getting reasonable analysis results and complete analysis method.

The rest of the paper is organized as follows. In Section 2, we introduce applying ANP to calculate index weight. In Section3, we introduce the quality evaluating model of landing using MEAM. In section 4, case is studied. Finally, in Section 5, conclusions are made.

2 APPLYING ANP TO CALCULATE INDEX WEIGHT

In 1996, Saaty proposed network analysis method (ANP) on the basis of Analytic Hierarchy Process (AHP). ANP allows multiple indexes that can be quantified or difficult to quantify, and considers the association or feedback relationships between elements at different levels and elements within a set of elements. Therefore, compared with AHP, ANP reflect and describe the decision problem more realistically. This study adopts the method proposed in document by Sun Hongcai (2011), and has the following steps:

2.1 *Determining element hyper matrix*

According to the scale defined in Table 1, taking one element $P_s(s=1,2,\ldots,m)$ in the control layer as a criterion, taking the element $e_{jl}\left(l=1,2,\ldots,n_j\right)$ in $C_j=\left(j=1,2,\ldots,N\right)$ as a sub criterion, other elements in the element group $C_j=\left(j=1,2,\ldots,N\right)$ will be compared according to their impact on $e_{jl}\left(l=1,2,\ldots,n_j\right)$, and $N\times\sum n_j=\left(j=1,2,\ldots,N\right)$ judgement matrices can be obtained; calculate the eigenvectors corresponding to the maximum eigenvalue of each matrix, and then the consistency test is performed. If checked, these eigenvectors are normalized; if not checked, a comparison matrix is constructed. These normalized eigenvectors form a $\sum n_j\left(j=1,2,\ldots,N\right)$ order super matrix, and the matrix consists of $N\cdot N$ block matrices.

Table 1. Judgment scale definition.

Scale	Definition
1	Factor *i* is as important as factor *j*
3	Factor *i* is slightly more important than factor *j*
5	Factor *i* is obvious more important than factor *j*
7	Factor *i* is strongly more important than factor *j*
9	Factor *i* is extremely more important than factor *j*
2,4,6,8	The median of the adjacent judgments above
Reciprocal	If the ratio of factor *i* to factor j is a_{ij}, the ratio of factor j to factor i is $a_{ji}=1/a_{ij}$

2.2 *Determining the weight matrix of elements*

Taking one element $P_s\left(s=1,2,\ldots,m\right)$ in the control layer and one element group as criteria. Comparing other element groups with the criteria and *N* judgement matrices can be constructed. It is also necessary to check the consistency of these judgment matrices and find the eigenvectors, and these normalized eigenvectors are constructed into a weighted matrix of order *N*.

2.3 *Determining weighted super matrices*

Multiplying each element of the weighted matrix in step 2 with a block of matrices in step 1, a weighted super matrix is formed. The weighted super matrix reflects the control action of the element group on the element and the feedback of the element to the element group.

2.4 *Calculating index weight*

After obtaining the weighted super matrix, the relative sorting vector of the elements is determined by the corresponding calculation method according to the subordinate matrix type, that is, the weight of the *N* elements.

3 QUALITY EVALUATING MODEL OF LANDING USING MEAM

MEAM is the rule and method of studying the problem of contradiction, it is the edge subject of systematic science, mathematics and thinking science. It is a transverse subject which is applied widely in natural science and social science. It has two theories: one is the matter element and the matter element theory, the other is the mathematical tool based on the extension set (Cai Wen 1999).

The ordered triple consists of matter, character and quantity are regarded as the basis element to describe matter in matter element analysis, denoted as: *R = (N, C, V)*, where *N* refers to matters, *C* refers to the characteristics which can show nature, function of matters and relationship between behavior and matters. *V* is the quantity of *C*, which determine scope of one characteristic. MEAM studies the extension of matter elements by means of extension sets which is determined by correlation functions and the specific conditions of the matter element.

3.1 *Index system and the level limit of each index*

Among the data recorded, there are 6 indexes, which are ground velocity, distance to be flown, roll angle, angle of pitch, lateral acceleration, normal acceleration. Both ground velocity and distance to be flown

are indexes that reflect the condition related to ground. Similarly, roll angle and angle of pitch are angle indexes, lateral acceleration and normal acceleration belong to acceleration category. Considering these characteristic and the usage of Super Decisions Software which is used to implement ANP, this paper build the index system (see Figure 1).

Each landing quality index will be rated as "excellent quality—level 1", "quality between excellent and good—level 2", "good quality—level 3", "quality between good and qualified—level 4", "qualified—level 5", recorded as „„. All 5 levels can not only avoid excessive deviation because of few levels, but also decrease the work of calculation to a certain range (Xu Yonghai & Xiao Xiangning 2004). Level limit of each index is determined by analyzing raw flight data (see Table 2).

3.2 *The establishment of matter element model*

For one flight, V is the quantification of Index C, $R=(N, C, V)$ is the basic element (Cai Wen et al. 1997). Angle of pitch, distance to be flown, roll angle, normal acceleration, lateral acceleration and ground velocity will be used to describe the landing quality. They are recorded as c_1,c_2,c_3,c_4,c_5,c_6, and the corresponding quantity are v_1,v_2,v_3,v_4,v_5,v_6, so it can be expressed as

$$\mathrm{R}(\mathrm{N},\mathrm{C},\mathrm{V})=\begin{vmatrix} N & c_1 & v_1 \\ & c_2 & v_2 \\ & \vdots & \vdots \\ & c_6 & v_6 \end{vmatrix} \tag{1}$$

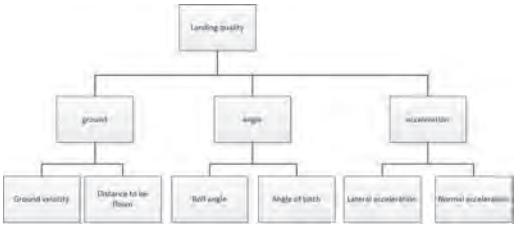

Figure 1. Evaluation index system of landing quality.

The classical field matter element of evaluation of landing quality is

$$R_{0j}\left(N_{0j},C_i,V_{0j}\right)=\begin{vmatrix} N_{0j} & c_1 & v_{01j} \\ & c_2 & v_{02j} \\ & \vdots & \vdots \\ & c_6 & v_{06j} \end{vmatrix} = \begin{vmatrix} N_{0j} & c_1 & \langle a_{01j},b_{01j}\rangle \\ & c_2 & \langle a_{02j},b_{02j}\rangle \\ & \vdots & \vdots \\ & c_6 & \langle a_{06j},b_{06j}\rangle \end{vmatrix} \tag{2}$$

where N_{0j} is the level j of landing quality, $j = 1$ indicates that the quality of the landing is excellent, $j = 2$ indicates that the quality is between excellent and good, $j = 3$ indicates that the quality is good, $j = 4$ indicates that the quality is between good and qualified, $j = 5$ indicates that the quality is qualified. C_i are six characteristics, $i = 1$–6 respectively represents angle of pitch, distance to be flown, roll angle, normal acceleration, lateral acceleration and ground velocity. v_{0ij} is the range of c_i, namely classical field. Classical field is an interval range, which indicates the basic interval of the variation of landing quality, and the range of v_{0ij} is interval $< a_{0ij},b_{0ij} >$, which can be recorded as: $v_{0ij} = < a_{0ij},b_{0ij} > (i = 1, 2, \ldots 6)$.

Segment field matter element is

$$R_p\left(\mathrm{N},C,V_P\right)=\begin{vmatrix} N & c_1 & v_{p1} \\ & c_2 & v_{p2} \\ & \vdots & \vdots \\ & c_6 & v_{p6} \end{vmatrix} = \begin{vmatrix} N & c_1 & \langle a_{p1},b_{p1}\rangle \\ & c_2 & \langle a_{p2},b_{p2}\rangle \\ & \vdots & \vdots \\ & c_6 & \langle a_{p6},b_{p6}\rangle \end{vmatrix} \tag{3}$$

where N is all quality levels, c_i are six characteristics, v_{pi} is the range of c_i, namely segment field. $v_{pi} = < a_{pi},b_{pi} > (i = 1,2,\ldots,6)$, obviously, $v_{0ij} \in v_{pi}$ $(i = 1,2,\ldots,6)$.

Table 2. Level limit of landing quality index.

indexes	Q1	Q2	Q3	Q4	Q5
Angle of pitch/°	[0,0.800)	[0.800,1.600)	[1.600,2.400)	[2.400,3.200)	[3.200,4.000]
Distance to be flown/m	[0.50.00)	[50.00,100.00)	[100.00,150.00)	[150.00,200.00)	[200.00,250.00]
Roll angle/°	[0,1.000)	[1.000,2.000)	[2.000,3.000)	[3.000,4.000)	[4.000,5.000]
Normal acceleration/m·s^{-2}	[13.000,17.400)	[17.400,21.800)	[21.800,26.200)	[26.200,30.600)	[30.600,35.000)
Lateral acceleration/m·s^{-2}	[0,1.200)	[1.200,2.400)	[2.400,3.600)	[3.600,4.800)	[4.800,6.000]
Ground velocity/m/s	[23.000,25.000)	[25.000,27.000)	[27.000,29.000)	[29.000,31.000)	[31.000,33.000]

For an evaluation flight, the measurement data and analysis results are represented by matter element R_0 called landing quality to evaluate matter-element. N_0 stands for quality level, v_i is the quantity of c_i.

$$R_0(N_0, C, \mathrm{V}) = \begin{vmatrix} N & c_1 & v_1 \\ & c_2 & v_2 \\ & \vdots & \vdots \\ & c_6 & v_6 \end{vmatrix} \tag{4}$$

Extension set is characterized with the correlation function, and the range of correlation function is the whole real axis, manage to express the correlation function of extension set by algebraic formula, so qualitative question will be quantitative. The correlation function values is calculated by formula (5):

$$K_j(v_i) = \begin{cases} -\dfrac{\rho(v_i, v_{0ij})}{|v_{0ij}|}, v_i \in v_{0ij} \\ \dfrac{\rho(v_i, v_{0ij})}{\rho(v_i, v_{pi}) - \rho(v_i, v_{0ij})}, v_i \notin v_{0ij} \end{cases} \tag{5}$$

And

$$\begin{aligned} \rho(v_i, v_{0ij}) &= \left| v_i - \frac{1}{2}(a_{0ij} + b_{0ij}) \right| - \frac{1}{2}(b_{0ij} - a_{0ij}) \\ \rho(v_i, v_{pi}) &= \left| v_i - \frac{1}{2}(a_{pi} + b_{pi}) \right| - \frac{1}{2}(b_{pi} - a_{pi}) \\ (i &= 1,2,\cdots,6; j = 1,2,\cdots,6) \end{aligned} \tag{6}$$

Comprehensive correlation degree is calculated by formula (7):

$$K_j(P_0) = \sum_{i=1}^{6} w_{ij} K_j(v_i) \tag{7}$$

where w_{ij} represents the weight of each evaluation index, $K_j(P_0)$ represents the correlation degree between the landing quality and the level j. If $K_j = max\{K_j(P_0)\}(j = 1,2,\cdots,6)$, the quality of the landing P_0 is to be evaluated is level *j*.

4 CASE STUDY

4.1 *Landing quality indexes of the subject to be assessed*

Considering the use of MEAM, this case filter out 5 flight with their data at the time of landing (see Table 3).

Table 3. Flight data.

Evaluation index	No. 1	No. 2	No. 3	No. 4	No. 5
Angle of pitch/°	1.387	1.200	3.041	3.159	1.939

$k_3(v_4)$	$k_3(v_4) = -0.548$	$k_3(v_4) = -0.811$	$k_3(v_4) = -0.969$	$k_3(v_4) = -0.987$	$k_3(v_4) = -0.285$
$k_4(v_4)$	$k_4(v_4) = -0.699$	$k_4(v_4) = -0.874$	$k_4(v_4) = -0.937$	$k_4(v_4) = -0.991$	$k_4(v_4) = -0.523$
$k_5(v_4)$	$k_5(v_4) = -0.774$	$k_5(v_4) = -0.906$	$k_5(v_4) = 0.063$	$k_5(v_4) = -0.993$	$k_5(v_4) = -0.643$
$k_1(v_5)$	$k_1(v_5) = 0.082$	$k_1(v_5) = 0.131$	$k_1(v_5) = 0.263$	$k_1(v_5) = 0.393$	$k_1(v_5) = -0.439$
$k_2(v_5)$	$k_2(v_5) = -0.812$	$k_2(v_5) = -0.869$	$k_2(v_5) = -0.738$	$k_2(v_5) = -0.607$	$k_2(v_5) = -0.252$
$k_3(v_5)$	$k_3(v_5) = -0.541$	$k_3(v_5) = -0.935$	$k_3(v_5) = -0.869$	$k_3(v_5) = -0.803$	$k_3(v_5) = 0.244$
$k_4(v_5)$	$k_4(v_5) = -0.694$	$k_4(v_5) = -0.956$	$k_4(v_5) = -0.913$	$k_4(v_5) = -0.869$	$k_4(v_5) = -0.100$
$k_5(v_5)$	$k_5(v_5) = -0.770$	$k_5(v_5) = -0.967$	$k_5(v_5) = -0.934$	$k_5(v_5) = -0.902$	$k_5(v_5) = -0.357$
$k_1(v_6)$	$k_1(v_6) = -0.814$	$k_1(v_6) = -0.320$	$k_1(v_6) = -0.437$	$k_1(v_6) = -0.355$	$k_1(v_6) = -0.446$
$k_2(v_6)$	$k_2(v_6) = -0.752$	$k_2(v_6) = -0.109$	$k_2(v_6) = -0.249$	$k_2(v_6) = -0.091$	$k_2(v_6) = -0.261$
$k_3(v_6)$	$k_3(v_6) = -0.628$	$k_3(v_6) = -0.054$	$k_3(v_6) = -0.252$	$k_3(v_6) = 0.233$	$k_3(v_6) = 0.218$
$k_4(v_6)$	$k_4(v_6) = -0.257$	$k_4(v_6) = -0.370$	$k_4(v_6) = -0.101$	$k_4(v_6) = -0.259$	$k_4(v_6) = -0.089$
$k_5(v_6)$	$k_5(v_6) = 0.257$	$k_5(v_6) = -0.527$	$k_5(v_6) = -0.357$	$k_5(v_6) = -0.444$	$k_5(v_6) = -0.354$

$$R_5 = \begin{vmatrix} N_5 & c_1 & 1.939 \\ & c_2 & 27.46 \\ & c_3 & 0.857 \\ & c_4 & 19.291 \\ & c_5 & 3.307 \\ & c_6 & 28.564 \end{vmatrix}$$

After inputting the matter element to be evaluated to the matter element model, the results can be output (see Table 4).

4.3 *Applying ANP to determine index weight*

As shown in chapter 2, the calculation of ANP is very complicated, this study uses Super Decisions software (SD) to calculate the weights of indexes. 3 first level indexes shown in Figure 1 are input to SD as 3 clusters, 6 second level indexes shown in Figure 1 are input to SD as 6 nodes, then establish connections between groups and groups, nodes and nodes, and the ANP model is established (see Figure 2).

The direction of the arrow indicates the dominance of one group over the other. For example, ground velocity has effect on index distance to be flown, so there is a loop on the cluster ground.

This study uses the standards shown in Table 1 to compare different indexes, according to the expert's judgment, the specific data is input into the SD and the result is calculated (see Figure 3)

The results will be calculated by inputting the data of Table 3 and Table 4 to the formula (7) (see Table 5).

4.4 *Analysis and comparison of the results*

As can be seen from the Table 5, the quality level of No. 1 flight is 1, namely excellent quality, No. 2 flight and No. 4 flight are the same as No.1. The quality level of No. 3 flight is 5, namely the quality is qualified. The quality level of No. 5 flight is 2, namely quality between excellent and good. The results calculated by CWM are compared with the results obtained from MEAM (see Table 6).

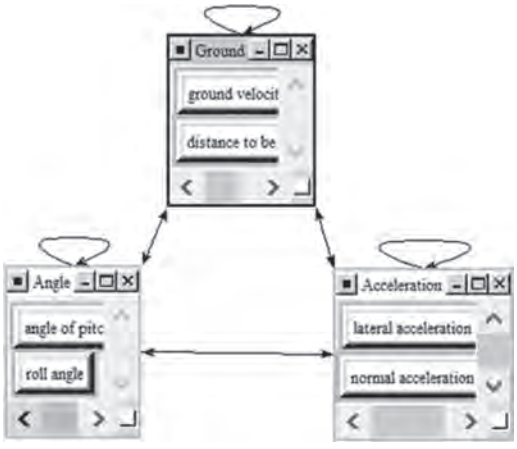

Figure 2. ANP model.

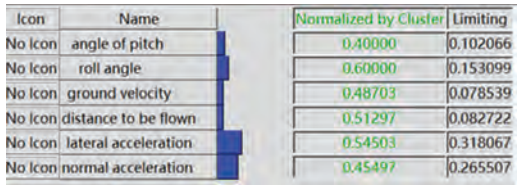

Figure 3. Weight of each index.

Table 5. Comprehensive correlation degree.

Correlation degree	Q_1	Q_2	Q_3	Q_4	Q_5
$K_j(N_1)$	–0.008	–0.354	–0.517	–0.639	–0.673
$K_j(N_2)$	–0.088	–0.581	–0.692	–0.686	–0.584
$K_j(N_3)$	–0.397	–0.581	–0.659	–0.664	–0.386
$K_j(N_4)$	0.020	–0.647	–0.704	–0.740	–0.788
$K_j(N_5)$	–0.218	–0.058	–0.083	–0.436	–0.543

Table 6. Evaluation results comparison.

Evaluation method	No. 1	No. 2	No. 3	No. 4	No. 5
MEAM	Q_1	Q_1	Q_5	Q_1	Q_2
CWM	Q_2	Q_2	Q_4	Q_2	Q_2

As shown in Table 6, the results of two methods are almost different. Only the result of No. 5 flight is same. But it is obvious that their results are similar, and there is not much discrepancy.

The reason why this happened is that the numerical values they calculated are different. The ANP calculates the weight of each index more accurately. The CWM only takes into account the level of index, but the MEAM calculates the correlation degree between the index and each level. The MEAM considers more information, the comprehensive correlation degree of MEAM is further deepened on the basis of correlation degree.

5 CONCLUSIONS

Firstly, based on extension mathematics, reasonably using correlation function to extend the interval to (–∞, +∞), MEAM considers more information, so the result can be more objective.

Secondly, ANP and MEAM is suitable to evaluate the landing quality and we can get satisfactory result. The process of analysis and the result is helpful to improve the landing quality and guide pilots. Thirdly, although CWM is the classical method, integrating ANP with MEAM is better in evaluating landing quality. Finally, ANP and MEAM is seldom used in the field of landing quality level evaluation, so the selection of evaluation index, the determination of the range of the value of evaluation can be further discussed and revised. In this study, the division of levels is based on linear data. There are lots of nonlinear data in real life, so it can be further studied to evaluate objects with nonlinear data.

The reason why ANP is chosen, rather than AHP, is that ANP can eliminate the interaction between indicators and more scientifically and objectively calculate the weight of indexes. However, in ANP, the expert scoring method is used to construct a comparison matrix between indexes. This method is very subjective, and in the future research, we will try to find a more objective and reasonable method for this problem.

Approach to a Bayesian decision model for cost-benefit analysis in security risk

D. Lichte & K.-D. Wolf
Institute for Security Systems, University of Wuppertal, Velbert, Germany

ABSTRACT: Security risk analysis and management for infrastructures is a challenging task as the uncertainties regarding both, the capabilities of security systems and various threat scenarios are high. Especially cost-benefit analysis regarding the investment in physical security systems to reduce the overall vulnerability of infrastructures is a complex problem. This paper presents an approach that is based on a quantitative model for vulnerability analysis previously introduced by the authors. Based on the model a Bayesian Decision Network (DN) is derived. The result of the DN is a Return on Security Investment (ROSI) based on the principle of the weakest path. The ROSI can be used to find the best outcome resulting from different configurations considering mitigation of security risks and required investments in security measures. In a last step the application of the developed approach to a simplified infrastructure is presented. Finally, the results are summarized and discussed.

1 INTRODUCTION

Security risk analysis and management of infrastructures are important issues because of a rising number of attacks with different targets, e.g. financial interests, sabotage or terrorism. At the same time they represent a challenging task, as the uncertainties regarding both, the capabilities of security systems and various threat scenarios, are high.

Especially cost-benefit analysis regarding the investment in security systems to mitigate the overall vulnerability of infrastructures subject to different types of threats is a complex problem. Although numerous approaches for (physical) security risk assessment and analysis exist, there are only few that consider uncertainty for threats and abilities of security systems. As existing methods for cost-benefit analysis are based on these approaches, they mostly do not consider uncertainties either. Additionally, most methods focus on a single attack scenario lacking a holistic view of the different feasible attack paths in an infrastructure equipped with a security system.

This paper presents an approach to a risk model that is based on a quantitative model for vulnerability analysis previously introduced by the authors. The quantitative vulnerability model is enhanced using Bayesian Decision Networks. Bayesian Networks (BN) allow a graphical representation of the security system and its function in a considered infrastructure. Additionally, a decision network (DN) based on an influence diagram is developed. The DN enables the analysis of outcomes resulting from different configurations considering mitigation of security risks and required investments in security measures. Based on a return on security invest (ROSI) analysis, the most valuable configuration can be chosen.

Therefore, the structure of the quantitative vulnerability model is transferred into BN structures and the probability density distributions of the used model are discretized to consider uncertainties. In a second step the paper explains the implementation of the BN into the DN based on security risks and security investments resulting from different configurations of the security system. The last step describes the application of the developed approach to a simplified infrastructure. Finally, the results are summarized and discussed.

2 STATE OF THE ART

2.1 *Security risk assessment*

Security comprises a number of issues covering different fields of expertise; therefore a comprehensive view is needed to conduct a holistic security assessment (Harnser Group 2010). Physical security as one part deals with the protection of infrastructures from intentional physical attacks (Beyerer et al. 2010). The aim of physical security measures is to prevent an attacker from reaching his objective by different means of protection, detection and intervention and also set up resilient structures to mitigate the consequences of successful attacks (Garcia 2008).

The corresponding security risk definition can be defined as (Contini et al. 2012, Mc Gill et al. 2007):

$$Risk = Threat \cdot Vulnerability \cdot Consequence \quad (1)$$

This definition combines—based on a quantitative analysis—consequences of attacks and probabilities of threat scenarios with the risk of individual attacks being successful, defined as vulnerability. The above quantitative definition of risk may help to deduce acceptable risks and necessary measures to mitigate risks (Broder & Tucker 2012). Inherent uncertainties regarding the three risk factors should be cautiously considered (Campbell & Stamp 2004).

Various approaches for security risk assessment have been developed that may be divided into qualitative, quantitative and hybrid methods (Meritt 2008). Qualitative methods are mostly based on expert knowledge, while existing quantitative methods use discrete probabilities. The former are more widespread because of their ease of use, while at the same time the application of expert knowledge can lead to inaccurate or even wrong results (Landoll 2011). Additionally, some quantitative methods aiming at cost-benefit analysis have been developed. Typically, cost-benefit analyses of security measures would account for potential financial losses as a result of an attack, the probability of occurrence of various attack scenarios and the vulnerability of the security system (Flammini et al. 2009). This analysis yields accurate results but raises the complexity compared to qualitative methods (Landoll 2011).

2.2 *Cost-benefit analysis in security risk assessment*

Generally, a cost-benefit analysis for security measures is difficult, as the benefits for the measures are hard to evaulate (Butler 2002). Thus, the support of decision-making concerning security investments is a developing area (Abrahamsen et al. 2015).

Different approaches were proposed in an IT-security context that are based on methods and models of vulnerability analysis to include the effectiveness of countermeasures into the general risk assessment. For example, (Bistarelli et al. 2006) propose defense trees as an enhancement of attack trees to calculate the effectiveness of possible security measures. The SAEM method proposed by (Butler 2002) is based on expert knowledge and aims at including the estimated effectiveness into the risk assessment. An interesting approach is the definition of a return on security investment (ROSI). The ROSI is a ratio of mitigated consequences of attacks and the investment for the therefore needed security measures (Sonnenreich et al. 2005). Although proposed in an IT-context, a more general use in security risk assessment is conceivable.

In the area of physical security risk assessment only a few approaches exist that provide strategies for decision-making with respect to security measures. Wyss et al. propose a security risk metric that similar to the IT—related methods is based on the vulnerability analysis. The basic idea of the method is a rather general approach that every applied measure should make the easiest path towards a successful attack as difficult as possible considering the constraints of costs, operational and programmatic restrictions (Wyss et al. 2010). Another approach analyzes costs and benefits of different measures of aviation security (Stewart & Mueller 2013). Here, a current state is compared to different security measures with the same goals by a break-even analysis to find an estimated minimal probability of successful attacks to equal investment costs.

In conclusion, cost benefit analysis in security risk assessment is mostly based on the sub-part vulnerability assessment. A precise estimation of the inherent benefits of security measures is difficult as even the overall abilities of security measures are often uncertain. Therefore, existing methods lack a detailed coupling to the basic vulnerability assessment and rather supply general decision strategies. Additionally there are no methods of cost-benefit analysis based on quantitative methods, which are able to consider the above mentioned uncertainties to tackle this problem.

2.3 *Vulnerability assessment in security risk assessment*

Quantitative vulnerability analysis as part of the quantitative risk analysis is mostly based on methods adapted from reliability and general risk analysis. Here, the considered model is dependent on given attack scenarios (French & Gootzit 2011). This dependency is detrimental to a comprehensive analysis as knowledge about the behavior of a potential attacker may be insufficient (Cox Jr. 2009). The different modeling approaches can be further split up into mainly analytical but also formal methods. An overview of approaches is given by Nicol et al. (Nicol et al. 2004). Analytical methods are often based on attack trees, which can be seen as a derivative of fault trees already introduced by reliability analysis. Attack trees were first used by Schneier (Schneier 1999) for IT-security analysis and have been further developed by different authors since then, summarized e.g. by Vintr et al. (Vintr et al. 2012).

Contini et al. have introduced incoherent attack trees to characterize the dynamic behavior of the considered system (Contini et al. 2008). Additionally, they integrated simple probability distributions for protection into attack tree models to investigate the chronologic sequence of attacks. Hence, it is possible to analyze the security system's ability for an attack intervention by comparing the probabilities of residual protection and system's response (Contini et al. 2012).

Garcia describes this relation (Garcia, 2008), and thus uses feasible attack paths as part of different attack scenarios and corresponding barriers. The model is time-based and introduces the term of the critical detection point that is the latest possible point of detection that ensures a successful intervention.

Summarizing, the different existing approaches to analytical modeling and analysis of vulnerability are lacking the consideration of uncertainties in the system parameters and overall behavior. Additionally, these approaches do not allow a scenario spanning analysis of the whole security system as the analysis depends on specific scenarios.

2.4 *Bayesian (Decision) networks and influence diagrams*

Bayesian Networks (BN) are based on Bayesian probabilistics interpreting probability as a degree of belief. BN represent a combination of probability and graph theory. A BN therefore quantifies dependencies between various data, information or knowledge considering uncertainties (Jensen & Nielsen 2007). BN consist of nodes and connecting edges in directed acyclic graphs (DAG) linking parent and children nodes. BN therefore consist of (Gribaudo et al. 2015):

- Variables (nodes) with a finite set of states
- Directed edges between the nodes
- A conditional probability table describing the result of each node

The joint probability distribution for a set of nodes $U = \{A_1, \ldots, A_n\}$, is defined as:

$$P(U) = \prod_{i=1}^{n} P(A_i \mid parents(A_i)) \tag{2}$$

Influence diagrams extend the definition of BN to enable the consideration of decision problems by using the BN DAGs (Howard & Matheson 2005). The goal of these diagrams is to find the decision alternative that delivers the highest expected utility (Shachter 1986).

As the structure is similar to BN, influence diagrams also include chance nodes. Additionally three more types of nodes are added (Howard 1988):

- Decision nodes allow decision alternatives that may be controlled by the decision maker.
- Deterministic nodes represent constant values that only depend on the states of their parent nodes.
- Value nodes represent the utility function implemented into the decision process.

Influence diagrams are used in different fields, where DN are set up to visualize the structure and to support decision-making processes. Despite a widespread use of influence diagrams and DN for a wide range of decision problems, e.g. cost-benefit investment decisions in financial disciplines their use in security risk assessments is not very common. An approach to use BN to describe the security vulnerability of gas pipelines is described in (Fakhravar et al. 2017).

3 APPROACH

This paper presents an approach for cost-benefit analysis based on a quantitative model for vulnerability assessment that uses probability density functions (pdfs) introduced already by the authors (Lichte & Wolf 2017). The approach discretizes the pdfs and sets up a model that reflects the described functional relations in a BN based on conditional probabilities. Thus, the characteristics of single barriers are defined as submodels that include the barrier vulnerability. These submodels are then assembled to attack paths resulting from the topology of a considered infrastructure at a higher level model. Within the higher level model it is possible to derive the strength of the infrastructure to block possible attacks by combining the barrier vulnerability in the BN. The strength of a single attack path is considered as the complement of its vulnerability in accordance with the underlying model. Subsequently, the cost benefit DN based on an influence diagram is added. Therefore threat and consequence as the decision utility are implemented to establish a complete risk model. The cost benefit network calculates a return on security investment (ROSI) of different configurations based on an approach introduced in (Sonnenreich et al. 2005).

Finally the proposed approach is applied to a simple exemplary infrastructure composed of four barriers that allow four partly overlapping attack paths.

3.1 *Basic assumptions*

The underlying model is based on four basic assumptions, which characterize the most relevant behavior of a security system in an infrastructure (Lichte & Wolf 2016). These assumptions are used

in the probabilistic description of the systems' relations.

1. The weakest path of the security system determines the system's vulnerability as the chosen path of the attacker is uncertain.
2. The combination of protection and observation at barriers is necessary as an attacker is always able to break through a barrier given infinite time without being detected.
3. The detection of an attack is possible only if the protection is sufficient to prevent a break-through under observation until detection.
4. After detection, an attack can be stopped only if the residual protection along the remaining attack path lasts long enough to prevent the attacker from reaching the asset until intervention is completed.

3.2 *Discretization of the input PDFs*

The model comprises the three main input parameters protection P, observation O and intervention I, which are described as pdfs. To use these input parameters in a convenient BN with limited complexity, the describing pdfs have to be discretized.

Figure 1 uses the example of a normal pdf: the values for the intervals are derived by integrating the pdf within the upper and lower boundaries l and u of the intervals.

$$\int_{l}^{u} p_i(t)\,dt \tag{3}$$

The size of the intervals used in the BN should be determined with respect to the considered infrastructure and security measures as well as the intended accuracy. The observation period for P and O is equal and related to the single barriers, while the period for intervention is usually longer as it is related to the behavior of the whole system. For calculation reasons, the discretization intervals should be of the same size, so the number of intervals n_I in the description of I grows in relation to the number of barriers.

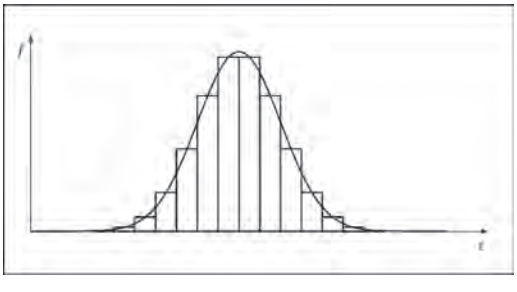

Figure 1. Schematic discretization.

$$n_I = n_B * n_{O,P} \tag{4}$$

Hence, the nodes for the input parameters protection, observation and intervention are built as prior distributions.

With the distribution nodes built at an earlier stage it is possible to derive the BN for barrier vulnerability based on the four assumptions about the behavior of a security system.

3.3 *Bayesian network for barrier vulnerability*

Basically, a combination of three different relations of the input parameters is needed to describe the characteristics of the security measures at a barrier of a security system: Detection D, residual protection R and timely intervention T.

A detection D of an attacker is triggered with the probability that the protection measure at a barrier prevents an attacker from a break-through until an observation is completed with detection. This allocates the conditional probability

$$D = P(t_p > t_o) \tag{5}$$

In the context of BN this can be interpreted as a chance node. The distribution table represents the following probability condition:

$$\forall k,l : P_D = P\left(D \mid t_{Pl}, t_{Ok}\right) = \begin{cases} 1 & \text{if } t_O\left(t_{Ok}\right) < t_P\left(t_{Pl}\right) \\ 0 & \text{else} \end{cases} \tag{6}$$

wherein t_P and t_O denote the time for protection and observation, k and l denote the running index of the corresponding time interval.

The second key relation in the vulnerability model is the ability for a timely intervention T. This parameter is based on the pdf I of the time needed for intervention t_I and the residual protection R and is therefore defined by the conditional probability given by:

$$T = P(t_{RP} > t_i) \tag{7}$$

The residual protection is the sum of all protection measures at the residual barriers of the system on the attack path. Figure 2 shows the BN for the vulnerability assessment of a barrier containing the nodes for detection and timely intervention.

As depicted, the node for timely intervention has the parent nodes "D", "I" and "P" of barrier i. Additionally, the protection nodes of *n* residual barriers are connected as barrier nodes. The resulting general distribution table reflects the following conditional probability for timely intervention:

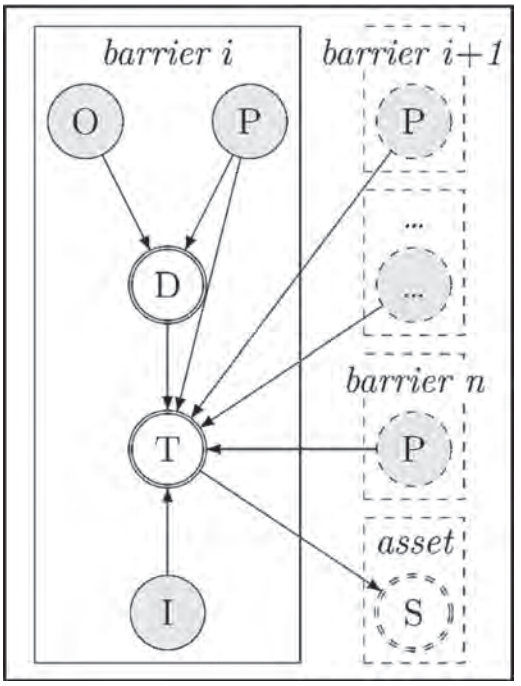

Figure 2. BN for barrier vulnerability.

$$\forall l^i,\ldots,l^n \quad \left(P_T = T \mid D, t_{\mathrm{Im}}, t^{(i)}_{Pl^{(i)}},\ldots,t^{(n)}_{Pl^{(n)}}\right) = \begin{cases} 1 & \text{if } t_I\left(t_{\mathrm{Im}}\right) < t^{(i)}_P\left(t^{(i)}_{Pl^{(i)}} + \ldots + t^{(n)}_P\left(t^{(n)}_{Pl^{(n)}}\right)\right) \\ 0 & \text{else} \end{cases} \tag{8}$$

In (8) $t^{(i)}_P$ denotes the protection time of the i-th barrier so that $t^{(i)}_{Pl^{(i)}}$ describes the state of the protection time of the i-th barrier falling into the l-th time interval.

According to the basic assumptions, the strength of a barrier is determined by the possibility to timely intervene an attack given its detection. As vulnerability is the complement of a barrier's strength, the BN for vulnerability is fully derived. In the next step the network for the system's vulnerability and risk assessment is set up.

3.4 *System vulnerability and risk assessment network decision network*

The risk assessment network consists of barriers of an attack path, an asset as target of an attack, a threat node and cost utility describing possible consequences of a considered attack. Both, the barrier nodes as well as the asset nodes comprise subsystems. The subsystem in the barriers contains the vulnerability model, while the subsystem of the asset comprises the computation of the ability of the attack path to block an attacker. Figure 3 depicts the DN for risk assessment.

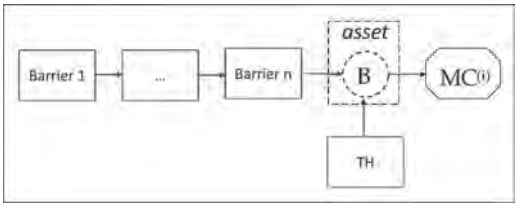

Figure 3. DN for risk assessment.

The deterministic node "B" within the submodel of the asset describes the ability of a blocked attack. The node depends on the parent nodes "T" for the timely intervention of all *n* barriers on the attack path. Additionally, the threat node "TH" serves as a parent node. An attack is blocked when the attacker is detected at a barrier and if a timely intervention—starting at the same barrier—is possible. The conditional probability for the evaluation of the deterministic function of the node "B" is then given by:

$$P_B = P\left(B \mid TH, T, \ldots, T^{(n)}\right) = \begin{cases} 1 & \text{if } P_D = 1, P_T = 1 \\ 0 & \text{else} \end{cases} \tag{9}$$

The parent node "TH" describes the probability of the occurrence of a threat and serves as a factor for the calculation of the general probability of a blocked attack (node "B").

Finally, a value node "MC" is added with the node "B" as a parent (see Fig. 4) to represent the consequences in the risk function in (1). Herein, the possible consequence is inserted as a constant monetary value. The calculated result of the utility function is the value of the consequences mitigated by the installed security measures on the attack path of the infrastructure. The linear utility function yields to:

$$MC = P_B \cdot Value \tag{10}$$

Thus, the derived DN enables a computation of the mitigated consequences and the remaining risk on the considered attack path. Similarly, other feasible attack paths of a system can be set up using the same values for the different threat nodes "TH" and the utility nodes "MC" respectively. Following the principle of the weakest path, the overall risk of a system with n paths is obtained by:

$$R_{System} = \max[\left(1 - MC^{(i)}\right),\ldots,\left(1 - MC^{(m)}\right)] \tag{11}$$

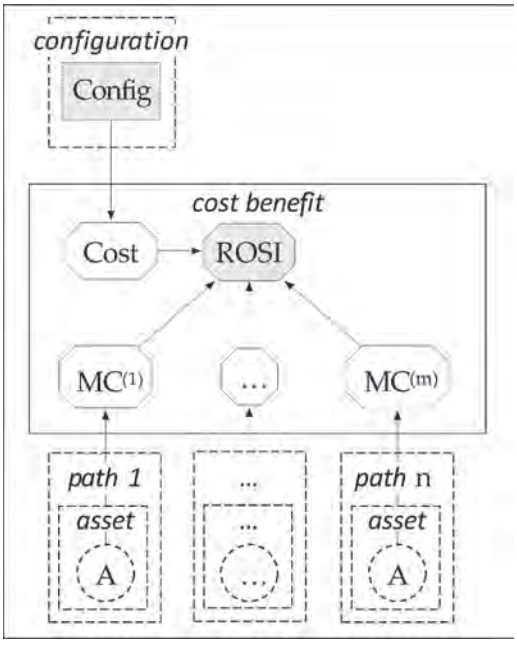

Figure 4. DN for cost benefit analysis.

3.5 *Cost benefit decision network*

Proceeding from the mitigated consequences, a cost benefit DN is constructed by adding a decision node to enhance the DN with the capabilities of an influence diagram. The decisions in the node symbolize the different configurations of the security system that are part of the analysis as shown in Figure 5. The decision node varies the values of the parameters for protection and observation measures at all barriers as estimated for the different configurations. These values need to be inserted into the "P" and "O" nodes in the subsystem of the vulnerability analysis, where the same barriers on different attack path are assigned the same values (see Fig. 4).

As depicted in Figure 4, a value node is additionally added to reflect the costs of the different configurations introduced by the decision node. Finally, the value node for the return on security invest (ROSI) is introduced. It combines the value of the mitigated consequences depending on its configuration and calculated in the risk assessment network with the costs of the configurations. The calculation of the ROSI is based on the principle of the weakest path, as the weakest path is the decisive path in case of an occurring attack. Hence we yield the following utility function for the number of *n* attack paths:

$$ROSI = \frac{\min\left(MC^{(i)},\ldots,MC^{(m)}\right) - Cost}{Cost} \qquad (12)$$

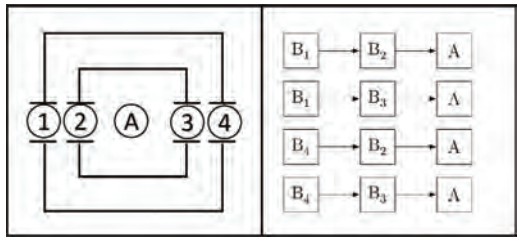

Figure 5. Structure and attack paths of the exemplary infrastructure.

This utility function computes a ratio between the mitigated consequences of the weakest path and the needed investment to realize the required security measures (Sonnenreich et al. 2005). In order to decide whether to invest or not the following basic rules do apply:

- Invest for $ROSI^{(i)} > ROSI^{(i+1)},\ldots,ROSI^{(n)} > 0$
- Do not invest for $ROSI \leq 0$

Thus, the basic decision whether to invest or not as well as the decision which configuration should be realized are possible.

In the next step the derived DN is applied to an exemplary simple infrastructure.

3.6 *Application of the DN to an exemplary infrastructure*

The DN is applied to a notional simplified infrastructure. Its structure is shown on the left part of Figure 5. The security system of the infrastructure consists of four barriers enabling four feasible attack paths.

The four attack paths within the infrastructure consist of two barriers (see Figure 6, right). Three different configurations are analyzed for a decision whether to invest and which configuration to choose. The values of the parameters for the barriers dependent on configuration and the costs for the configurations are listed in Table 1.

The intervention time does not depend on the configurations and is set to the values listed in Table 2.

The DN based on the exemplary infrastructure is depicted in Figure 6.

Finally, the vulnerability as well as the ROSI of the different configurations are calculated. The results are shown in Table 3.

Based on the results, the medium configuration is the optimum decision based on the DN and the ROSI formulation as it shows the best ratio between mitigated consequences and the required investment. It is also visible that the weakest attack path of the security system changes depending on

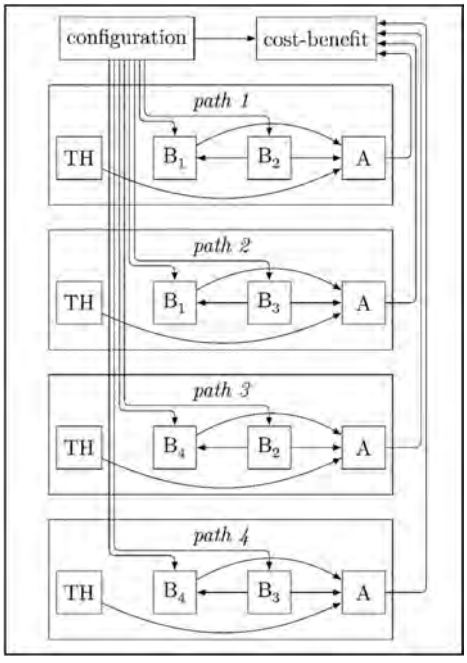

Figure 6. Overall DN for the exemplary infrastructure.

Table 1. Input parameters for P and O and needed investment for different configurations.

Config	1 (50 k$)		2 (150 k$)		3 (300 k$)	
Param. [μ, σ]	P	O	P	O	P	O
Barrier 1	180,30	240,60	180,30	150,60	240,40	240,60
Barrier 2	120,20	150,20	150,20	150,20	120,20	90,20
Barrier 3	60,20	120,30	180,20	120,30	60,20	30,10
Barrier 4	60,20	180,60	60,20	90,30	240,30	180,60

Table 2. Input parameters for I.

	I [μ,σ]
Barrier 1	360,60
Barrier 2	30,5
Barrier 3	30,5
Barrier 4	180,30

Table 3. Results for ROSI and Vulnerability.

Config	ROSI	V	Path
1	0.5692	0.4614	4
2	0.5909	0.4034	3
3	0.1950	0.1037	1

the configuration (see Table 3). The definition of the ROSI utility function considers this behavior of the vulnerability assessment model.

4 CONCLUSION

This paper proposes a new approach regarding cost-benefit analysis in physical security analysis using DN based on BN as well as influence diagrams. The approach enables the assessment of the vulnerability of the considered infrastructure and introduces a decision network that uses the ROSI as a utility function to support decision-making regarding a security investment. The vulnerability assessment is based on a model introduced by the authors using pdf-based parameter descriptions.

In a first step those pdfs which were used to describe the input parameters now are discretized for a further use in BN. Subsequently the BN submodel describing the characteristics of a security system regarding its vulnerability is derived and a risk assessment network based on attack paths is deducted introducing threat probability and a consequence utility function. Following, a decision between different configurations and related investment costs is implemented to establish a DN. In a last step the ROSI utility function is derived based on mitigated consequences of the weakest path and the costs of the different configurations. The ROSI function supports decision-making between different configurations introduced by the decision node. The application to an exemplary infrastructure shows the use of this approach and the consideration of the weakest path in the ROSI function.

Further research is needed to refine and further develop the presented approach. A software implementation would be useful to automate the discretization of the pdfs and the model building. Additionally, the definition of the threat probability as well as the consequence utility function need to be addressed to in more depth. The investment costs for security measures also should be analyzed in greater detail. Especially the implementation of a measure to relate the costs to a possible barrier related effort, e.g. the length of perimeter barriers or observation distances, would be useful.

Risk prediction method of aircraft hard landing based on flight data

Liping Zheng, Jinsong Xie & Silin Qian
School of Reliability and Systems Engineering, Beihang University, Beijing, China

ABSTRACT: The paper aims to develop the risk prediction model for aircraft hard landing with flight data analysis. The statistic data shows nearly half of the incidents occurred in the aircraft landing stage and hard landing is one of the main contributions. The paper firstly analyzes the possible factors of the hard landing and the data feature of flight data. Secondly, flight data are preprocessed by height slice and Principal Component Analysis (PCA). It is to solve the prediction accuracy and data redundancy problems. Then the study builds the mathematical model with the objective function of maximize the probability of hard landing accidents through historical samples. An algorithm based on golden section was provided, and threshold values of each index were found. Finally, the proposed method is validated by empirical research. The result suggests that the proposed method is feasible in hard landing risk prediction problem.

1 INTRODUCTION

Previous aviation safety management data show that although the average time of landing phase accounts for only 1% of the total flight time, the accident rate at this stage was the highest of all phases of the flight. Therefore, the flight risk control in the landing stage plays a very important role in the flight safety assurance of the aircraft. Moreover, analysis of aircraft hard landing event is a very important work in practice.

Hard landing, also known as hard landing, is an extremely important safety hazard for the impact of flight safety during the landing stage. Hard landing may cause damage to the aircraft structure, result in direct or indirect financial loss, damage to comfort and other adverse consequences. Hard landing can cause damage to aircraft components or systems under heavy loads (eg, landing gear, wings, etc.) and, in severe cases, damage to the aircraft and casualties. Boeing points out that the acceleration of the plane's vertical to the ground exceeds the specified limit when it touchdown, and it can be judged to be a hard landing. The Airbus defines hard landing as a phenomenon that the acceleration or speed of an aircraft vertical to the ground exceeds the specified threshold. Thus, the landing load (that is, the vertical acceleration when the aircraft landed) is to determine the landing of the aircraft or not the key indicator. Accurate landing loads are predicted prior to the aircraft landing can identify the risk of hard landing events in time, and take appropriate measures in time (such as go around), which can reduce the frequency of hard landing events to a certain extent, and improve the safety of aircraft landing.

To ensure flight safety, real-time monitoring of aircraft flight status is required. The aircraft usually contains a Quick Access Record (QAR) for recording flight parameters. The flight parameters reflect real-time status information of the entire flight phase of the aircraft and have high application value in performance testing, accident investigation, flight training and assessment, equipment maintenance and safety monitoring. However, due to the complexity of the flight data and the limitations of the data analysis methods, there is still a more in-depth data development value due to the low utilization of flight data in flight safety early warning.

This article aims to establish a model based on the flight parameters to predict the risk of a landing. In a certain environment, taking the hard landing event as an object, we identify the high-risk areas that can easily trigger QAR overrun events in the "space" formed by the key factors closely related to such overrun events. The remaining part of this paper is organized as follows. In section 2, the process of data preprocessing by flight data slicing and data reduction analysis is introduced. In section 3, the risk region optimization model and determination of region division point is presented. In section 4, the model is demonstrated with real flight data.

2 DATA PREPROCESSING

2.1 *Flight data slicing*

The original flight data are time series data, and each flight parameter varies with flight time. However, it was found in the study that there was great uncertainty in predicting the landing time before the landing of the aircraft, and the prediction deviations could be as high as several minutes.

In fact, the normal landing time of aircraft is only a few seconds. In the prediction deviations of several minutes' landing time, the aircraft is likely to have completed the landing or far from completing the landing. It is highly unreliable to predict the hard landing according to the time trend. On the other hand, the height of the plane from the ground can be measured in real time by radio signals and is truly reflected in the flight data. Therefore, in order to avoid the inconsistency in the flight height data interval of each flight frame, we need to carry out the high slicing processing of flight data before establishing the risk prediction model of hard landing.

Slicing processing of flight data is a method to intercept a part of the flight data according to the altitude of the flight, the intercepted data will be used as the basis for data analysis, and the rest of the data will be removed, we set the altitude of the flight data in the range of $[h_1, h_m]$ ($h_1 < h_m$), $\boldsymbol{N}$ is the number of slices, the condition of the model is:

$$\boldsymbol{\omega} = \boldsymbol{h} = (h_1, h_2, \ldots h_N)$$

Satisfy the following formula:

$$h_i = h_1 + (i-1) \times d \tag{1}$$

$$d = \frac{h_m - h_1}{N-1} (N \geq 2) \tag{2}$$

where d stands for high interval of slice, $1 \leq i \leq$ N.

2.2 *Dimension reduction analysis*

There are many flight parameter variables in flight data. Too many variables can cause serious correlation. On the one hand, it will cause redundancy of models and reduce the efficiency of model operation. On the other hand, useless information will also cause bias in model prediction. As a method of statistical analysis, factor analysis had a good performance in data dimension reduction, the basic principle is to integrate multiple variables into a few indicators under the premise of losing less original information, so as to study all aspects of the information. After synthesizing a few indicators, the information contained are not repeated each other, i.e. variables are not related. For that reason, this paper is proposed to use factor analysis to reduce the dimension of flight data in order to extract key and valuable data from a large number of flight parameter variables.

The parameter analysis of flight parameters must first standardize the original flight parameters, and set up the k flight data with standardized treatment.

$X = (X_1, X_2 \ldots X_m)$ is a variable, m common factor of flight data is $F = (F_1, F_2 \ldots F_m)$, and $m < k$. The model is as follows:

$$\begin{cases} X_1 = a_{11}F_1 + a_{12}F_2 + \ldots + a_{1m}F_m + \varepsilon_1 \\ X_2 = a_{21}F_1 + a_{22}F_2 + \ldots + a_{2m}F_m + \varepsilon_2 \\ \ldots \\ X_k = a_{k1}F_1 + a_{k2}F_2 + \ldots + a_{km}F_m + \varepsilon_k \end{cases} \tag{3}$$

where a_{ij} is factor loading, ε_1, ε_2, …, ε_k is residual term.

Common factor of flight data in the model, "Flight data factor" for short, that is, a few key flight data information obtained after dimensionality reduction of the original flight data. This information will serve as the modeling data basis for the risk prediction model of hard landing.

3 MODEL AND ALGORITHM DESIGN

Hard landing is an important hidden danger for aircraft landing safety. There are many factors that affect the landing safety of aircraft. It can be divided into three main categories: human factors, body factors and meteorological factors. Human factors include unskilled operation, misjudgments, and operation errors caused by psychological factors, and so on. Body factors include the maintenance support of the aircraft, the level of reliability, and so on. Meteorological factors include the reduction of visibility caused by rain and snow and the deviation of the flight attitude caused by the side wind. The impact of these three kinds of factors on aircraft landing safety can be concentrated in the flight data. A large number of flight data are recorded in flight data. These flight data reflect the flight status and index parameters in real time, and provide important monitoring basis for aircraft flight safety. In this paper, we take the landing load overrun event in the landing stage as the object, and find out the high-risk area which is easy to trigger hard landing events in the "space" closely related to the event. The so-called high-risk area refers to the combination of certain factors in the span range of influencing factors for hard landing events. In the subspace represented by these combinations, the probability of a landing load over the limit event tends to be 1.

3.1 *Risk region optimization model*

After reducing the dimension of flight data, at the height of 9 *m*-2 *m* before landing, the value of the m flight data factor and Its Variation Track play a major role in the occurrence of hard landing events. Therefore, the high risk areas are divided according to the space of m flight data factor and its change rate. In the process of division, the total number of samples to meet the space is not less than a certain proportion. That is, the nature of the space is established in a certain probability. Then, the partition point is optimized and the location of the partition point is adjusted to maximize the probability of the hard landing event in the high-risk area.

The symbols are as follows:

A, B, C indicate the state value of 3 factors at the radio height 9m; ΔA, ΔB, ΔC respectively indicate the change rate of the flight data factor *A, B, C* from the radio height of 9 to 2m. *N* represents the number of all the samples; $0 < P < 1$, indicating that the sample size of the region should be kept at a certain level after the division; L^* represents the "high-risk area" threshold; *L* indicates that the number of overrun samples of triggered landing load in a certain region accounts for the proportion of the total number of samples in the region; *R* represents "high risk areas", when and only when the proportion of the flight overrun samples in the region is higher than that of L^* in the region. R_1 represents the number of flight overrun samples in "high risk areas"; R_2 represents the number of normal samples in the "high risk area"; H_1^i, H_2^i respectively represents the division point on the *i* factor, which is a decision variable.

Find the optimal model for high-risk area:

$$\max(L(H_1^i, H_2^i)) \ldots \mathrm{i} = A, B, C, \Delta A, \Delta B, \Delta C \quad s.t. \tag{4}$$

$$(R_1 + R_2)/N \geq P \tag{5}$$

$$R_1/(R_1 + R_2) \geq L(H_1^i, H_2^i) \tag{6}$$

H_1^i, $H_2^i \in$ [Minimum value of *i* factor and maximum value of *i* factor] (7)

Among them, formula (4) is the objective function, which indicates that the threshold of "high-risk area" is maximized under the value of different division points. Formula (5) indicates that the proportion of samples in the division area is not less than that of a given parameter *P*. Formula (6) indicates that the region should satisfy the definition of high-risk area; formula (7) represents the range of decision variables.

3.2 *Search of partition points*

The search for the division points adopts the golden section method with one dimension optimization. The golden section method also known as extreme and mean ratio, refers to a line segment is divided into two parts; the part with the length ratio is equal to the other part and this part of the ratio. The ratio is an irrational number, and the approximate value of the first three digits is 0.618, so it is also called the 0.618 method.

The order of Iterative Refinement will affect the result, therefore, combining the experience of the expert, the iteration sequence is ordered according to the size of the impact on the event, and the algorithm step is shown in Figure 1.

Sort $i = A, \Delta A, B, \Delta B, C, \Delta C$

$$H_2^i = i^- + 0.618(i^+ - i^-) \tag{8}$$

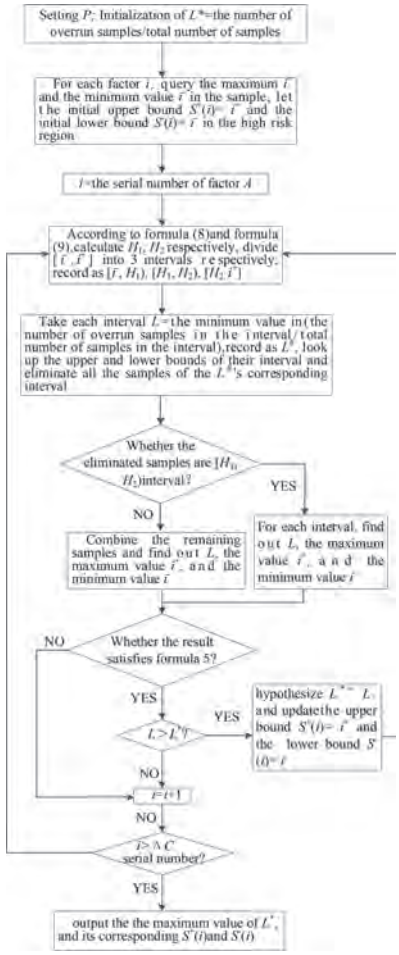

Figure 1. The diagram of algorithm step.

The point of this point on median symmetry is

$$H_1^i = i^- + 0.382(i^+ - i^-) \quad (9)$$

4 EXPERIMENT ANALYSIS

This research takes a certain type of UAV as the test object. After more than 10 years' research and test time, the UAV has completed dozens of scientific research flight tests and batch production. At present, dozens of Unmanned Aerial Vehicles (UAVs) have been delivered to many batches of the troops, with a cumulative flight time of more than 200 hours. The paper obtains the flight data of the aircraft during the landing and decline stage including 19 flight data variables in 45 sorties. 19 variables of flight data are respectively radio altitude, elevation angle, pitch rate, roll angle, roll angle rate, course angle, yaw angular velocity, aileron displacement, rudder displacement, altitude rate, elevator displacement, forward acceleration, normal acceleration, lateral acceleration, engine speed, atmospheric height, airspeed, the lateral offset and ground speed. The critical value of landing load to judge whether a hard landing is or not is 18.0 m/s^2, When the aircraft landing load is more than 18.0 m/s^2, the landing is considered to be a hard landing. During the 45 landing sorties, a hard landing occurred during the landing of fourth, fifth, sixth, 10, 14, 16, 17, 20, 24, 25, 26, 29, 30, 34, 35, 39, 40, 42, 45, respectively. Removing the flight data after landing, the unified limited flight height is 9 *m*-2 *m*, and the flight data of each landing gear are sliced at each 0.5 m by the flight height, the missing data were filled by averages, and 15 data slices were obtained and the slice data were integrated. A total of 675 data of 15 altitude values of 45 flight sorties were finally obtained, as shown in Table 1.

18 input variables of flight data were tested with KMO test. The results were 0.579 and more than 0.5, which showed that the variable of flight data was suitable for factor analysis. The results of the dimensionality reduction analysis of the parameters of the flight data are shown in Table 2.

If the extracted eigenvalue is greater than 1, the eigenvalue is considered as a flight data factor, the analysis results show that, when 18 fight data variables are reduced to 3 flight data factors, 87.278% of the raw information of the flight data can still be retained. According to the order of the number 1–3 in the table, the three flight data factor variables are defined as *A, B, C,* respectively, flight data factor after dimensionality reduction makes the model simplified, in this way, the original information of the flight data is preserved as much as possible, and the expected effect is achieved.

Table 2. The results of the dimensionality reduction analysis of the parameters of the flight data.

	Initial eigenvalue			Extraction of square sum load		
Component*	Total	Variance ratio	Cumulative ratio	Total	Variance ratio	Cumulative ratio
1	5.194	57.711	57.710	5.194	57.711	57.710
2	1.646	18.293	76.004	1.646	18.293	76.004
3	1.015	11.274	87.278	1.015	11.274	87.278

45	2	2.16987	4.05408	…	27.26024	…	21.45645	4854

Table 3. High-risk area*.

Parameter	A	ΔA	B	ΔB	C	ΔC
Upper boundary	0.62	–0.05	0.85	0.30	0.74	–0.64
Lower boundary	0.19	–0.41	0.92	–0.70	0.34	–0.23

*$P = 0.3$.

Using the algorithm in the third section to solve the model, the result is $L^* = 0.6$, the results of the high risk area after standardization are shown as shown in Table 3, and the standardization process is as follows:

$$\overline{x}_i = \frac{x_i - x_{\min}}{x_{\max} - x_{\min}} \tag{10}$$

where, x_i represents the flight data.

We randomly selected 10 samples for testing and analysis, and 4 samples were found to fall into the area, of which three were QAR landing load overrun samples.

According to the calculation results, the average probability of the occurrence about landing load overrun in the analysis sample is 0.412. From the analysis results, the possibility of the occurrence about landing load overrun in the area is higher than the average occurrence probability, which indicates that the area marked in Table 3 belongs to the high-risk area of the hard landing event.

5 CONCLUSION

This paper establishes the risk prediction model for aircraft hard landing by determining the high risk area with flight data analysis. Through the high slicing processing of the original flight data, the unified flight data can be obtained at a certain height. In addition, factor analysis, as a tool for data reduction processing, can simplify more parameters and maximize the information of data. We selected flight data (including human, aircraft and environmental factors) in 9-2 *m* to predict the risk of a hard landing event. In the sense of certain probability, the division point is optimized. By adjusting the location of the division points, the probability of a hard landing event in a high-risk area is maximized. The results show that the identified high risk area can identify the exceeding limit of landing load. For future research, we will pay more attention to how to improve the accuracy of recognition. At the same time, further demonstration is needed for the selection of the predicted height.

EU risk governance of migrants and refugees' influxes: A realistic foundation for crisis governance?

B.I. Kruke & C. Morsut
Centre for Risk Management and Societal Safety, University of Stavanger, Stavanger, Norway

ABSTRACT: Wars, political instability, poverty and ecosystem's alterations force several people to look for better living conditions and security. Europe has become a safe haven for migrants and refugees, particularly since 2015, when thousands of people crossed the European borders on daily basis. In this paper, we aim at studying the development and the management of the 2015 migrant and refugee influx into Europe at the European Union (EU) level in terms of risk and crisis governance, mainly through the lens of the International Risk Governance Council (IRGC) Risk Governance Framework. The 2015 mass influx into Europe showed the EU's inability to cope with such an event, with a subsequent fragmented response consisting of mainly national security initiatives. A main reason behind the inadequate overall joint crisis governance at EU level has been a weak supranational risk governance, mainly due to national political, economic, security and cultural differences.

1 INTRODUCTION

Migration is an old phenomenon. People have always been on the move. Push and pull factors will endure and people will continue to leave their home because they have to or because they want. Wars, permanent conflict, political instability, ecosystems' negative alteration due to the climate change are all push factors that force people to leave and to seek refuge or better life conditions. This kind of migration has given rise to a series of challenges to Europe: the so-called 2015 migrant and refugee crisis, characterised by a high influx of people crossing the Mediterranean Sea, is an example in this sense. In 2015, more than a million people reached Europe (UNHCR 2017) in perilous ways, putting under pressure the aid and reception mechanisms existing at national and European Union (EU) levels. Rescuing people from the sea, giving them first assistance, providing shelters and distributing food were activities performed be a variety of non-governmental, governmental and supragovernmental actors in a complex frame. National authorities, the EU, the United Nations High Commissioner for Refugees (UNHCR), the International and national Red Cross, several NGOS, but also private citizens offered their assistance in 2015. They continue these tasks since the so-called crisis has become more a structural occurrence rather than a one-off event.

A short terminological clarification of the terms migrant and refugee is needed at this point, before proceeding with the goal of our paper. The 1951 Refugee Convention defines a refugee a person crossing a national border seeking protection from political or other forms of persecution (UNHCR 2010), while a migrant is a person who chooses to move mainly to improve his/her living conditions (a better job, education or family reunion are reasons behind the choice) (UNHCR 2016). Unlike refugees, who cannot safely return home, migrants face no such impediment. However, in describing the 2015 massive influx of people into Europe, the UNHCR employed both terms, since it was difficult to differentiate between the two groups, those escaping from various political instabilities and those impelled by economic reasons (economic migrants). We will follow the UNHCR's terminology in this paper.

We aim at studying the development and management of the 2015 migrant and refugee crisis at the EU level in terms of risk and crisis governance, mainly through the lens of the International Risk Governance Council (IRGC) Risk Governance Framework. Our analysis rests upon previous research we conducted on resilient crisis management (Morsut and Kruke 2014, Kruke and Morsut 2015), on reliable crisis governance (Morsut and Kruke 2016), and on the relationship between risk and crisis governance (Morsut and Kruke 2017). This paper first presents the conceptual framework applied in our case. Secondly, by drawing from document analysis of EU policy and legal documents, it outlines the EU risk and crisis governance towards migrants and refugees according to the IRGC Risk Governance Framework, to answer the

following question: to what extent did the EU crisis governance follow a thorough risk governance process in coping with the influx of refugees and migrants?

2 CONCEPTUAL FRAMEWORK

2.1 *Risk*

Risk is related to a possible future state of affairs. Risk may be defined as "an uncertain consequence of an event or an activity with respect to something that humans value" (IRGC 2005: 19), or a situation or event where something of human value (including humans themselves) is at stake and where the outcome is uncertain (Rosa 1998, 2003). The uncertain consequences—understood in terms of likelihood and severity—can be positive or negative. The degree of 'positiveness' or 'negativeness' depends very much on peoples' perceptions. However, most people relate risk to something negative. Kates et al. (1985: 21) describe risk as the possibility that an undesired state of reality (adverse effects) may occur as a result of natural events or human activities. This implies that there is a possibility for a negative result of a natural phenomenon or human activity. However, the impact of this phenomenon or activity is unknown, as the probability for the occurrence. Uncertainty characterises the phenomenon or activity in question. Uncertainty, together with values, is central to Aven and Renn's understanding of risk, which refers to uncertainty about and severity of the consequences (or outcomes) of an activity with respect to something that humans value (Aven and Renn 2009: 1). Thus, risk is inherently a subjective phenomenon, a social construction. Expert judgements is necessary, but not adequate, to understand and manage risk. In addition, risk perception, public values and stakeholders' understanding may also be important to consider. Thus, differences in approaching the risk between the public and the so-called experts are likely to be seen (Sjöberg 1999).

Risk perception, in particular, has its roots in cognitive psychology and has given rise to a vast literature on the relationship between the perceived risk and the real foundation of risk (Slovic 2000). Culture, gender and knowledge availability influence the perceived risk and the actions taken accordingly, both by individuals and by decision makers. Risk perception, as a social and cultural construct, reflects values, symbols, history and ideology (Weinstein 1980). Differences in risk perception between the public and the so-called experts may hamper risk management approaches and rational decision-making. This conflict between expert and public risk perception is at the basis of the social dilemmas of risk management (ibidem) and of risk governance.

2.2 *Risk and crisis governance*

Governance lacks a univocal meaning since it rests in several disciplines that discuss the governance from their standpoint (see Kjær 2004; Peters 2000; Pierre 2000; Stoker 1998). Thus, our understanding of governance differs according to who exerts governance. Governance is often seen in relation to government and governability (Renn et al. 2011). Government may be understood as setting and administering the public policy, while governability is understood as the overall capacity for governance of any societal entity or system (Kooiman et al. 2008). Some scholars consider the state as the main actor exerting governance (Bevir et al. 2003). In this understanding, governance is closely related to government. Governance, on the other hand, is understood in terms of socio-political interaction patterns, where management and decision-making are conducted within a framework of institutional diversity (Morsut and Kruke 2017). This diversity is formed by several stakeholders—state authorities, trade associations, NGOs, civil society, private actors (Kooiman 2003; Krahmann 2003; Bogason 1996), networks (Sørensen and Torfing 2007) and supranational organisations, such as the EU (Marcussen and Torfing 2007). Governance, therefore, entails stakeholders' involvement (Renn 2008) to a much greater degree than government.

Scholars define and characterise governance at various levels. At a national level, Nye and Donahue (2000) describe governance as structures and processes for collective decision-making involving governmental and non-governmental actors. The joint approaches between public and private actors are prominent in this understanding of governance. The same is the case with Rosenau's understanding of governance at a global level (1992). Here, governance embodies a horizontally organized structure of functional self-regulation, encompassing state and non-state actors, bringing about collectively binding decisions without superior authority (ibidem).

The term risk governance involves the translation of the substance and core principles of governance to the context of risk-related decision-making (van Asselt and Renn 2011). A successful risk governance approach leads to a so-called dynamic non-event (Weick 2011). However, if the non-event becomes an event, in the form of a crisis, this crisis needs to be managed by a crisis governance, defined as "to what extent the relationships among economic and political, formal and infor-

mal institutions are able to manage crises" (Kruke and Morsut 2015: 187). In this respect, there is a clear relation between the quality of risk governance and an effective crisis governance.

2.3 *The IRGC risk governance framework*

The IRGC has elaborated a Risk Governance Framework for a systemic risk governance approach. The Framework goes beyond a naïve understanding of risk as an objective category and a relativistic perspective where all risk judgements are subjective reflections of power and interests (Renn 2008). The Framework is characterised by two interlinked spheres: the assessment and the management sphere.

The former deals with the generation of knowledge, whereas decisions and implementation of actions are conducted in the latter. Each sphere is divided into phases (IRGC 2005) briefly described here:

Pre-assessment:
The purpose is to capture both the variety of issues that stakeholders and society may associate with a certain risk as well as existing indicators, routines, and conventions that may prematurely narrow down, or act as a filter for, what is going to be addressed as risk. Typical activities in the pre-assessment are:

- Problem Framing: different perspectives of how to conceptualize the issue;
- Early warning: systematic search for new hazards;
- Screening: establishment of procedures for screening hazards and risks;
- Scientific conventions for risk assessment and concern assessment: assumptions and parameters of scientific modelling and evaluating methods and procedures for assessing risks and concerns.

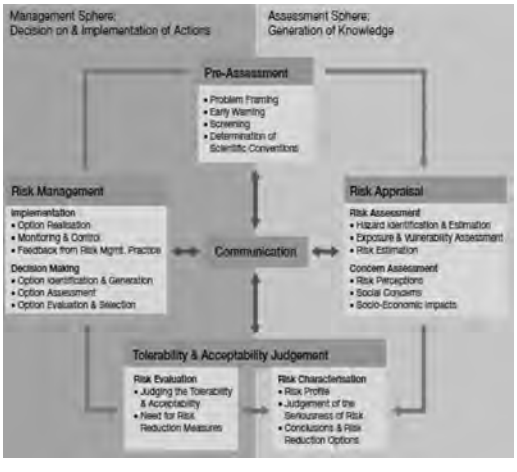

Figure 1. IRGC framework (IRGC 2005: 13).

Risk Appraisal:
Main activities in risk appraisal are the development and the synthesis of the knowledge base as a foundation for a decision on whether or not a risk should be taken. If the decision is to take the risk, then a follow-up activity is to map available options for avoiding, mitigating, reducing or handling the risk. Risk appraisal comprises both a scientific risk assessment and a concern assessment. The scientific risk assessment deals with the risk's factual, physical and measurable characteristics, including the probability of occurrence (or a probability distribution over a range of negative consequences) (IRGC 2005: 14). The concern assessment is a systematic analysis of the associations and perceived consequences (benefits and risks) that stakeholders, individuals, groups or different cultures may associate with a hazard or a cause of hazard (ibidem).

Tolerability and acceptability judgement:

- Risk characterisation: Collecting and summarizing all relevant evidence necessary for making informed choice of tolerability and acceptability of the risk in question and suggesting potential options for dealing with the risk from a scientific perspective.
- Risk evaluation: Applying societal values and norms to judge tolerability and acceptability and, consequently, to determine the need for risk reduction measures.

Risk Management:

Decision-making:

- Option identification and generation: Identification of potential risk-handling options, particularly risk reduction (i.e. prevention, adaptation and mitigation, as well as risk avoidance, transfer and retention);
- Option assessment: Investigations of the impacts of each option (economic, technical, social, political and cultural);
- Option evaluation and selection: Evaluation of options (multi-criteria analysis).

Implementation:

- Realization of the most preferred option;
- Monitoring and feedback: Observation of the effects of implementation (link to early warning). Ex-post evaluation.

In all phases risk communication is essential to enlighten the risk process for all not involved relevant stakeholders, including civil society, and to maintain trust among these (IRGC 2005).

3 THE CASE: THE 2015 INFLUX OF MIGRANTS AND REFUGEES INTO EUROPE

The UNHCR started to collect data on migrants and refugees' Mediterranean Sea crossing since 2007.

As Figure 2 indicates, the statistics show a peak in 2015 with more than one million people. Despite of a decrease in 2016, Europe still faces a substantial flow of migrants and refugees across the Mediterranean. Syria, Afghanistan, and Iraq are the top three countries of escape due to a prolonged warfare (UNHCR 2016a). Challenges of reception and management of refugees and migrants remain the same, since permanent solutions are still not in place.

Migration (by force or by choice) is a global phenomenon as much as is an old one. Refugees and migrants moving to Europe are much less than the quantity of people moving to other regions of the world. The vast majority of migrants continues to be hosted by developing countries, particularly those that are proximate to the migrants and refugees' countries of origin: for instance, the bulk of the Syrian refugees is hosted by Turkey (2.2 million), Lebanon (1.2 million) and Jordan (almost 630,000), according to figures recorded in December 2015 (IOM 2017a). In the case of Europe, the events of 2015 were particularly challenging for the frontline EU member states like Italy and Greece. They received the highest number of refugees and migrants (respectively 153,842 and 856,723 - UNHCR 2017a). Transit countries in Central and Eastern Europe and major destination states, such as Austria, Belgium, Finland, Germany, Sweden and the Netherlands, experienced challenges in handling the flow of migrants and refugees, as well.

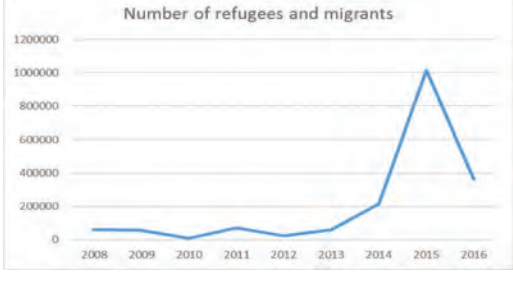

Figure 2. Overview of refugees and migrants crossing the Mediterranean Sea 2008–2016 (UNHCR 2017).

3.1 *The EU risk governance*

The EU's legal and operational asylum structure, the Common European Asylum System (CEAS), aims at harmonising the national asylum policies of the EU member states. The CEAS was decided in 1999, at the European Council of Tampere, and completed in 2005, with revisions between 2011 and 2013. The CEAS contains a series of legislative measures that cover all the phases of asylum seeking, from the entrance into the EU territory to the application process, from the rights to the duties an asylum seeker has once he/she is deemed qualified to stay. The rationale behind the CEAS is twofold: in the short term, the EU aims at achieving "common standards for fair and efficient asylum procedures in the Member States" (Council 2013: np). In the longer term, the EU wants "Union rules leading to a common asylum procedure in the Union" (ibidem).

The EU has only partially succeeded in these goals, since the reception of migrants and refugees remains largely a national affair. Despite of the rather positive experience from the refugees' flows following the Balkan wars in the 1990s, the 2015 influx showed a unilateral response among the member states, which exacerbated the distance between the EU's legal architecture and the national approaches to immigration.

The CEAS rests on two pillars: Directives and Regulations. The main Directives are the Asylum Procedures Directive (Council 2013), the Qualification Directive (Council 2011) and the Reception Conditions Directive (Council 2013a).

The Asylum Procedures Directive contains principles and criteria on how to apply for asylum in the EU territory. The member states have the main responsibility for the asylum procedure, while the EU mainly supports them through the European Asylum Support Office (EASO) (see below) and the European Refugee Fund. The Qualification Directive describes which kind of issues member states should take into account when processing an application (legislation from the country of origin, statement from the applicant and so on). In this case, as well, the member state has the primary task to deal with the application by verifying the validity of the information provided. The Reception Condition Directive specifies a minimum and common standard of access to housing, food, clothing, health care, education and employment.

Two Regulations (the EURODAC Regulation and the Dublin Regulation) complete the architecture. The former (Regulation 2013) established the EU asylum fingerprint database in 2003 and supports the latter (Regulation 2013a), which sets the

criteria for the examination of an asylum application. The Dublin Regulation aims at preventing the so-called asylum shopping (an applicant looks for the member state with the most indulgent asylum procedures) and the indiscriminate circulation of people that move inside the EU territory (the Schengen area) while waiting for the conclusion of the application process. These two criteria foresee that an asylum seeker should apply in the first country of entrance. In 2015, the high influx of migrants and refugees put under pressure two countries of entrance, namely Italy and Greece. The combination of high numbers and poor reception capacities showed that the Dublin Regulation could not work in such conditions.

Two agencies assist the member states in the implementation of the Directives and Regulations' legal measures: (1) the European Asylum Support Office (EASO 2017), created in 2011; (2) FRONTEX, which, since 2004, is the European Border and Coast Guard responsible for border monitoring and management (FRONTEX 2017). At the end of 2014, FRONTEX started Operations Triton in the Central Mediterranean and Poseidon in the Greek sea to control the EU maritime borders and to conduct search and rescue operations for people crossing the Mediterranean Sea (EEAS 2017).

It is worth mentioning the 2001 Directive on temporary protection (Council 2001), which is not included in the CEAS. This Directive foresees a temporary protection status in all EU countries, promoting a balance of efforts between member states receiving migrants and refugees, following a Council Decision that confirms a mass influx of displaced people and states the groups in need for protection.

3.2 *The EU crisis governance*

The EU crisis governance of the 2015 influx of migrants and refugees did not develop according to the Common European Asylum System. The EU response was undermined by national fragmented responses consisting of different emergency measures such as the enforcement of border controls, containment of the number of people crossing national borders, also with the use of force, construction of fences, and the rejection by force or the arrest of people who entered the national territory illegally (Morsut and Kruke 2017). These measures were taken unilaterally, with no consultation among states, which, for example, share the same border, causing tensions between neighbours. Both the European Commission and the Council launched a series of new initiatives (contained in three implementation packages—see Morsut and Kruke 2017) calling for unity and solidarity among the member states, seeking to coordinate the response at supranational level. The main attempt was to balance the burden and commitment between the frontline member states Italy and Greece and the rest of the EU member states.

The first package included a strengthening of operation Triton to handle search and rescue operations and combat smuggling in the Mediterranean Sea, and a temporary relocation scheme for asylum-seekers from Italy and Greece to the other Member States (European Commission 2015).

The second package included an extended emergency relocation proposal and a permanent crisis relocation mechanism to be activated when the Commission determined that a national asylum system was under pressure due to a large and disproportionate influx of third-country nationals (European Commission 2015a).

The third package, highly influenced by the terrorist attacks in Paris in November 2015, contained new measures regarding the protection of EU external borders (Morsut and Kruke 2017).

The relocation scheme in package two was officially concluded in September 2017, but less than a fifth of the original target was relocated (IOM 2017). The relocation mechanism recalls the temporary protection of the 2001 Directive (Council 2001), which was not used to cope with the influx of migrants and refugees in 2015.

In Italy and Greece migrants and refugees were taken to reception centres, to apply for asylum (as the Dublin Regulation foresees). However, both the Italian and the Greek reception systems were not able to absorb all the migrants and refugees giving them adequate shelter and the possibility to start the asylum process (UNHCR 2015). The EU intervened financially to implement hotspots in Greece and Italy, to identify, register and fingerprint migrants and refugees and to provide assistance. However, their implementation took time, leaving people literally left to themselves. In other parts of Europe, as well, assistance to migrants and refugees was limited: the camp called the Jungle on the outskirts of Calais was a striking example. In 2015, between 6,000 and 10,000 refugees, asylum seekers, and migrants, including many unaccompanied children, lived there under very poor conditions (Human Rights Watch 2017).

4 DISCUSSION

The application of the Risk Governance Framework to our case raises some interesting issues, especially related to the assessment sphere, but also in the management.

In the pre-assessment phase, framing and early warning "provide a structured definition of the problem and how it may be handled" (IRGC

2005a: 8). The EU legal and operational architecture, briefly described above, seems very promising on paper. It captures the main issues related to an influx of people into Europe and appears able to secure the ways to cope with this risk. It calls for a common and shared responsible immigration management; clearly defines the obligations of the member states and which kind of support they receive from the EU; provides a fair balance of efforts between member states; follows all the asylum seeking circle from the application to the granting of the protection, including the criteria to guarantee the person a full integration into the European society. The two maritime operations, Triton and Poseidon, seem relevant to decrease the risk of receiving a high number of migrants, but also for search and rescue of migrants.

However, there are signs of an inability to capture what stakeholders and society may associate with the risk (IRGC 2005) related to a massive influx of migrants and refugees. We argue that there may be a paradox between the Directives and the Dublin Regulation. The main goal of the Directives is to harmonise the national asylum systems according to the principles of solidarity and fair burden sharing. The Dublin Regulation aims at preventing asylum shopping and indiscriminate circulation of people inside the Schengen area, while waiting for the conclusion of the application process. Nonetheless, as for the asylum shopping, this is an admission that there are differences in the national asylum systems, which the Directives clearly have not solved. As for the indiscriminate circulation, the Dublin Regulation does not ensure a sustainable sharing of responsibility across the member states, which is exactly the opposite of the principles of the CEAS (solidarity and fair burden sharing) as such. The EU responded with new measures (the relocation mechanisms and the hotspot implementation in Italy and Greece) contained in the implementation packages. This showed that it was difficult to sustain the CEAS.

As for the FRONTEX operations Triton and Poseidon, their main contribution in 2015 (which continued in 2016 and 2017) became the rescue of migrants and refugees crossing the Mediterranean Sea with less focus on the control of the EU maritime external borders (FRONTEX 2017). This is a reactive approach and an indication of incapacity to frame the problem, in other words to see the pre-assessment, risk appraisal and risk management of the situation in Europe in relation to the root causes of migration. In this respect, the EU risk governance did not consider the wider political, security and economic instabilities making people leave their homes for Europe. Thus, monitoring and feedback according to the Framework (IRGC 2005) and, more specifically, the observing and feedback of the implementation of responses in 2015 need to address the reasons behind the EU reactive approaches and to develop proactive approaches and awareness of root causes, since the 2015 influx was not a one-off event.

In general, the CEAS degree of compliance in the events in 2015 was very poor, since the CEAS seems inadequate to account for a dynamic societal and political context, which is an important factor for framing and early warning, according to the IRGC. This context is made of member states, which reacted in different ways (the national fragmented responses) and undermined the principles of the CEAS, namely solidarity and fair burden sharing (the relocation mechanisms in the implementation packages). This shows the extent to which the CEAS is not implemented at national level and the member states retain their sovereignty on immigration policies. The views on the issue were clearly conflicting between the EU and the member states.

In addition, the unclear divide between people in need of protection and economic migrants was a challenge. The CEAS is designed to manage a tidy, small-scale and easy recognisable group of refugees, not the 2015 high number of people with different backgrounds crossing the Mediterranean Sea. Furthermore, the EU and its member states did not recognise and detect the risk of a massive influx in time. At supranational level, the EU crisis governance of the high influx was more based on an incremental approach rather than an implementation of the CEAS. The CEAS was the result of a risk governance approach based on an evaluation of the risk which had not taken into account certain features (high numbers, lack of cooperation, arrivals in few countries, poor receptions mechanisms and so on). At national level, the crisis governance seemed to be directed by pure nationalistic choices.

These reflections lead to the risk appraisal in our case. The EU did not consider the risk in all its characteristics and effects in the years prior to 2015. Migration is not a risk per se, but it became a risk due to inadequate risk appraisal, by not considering all issues related to migration according to a holistic view of the challenges. Concerns and perceptions at national level raised controversial issues in terms of solidarity, sustainability and capacities at EU level, which the EU was unable to address. For example, the reception facilities of Greece and Italy were not able to satisfy the needs of all the people coming. Unacceptable living conditions and slow bureaucratic national asylum processes may very easily lead people to become part of that substrate of the society, surviving through illegal expedients. This nourishes mistrust and fear towards immigrants establishing a vicious circle, where immigrants are increasingly isolated by the host

society and the host society intensifies its intolerance towards immigrants because they live at the margins of the same society. In addition, mistrust is directed also towards those segments of the society who assists the irregular migrants, also risking legal prosecution (Human Rights Watch 2017).

A scientific risk assessment, of factual, physical and measurable characteristics of the risk (IRGC 2005), using statistics at global level, could have scaled back societal negative perceptions, since developing countries are still the main recipient countries. A proper concern assessment of the perceived consequences (IRGC 2005) and a following risk communication strategy may have laid the foundation for a relationship of trust among the different stakeholders, in particular the EU and member states. The EU seemed incapable of perceiving the concerns of the various stakeholders and the public. This led to opposition and protest against the EU risk governance, through national measures of crisis governance.

Many stakeholders, and the public at large, are not formal parts of the process of addressing and handling risk. They, nevertheless, need to perform their own informed risk-related decision-making and choices about the risk in question, through a balance of factual knowledge based on risk perception and personal interests. Reliable risk communication may therefore bridge conflicting viewpoints and, as well, increase the likelihood of shared risk acceptance among different stakeholders: risk evaluators and managers, mostly involved in the risk process, researchers and policy makers, across academic disciplines and institutional barriers, and the people affected by the process (Renn 2008).

Terror was another factor not taken into consideration in the pre-assessment phase of the EU risk governance, nor was it a part of the concern assessment in the risk appraisal phase prior to 2015. The threat of terror attacks from IS fighters and European citizens returning to Europe after fighting for IS in Iraq and Syria influenced the last implementation package in 2015 and turned many European citizens against refugees coming from those areas. This threat was a major social mobilisation factor influencing national policies and approaches.

5 CONCLUSIONS

The IRGC Risk Governance Framework has been a useful tool for studying the features of a supranational system of risk governance as the CEAS and the way it was applied in our case.

We can conclude that the EU crisis governance of the 2015 influx did not adhere to the EU risk governance approach put previously in place. The responses in 2015 seemed to be more directed to preserve the Dublin Regulation at all costs, when it was clear that the system shaped by this Regulation is not made for a mass influx situation. In addition, the fair burden sharing presupposes a supranational approach, not followed by the member states which decided for a narrow national approach.

We argue that the main reason behind the inadequate overall joint crisis governance at EU level was a weak EU risk governance of the pre-crisis activities prior to 2015, which did not take into consideration the impact of national political, economic, security and cultural differences among European countries. It seems clear that the asylum shopping is an admission that the differences in the national asylum systems have not been harmonised by the Directives put in place before 2015. The EU did also not adequately consider the social mobilisation potential of a high number of migrants and refugees, including a possible number of IS fighters.

The analysis of the 2015 events through the pre-assessment and the risk appraisal phases has pointed out that the EU risk governance of the 2015 events was based on fragile premises, since both the pre-assessment and the risk appraisal were elaborated upon inadequate and not complete pieces of information. The use of big data and alternative data (Facebook, Twitter, Instagram and mobile phone data) could have contributed for a better understanding of migration-related phenomena.

Unforeseen events with a major accident potential—a study of some examples from the Norwegian oil and gas industry

W. Røed
University of Stavanger, Stavanger, Norway

ABSTRACT: Many severe accidents such as Piper Alpha and Deepwater Horizon are mainly a result of long event sequences, which have developed gradually for a significant period, before it comes to a point of no return where control is lost, and emergency preparedness has to take over. During the significant build-up period, sometimes referred to as a 'spiral to disaster', there are often several opportunities where control could have been regained, if the awareness and understanding of the sequence of events had been sufficiently understood. However, since it was not, the opportunity to prevent the major accident failed. This paper presents and discusses some selected historical accidents and near-misses in the Norwegian oil and gas industry, the aim being to improve the understanding of accident propagation and in particular signals and warnings that could have been seen, but was not. The ambition is to achieve insight that can be used to improve future risk assessments and the ability to detect unforeseen events in general.

1 INTRODUCTION

As emphasized by Vinnem and Røed (2014), many accidents in the industry such as Piper Alpha (Cullen, 1990), Longford (Hopkins, 2000), Texas City (CSB, 2007) and Deepwater Horizon (Presidential commission, 2011) are mainly a result of long event sequences, which have developed gradually for a significant period, before it comes to a 'point of no return' where control is lost, and emergency preparedness has to take over. During the significant 'build-up' period, sometimes referred to as 'spiral to disaster', there are usually several opportunities where control might have been regained, if the awareness and understanding of the sequence of events had been sufficiently understood. But since it was not, the opportunity to prevent the major accident hazard failed. The present paper studies in detail some historical events and describes what contributed to the 'spiral'.

In the study, selected historical near-accident events in the Norwegian oil and gas industry have been reviewed. They were selected based on having a potential to escalate and result in a major accident, often referred to as accidents with more than two fatalities (Vinnem and Røed, 2015) or with other extensive consequences, for example to the environment or assets (PSA, 2016).

The goal of the analysis is not to obtain more accurate probability estimation of major accident events, but to improve the overall risk management linked to such events. In particular we are motivated by the fact that involved personnel are often not able to see what is coming, although in hindsight, it may be concluded they should have—the signals and warnings were there, but the system and risk understanding was poor. And then, after the accident has occurred, the accident propagation becomes "obvious", and it is questioned "How could this occur without being noticed?" The aim of the study is to give increased understanding of how some accidental events have propagated—knowledge that can contribute to prevention of such events in the future.

The paper is organized as follows: In chapter 2 we introduce the selected events and the criteria they were selected based upon. In Chapter 3, the results and implications of the results are presented and discussed. Chapter 4 provides a discussion, and in Chapter 5 we draw some concluding remarks.

2 THE SELECTED EVENTS

The study includes 16 selected events in the Norwegian oil and gas industry in the period 2008–2015, as demonstrated in Table 1. This includes all publically known events with an accident investigation report available in the public domain and with a major accident potential, as explained in the previous section. For two events, we have used company reports, and for the remaining 14 events, the accident investigation was performed by the petroleum safety authorities in Norway. The above comprises 12 unignited hydrocarbon leaks, one non-process fire, one oil spill to the sea, one loss of well control and one situation with loss of buoyancy/stability

on a floating production unit. Events before 2008 were excluded since they are considered less relevant for today's safety regime and since the quality of the accident investigation reports has increased over time and in particular after 2008.

Table 1. Events included in the study.

Charact.	Description
10.01.2008 Draugen* Unign. HC	A hydraulic hose broke. Due to poor design, pressure surge occurred. This caused automatic release of an offloading hose, resulting in 6 m^3 oil spill.
24.05.2008 Statfjord A* Unign. HC	Oil leak during hot tapping. Release of 156 m^3 oil in the utility shaft and 70 m^3 to sea. Flashing equal to 0.9 kg/s gas.
12.09.2008 Oseberg C* Unign. HC	A solenoid valve was replaced with a wrong spare. Due to lack of flushing, the process valve opened very quickly initiating a hammer effect, causing a 26 kg/s gas release with total amount 1500 kg.
19.05.2009 Kollsnes** Unign. HC	Flange bolts were installed with the wrong torque. This resulted in a 12 ton condensate leak with initial leak rate 22 kg/s.
05.11.2009 Veslefrikk* Well event	Release of 3450 m^3 oil based cuttings and 93000 m^3 oil containing slop from an injection well to the sea bed.
08.02.2010 Mongstad** Unign. HC	During installation of insolation, it was drilled through a line filled with LNG, resulting in a 0.08 kg/s gas leak with total release of 300 kg.
12.09.2010 Mongstad** Unign. HC	A wrench was used to stop an observed leak. Technical equipment loosened and was blown 30 meters by the pressure.
04.12.2010 Gullfaks B* Unign. HC	During leak testing and maintenance work on a choke valve, internal leaks resulted in release of 1.3 kg/s and total amount 800 kg.
13.07.2011 Valhall* Non-process fire	A fire occurred in a crane engine resulting in burning/glowing particles from the exhaust igniting a vent stack.
26.05.2012 Heimdal* Unign. HC	Valves were opened in the wrong sequence resulting in a pressure build-up. Due to poor design, a pipeline burst.
12.09.2012 Ula* Unign. HC	Repair of a seepage of produced water was postponed to the upcoming revision stop. Before being repaired, the bolts failed due to corrosion, resulting in release of 20 m^3 oil and 1600 kg of gas.
07.11.2012 Floatel Superior* Loss of stab.	Anchor bolsters were not constructed to withstand expected weather conditions. This resulted in loose anchors hitting and penetrating the vessel, causing severe listing.
17.06.2013 Oseberg A* Unign. HC	Gas leak due to rupture in the blow-down line from the test separator. The line was not designed for sand in the well flow, and the segment was not sufficiently segregated from another segment.
05.01.2014 Hammerfest LNG** Unign. HC	Loss of seal liquid in a packing box resulting in a 0.1 to 0.3 kg/s HC gas leak with total amount 250–750 kg.
26.01.2014 Statfjord C* Unign. HC	Oil leak with initial leak rate 20.8 kg/s from sump tank to the cellar deck and to sea. 40 m^3 oil was spilled to sea and 2 m^3 oil was spilled on the installation.
18.01.2015 Gudrun* Unign. HC	The design included an insufficiently dimensioned control valve. This caused high vibrations resulting in a burst pipe. The result was a 8 kg/s release of 2.8 tons condensate.

In order to analyse each event at a sufficient level of detail, we have identified barrier elements that did not perform as intended during the accident propagation, and then studied each of these failures more in-depth. During the categorization process, the lists of root causes presented in the investigation reports were used as a basis, although for some of the events, some of the root causes mentioned in the reports were combined and presented in a simplified manner. To some extent, interpretation of the information in the accident investigation reports was needed during the identification process. The number of barrier elements varied from 1 to 6 for each event with a total of 53 barrier elements for all the 16 events together.

3 SAFETY BARRIER PERFORMANCE

3.1 *Safety barrier performance categorisation*

The performance of safety barriers can be measured in several dimensions such as capacity, reliability, availability, accessibility, efficiency, ability to withstand loads, integrity and robustness (PSA, 2015). In the present paper we have considered integrity/availability (was the barrier ready to be used?), functionality (did it work as intended?) and robustness (did it "survive" the accidental conditions?). For example, lack of a mandatory risk analysis is considered loss of availability, since the activity was not carried out at all. Incorrect planning is considered loss of functionality, since the

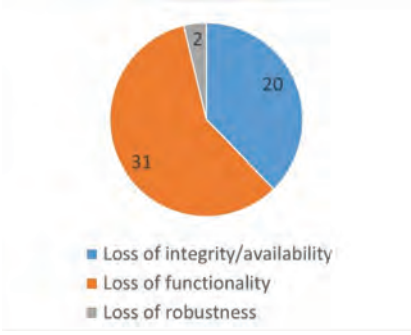

Figure 1. Barrier element performance categories.

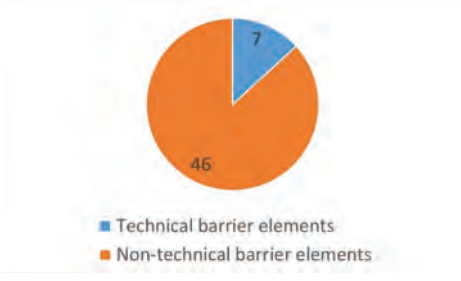

Figure 2. Technical and non-technical barrier elements.

planning was carried out (available) but failed and was inefficient. An example in the robustness category is technical equipment that failed due to vibration, i.e. the barrier element was vulnerable—not able to withstand the accidental loads (vibration). Out of the 53 barrier elements studied, 20 barrier elements had loss of the integrity/availability, 31 had loss of functionality and two had loss of robustness as shown in Figure 1.

Figure 2 presents the number of technical and non-technical barrier element failures. There are numerous barrier definitions, see for example the discussions by Lauridsen et al. (2016) and Øien et al. (2015). In the Norwegian petroleum industry it is often distinguished between operational, organizational and technical barrier elements, sometimes also simplified to technical and non-technical barrier elements as in Figure 2. Out of the 53 barrier elements studied, only 7 were technical barrier elements while 46 were non-technical, i.e. operational or organizational. This is in line with other research showing that a high fraction of root causes in accident investigation reports are non-technical, see for example Vinnem and Røed (2015) and Mostue et al. (2014).

3.2 *Barrier element failures—did anyone suspect the failures*

It is sometimes distinguished between known knowns, unknown knowns and unknown unknowns in the research literature. Secretary of Defense Donald Rumsfeld explained these terms in a press briefing February 12, 2002 (later elaborated on in Rumsfeld, 2011):

> "*…there are known knowns; there are things we know we know. We also know there are known unknowns; that is to say we know there are some things [we know] we do not know. But there are also unknown unknowns—the ones we don't know we don't know*."

Inspired by the above terminology, Aven and Krohn (2014) introduced three categories of failures: a) Events that were completely unknown to the scientific environment (unknown unknowns), b) Events that were not on the list of known events from the perspective of those who carried out a risk analysis (or another stakeholder), and c) Events on the list of known events in the risk analysis but found to represent a negligible risk.

These categories correspond to unknown unknowns, unknown knowns and known knowns, correspondingly. As emphasized in Figure 3, out of the 53 barrier elements studied, none were in the a) category, 14 were in the b) category, and 39 were in the c) category. Examples in the b) category are a missing orifice that the personnel were not aware of and lack of identification of the major accident potential during a risk assessment. In the c) category, examples are overruled inspection intervals, known violations, work practice different than prescribed and required risk assessments not being performed. For the majority of the barrier element failures in category c), someone in the organization had knowledge about weaknesses indicating that the barrier element was, or could be, deteriorated. However, the probability of this resulting in a major accident hazard was considered sufficiently low to accept the risk, although in most cases the risk was not formally assessed and accepted according to company procedures.

The above classification was to some extent subjective, and in particular it was difficult to distinguish between the b) and c) categories for some events. If the b) criterion "or another stakeholder"

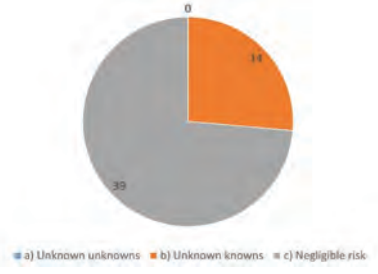

Figure 3. Event categorisation.

had been interpreted as anyone in the organization, there would be more c's and fewer b's giving even stronger evidence that known knowns was the most frequent challenge for the studied events. From a risk management perspective, it is good news that there were no events in category a) and few events in category b), since the knowledge and understanding of the situation, and thus the ability to manage the risk in a proper way, is stronger for the barrier failures in category c) than for the ones in category a) and b).

3.3 *Barrier element failures—who knew about it*

So far, we have seen that for many of the barrier element failures, someone knew there were deteriorated or weakened barrier elements, and since the activity was not stopped, this means the risk was formally or informally accepted. Now we will discuss who had this knowledge. We have distinguished between i) personnel in the sharp end of the organization, such as process operators and maintenance personnel offshore, and ii) personnel in the blunt end, such as project planners and managers working onshore. The latter was only studied when criterion i) was not met.

As illustrated in Figure 4, For 28 out of the 53 barrier element failures, the weaknesses were known by personnel in the sharp end. Examples are lack of compliance, insufficient knowledge about procedures, lack of risk assessment, insufficient maintenance and known weaknesses in design. For 12 of the barrier element failures, weaknesses were known to someone else in the organization. Examples are insufficient design or fabrication, unclear responsibilities, poor quality of a risk assessment and insufficient maintenance. For the remaining 13 barrier element failures, there is insufficient information in the accident investigation report to make a proper categorization; it is not explained in detail who knew what. This is not a surprise as it is not common to include such a level of detail in studies of near-misses and non-catastrophical events, as the ones being studies in this paper. The above implies that to some extent we have needed to read between the lines, and sometimes we have made assumptions based on the information available in the reports.

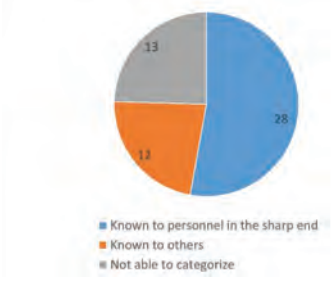

Figure 4. Who knew about the barrier element failures?.

3.4 *Surprises*

For 36 of the 53 barrier elements there were surprises. We have distinguished between two situations; i) it was a surprise that the barrier element actually failed (28 occasions) and ii) it was a surprise that the barrier element actually played a role as a safety barrier and was safety critical (8 occasions). The last category implies a lack of system understanding; the personnel involved did not realize that something being safety critical actual was. Examples in the first category are unknown built-in weaknesses, unclear responsibilities, insufficient planning or assessments ahead and technical equipment that was believed to be similar but was in fact not. Examples in the second category are safety-critical technical equipment considered non-critical for safety before the accident occurred. The majority of the surprises are of the first kind. This implies that for the majority of the situations with surprises, it was realized that weaknesses in the barrier element could potentially result in an accident, but it was a surprise that the barrier element actually failed and that the even actually occurred.

The above surprises are discussed from a viewpoint of before the accident occurred. During our work, we also wanted to find out if it, after the accident occurred, still was a surprise that some barrier elements contributed to the accident occurring. No such surprises were found. At first glance this may seem surprising in itself, but in fact, it is not: Since we used accident investigation reports as our source of information, and the barrier elements in our study were chosen because they contributed to the event occurring, it is not surprising that each of the barrier elements' contribution to the event occurring easily can be explained in hindsight. The above emphasizes the importance of realizing that the present study relies purely on information in accident investigation reports, and that this must be kept in mind when the results are interpreted. As elaborated on by Damnjanovic and Røed (2016), investigation reports by definition provide information about the propagation of the events and work processes only when an accident occurs. It is a general industry challenge that we do not have a full understanding of the events and work flow in situations with success and no accident occurs. This challenge has inspired scientists working in the field of resilience, as elaborated on by Nemeth and Hollnagel (2014), Hollnagel et al. (2013) and others.

3.5 *Early warnings*

For 29 of the barrier element failures there were early warnings indicating that something abnormal

was occurring. For 20 occasions, there were no early warnings and for the remaining four cases, we do not have sufficient information to make a proper categorization. We have divided the warnings into five groups based on their characteristics:

i. A physical warning (phenomenon) occurred in advance to the incident, with sufficient time to recover if it had been recognized (6 occasions)
ii. A similar or near to similar situation was experienced earlier on the same site (2 occasions)
iii. Uncommon solution, different from conventional solutions, but implications of this was not sufficiently recognized (5 occasions)
iv. Degradation was seen or could (should) have been seen by required maintenance/inspection (6 occasions)
v. Insufficient governing documents or poor adherence to governing documents (10 occasions)

The first category includes a physical warning in advance to the event, with sufficient time to recover the situation. Examples are an increase or drop in pressure, anchors that slammed into the vessel in harsh weather and severe vibrations in process equipment. These are 'strong' warnings since they clearly indicate that something abnormal is going on. Also category iv) includes rather strong warnings with situations that could, and should, have been detected by maintenance and inspection programs. Examples are visible degrading of a hose, valves with observed internal leakage, insufficient maintenance of a crane engine and lack of testing according to the maintenance program. Category ii) includes occasions where a similar or near to similar situation had been experienced at the same site, for example a known challenge that technical equipment had been fabricated without a safety critical item installed. Category iii) includes situations where a nonconventional solution is used, and where related implications were not fully understood or recognized. Examples are a change in the commissioning phase not being validated, and an emergency shutdown system for which parts of the system could be put out of operation. Category v) includes warnings in terms of an insufficient management system or a culture with poor adherence to procedures or requirements specified in the management system. Examples are errors and inconsistencies on a work permit, lack of sufficient resources and competence related to a work task being performed and insufficient barrier strategy and barrier design. With 10 occasions, this is the most common early warning category. Unfortunately, this category also includes the 'weakest' warnings, since there may be many such breaches without an accident or near miss occurring. This means that it was difficult to realize the 'spiral to disaster' had started.

Nine of the barrier element failures included poor quality of risk assessments or required risk assessments not being performed at all, although none of these deficiencies had early warnings. One important objective of a risk assessment is to identify potential hazards, and the above emphasizes the importance of risk assessment actually being performed—with sufficient quality, and the importance of having mechanisms in the organization ensuring that this is the case. If potential hazards are not identified at all, there may be no or few early warnings, and existing warnings may be overlooked. This may potentially result in poor risk management and acceptance of risks based on an insufficient basis.

4 DISCUSSION

A traditional view on barrier management is to establish a sufficient number of barriers and ensure they perform as required. With reference to James Reasons's Swiss Cheese model (Reason, 1990), this means installing a sufficient number of cheese slices with no (or few) holes. However, as stated by the National Commission investigating the Macondo accident (Presidential commission, 2011), 'Complex systems almost always fail in complex ways'. This statement emphasizes that barrier management is not simple at all: For the Macondo accident lack of sufficient safety barriers were easily pinpointed in retrospect, but it was not evident until the accident occurred.

For the majority of the events studied in the present paper, more than one barrier element failed and contributed to the event occurring. The number of barrier element failures varies from 1 to 6 for each of the accidents within the classification used in the paper. As emphasized by Vinnem and Røed (2015), if root causes had been studied in more detail, more factors would most likely have been identified.

All events studied are near-misses; situations that potentially could have resulted in a major accident, but due to various circumstances did not. A question is then if the situations studied are relevant for learning about major accident prevention. We believe the study is relevant since only events with a major accident potential have been included in the study, as explained in the introduction to the paper. Thus, all events included can be considered lagging major accident precursors as discussed by for example Hopkins (2009), Kjellén (2009) and Vinnem (2010). This implies that the events study may bring relevant information to the table when it comes to causes and contributing factors to major accidents, but limited information about potential consequences.

It is important to be aware that the study considers a sample of selected events based upon the criteria explained earlier in the paper. It is not an empirical study with random events. This should be kept in mind when the results are interpreted. For example, it is a relevant challenge that the

number of barrier element failures identified in the accident investigation reports may depend on the severity of the accident, since it is likely that severe accidents are investigated to a higher level of detail, and thus, more barrier element failures are highlighted in the reports. This may partly explain why the number of barrier failures varied between 1 and 6 for the events studied.

5 CONCLUSION

In this paper, 53 barrier element failures related to 16 historical events with a major accident potential in the Norwegian petroleum industry have been studied. The majority were non-technical barrier element failures associated with loss of functionality. In many cases, someone in the organization, typically in the sharp end, knew about weaknesses indicating that the barrier element was, or could be, deteriorated. For many of the events there were surprises. For the majority of the cases, it was a surprise that the barrier element(s) actually failed, but for some cases, it was also a surprise that the barrier element that failed actually was safety critical. For more than half of the barrier element failures, there were early warnings. Approximately half of the warnings were 'strong' warnings, such as a physical phenomenon that occurred in advance to the incident, with sufficient time to recover if it had been recognized and physical degradation that was seen or could have been seen by required maintenance and inspection. The resulting half were weak warnings, such as unconventional design or similar events being experienced previously on the same site.

Since only 16 historical events have been studied, care should be taken when interpreting the results. However, some general reflections have been made:

As demonstrated in previous studies, the present paper confirms that it is important to pay attention to non-technical barrier elements when risk is managed in organizations. The study also indicates that the main challenge is not events coming totally out of the blue. More often, someone in the organization, typically in the sharp end, are aware of barrier deteriorations and that these deteriorations may result in an accident. However, it is considered unlikely that an accident will actually occur. Since the activity is continued with deteriorated barrier elements, the increased risk is formally or informally accepted by someone in the organization.

Analysis of 985 fire incidents related to oil- and gas production on the Norwegian continental shelf

C. Sesseng, K. Storesund & A. Steen-Hansen
RISE Fire Research AS, Trondheim, Norway

ABSTRACT: Fire is a major threat in the petroleum industry. However, little has been published about the fire related incidents that have occurred in the Norwegian petroleum sector. To gain more knowledge, data from 985 incidents in the 1997–2014 period has been analysed. Examples of factors studied are type of facility involved, involved area or system, consequences and severity level. The analysis of the fire incidents reveals that even though many incidents are reported, the large majority of these have not imposed risks for severe fire accidents. It has also provided valuable information regarding possible dangerous situations, commonly involved areas, types of equipment as well as types of activity that were involved. Twenty-nine percent of the incidents were false alarms, which must be regarded as a high number in an industry where any production stop could be extremely costly.

1 INTRODUCTION

In Petroleum Safety Authority Norway's (Ptil) assessment of the risk level in the petroleum industry on the Norwegian continental shelf, defined situations of hazard and accidents (DFUs) are defined and utilised. A DFU is an unplanned event which has led, or may lead, to loss of life and other values. Also, a DFU must be an observable event which it is feasible to measure accurately (Vinnem et al., 2006). Different DFUs are associated with different risk areas. According to Ptil's annual report on trends in risk level, there has been a declining trend in DFUs occurrences associated with major accident risk from 2004 to 2014 (Petroleum Safety Authority Norway, 2016). In the period there were no hydrocarbon fires, but there were hydrocarbon leakages with ignition potential. However, a fraction of the observed DFUs were fires and explosion not involving hydrocarbons. Even though fire occurrences are few compared with other DFUs, fires have disastrous potential, and a fire preventive focus should be maintained.

The current study has a quantitative approach and look in depth into the fire incident statistics, with false alarms included, to gain more knowledge about the incidents, where they occurred and what their outcomes were, in order to found a basis for future work aiming to improve fire safety, improve detection reliability and prevent false alarms in the petroleum industry.

2 DATASET

The dataset which found the basis for this study is an extract of Ptil's fire incident statistics. RISE Fire Research received authorization from Ptil to analyse this set of data, and gained access to all relevant incidents over the defined period of time. The database contains fire incidents, small and large, which are systematically reported to the authority. The sample comprises 985 reported incidents from all facilities and operators in the areas within Ptil's jurisdiction in the 1997–2014 period. The incidents included in our selection were reported as one of the following incident types: ignited hydrocarbon leakage, fire/explosion in other areas, fire/explosion in other areas (not hydrocarbon fire), and fire/explosion in other areas (not hydrocarbon explosion).

The dataset comprise information about time of the event, at which facility and in which area or system it occurred. Furthermore, the severity together with actual and potential consequence of the incidents are classified and registered. Also, there is a free text field where each incident is described in short.

The severity of the incidents is assessed and reported according to a 5-point scale, where the different values are defined as follows: 1–not notifiable, 2–simpler follow-up, 3–potential under minor changes, 4–severe or 5–large potential/serious accident/death.

3 METHOD

In the current study, the analyses are based on fire statistics from Ptil. The study has a quantitative approach, which implies that the individual cases have not been studied in detail, except for information extracted from free text fields in the statistics database. The results from the analyses are presented as descriptive statistics.

4 RESULTS

4.1 *Sample description*

During the 1997–2014 period there were 985 reported fire incidents on the Norwegian continental shelf. From 14 incidents the first year of the period, there has been an increase over the period, ending on 66 incidents in 2014. In 2006, there was a peak with 84 reported incidents, see Figure 1.

The figure shows the development in number of incidents, distributed over severity degree over the period. Most incidents (91.2%) are classified with severity degree 2, which are incidents which require minor follow-up, whereas the remaining incidents are classified as one of the other severity degrees. For readability, the incidents in these categories are presented as one bulk in Figure 1. Most of the incidents in this bulk were incidents with severity degree 4 (n = 63). In addition there were 6 serious accidents (degree 5).

There is a leap in number of incidents from 2005 to 2006. The average number of incidents for the years before the leap, i.e. 1997–2005, is 35, whereas the corresponding number for the 2006–2014 period is 75. This corresponds to a 216% increase. As will be demonstrated in section 4.5, this is related to an increase in the number of reported false alarms.

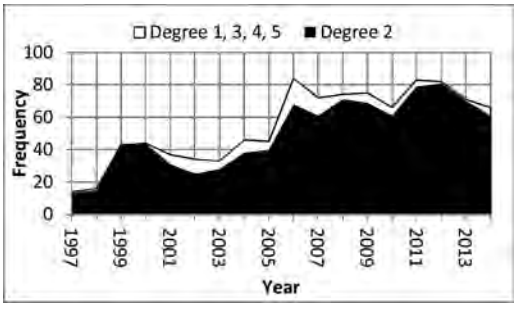

Figure 1. Number of reported incidents, distributed over severity degrees. Degree 2 (n = 898) is presented as one category, whereas degrees 1 (n = 15), 3 (n = 3), 4 (n = 63) and 5 (n = 6) are collapsed into one category for readability, N = 985.

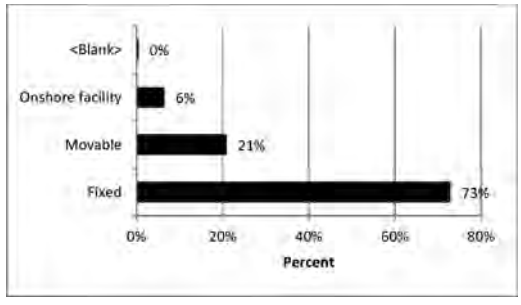

Figure 2. Distribution of incidents between different facility types, N = 985.

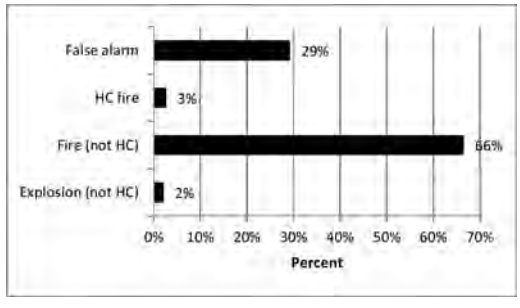

Figure 3. Actual outcome of reported alarms, N = 985.

Further, 2006 also stands out because the number of incidents with severity degree 4 is over twice as high as any other year in the period (15 incidents, compared with the year with the second highest number of degree 4 incidents: 7). The median over the period is 4.

A vast majority of the reported incidents occurred on fixed installations (73%), whereas one out of five incidents was related to movable installations. A minor proportion (6%) was incidents occurring in onshore facilities.

Over 70% of the incidents were real fire and explosion incidents. However, as Figure 3 demonstrates, a vast majority of the incidents were non-hydrocarbon fires, but rather fires in electrical systems, overheated machinery etc. Almost one third of the incidents were classified as false alarms.

4.2 *Type of area/system involved*

The incident reporting system on which this analysis is based upon is designed so that there is one variable to register both the area and system involved, i.e. one cannot discriminate between different systems in one specific area. E.g. a fire may start in an electric installation, but it is not specified if the electric installation is in the living quarter, main process or other areas of the facil-

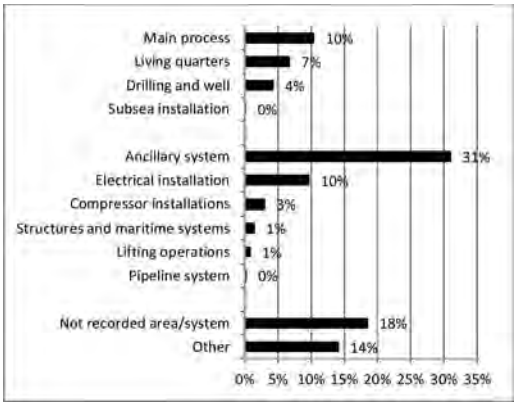

Figure 4. Distribution of incidents between different areas (top group) and systems (middle group). Incidents without recorded area or system is shown in the bottom group, N = 985.

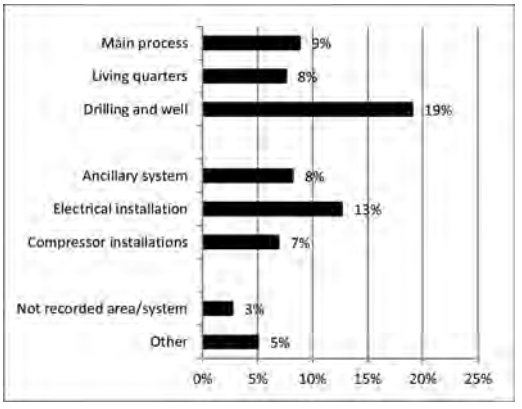

Figure 5. Incidents causing drilling downtime, distributed over the area or system the incident occurred in. Areas and systems with fewer than 20 reported incidents are excluded from the figure, n = 76.

ity. In Figure 4, and the figures following, areas and systems have been split into two separate groups, where the first group represent areas and the second group represent systems. The areas and systems are sorted with descending number of reported incidents within each group.

Further, incidents with no area or system recorded, or incidents in other areas or systems constitute a third group. The categories in the latter group are relatively large, with 18% and 14% of the incidents, respectively. The majority of the incidents within these categories (88%) were reported between 1997 and 2002. Also, it is seen that there is a distinction between the categories. While most of the incidents tagged with "Not recorded area/system" were reported before 2002, the main part of the incidents tagged with "Others" was reported after 2004.

With reference to Figure 4, one sees that of all reported incidents, nearly one third occurred in ancillary systems. These systems comprise, among others, communication systems, electrical power supply systems and water treatment facilities. In short, systems not related to separation, production and transport of hydrocarbons. An equal proportion incidents occurred in areas and systems not specified. The remaining incidents were distributed over main process (10%), electrical installations (10%), living quarters (7%) and others (9%).

4.3 *Consequences*

Of the 985 reported incidents in the period, only 8% resulted in drilling downtime whereas 23% caused production stoppage.

Not surprisingly, one fifth of all incidents causing drilling downtime occurred in the drilling and well area, see Figure 5. Of all incidents causing

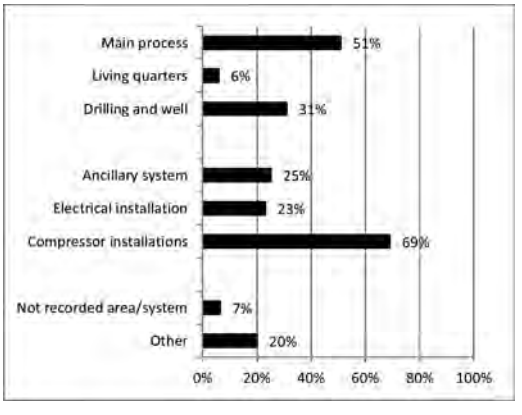

Figure 6. Incidents causing production stoppage distributed over the area or system the incident occurred in. Areas and systems with fewer than 20 reported incidents are excluded from the figure, n = 231.

production stoppage, half of them occurred in the main process and one third occurred in the drilling and well area, see Figure 6.

4.4 *Severity level*

The vast majority (91%) of the reported incidents were classified as incidents requiring simpler follow-up (severity degree 2), whereas only 3 incidents (≈0%) had the potential of becoming a severe situation under minor circumstantial changes (degree 3). Six percent of the incidents were regarded as severe (degree 4) and <1% (6 incidents) had a large potential or were large accidents, but none resulted in fatalities. Three of these occurred at onshore facilities. In addition, there

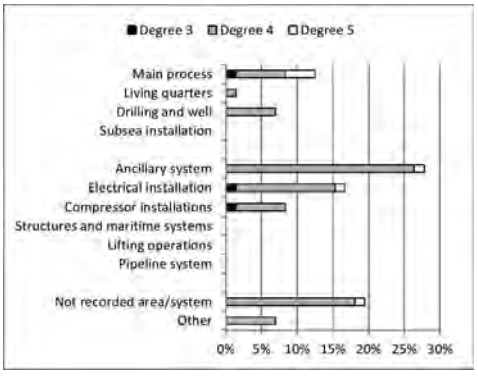

Figure 7. Incidents with severity degree 3 (n = 3), 4 (n = 63) or 5 (n = 6), distributed over different areas and systems, total n = 72.

were 15 incidents (2%) which had the lowest severity degree (degree 1), even though these incidents are not notifiable.

Examples of incidents on severity level 3 are fires that were extinguished after a short period of time, either by automatic extinguishing systems or by manual effort. A fire in an HVAC module with smoke spread to the living quarter, on the other hand, was classified as severity degree 5.

It is not straight-forward to analyse trends in severity degree over time, since there are few incidents with severity degree other than 2. However, it is seen qualitatively that the proportion of incidents with severity degree 4 is lower in the period 2008–2014 (average 3,4%) than it was between 2001–2007 (average 12%). The same trend is seen when adjusting for the increase in false alarms after 2006 which yields a decrease in degree 4 incidents from an average of 19.5% in the first period to 5.3% in the second period. Also, there has not been an incident with severity degree 5, since 2008. It therefore seems that there is a decline in the degree of severity of the incidents in the sample over time.

When studying the distribution of the incidents with severity degree 3 or higher over the different areas and systems, it is seen that most incidents occur in the main process and drilling and well areas, see Figure 7. Correspondingly, one fourth of the incidents with this severity took place in ancillary systems and 15% in electrical systems.

Even for these degrees of severity, there are around one fifth of the incidents, whereof one incident was classified as *large potential/serious accident/death* (degree 5), where area or system has not been recorded.

4.5 *False alarms*

False alarms are alarms caused by other circumstances than fire and explosion. According to ISO/DIS 17755–2, a false alarm is an alarm for which no fire occurred or […] due to accidental operation of fire alarm devices (ISO, 2010). The most frequent causes observed in the sample were detectors malfunctioning, misinterpretation of the situation by the detection system, technical and human errors. Examples of misinterpretations are sandblasting dust being detected as smoke, heat from sauna detected as heat from fire, heated leakage of lubricating oil detected as smoke and steam from cleaning detected as smoke.

The number of false alarms was quite low in the first half of the focus period, see Figure 8. Up until 2005, there were only a few cases, whereas in 2006 there is a leap, and in the years following the average number of false alarms per year is 29. This is probably not a real increase in false alarms, but rather an effect of a new reporting scheme, where more incidents are included than before.

From 2006 towards the end of the period, there is a seemingly decrease in the number of false alarms. However, the trend has not been checked statistically or adjusted for changes in the petroleum activity on the continental shelf.

One third of all false alarms occurs in relation to ancillary systems, and one fifth occurs in the main process, see Figure 9. In fact, when taking

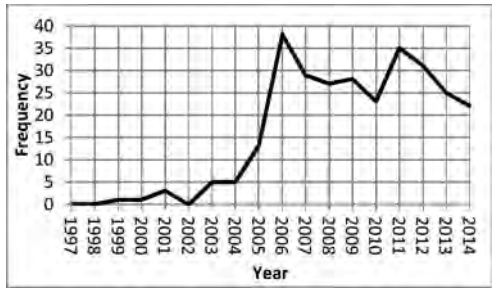

Figure 8. Number of reported false alarms each year, n = 286.

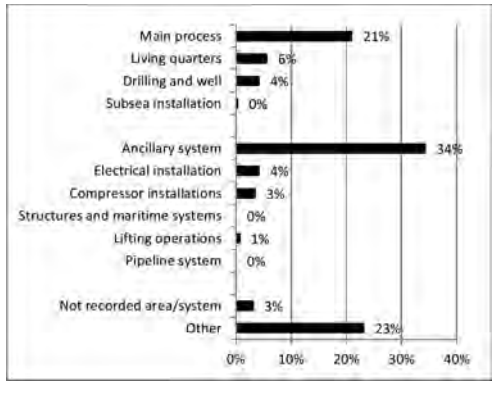

Figure 9. False alarms reported, distributed over areas and systems, n = 286.

into account the number of incidents in each area or system, it is seen that 60% of all reported incidents in the main process are false (Figure 10). This is almost twice as large proportion of false alarms than any other area or system (disregarded the incidents categorised as "other", as this category most likely constitutes numerous sub-categories).

Table 1 presents an overview of how many of the false alarm incidents, in each area or system, which caused either drilling downtime or production stoppage. The table should be read with caution, as some of the areas or systems have very few incidents, which may yield large percentages.

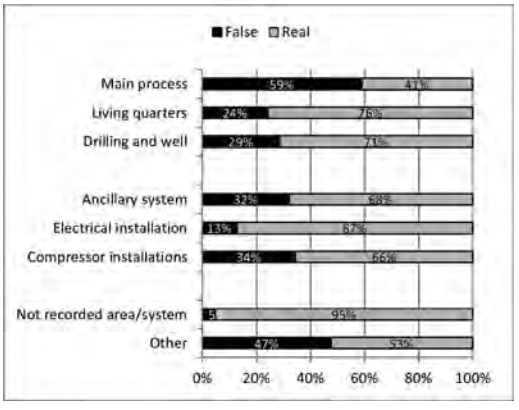

Figure 10. Proportion of real and false alarms for each area and system. Areas and systems with fewer than 20 reported incidents are excluded from the figure. Main process n = 102, living quarters n = 66, drilling and well n = 42, ancillary system n = 305, electrical installations n = 95, compressor installations n = 29, not recorded n = 182, other n = 139, total n = 960.

Table 1. The number of false alarms which caused either drilling downtime or production stoppage.

	Caused drilling downtime		Caused production stoppage		
Area/system	[freq.]	[%]	[freq.]	[%]	n
Main process	6	10%	39	65%	60
Living quarters	2	13%	1	6%	16
Drilling and well	1	8%	4	33%	12
Subsea installation	0	0%	1	100%	1
Ancillary system	6	6%	30	31%	98
Electrical installation	0	0%	1	8%	12
Compressor installations	0	0%	7	70%	10
Structures and maritime systems	–	–	–	–	0
Lifting operations	0	0%	0	0%	2
Pipeline systems	–	–	–	–	0
Not recorded area/system	0	0%	3	33%	9
Other	5	8%	23	35%	66
All	20	7%	109	38%	286

Nonetheless, 7% of the false alarms resulted in drilling downtime and 38% caused production stoppage. In addition, a total of 129 false alarm incidents (45%) resulted in personnel mustering to life boats.

Furthermore, 65% of the false alarms occurring in the main process caused production stoppage. Similarly, 31% of the false alarms caused by ancillary systems had the same consequence.

Fewer false alarm incidents caused drilling downtime. Again, false alarms occurring in the main process or ancillary systems are the main cause for drilling downtime.

5 DISCUSSION

5.1 *Incidents*

Over the 18 year period there were almost 1000 reported fire incidents on the Norwegian continental shelf, and it is seen that there was almost twice as many incidents in the second half of the period compared to the first half. The increase is probably an effect of a shift in reporting regime, where more incidents (mostly false alarms) than before were included. There is therefore reason to believe that there were even more incidents in the first half of the period than what has been reported, but that most of the unreported incidents were false alarms incidents.

The analysis of the fire incidents reveals that even though many incidents are reported, the large majority of these have not imposed risks for severe fire accidents. There also seems to be a positive trend regarding the severity degree of the fire incidents, as there is a decline in the number of severe incidents and major accidents. However, the current analysis has not adjusted for the activity level in the Norwegian sector or other possible covariates. Also, in general one should be careful to draw any conclusions based upon the trend of a single indicator, as there may be other indicators not investigated in the current study which may affect the fire safety level negatively (Vinnem, 2010; Vinnem et al., 2006).

Also, since the current study is retrospective in nature, it is important to emphasize that a possible change in the conditions which may affect the fire safety level will not be observed in the incident statistics until later, and that the apparent trend is only valid for the focus period (Vinnem et al., 2006).

The current study does not conclude on the underlying causes of fires offshore. Future studies should therefore focus on revealing such causes in addition to triggering factors for the fire incidents. This can be done by examining investigation

reports from the different incidents and by performing interviews with key personnel with the operators. A study with such a design, investigating the underlying causes for 35 fires in electrical equipment on offshore platforms in the Norwegian sector, is reported in (Storesund et al., 2012). The study categorised the causes according to the Human–Technology–Organisation perspective, which may be helpful when trying to sort and reveal patterns in causes and find suitable and targeted measures.

5.2 *False alarms*

A great proportion of the reported incidents in the period were false alarms, and a relatively large fraction of these have been shown to cause production downtime and consequently economical losses. The classic ever-returning dilemma of smoke and fire detection is that increasing the detectors' sensitivity to detect fires as early as possible also causes an increase in number of false alarms. Correspondingly, decreasing the sensitivity to eliminate false alarms affects fire detection time negatively.

One of the main reasons for false alarms is that the detection system misinterprets the situation, and for instance takes steam or dust as smoke. However, detection systems have become smarter and there are several technologies available that contribute to reduce the number of false alarms caused by misinterpretation of the situation.

E.g. studies have shown that multi-sensor detectors with CO sensor can both decrease detection time for certain types of fires in addition to reducing the number of false alarms (Cestari et al., 2005; Sesseng et al., 2016; Sesseng and Reitan, 2016). The mentioned studies have only investigated the residential case, and there may be areas where such detectors are not suitable. Still, there is reason to believe that many areas may take advantage of this technology, e.g. living quarter, workshops etc.

The next main causes for false alarms are technical errors and malfunctioning detection systems. At the same time, compared to other barrier elements, fire detection systems have the lowest failure rate when tested. Each year, some 50,000 tests of fire detectors are performed on offshore facilities in the Norwegian sector, and since the beginning of the reporting of these tests in 2002 the mean fail rate has been declining. In 2002, around 0.9% of the tested detectors failed the tests, whereas only 0.1% failed in 2015 (Petroleum Safety Authority Norway, 2016, 2015, 2010; Vinnem, 2010). The trend is positive, and it should therefore be a continued focus on maintenance and testing.

The last main cause for false alarms is human errors. This could be due to work made in the proximity of a sensor, work during service and testing of the system or failure to comply with procedures. This is most likely best managed by improved routines for work and risk assessment as well as focusing on procedural compliance.

Obviously, if the number of false alarms can be reduced there will be great economic benefits. The majority of installations on the Norwegian shelf is ageing, and anecdotal evidence suggests that some having old or outdated detection systems. It should be investigated whether an upgrade of the fire detection systems could reduce the number of false alarms and, consequently the number of false alarms resulting in production stoppage and mustering.

5.3 *Reporting*

The current reporting scheme has certain shortcomings. By registering information concerning system and area in the same variable, information is lost. The obvious consequence is that one would have to choose to register either area or system, which would be at the reporter's discretion. Besides, a specific type of system, e.g. ancillary systems, could be found in several areas, but may constitute different risks in different areas, which makes the available information of limited value. The reporting scheme ought therefore to be changed such that more details regarding involved area and system are recorded.

A large number of incidents categorised as "Not recorded area/system" was reported before 2002. Almost half of the incidents categorised as "Other" were false alarms and could, through the free text description, be derived to specific areas/systems. This shows that in some ways the procedure and culture of reporting seems to have improved over the years. At the same time it appears that it may be difficult to categorise false alarms.

6 CONCLUSIONS

The numbers show that there is room for improvement regarding fire safety in the petroleum production on the Norwegian shelf. There are many incidents, although with low degree of severity. Future work should focus on investigating the underlying causes and triggering factors of the fire incidents, to be able to find focused fire preventive measures.

There is also a large number of false alarms, which may be quite costly if they cause production downtime. A more thorough investigation would be informative concerning what types of equipment are causing false alarms. This could found the basis for targeted measures decreasing the occurrence of false alarms and downtime and thus increasing the economic profit of the installations.

The numbers also show that severe incidents do not occur often, something that may be explained by good control of barriers. However, there are still some incidents that occur that have the potential of developing into a severe incident. Hence, there must still be a focus on barriers preventing the consequences of an escalating incident.

Implications from major accident causation theories to activity-related risk analysis – an application to the Norwegian Atlantic salmon farming industry

X. Yang, I.B. Utne & S.M. Holen
Department of Marine Technology, NTNU, Trondheim, Norway

I.M. Holmen
SINTEF Ocean, Trondheim, Norway

ABSTRACT: The Norwegian Atlantic salmon farming industry is exploring the possibility to run fish farms in more exposed locations. The severe wave and current conditions, irregular wind, sheer remoteness, and limited weather window challenge the operational planning to avoid accidents. The objective of this paper is to present results from applying a generic list of safety-critical parameters to a net cleaning operation to assess their usefulness and relevance in aquaculture. The list was proposed based on implications from major accident causation theories in safety research. The case study demonstrated that the list is a useful operational planning tool to identify activity failure mechanisms that have potential to cause accidents. The results also have implications to how to use barrier principles in aquaculture in general.

1 INTRODUCTION

The economic value created from Norwegian aquaculture is expected to reach 25.3 billion Euro by the year 2050, which means that the production will increase fivefold compared to the year 2010 (Olafsen et al., 2012). Despite the positive prediction, the fish farming industry is facing the challenge of the fewer available locations in the sheltered coastal environment and increasing negative ecological consequences due to sea lice, fish escapes and farm waste on the seabed (Holmer, 2010). One attempt to solve these challenges is to move fish farms to more exposed locations. This means that the fish farms have to deal with the amplified risk to both fish and human due to severe wave and current conditions, irregular wind and sheer remoteness. Many technical solution concepts are initiated based on extensive offshore experience from Norwegian oil and gas industry. The Norwegian Directorate of Fisheries, which is responsible for sustainable management of marine resources and marine environment, has approved several concepts that are based on offshore technology (Norwegian Directorate of Fisheries, 2017). These include Ocean Farm 1 from Ocean Farming AS, Havfarm NSK 3417 from Nordlaks Oppdrett AS, and Aquatraz from MNH production. Ocean Farm 1 has been put into pilot operation in Frohavet, Norway (KYST, 2017). Some fish farmers have even started running test facilities by expanding existing systems towards exposed areas with few significant technological and operational changes.

Despite the amplified risk due to exposed locations, the motivation for performing risk assessments is relatively low in parts of the aquaculture industry (Holmen et al., 2017). Aquaculture is different from an offshore industry where both authorities and companies have put significant efforts into systematic risk management. The similarity of the offshore locations and operating environment opens the discussion if aquaculture can or should learn safety practices from the offshore oil and gas industry. One distinction is that the offshore industry has been implementing a system-based risk analysis, while aquaculture considers more day-to-day practical routines (Pettersen, 2017). The system-based risk analysis is represented by Quantitative Risk Analysis (QRA). Take the hazardous event hydrocarbon leak as an example. The piping items (e.g., flanges, valves, instruments and process equipment, such as pumps, vessels) and technical safety barrier systems (e.g., gas detector, fire extinguishing system, and firewall) are modelled to derive a basic risk level from the design of the facility. The results are documented, and the technical conditions of these systems are followed-up during operation.

In a typical commercial fish farm today, the major operations include transferring the fish, delivery of feed to the fish farm, fish feeding, daily inspection, health and biomass control, oxygen measurement, net cleaning, removal of dead fish, delousing, and IMR (Inspection, Maintenance and Repair) (Bjelland et al., 2016). These routine operations in the fish farms dominate the variable

risk on a daily basis. This means that not only the technical condition of the fish cage, but also the operational and organizational factors, external impacts, such as the operating environment, the involved working units (e.g., service vessel, workboat) should all considered to keep the risk at an acceptable level (Yang and Haugen, 2016).

Yang and Haugen (2018) have looked into implications from major accident causation theories to activity-related risk analysis and proposed a generic list of safety-critical parameters to reveal possible activity failure mechanisms that may lead to major accidents. The list was generated from the principles and critical factors addressed in various accident causation perspectives, including the Energy-barrier perspective (Gibson, 1961), Man-made disasters theory (Turner, 1978), Conflicting objectives perspective (Rasmussen, 1997), Normal accident theory (Perrow, 1984), System-Theoretic Accident Model and Processes (STAMP) (Leveson, 2012), High-Reliability Organization (HRO) (Roberts, 1990) and Resilience Engineering (RE) (Hollnagel et al., 2006).

The objective of this paper is to present and discuss the results of applying these generic safety-critical parameters to daily fish farming operations to assess their practical usefulness and relevance in aquaculture. Net cleaning operation, which takes place approximately every two weeks, is chosen for the case study.

2 METHODOLOGY

Net cleaning, a critical and frequent operation in the marine fish farm to remove biofoulings (e.g., seaweed and mussels) on the net, was selected as a case in this paper. A professional service company provided a net cleaning procedure and related operational risk analysis document to the authors. However, the issues covered in that analysis are somewhat coarse. The Norwegian aquaculture industry is, in general, lacking full accidents/incidents statistics and in-depth analysis. Moreover, the risk factors during operations are not systematically identified and understood by the operators (Holmen et al., 2017b), which is challenging when attempting to collect safety-critical parameters (SCP) in the case study.

A preliminary list of SCPs was identified and collected from several reports (Føre and Lien, 2014, Føre and Thorvaldsen, 2017, Holmen et al., 2017a). The list serves as an input to interviews with one expert in the net cleaning operation, one captain and one TQM (Total Quality management) manager from a marine operation service company. A joint workshop was planned but could not be arranged due to schedule conflicts of the above participates. The interviews were structured focusing on the following questions:

- Are safety-critical parameters identified in the preliminary list important? If not, what else has the direct and significant influences to the different dimensions of risk (cf. Section 3.2)?
- What are the major hazardous events in each task, and what could be proactive and reactive barriers?

As a result, the preliminary list has been verified by field experts and revision has been made based on the feedback.

3 CASE DESCRIPTION

3.1 *Net cleaning operation*

The biofoulings can be a suitable habitat for sea lice larvae and may stop the oxygen supply to the farmed salmon due to reduced flow and water exchange inside and outside the net.

The cleaning operation is performed in various ways among service companies. In this case, a Remote Operated Net Cleaner (RONC) is used, and two operators are assigned to the job (Figure 1). The cleaner is remotely controlled by monitoring its movement from a screen in the wheelhouse onboard a service vessel.

The operation can be decomposed into five tasks: service vessel arrives at the cage, launch of RONC, a cleaning operation, recovery of RONC, and departure to the next cage or return to the port. The detailed procedures are described in Figure 2.

3.2 *Operational planning from risk perspective*

The risk dimensions that need to be considered in fish farming operations are risk to personnel, risk to material assets, risk to the environment (e.g., fish escape and pollution), risk to fish welfare, and food safety (Yang et al., 2017). Prevention of fish escape, which is considered as a threat to the wild fish population and environment, is an important focus of authorities. Personal safety is gradually gaining attention, ever since the aquaculture industry is realized to be one of the most dangerous professions in Norway (Aasjord and Geving, 2009). Fish health and fish welfare are other rising concerns, as sea lice have become a significant disease problem (IMR, 2017). The risk to marine assets has received

Figure 1. Net cleaning operation (from AQS website for illustration purpose).

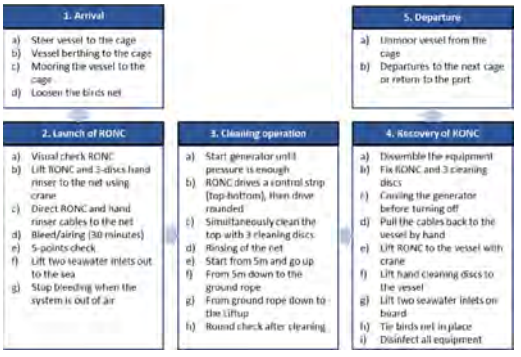

Figure 2. Stepwise procedure for net cleaning operation using RONC.

little attention. However, loss of service vessels or in a worst-case scenario, the fish farm, will give companies significant financial and reputation damage. The last dimension, food safety, is strictly controlled by the Norwegian Food Safety Authority and this aspect falls outside the consideration of this paper for short-term operational planning.

The exposed locations of the fish farms reduce the weather window and amplify the operational risk during net cleaning, especially for the personnel and the fish. The narrow weather window requires the operators to be well prepared, to foresee, and reduce the associated risks to be as low as reasonably possible while doing short-term planning.

4 APPLICATION OF THE SAFETY-CRITICAL PARAMETERS

4.1 *Safety-critical parameters*

Safety-Critical Parameters (SCPs) are the factors that have direct and significant influences on the risk involved in performing one activity (Yang and Haugen, 2016). They address possible failure mechanisms, and these are used to avoid active failures and latent errors that have major accident potential on an activity level (Yang and Haugen, 2018). The proposed generic parameters cover four aspects: input, control, process, and interaction. These SCPs are described shortly in Table 1. The readers are referred to Yang and Haugen (2018) for a full description.

Table 1. Safety-critical parameters categories descriptions adapted from (Yang and Haugen, 2018).

Aspect	SCP category	Short description
Input	Work instruction	Stepwise description of a job
	Operational limitations	e.g., weather, restricted area, restricted time, to ensure acceptable risk
	Plant drawings	Documents that demonstrate the technical systems
	Process input	Materials, tools, and spares that are consumed/used in the activity
Control	Proactive barrier systems	Barrier systems to prevent hazardous events from happening
	Recovery barrier systems	Barrier systems to reveal and recover from latent errors
	Reactive barrier systems	Barrier systems to mitigate the consequences of hazardous events
	Temporary barrier systems	Replacements for temporarily unavailable barrier systems
	Competence of operator—process model of the task	The competence of operators related to how to perform a specific task
	Competence of operator—process model of the system	The competence of the operators to interpret the current state of the controlled process
	Personnel exposure	The necessary number of workers.
Process	Physical *process* system	The physical system that the operator interacts
Interaction	Other concurrent control actions	Other on-going activities, which may have hazardous interactions with the activity.
	Environmental disturbance	Undefined or out-of-range environmental disturbance while performing the activity.

4.2 *Adaptation to net cleaning operation*

The original SCP framework focuses mainly on personal safety in the context of a hydrocarbon leak in oil and gas industry. When the framework is applied to aquaculture, it is essential to also consider fish welfare, risk to the environment (e.g., fish escape), and risk to marine assets. Further identification of special hazardous events that give rise to the above risk concerns (in addition to personal safety) is necessary. The SCP categories of barrier systems (i.e., proactive barrier systems, recovery barrier systems and reactive barriers systems) are removed from Table 1. Instead, the barrier systems are illustrated in connection with each hazardous event as shown in Figure 3 to better show their functions in preventing the hazardous events and mitigate the consequence.

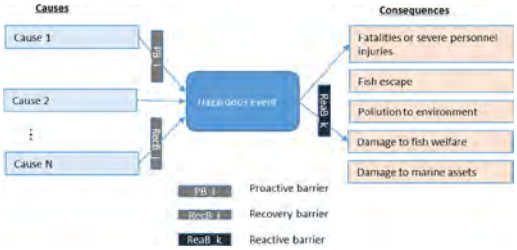

Figure 3. Illustration of a hazardous event, causes, consequences and barrier systems.

Another adaptation can be found under the category "process". The fish farming industry is dealing with live animals. During net cleaning, the salmon, and cleaner fish stay in the cage. So besides the "physical process system," another SCP; namely "fish", is added to emphasize the risk dimension of fish welfare.

5 RESULTS

The five tasks are combined into three because of their similarities: service vessel arrival and departure, RONC launch and recovery, and cleaning operation. This section describes the SCPs for these tasks in detail following the SCP categories proposed in Table 1 and Figure 3.

The possible hazardous events and their relevance to each task are listed in Table 2, with the primary concern indicated with *. These hazardous events are identified based on the findings from Holen et al. (2017a), Holen et al. (2017b), Føre and Thorvaldsen (2017), Føre and Lien (2014) and risk analysis document provided by the service company. Some hazardous events are relevant to several tasks. Therefore, the reactive barriers upon the occurrence of the hazardous event are illustrated in Section 5.4, instead of discussing them separately under each task.

5.1 *SCPs for service vessel arrival and departure*

The major hazardous event that may happen during service vessel arrival and departure is "service vessel collides/contacts with the fish farm". Figure 4 summarizes the possible causes, existing proactive (PB_i), recovery barriers (RecB_j) which are derived from discussions with the company and results in Yang et al. (2017).

Another hazardous event is "man overboard" while mooring the vessel to the cage. The anti-skid surface of the floating collar and shoes are the only existing barriers. To prevent oil spill (e.g., diesel oil, hydraulic oil) from the service vessel, the proactive barrier is also the 5-point check, which includes motor oil, hydraulic oil, coolant, seawater filter, and visual inspection.

Table 2. Possible hazardous events in net cleaning operation and their relevance to each task.

Hazardous event	Arrival and departure	RONC launch and recovery	Cleaning operation
Service vessel collides/ with fish farm	X*	X	
Holes in the net			X*
Oil spill from the service vessel	X	X	X
Dropping/swinging objects		X*	
Loss of growth of fish			X
Personal injury		X	X
Man overboard	X	X	X

*Primary concerned hazardous event.

5.2 *SCPs for RONC launch and recovery*

The primary hazardous event that may happen during launch and recovery of RONC using crane is "dropping/swinging objects." Figure 5 shows the possible causes, existing proactive (PB_i), and recovery barriers (RecB_j), which are derived from Holen et al. (2017b), and discussions with the company.

Another hazardous event could be the "holes in the net" due to entanglement between the hook and the net. However, this is relatively rare. "Man-over board" is also a possible hazardous event. Another concern is the "personal injury" while using the crane. The injuries include entanglement, crush, and back injuries (Holen et al., 2017a). In this case, no proactive barriers are set to prevent such injuries.

5.3 *SCPs for cleaning operation*

Figure 6 shows the primary hazardous event during the cleaning operation – "holes in the net" and possible causes and existing barriers, which are derived from Føre and Lien (2014), Føre and Thorvaldsen (2017), Jensen et al. (2010) and discussion with net cleaning operators.

"Personal injury" and "loss of growth of fish" are also relevant to this task. The various causes and barriers are described in Figure 7 and Figure 8 separately.

5.4 *Reactive barriers*

The hazardous events that are discussed above are further analysed to identify the barrier systems that aim to mitigate or reduce the possible consequences to the fish, the personnel, and the environment (Figure 9). The existing barrier systems are collected by interviewing the service company.

Table 3. SCPs for service vessel arrival and departure.

SCP category	SCPs
Work instruction	See Figure 2
Operational limitations *(limitations to arrival)*	Generic vessel limitations: stability, loading, maximum passenger, minimum crew
	Weather limitation: wind, wind direction, current speed, wave height, visibility
	Restricted mooring points
	Restricted time of operation
Plant drawings *(layout of the cage)*	Actual positions of mooring lines of the cage
	Actual positions of bridles of the cage and the net (due to deformation)
Process input *(Tools, materials, spare parts that are used)*	Condition of navigation system
	Condition of telecommunication system
	Condition of mooring line
Competence of operator—process model of the task *(Competence of completing arrival and departure)*	Competence of maneuvering the vessel
	Knowledge of influences of the weather condition to maneuvering: season, rain, wind, wave, current, fog, icing condition, darkness.
	Competence of safe mooring
Competence of operator—process model of the system *(knowing the vessel)*	Knowledge of the condition of the vessel; how the vessel reacts upon maneuvering
	Knowledge of the safety systems: emergency stop, rescue equipment, firefight system
Personnel exposure	Two operators in the wheelhouse
Physical process system *(The vessel itself)*	Technical condition of the vessel: propulsion system, power system, side propellers, etc.
	The disinfection status of the vessel
	The size of the vessel: length, width
Fish	Non-applicable
Other concurrent control actions	No other ongoing activities
Environmental disturbance	Unexpected big waves and strong current from, e.g., passing vessels
	Changed wind speed, wind direction

Table 4. SCPs for RONC launch and recovery.

SCP category	SCPs
Work instruction	See Figure 2
Operational limitations *(limitations in launch and recovery operation)*	Weather limitation: wind, wind direction, current speed, wave height, visibility
	Generic crane limitations: max. Lifting moment, capacity, slewing torque, etc.
Plant drawings *(layout of the cage)*	Bird net, the height of the railing
Process input *(Tools, materials, spare parts that are used)*	Technical condition of the crane
	Interface with the RONC: crane fastening, crane lifting straps
	Velocity of the crane tip
	Condition of the technical communication system
Competence of operator—process model of the task *(Competence of completing launch and recovery)*	Knowledge of the stability of the vessel: ballast tank, weight distribution, wind-exposed surface
	Knowledge of influences of the weather condition to launch and recovery: rain, wind, wave, current, fog, icing condition, darkness. Knowledge of operating crane: relative movements between the vessel and the cage
Competence of operator—process model of the system *(knowing the RONC)*	Knowledge of the condition of the RONC
Personnel exposure	One operator on the deck, one operator on the wheelhouse
Physical process system *(The RONC)*	The condition of the RONC: weight, size, disinfection status
Fish	Non-applicable
Other concurrent control actions	No other ongoing activities
Environmental disturbance	Unexpected big waves from, e.g., passing vessels
	Changed wind speed, wind direction

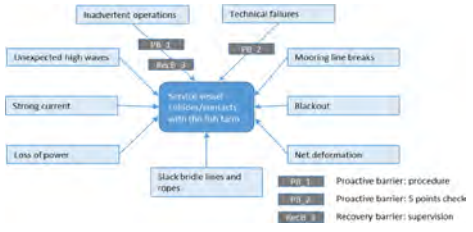

Figure 4. Causes of service vessel collision/contacts with the fish farm and existing barriers to prevent.

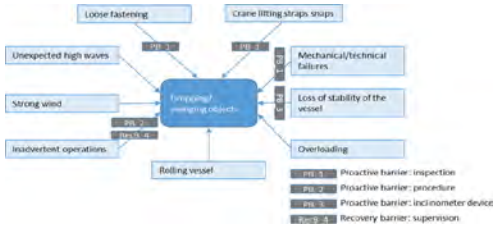

Figure 5. Causes of dropping/swinging objects and existing barriers to prevent.

Table 5. SCPs for cleaning operation.

SCP category	SCPs
Work instruction	See Figure 2
Operational limitations *(limitations in cleaning)*	Weather limitation: current speed, current direction, visibility underwater Generic RONC limitations: max. working water pressure, speed Strength of the netting Restricted time for operation
Plant drawings *(layout of the cage)*	Remaining systems in the cage Actual position of the net (due to deformation)
Process input *(Tools, materials, spare parts that are used)*	Technical condition of the equipment: RONC, high-pressure unit, inlets of the sea water, cables and hoses, power supply, sharp edges, cracks, loose screws RONC spare parts: discs, nozzles
Competence of operator—process model of the task *(Skill of cleaning)*	Knowledge of cleaning techniques Knowledge of RONC untangling and retrieve techniques Knowledge of disinfection techniques
Competence of operator—process model of the system *(know the RONC and the net)*	Knowledge of remotely maneuvering RONC and RONC behavior in different current speed and direction Knowledge of the status and actual position of the net Knowing the actual position of RONC during cleaning
Personnel exposure	One operator on the deck, one operator in the wheelhouse
Physical process system *(The net itself)*	The actual position of the net The condition of the net: type, slackness, age, degree of wear, existing holes, vulnerable parts (e.g., side rope). Possible items on the net: lost knives, fish hooks, mussels
Fish	Oxygen level, type of fouling, possible disease, possible hydroid
Other concurrent control actions	No other ongoing activities
Environmental disturbance	Unexpected big waves from e.g., passing vessels Changed wind speed, wind direction

6 DISCUSSION

6.1 *Applicability of the SCP list*

In today's fish farm, it is a common practice to hire marine operation service companies to carry out various fish farming operations, such as net cleaning, delivery of feed, delousing and so on. Safe operations are heavily dependent on the experience of the operators. The rapid development of the industry follows a fast employment growth in these service companies. Concerns about employee inexperience arise from both the industry and the authorities. It is especially challenging to get skilled staff at exposed locations (Johannesen and Sæther, 2017). The industry is also experiencing technological innovations (Bjelland et al., 2015). The rapid emergence of new systems demands operators to learn about the system and operational techniques quickly to cope with unforeseen challenges. "Planning in details is the keyword," as reflected by Marine Harvest who has been running test facilities in exposed locations (Johannesen and Sæther, 2017).

The generic list of safety-critical parameters provides systematic guidance to identify the vital information that needs to be collected for a detailed operational planning. The detailed information can assist the decision-maker to approve the operation by considering the risk to personnel, environment and the fish. The information can also give the operators a reasonable anticipation of what may happen and what are or could be the proper reactions. The results from the case study show a significant number of critical operational risk factors that origin from experiences and understanding of the systems. These factors will also facilitate the training and learning process of junior operators to operate more safely.

6.2 *Challenges regarding using the SCP list*

The main challenge with using the SCP list lies in acquiring the information under each parameter. The service companies have specialized equipment, service vessel and expertise for performing the operations. They may not have enough knowledge about the specific site they are working on, such as the design of the cages, locations of mooring lines, systems equipped inside the net, the health status of the fish, and the possible presence of knives, fishing hooks and so forth. The above information could be available upon request, but a close cooperation and effective communication between the service companies and fish farmers are challenging, as revealed by Føre and Lien (2014). The listed SCPs can improve the communication by indicating clearly what information the service company is seeking.

It is also challenging to collect operational limitations, which is identified as one of the critical underlying causes of accidents by Norwegian Maritime Authority (NMA, 2017). It is not common for the service company to have written operational limits regarding weather conditions. It is subject to the captain's judgment and experience to decide whether the operation is feasible. Moreover, on some sites, the weather changes quickly, which makes it challenging to derive standard operational limits.

Another challenge is to understand the influence of the planned operation to fish welfare and fish health, which has not been paid much attention to yet. For instance, hydroid in the washed off waste damages the salmon gills (Saue, 2017). Gill diseases have been associated with reduced growth and large-scale mortality (Mitchell and Rodger, 2011). This may be out of the knowledge of the service company until symptoms become relatively severe. Acquiring such information requires a close follow-up of fish health after the operation and knowledge about the latest research findings.

6.3 *Applying barrier principle in aquaculture*

Using a barrier perspective as a strategy to reduce risk, especially fish escapes, gains more and more attention both from the industry and the government (Ministry of Trade Industry and Fisheries, 2017). The barrier perspective is one of the major accident causation theories behind the generic SCP list. Identification of barriers is an essential part in the case study, and the results show that in current fish farms, barrier systems have been partially placed and functioning, even though no explicit "barrier" label is given yet. For example, supervision is somewhat prevalent in the industry, as a response to the increasing use of junior operators. The senior operators on the site can correct the possible latent errors made by juniors during the operation. This correction is a typical recovery barrier. In fact, compared to supervision, certifications and procedures are not widely adopted practices in the service companies yet. The safe operations are heavily dependent on operator experience, from which the SCPs are derived. The results have several implications for implementing a barrier perspective in the industry in general.

First, clearly defined hazardous events are helpful to identify which barriers are in place, and which could be missing. Definition of hazardous events can be subjective, and this will influence what could be the proactive barriers or reactive barriers. For example, both holes in the net and fish escape can be defined as a hazardous event, but the reactive barriers will differ. ROV or diver

inspection and repair of the holes can be reactive barriers to "holes in the net", while escaped fish retrieve is the reactive barrier. It is beneficial to have standard definitions of hazardous events in the industry to facilitate a common understanding of the reactive barriers.

Second, the performance of the barrier systems should be evaluated in different operations. For instance, holes in the net are the most direct cause of fish escape in period 2010–2016 (Føre and Thorvaldsen, 2017). The reactions (reactive barriers) to the holes vary from operation to operation. Immediately after and during the net cleaning operation, the camera equipped with RONC can be used to inspect whether holes are present. In some cases, the RONC itself has been used as a temporary barrier in front of the hole to prevent fish escape. For other operations, such as delousing, ROVs or divers have to be sent out separately to do the inspection. Even though the inspection can be a reactive barrier in both operations to prevent fish escape, the response time in different operations is different. In turn, this influences the performance of the barrier systems, which affects potential consequences (Sklet, 2006).

Third, it is necessary to be aware that all kinds of functions, elements, and systems that are associated with safety can be given the label "barrier" (Rollenhagen, 2011). On one hand, there is a potential for setting up more effective proactive and reactive barrier systems in the case study. For example, absorbent boom/sheets can be equipped on board the vessel in case of oil spill. On the other hand, purely depending on barrier systems may not be enough for preventing accidents, even though operator's knowledge about all the SCPs (including operational limits) identified in the case study can be labeled as "barriers." Precautions should be taken when defining the barrier systems.

7 CONCLUSION

The case study in this paper illustrates that the proposed safety-critical parameters provide a systematic overview of the critical risk factors in specific fish farming operations for operational planning, considering the risk to personnel, fish escape, fish welfare and marine assets. The results also have implications to how to use barrier principles in aquaculture in general. The collected information by using SCP for fish farming operations can be used to improve the learning process of junior operators and to facilitate communication between the fish farmer and service companies.

The case study opens up the possibility of applying the SCP framework to other more complex operations in aquaculture. Furthermore, the priority of the SCP should be evaluated based on experiences from the senior operators, and relevant accidents and near misses. Prioritization of the risk factors is considered as further work in the following research.

ACKNOWLEDGEMENTS

This work has been carried out as part of the Reducing Risk in Aquaculture project. The Norwegian Research Council is acknowledged as the main sponsor of project number 254913. Heidi Moe Føre at SINTEF Ocean is acknowledged for their valuable input to this case study.

Using microworlds to study critical infrastructure protection—the effect of incentives on risk management

J. Lindström & H. Lindbom
Lund University, Lund, Sweden

ABSTRACT: A computer simulated microworld was used to study risk management in a critical infrastructure context. 36 students assumed the role of an electric distribution company Chief Executive Officer (CEO) making decision on how to spend resources between investments in risk reduction and other investments. We studied the effect of differences in terms of the incentives to invest in risk reduction and the extent that the participants had access to a risk assessment. We found that both independent variables influenced the total resources spent on risk reduction and total losses due to storms. If the company had to bear a larger part of the total losses due to a storm their propensity to invest in risk reduction increased. In addition, if the participants were provided with a simple risk assessment to support their decisions they invested more resources in risk reduction, and they were also more successful in limiting the total losses due to storms.

1 INTRODUCTION

The functioning of modern societies is dependent on the services provided by an interconnected web of critical infrastructures (CI:s). Although what counts as a CI might differ between countries, telecommunication, electric power, transportation and water supply systems are usually considered to be CI:s. Such systems can have a considerable geographic extent, sometimes covering entire nations, or even continents.

Two trends in the development of CI:s are especially important for the ability to manage risks associated with them. First of all, they are becoming increasingly interconnected growing into so called "system of systems" (Kröger, 2008, OECD, 2011) and thereby increasing the risk of transboundary crises, i.e. crises that "affect multiple jurisdictions, undermine the functioning of various policy sectors and critical infrastructures, escalate rapidly and morph along the way" (Ansell et al., 2010). Thus, what might previously have resulted in a local disruption of some services might nowadays spread quickly and grow into a full-blown crisis.

Secondly, the planning, operation and management of these systems have become increasingly fragmented (Almklov & Antonsen, 2010, de Bruijne & van Eeten, 2007). A system that used to be run by one organization can nowadays be managed by a multitude of different actors. Thus, at the same time as the systems are growing more interconnected, the management of them are becoming more fragmented (de Bruijne & van Eeten, 2007).

When CI:s and their associated risks are becoming increasingly connected it is no longer viable to approach risk management in a "silo-based" fashion, focusing on one actor and one system at a time. This conclusion has influence the corporate world (Gordon et al., 2009) as well as in governmental efforts to manage risk through so-called 'all-hazards' and 'whole-of-society' approaches (OECD, 2009).

Notwithstanding the fact that there are efforts to manage risk from a more holistic perspective, it is very difficult to know if approaches such as the ones exemplified above actually leads to more effective management of risk (Rivera et al., 2017, Hoyt & Liebenberg, 2011). Therefore, there is need to better understand risk management in general, and specifically in an interconnected world.

There are many different methods one can use to try to increase our knowledge of risk management. Here we present the initial results from a study making use of a method that has not been used much in the present context; a computer simulated

microworld. The focus of the study is on two aspect that can influence risk management: differences in incentives for investments in risk reduction and the extent to which risk assessments are available when making such investment decisions.

2 USING MICROWORLDS TO STUDY RISK MANAGEMENT

There exists a multitude of definitions of risk (see e.g. Aven and Renn, 2009), and there are also several definitions of risk management. For example, the SRA Glossary defines it as "Activities to handle risk such as prevention, mitigation, adaptation or sharing" (Society for Risk Analysis, 2015), and it is also noted that risk management "…often includes trade-offs between costs and benefits of risk reduction…". Other definitions, like the ones suggested by International Organization for Standardization and United Nations International Strategy for Disaster Reduction (ISO, 2009, UNISDR, 2009) also emphasize the fact that risk management is about doing something, e.g. prevent, mitigate, etc., in order to achieve something, i.e. the handling of risk.

To study risk management is thus about studying a purposeful activity, or a number of activities. Such studies can be conducted in many different contexts where the focus might be on one person, a group, an entire organization, or even multiple organization. And they can also be performed within different scientific disciplines, have different ambitions, and be based on different theoretical frameworks. It might, for example, involve field studies focusing on organizations (e.g. research on High Reliability Organizations, as described by Roberts (1990)), or laboratory research focusing on individual decision making (e.g. Tversky and Kahneman, 1974).

Here the focus is on using a computer simulation, a so called microworld to study risk management. Microworlds have been used for some time as a means to capture some of the complexity of real life problem contexts. In a micorworld-study the participants interact with a computer simulation and receive continuous feedback on the effect of their actions. Brehmer & Dörner (1993) describes the use of microworlds as a way to escape "…both the narrow straits of the laboratory and the deep blue sea of the field study". They refer to the fact that laboratory experiments often get criticizes by field researchers for lacking relevance, and vice versa that laboratory researchers criticize field researchers for lack of control of confounding variables. A micorworld is something in between a laboratory experiment and a field study. It retains the possibility to control the variables under study, but at the same time offer more realistic conditions in terms of task complexity.

In terms of realism, there are some clear characteristics of real risk management problems that microworlds are especially suitable to capture. Risk management usually require *a series* of *dependent* decisions. For example, a decision to invest in risk reduction will be influenced by previous investment decisions. The previous decisions determine, to a certain extent, the present level of risk. And, a lower level of risk will, in general, make it more difficult to find good investments to decrease the level of risk more (decreasing marginal utility of investments). Thus, the decisions that led up to the present situation (risk level) all have an influence of the current decisions.

Moreover, the risk management problem will *continuously change*. Both as a consequence of the actions taken by the risk manager, but also due to other factors. These characteristics are identical to those described for dynamic decision problems (Edwards, 1962, Brehmer, 1992).

In terms of problem complexity, microworlds allow us to extend the study of risk management from using lottery-like situations where the focus is on the participant's *judgements*, and how they make them, to more complex game-like situations where the focus is on *control*. To frame risk management as a control problem is not new but has been proposed as a prerequisite for understanding it in a dynamic society (Rasmussen, 1997). In the microworld context, control refers to "…an attempt to achieve some desired state of affairs" (Brehmer, 1992). To try to achieve control in the present context of risk management means to achieve a suitable balance between the costs and benefits of risk reduction. Clearly, judgements, for example about the likelihood of various events, are an important part of trying to achieve control. But, there is much more to the control problem than merely judgements.

Yet another feature of microworlds that makes them suitable for studying risk management is the fact that one can study how successful participants are in trading off the costs of risk reduction investments with their associated benefits. This is usually difficult to achieve in a field study, especially if one focus on low-probability high-impact events (Rivera et al., 2017). Neither the simple experiments lacking the dynamic nature of microworlds can adequately capture it.

In a critical infrastructure context, negative consequences can be described in terms of failure to maintain vital societal functions (see for example the definition of CI in the EU council directive 2008/114/EC). Thus, a relevant risk management problem is how successful the operators of CI:s are at trading off the costs of investments in risk

reduction versus the benefits the investments provide in terms of reduced occurrence and/or consequences of failures of vital societal functions. However, due to the interconnected nature of CI:s, and their potential devastating societal consequences, an equally interesting question is how their tradeoffs affect the consequences suffered by the *users of the services*. Part of the study presented here is aimed at investigating such consequences.

3 A TWO-LOOP MODEL OF RISK MANAGEMENT

One of the most straightforward control-loop models of risk management one can use is a model focusing on the relationships between risk management decision and losses/consequences (measured in a suitable way) as illustrated in the left part of Figure 1. Such a model ignores many important aspects of risk management, for example, how people make decisions (as for example studied in the Naturalistic Decision Making or the Heuristics & Biases traditions, see Kahneman & Klein (2009) for a review of the two traditions), or why and how people identify something as a risk (see for example Boholm & Corvellec (2011)). Nevertheless, it captures some of the important dynamics of risk management, i.e. past decisions may influence future ones, and it can be used as a basis for studying differences in risk management arising from different incentives to invest in risk reduction. For example, it is reasonable to assume that if the negative consequences an actor might suffer due to a specific activity are reduced, the actor's interest in investing in risk reduction will also be reduced.

The one-loop model focuses on an actor's *concrete experiences* in terms of investments in risk reduction, which might lead to a change in the system of interest, which then might lead to less negative consequences. If the likelihood of experiencing losses is relatively high one would expect the control problem to be relatively easy for a risk manager. He/she continuously gets feedback on the effect of various investment in risk reduction and can therefore find a balance between the cost of investments and the benefits they bring. However, if the focus is on low likelihood/high consequence events the problem is not so easy. Often there will be no losses at all, and therefore one might question the effectiveness of investments. Similarly, when severe losses eventually occur, it is very difficult to determine if the investments made so far had any effect on the outcome. In general, less frequent events generating losses will mean that the control loop is weaker.

Figure 1. Illustration of the two-loop model of risk management.

The one-loop model relies on what *has previously happened* in a system, but from a risk management perspective *what can happen* in the system is also very important. The question of what can happen together with judgements of how likely it is and the consequences thereof is an important part of risk assessment (Kaplan & Garrick, 1981, Aven, 2010). Therefore, we can complement the one-loop model with another loop that connects the risk management decision to a *description of risk* (Aven, 2010). The implication of this second loop is that a decision to invest in risk reduction can be influenced by a description of risk from the system of interest (e.g. in the form of a risk analysis). The decision can, in turn, influence future state of the system, which can then give rise to a new description of risk, and so on.

Thus, this second loop focuses on *what might happen* in the system of interest. The description of risk will most likely also be influenced by previous consequences in the system (and perhaps similar systems), but that relationship is not explicitly illustrated in Figure 1. Moreover, the two loops represents two types of analytical processes previously termed experiential and analytic processing (Marx et al., 2007).

The two-loop model is the basis for the experiments presented below. In a CI context, it describes the decisions that a CI operator might make to invest in risk reduction, and how the investment might influence the infrastructure (state of the system), which might then influence the occurrence and/or magnitude of negative consequences due to unwanted events (depending on the CI it might for example be storms, technical failures, floods, etc.). It also describes how the same decisions and following change of the CI might influence future descriptions of risk, which might in turn influence future decisions.

The "other factors" are included in the model as a reminder that risk management is not a closed system and that there are many other factors than the ones included here that influence risk management in practice. For example, there are many other factors that influence the state of a CI system apart from investment in risk reduction, such as various performance objectives of the CI operator.

4 THE EXPERIMENTS

4.1 *Overview*

The aim of the experiment was to investigate the effect of differences in incentives to invest in risk reduction, and if such effects could be influenced by the extent that risk assessments are available to support the investment decisions. The importance of incentives for risk management in CI:s is salient in many sectors where CI:s are operated. A specific form of incentives is related to the two-loop model presented above. It concerns the magnitude of the negative consequences affecting a CI operator in case of a failure to maintain the vital societal function in question (e.g. electric power supply). One can imagine two extreme situations in this respect. In practice the situation for most CI:s are probably somewhere in between the extremes. On the one hand, one can consider a situation where an operator of a CI does not suffer any negative consequences at all due to a failure to uphold the function of interest. Clearly, there are negative consequences of such a failure, but they will solely affect the users of the function in question. On the other hand, one might have a situation where the CI operator will have to compensate the users of the function to cover for the full consequences of a failure. The net consequences suffered by the users would then be zero and the CI operator will have to bear the full consequences of the failure.

In practice, it is difficult to imagine how these two extreme situations could occur. It would, for example, be very difficult to determine the compensation to the user of a function to compensate for "all" their losses. Nevertheless, the focus here is not to simulate real cases but rather to try to capture some of the important mechanisms influencing risk management in practice and investigate if they can be influenced in different ways.

4.2 *The microworld*

A microworld called MicroRisk was designed as part of several master thesis projects at Lund University. MicroRisk is a computer simulation that allows the participants in the experiment to interact with it using a regular computer and a web-browser. To implement the two-loop model of risk management in a CI context the particular study reported here used MicroRisk to put the participants in charge of a fictitious electric power company. A detailed description of the study, including the user interface, can be found in (Lindström, 2017). MicroRisk was run for a number of turns and after each turn the participants were asked to prioritize between investments to reduce the risk associated with the supply of electricity (e.g. strengthen grid, invest in repair capability, spare parts, etc.), and other investments. The choice was made by dividing 100 resource units between "other investments" and "risk reduction investments". Resource units (or simply units) was the way consequences (losses) and investments were measured in the simulation. Each turn there might be a serious storm affecting the power grid causing negative consequences (measured in units). The ultimate goal of the participants was to maximize the number of units spent on other investments minus the units lost due to storms.

The consequences of a storm were determined by the amount of resources the participants spent on risk reduction. The more they spent, the less the consequences of storms. This function was implemented in the MikroRisk by having the "state of the system" (Figure 1) being represented by one variable called *Level of risk*. The *Level of risk* was a number between 1 and 1000. At the start of each game the level of risk was set to 500. Each unit the participant would spend on risk reduction would then reduce one unit from the *Level of risk*. However, each turn 50 units were added to the *Level of risk* independent of the decisions made by the participants. It represents the fact that a system that is not maintained will degrade over time. Thus, a participant that chose not to spend anything on risk reduction would quickly degrade the system increasing the consequences due to storms significantly. It was only the potential consequences that were affected when changing the *Level of risk*, not the likelihood of a storm occurring. The maximum negative consequences that could occur, was a loss of 1000 units and the minimum was 1 unit. 1000 units would be lost if a storm occurred when *Level of risk* was at its highest value, and 1 units would be lost if it was at its lowest value. However, the relationship between *Level of risk* and the negative consequences was not linear. Investments when the *Level of risk* was close to the starting value of 500 was more effective than investments made when the Level of risk approached low values (diminishing marginal utility of investments).

Games were played during 30 turns. After the 30th turn of a game there was a 20% probability that it would end after each turn. Most games ended in between 30 and 40 turns, but in the analysis below we only use the 30 turns that were completed in all games. The participants did not know how many turns they were going to play. Neither did they know the probability of a severe storm each turn. Instead they had to infer the likelihood based on previous experience (left side of the loop in Figure 1). The number of storms during the thirty turns was set to four. In each game, they were randomly assigned to occur in four of the thirty turns.

There were four versions of the game played by the participants. The four versions differed with respect to two factors each having two possible states: *Incentives* (*Limit*/*No limit*) and *Risk assessment* (*RA*/*No RA*). The incentive to invest in risk reduction was varied by having two possible game-types. One type (*No Limit*) where the power-company would bear all losses due to storms and the users none. The other type (*Limit*) meant that there was an upper limit to the losses (200 units) that the power-company had to bear. Above 200 units, the company would only have to bear 15% of all exceeding losses (the remaining 85% of the losses affected the customers of the power company). The *Total losses* is the sum of the losses (in terms of units lost) affecting the power company *and* the customers. The *Total losses* is not dependent on whether incentives are limited or not, it is only dependent on the state of the system (*Level of risk*), which is only affected by the decisions made by the participants.

The *Risk assessment* factor was varied by either presenting a risk assessment to the participants to support their decisions (*RA*) or not (*No RA*). Thus, when no risk assessment was present, the loop on the right in Figure 1 was absent. The risk assessment was a simple text of the form "Given the present level of preparedness experts estimate the consequences of a severe storm to be a loss of somewhere between *X* and *Y* units". The interval between *X* and *Y* was arrived at by first calculating the true consequences, C_{true} (the consequences that would occur during a turn *if* a storm occurred) given the present *Level of risk*. Then a new value C_{est} was calculated by random in the interval [0.8 * C_{true}, 1.2 * C_{true}]. Then the interval between *X* and *Y* was calculated by multiplying C_{est} by a factor *k* ($X = C_{est} - (C_{est} * k)$, $Y = C_{est} + (C_{est} * k)$). The factor *k* was a random number (drawn every turn) between 0.1 and 0.5. Thus, the risk assessment would show the participants a relatively wide interval in the vicinity of C_{true}.

4.3 *The participants*

Participants consisted of students at Lund University that were recruited to the experiment by posting information about the experiment at different parts of the university. The 30 first to enroll in the experiment was given a movie ticket. There were 36 students that participated in the experiment. 16 (44,4%) females and 19 (52,8%) men (one person did not want his/her sex to be recorded). The students were predominately studying (or had just graduated) from engineering programs (22), but there were also students from biology (4), medicine (3), psychology (1), audiology (1), speech therapy (1), nursing (1), systems science (1), graphical design (1), and criminology (1).

4.4 *Procedure*

We used a fully crossed, 2 *Risk assessment* (*No RA*/*RA*) × 2 *Incentive* (*No Limit*/*Limit*), within-subject design. Thus, each participant played all four versions of the game. The order in which the games were played was randomized to minimize learning effects. The participants played the game using one of three computers in a closed off room at the Division of risk management and societal safety at Lund University.

In each version of the game we measured how much resources each participant spent on investments in risk reduction (*Total investments in risk reduction*), how much losses the company and the customers suffered (*Total losses*).

5 RESULTS

Three of the students did not complete all versions of the game. Their data was removed from the results. A two-way analysis of variance was conducted on the influence of the two independent variables (*Incentive*, *Risk assessment*) on the each of the dependent variables (*Total losses*, *Total investments in risk reduction*).

5.1 *Total losses*

The mean value for *Total losses* in game condition 1 (No RA, No Limit) was 1448 (*SD* = 1181), in condition 2 (RA, No Limit) it was 1183 (*SD* = 856), in condition 3 (No RA, Limit) it was 2004 (*SD* = 1324), and in condition 4 it was 1583 (*SD* = 1125). The results are illustrated in Figure 2 where a box-plot shows the median value and the 25th and 75th percentiles respectively (whiskers show the most extreme data points). The main

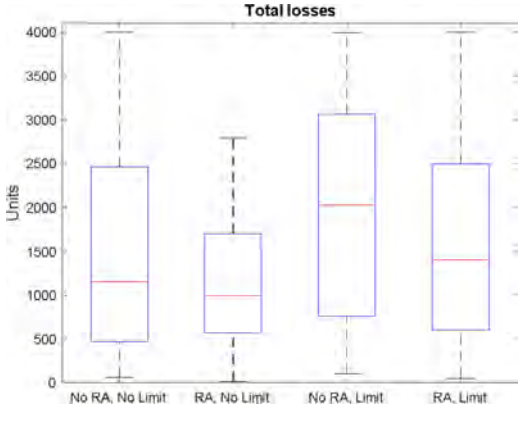

Figure 2. Box plot showing *Total losses* for all four game types.

effect for *Incentive* was significant $F(1, 32) = 7.47$, $p < 0.05$, as was the main effect for *Risk assessement* $F(1, 32) = 5.58$, $p < 0.05$. The interaction effect was not significant, $F(1,32) = .25$, $p = 0.62$.

5.2 *Total investments in risk reduction*

The mean value for *Total investment in risk reduction* in condition 1 (*No RA*, *No Limit*) was 1583 (*SD* = 354), in condition 2 (*RA*, *No Limit*) it was 1596 (*SD* = 254), in condition 3 (*No RA*, *Limit*) it was 1320 (*SD* = 475), and in condition 4 (*RA*, *Limit*) it was 1535 (*SD* = 382). The results are illustrated in Figure 3.

The main effect for *Incentive* was significant $F(1, 32) = 5.24$, $p < 0.05$, as was the main effect for *Risk assessement* $F(1, 32) = 7.42$, $p < 0.05$. The interaction effect was also significant, $F(1,32) = 6.45$, $p < 0.05$.

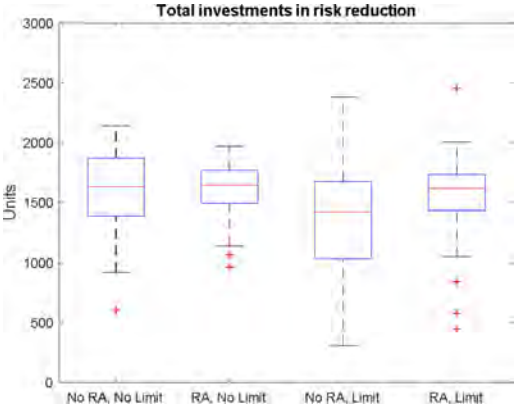

Figure 3. Box plot showing *Total investment in risk reduction* for all experimental conditions.

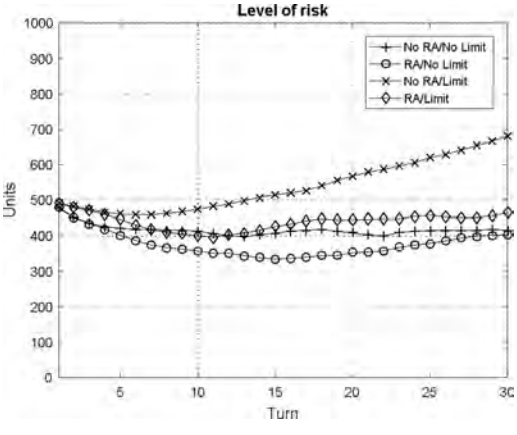

Figure 4. Mean value of the *Level of risk* for all participants.

5.3 *Level of risk*

During the games, we measured how the *Level of risk* varied. In Figure 4 the mean value of all participants *Level of risk* at different turns and during different versions of the game is shown.

6 ANALYSIS AND DISCUSSION

The results from the study show that both independent variables (*Incentive* & *Risk assessment*) have a significant effect on both *Investments in risk reduction* and on *Total consequences*. Taking the perspective of the *users* of vital societal functions, i.e. all actors dependent on the service in question and the public, it is especially interesting to note that the introduction of a simple risk assessment increased the investments in risk reduction. The increase was so strong that it essentially cancelled out the negative effect of reducing the participants' incentive to invest in risk reduction. The mean value of *Total investments in risk reduction* is essentially the same for the cases (*No RA*/*No Limit*), (*RA*/*No Limit*) & (*RA, Limit*) in Figure 3, whereas the mean value for (*No RA, Limit*) is significantly lower.

The result suggest that one can influence CI operators (and others) to invest more in robust services without using coercive measures, such as detailed regulations. Instead, one can influence their behavior in a positive way (for the users of the services) by introducing a risk assessment. This effect might be especially important in CI:s where the consequences due to severe interruptions of services are small for the operator compared to those suffered by the users of the services.

Moreover, while the results presented in Figure 2 illustrate the rise in *Total consequences* due to a reduction of incentives to invest in risk reduction (an expected effect) it also shows something interesting from a user of service-perspective. It shows that the introduction of a risk assessment not only led to more investments in risk reduction, it also had a significant effect on the *Total consequences*. Thus, the participant not only spent more on risk reduction, the investments were also effective in reducing *Total consequences*. One might assume that the reduction of *Total consequences* stem only from the fact that the participant spends more resources on risk reduction. In part, that is true, but comparing Figure 2 (*No RA*/*No Limit*, and *RA*/*No Limit*) to Figure 3 (*No RA*/*No Limit*, and *RA*/*No Limit*) also suggest that even without an increase in resources spent on risk reduction

the introduction of a risk assessment leads to less *Total consequences*. At least in contexts where the CI operator have to bear a large part of the negative consequences due to a service interruption.

Microworld experiments allow researchers focusing on risk management to study how the state of a system, and the risk associated with it, change over time (turns). Thus, using microworlds one can study risk management phenomena where longitudinal studies of the state of a system is crucial. One example is phenomena associated with a gradual increase in risk that goes unrecognized resulting in a system drifting into failure (Dekker and Pruchnicki, 2013). Figure 4 shows the mean value of the *Level of risk* in the four versions of the microworld. It is clear that one of the versions stands out from the rest in terms of a gradual increase in risk (*No RA*/*Limit*). A rising *Level of risk* due to economic pressure (in this case the incentive to select "other investments") can be counteracted by one or both of the two loops in Figure 1. The left side loop counteracts this tendency by concretely making the participants experience that they pay a price for allowing the *Level of risk* to become high in that the losses when a storm occurs also becomes high. However, when there is a limit to the losses suffered by the power-company, the concrete consequences felt by the participants are smaller compared to when there are no such limits. Thus, the left side loop is *weaker* in countering the economic pressure (that is the same in all cases) than when there are no limits.

The right-side loop counteracts the economic pressure by making clear for the participants what the consequences *can* be if a storm occurs. Although, this might not be as important as concretely experienced losses, it has the advantage of being present all the time (during all turns) as opposed to the concrete losses due to storms that is only experienced in four of the thirty turns. This makes it easier to use the risk description as a basis for the risk management tasks. An increase in investments in risk reduction would, in this case, immediately be visible in the risk description presented during the next turn. Thus, the participant would get a confirmation, although somewhat uncertain, that the investments have an effect.

However, in the (*No RA*/*Limit*) condition of the experiment this feedback is lacking and the right-loop is thus in its weakest form to counter the economic pressure. Moreover, in that condition the left-loop is also in its weakest form and that is an explanation offered by the two-loop model as to why the *Level of risk* is almost constantly increasing in one of the conditions in Figure 4, whereas in the other conditions it seems to be stabilized on much lower levels.

The relevance of the results to real problems of CI risk management is unclear and needs to be further studied. Nevertheless, based on the results it seems reasonable to focus on finding practical situations of CI risk management problems that might differ with respect to the conditions investigated here. Thus, we should look for situations where there are differences in terms of the consequences suffered by the *provider* of a vital societal function in case of a failure to supply it (left loop). And we should also look for situations that differ with respect to how often failure of functions occur (left loop). Moreover, situations differing with respect to how (if) risk analyses are used as a basis for decision making should also be identified. Based on further detailed study of such practical situations one might be able to improve the microworld studies linking them better to the practical cases and investigating whether the effects seen in the microworlds are also present in practice.

7 CONCLUSIONS

We have investigated the effect of different incentives for investing in risk reduction, and the effect of risk assessments, on risk management in a computer simulated microworld. The focus was on a situation where one actor supplies a service or function that is used by other actors. The risk management problem is related to how much the supplying actor will spend on risk reduction, focusing on protecting the service in question, given that the actor will suffer a certain amount of negative consequences in the event of a service failure.

Both factors had a significant effect on the dependent variables of the study. Manipulating the incentives to invest in risk reduction by changing the negative consequences suffered in case of a service failure affected both the amount of resources invested in risk reduction, and the total losses due to service interruptions. Moreover, a similar effect was observed when the extent to which the actor supplying the service in question had access to a simple risk assessment changed. Having access to a risk assessment (compared to not having such an access) resulted in more resources spent on risk reduction, and also in less total losses due to service interruptions.

Thus, the results indicate that risk management actions can be influenced in a predictable way just by providing access to simple risk assessments. Supplying a decision maker with a risk assessment in the experiments lead not only to an increased propensity to invest in risk reduction it also resulted in more well-balanced decisions that ultimately led to less total losses. The addition of a risk assessment can counter the effect of reducing the incentives to

invest in risk reduction. This effect is especially clear when the incentives to invest in risk reduction is low.

Although the practical implications of the results presented here are not clear, the results indicate that incentives and the extent to which risk assessments are used (and how they are designed) are two important factors for understanding risk management.

Lessons learned from an unexpected uranium accumulation event

D.G. Harrison & A. Smith
U.S. Nuclear Regulatory Commission, Rockville, Maryland, USA

ABSTRACT: On July 14, 2016, a nuclear fuel fabrication facility licensee notified the United States Nuclear Regulatory Commission (NRC) that significant amounts of uranium were discovered, potentially exceeding their Criticality Safety Evaluation (CSE) mass limits, during an annual inspection of a scrubber ventilation system. The licensee subsequently confirmed not only significant mass several times higher than the CSE mass limits in the scrubber and associated ventilation ductwork, but also significant concentrations of uranium. As part of the NRC's platform of continuous improvement, a lessons-learned activity was initiated to explore opportunities for improving the NRC's regulatory processes for early identification of facility operational issues and preventing such events in the future. This paper describes the event, some of the licensee's root causes that led to this event, some of the reasons why the NRC did not identify this condition (and similar conditions at this and other facilities) through its regulatory processes prior to the event, and the improvements being considered to enhance these NRC regulatory processes.

1 THE EVENT

1.1 *What happened?*

On May 28–29, 2016, a licensee conducted an annual inspection and cleaning of their scrubber ventilation system. The scrubber is one of the main air scrubbers for the nuclear fuel conversion process and is connected to numerous processes. When the scrubber ventilation system was inspected and cleaned, a large mass of material was found inside the large attached ventilation ducting and subsequently within the scrubber body itself. At the time, the licensee believed that the uranium concentration of the material removed from the scrubber was low. The licensee removed the material and sent samples for analysis of the composition. The licensee received the results of the initial lab analysis on May 30, 2016, which indicated a significant concentration of uranium. The licensee did not fully consider the results and restarted operation of the system. Over a month later, on July 13, 2016, the licensee received the results of additional lab analyses that confirmed the earlier results indicating that the concentration of uranium was almost fifty percent (50%) and significantly exceeded the Criticality Safety Evaluation (CSE) mass limit for the process. The licensee reported the event to the US Nuclear Regulatory Commission (NRC) on July 14, 2016.

1.2 *Why is this important?*

This event did not result in a criticality. However, because there were no physical controls or measures available to prevent a criticality (i.e., all controls and measures failed to prevent the accumulation of uranium significantly above the CSE mass limit), this event represented a significant safety concern. The subsequent discovery of similar conditions at this and other fuel fabrication facilities has reinforced the need to address the concerns and weaknesses raised by this event in both the licensees' and regulator's processes.

2 ROOT CAUSES FOR THE EVENT

2.1 *What led up to this event?*

Throughout a period of more than a decade before the event, a combination of process changes, analysis assumptions, and operational approaches created the environment for this uranium accumulation event, including the licensee's slow response, poor decision making, and delayed reporting.

In 2002 this scrubber replaced another scrubber and over a number of years ventilation discharges from other processes were rerouted to this scrubber. The scrubber was originally designed to scrub acidic off-gas; however, many of the current feed streams contain ammoniated (basic) off-gas.

The feed streams all tied together through a network of ventilation ductwork of various diameters to a large diameter section before entering the transition section of this scrubber, reducing the linear velocity of the flow and allowing greater reaction time between the scrubber solution and the incoming feed streams.

In June 2009 the licensee implemented a new safety basis for the scrubber ventilation system that lowered the CSE mass limit by more than a factor of 60 and installed expansion plenums on a vent line, which the licensee assumed would reduce the amount of particulates that would travel to the scrubber. However, the licensee never considered the potential for the uranium to accumulate in a chronic fashion within the scrubber ventilation system. Further, the licensee incorrectly assumed that only minor amounts of uranium powder were expected to accumulate in the scrubber ventilation system. In December 2009 the licensee identified significant accumulation and performed additional modifications to remove an ammonia line. In 2010 the licensee instituted periodic cleaning of various processes. In April 2015 the licensee revised a procedure and included a note that based on "past experience the [percentage of uranium] of the trapped powder is approximately 45–48%."

Material buildup was still periodically observed and in April through May of 2016 large slabs of material would become dislodged during pressure washing and fall into the scrubber ventilation transition section. The operators were directed to continue to pressure wash the material so it would dissolve. Though not the desired result, it was fortuitous that the material did not dissolve, because the insoluble ammonium-uranyl-fluoride mixture prevented the formation of a critical mass configuration.

2.2 *Why did the licensee choose not to report the event immediately?*

In accordance with the regulations, licensees should report an event to the NRC within one hour in which there are no Items Relied On For Safety (IROFS) available and reliable to perform their function that results in the failure to meet specified regulatory performance criteria. On May 30, 2016, the licensee received the results of a sample taken from the material removed from sections of the scrubber ventilation system that indicated high uranium concentrations. However, on May 31, 2016, the nuclear criticality safety engineer, unaware of the sample results and assuming low uranium concentration, declared that the accumulated material did not challenge the CSE mass limit. As a result, the licensee did not immediately perform a detailed evaluation to determine whether the material discovered could have exceeded the safety basis.

On June 1, 2016, after completion of the cleaning activities, the nuclear criticality safety engineer communicated to the process engineer that there were no issues from the NCS group with restarting the scrubber ventilation system. Even though the process engineer was aware of the sample result that clearly indicated the CSE mass limit had been exceeded and a detailed evaluation of the credited controls (i.e., IROFS) was needed (because it had failed to prevent the accumulation), the licensee restarted the system. Only after receiving additional lab results confirming the high uranium concentration did the licensee stop the process and report the event to the NRC on July 14, 2016.

2.3 *What were some of the root causes for the event?*

Fundamentally, because the licensee's configuration management program did not ensure that design and physical changes to the scrubber ventilation system and associated controls (i.e., the designated IROFS) were properly designed and implemented to prevent adverse impact to the scrubber ventilation system safety basis, material accumulated that reduced scrubber efficiency by increasing the amount of uranium carryover to the system and generating insoluble uranium bearing compounds. Complex chemical interactions from various input streams created ammonium uranyl fluoride, which is mostly insoluble in water and plated out on the scrubber ventilation surfaces and within the scrubber body. Over time, the assumptions in the licensee's safety basis became invalid.

Furthermore, although the licensee conducted periodic inspections of the ventilation ductwork and was detecting material accumulation, they did not effectively use procedures to weigh and sample the uranium concentration in the material collected, undermining their ability to properly evaluate scrubber performance. Since scrubber ventilation system visual inspections did not effectively detect and remove significantly concentrated uranium from the system, eventually the established CSE mass limit was exceeded.

The licensee completed its own root cause evaluation in October 2016 and identified two root causes and two contributing causes for the event.

Root Cause 1: Programmatic controls for configuration management did not have the rigor to mitigate increased uranium accumulation in the scrubber ventilation system when design changes were made to the system and when operational requirements for the scrubber spray system were changed in the procedure.

Root Cause 2: Management did not scrutinize the content of the CSE and as-found conditions in the scrubber ventilation system with

the questioning attitude and conservative bias required for a healthy nuclear safety culture. Further, management did not ensure the organization had sufficient procedures and training to recognize and respond to deviations from the safety basis described in the CSE.

Contributing Cause 1: Operating experience and the corrective action processes were not effectively used to pursue the actions needed to detect, estimate, and mitigate deposited uranium in the scrubber ventilation system.

Contributing Cause 2: The scope of licensee audits and assessments did not provide a comprehensive review of the nuclear criticality safety program with an appropriate level of intrusiveness as is applied to higher risk activities.

The licensee's root cause analysis team also concluded that the event occurred due to long-standing weaknesses in the safety culture at the facility. The organization did not exhibit the behaviors expected to recognize that nuclear work is unique and that complex technologies can fail in unpredictable ways, resulting in adverse latent conditions not being recognized. Weaknesses in this pattern of thinking contributed to invalid assumptions and non-conservative decisions not being challenged. As a result, CSE mass limits were not well communicated and instructions for verifying the effectiveness of criticality controls were not well established. The licensee's root cause analysis team also identified a number of corrective actions to prevent either recurrence or significant consequences.

3 THE POTENTIAL FOR THIS EVENT WAS NOT FLAGGED BY THE REGULATORY PROCESSES

While the facility conditions and the licensee's initial responses to the conditions indicate a breakdown in their processes and programs, the NRC's overall response to the event was appropriate and as to be expected. An Augmented Inspection Team (AIT) was chartered on July 28, 2016, to: 1) review the facts surrounding the failure to maintain the CSE mass limits and controls in the scrubber ventilation system and the potential for similar failures in other production areas using the same control protocols, 2) assess the licensee's response to the failures, and 3) evaluate the licensee's immediate and planned long-term corrective actions to prevent recurrence. Performance issues identified by the AIT were submitted for additional NRC inspection follow-up and further review and enforcement activities followed normal regulatory processes.

In addition, as part of the NRC's overall platform of continuous improvement, NRC management initiated a lessons-learned activity to explore opportunities for improving NRC regulatory processes in identifying facility operational issues and preventing such events in the future. The team was chartered on October 28, 2016, to evaluate five areas: the licensing process, the inspection program, the operating experience program, roles and responsibilities, and knowledge management. The first two areas (licensing and inspection) are specific programmatic areas that periodically interface with the licensee and their analyses and programs. The other three areas (operating experience, roles and responsibilities, and knowledge management) support improving the capability, efficiency, and effectiveness of the regulatory staff in performing their responsibilities in the first two areas.

The team reviewed numerous documents related to each of the evaluated areas, including licensing review staff guidance, inspection procedures, and management directives, and also reviewed documents directly associated with the event, including the AIT report, an information notice, and a confirmatory action letter. The team also conducted individual and group interviews of nearly all project managers, technical reviewers, inspectors, and managers within the NRC's fuel fabrication arena, including the highest level of management within the region responsible for inspection of these facilities.

Through this effort, the team made a number of specific observations and recommendations associated with each evaluation area. The team issued its report on January 31, 2017, and many of the observations are summarized in the following subsections.

3.1 *The first opportunity comes during facility licensing*

These facilities are typically large process facilities with numerous individual processes and associated analyses. There is significant review effort expended during licensing and license renewal. Much of this effort ties to fully understanding the facility and its processes and the review of the licensee's identification and control of the multitude of hazards associated with these processes. A significant focus of the review is on the potential for criticality events, but detailed reviews are not performed for all areas. Instead, consistent with the licensing review staff guidance, reviewers primarily review the overarching facility safety program (a "horizontal review") and sample specific areas for more detailed ("vertical slice") review. This prioritization of the scope, focus, and detail of review is based on many aspects, including operating experience and reviewer experience, but also relies heavily on the perceived risk associated with the process as conveyed by the

licensee's Integrated Safety Analysis (ISA). In fact, the current licensing review staff guidance specifically states that the reviewers should more closely review processes and systems with a relatively high unmitigated risk than processes and systems with low risk. In the context of this event, the scrubber ventilation system was considered low risk by the licensee based on the assumptions: 1) that only minor amounts of uranium powder were expected to accumulate in the scrubber ventilation system, 2) low uranium concentration would be present within the scrubber ventilation system, 3) minimal amounts of small uranium particles were entrained within the intake ventilation ductwork, and 4) the scrubber constantly diluted the uranium concentration with the addition of makeup water during normal operation and anticipated upsets. These assumptions by the licensee are reflected in their ISA and established controls (i.e., IROFS).

The NRC licensing review staff guidance does not establish the level of review for processes and systems determined by the licensee to be low risk. Further, there is no specific guidance for reviewing processes and systems determined to be low risk that rely heavily on licensee assumptions. This lack of guidance resulted in the reviewers not reviewing this system in any depth during the prior facility license renewal. As a result, during the prior license renewal and amendment reviews, the reviewers did not challenge the overall performance of the system and related controls, including the assumption of low accumulation.

3.2 *The inspection program complements licensing*

One of the main purposes of the inspection program is to confirm continued compliance with the regulations and conformance with the approved license. Similar to the license review process, it is not practical to perform entire facility inspections, but rather, inspectors use a sampling approach. This approach is particularly relevant for facilities that do not have resident inspectors, which is the case for the subject facility (i.e., NRC inspectors are not located at the facility on a daily basis). For these types of facilities, over the year, inspectors visit the facility periodically to inspect specific programmatic aspects of the license, such as plant modifications, fire protection, operational safety, etc.

Similar to the license review process, the current inspection focus is on perceived high risk areas of the facility, which is based on the licensee's ISA. Because the licensee considered the scrubber ventilation system to be low risk, as stated above, the NRC did not consider this system for detailed inspection. Several inspectors noted that had the system been part of a detailed inspection, the licensee's deficiencies in the CSE and implementation of associated management measures and controls would likely have been identified.

Various inspection procedures appear to recognize that inspectors should examine presumably low risk processes and systems, but again, very limited guidance is provided on how to select samples from such processes and systems or the focus of such inspections.

3.3 *Operating experience could have provided insight and focus on this system*

Operating experience can be a valuable tool to help provide additional input to determining the appropriate focus and scope of facility areas to review and inspect. However, most license reviewers and facility inspectors did not rely upon the fuel fabrication facility operating experience program, which had previously been identified as needing to be improved. In fact, most inspectors and many reviewers were not aware of the fuel fabrication facility operating experience database or did not know how to access it. For those that were aware of the database, they observed that the database contained only relatively recent, publically available, US data and were unsure if it could trend events to support use in inspection planning. Furthermore, while a criticality inspection procedure had recently been revised to include the consideration of operating experience in inspection planning, other inspection procedures did not give any formal, structured guidance on considering operating experience. All of these conditions were considered to limit the usefulness of the operating experience database to the license reviewers and facility inspectors.

3.4 *Understanding roles and responsibilities*

Understanding individual and organizational roles and responsibilities is key to efficient and effective regulatory reviews and inspections. At the NRC, the licensing reviews are performed within one organization located near Washington, DC, while the inspections are performed within another organization located in Atlanta, Georgia. Communication and collaboration is essential in ensuring full understanding of licensing reviews and their implications for the inspection regime, especially when the organizations are physically separated by such a great distance.

The licensed facilities are required to provide annual summaries that describe the prior year's facility and process modifications and separately updates to their ISAs. These summaries can be, and are expected to be, used to inform inspection planning for the subsequent year. In the past, the

NRC licensing organization primarily performed the review of these summaries and provided its input to the NRC inspection organization, but in 2016 the NRC changed the lead role for the ISA summary reviews to the inspection organization to avoid overlapping efforts. However, the expectation of obtaining insights from the facility licensing review project manager and technical staff in these annual submittal reviews was not clearly established. Likewise, it was recognized through the lessons learned effort that the licensing review staff guidance did not clearly establish an expectation for obtaining insights from the inspection organization. In both cases, the potential for missing valuable insights was identified since the regulatory guidance did not establish a formal expectation for the various regulatory staff to collaborate in these areas.

3.5 *Knowledge management*

It is recognized that knowledge management is inextricably linked to all the other areas evaluated by the lessons learned team. It is an element critical to performing technical evaluations of licensee submittals, selecting relevant inspection samples, administering a successful operating experience program, clearly understanding respective roles and responsibilities, assessing the significance of an event, etc. Most of the lessons learned team recommendations involve some aspect of knowledge management. However, the lessons learned team did identify some fundamental knowledge management issues.

The current licensing and inspection qualification programs rely heavily on documentation reviews supported with some coursework and site visits. Certain skills that are important to regulatory staff success, however, are mostly left for the staff to pursue outside the qualification program, such as critical thinking, effective communication, and conflict resolution. All of these aspects require continuous practice and reinforcement and are invaluable when performing license reviews, conducting inspections, and interacting at all levels of the organization.

In addition, ensuring all regulatory staff are kept informed of current (and periodically reminded of past) licensing, inspection, operational, and technical issues improves the understanding and ultimately, performance of the regulatory staff and organization as a whole. While the inspection organization held periodic knowledge management seminars of selected topics, such a program was not being fully implemented within the licensing organization. As a result, lessons learned by some regulatory staff were not being effectively shared among all the other regulatory staff.

4 LESSONS LEARNED TEAM RECOMMENDED IMPROVEMENTS TO THE REGULATORY PROCESSES

The lessons learn team recommended improvements in all five regulatory areas. Most recommended improvements are associated with the verification of the technical bases and assumptions in the licensee's ISA and improving the knowledge bases and resources used by the reviewers and inspectors.

For the license review process, the lessons learned team identified for further evaluation the need to clarify the licensing review staff guidance to include guidance on the examination of the technical justification for processes and systems designated as low risk, especially those justifications related to key analysis assumptions.

For the inspection program, the team identified for further evaluation the need to modify the scope and focus of inspections so that all facility processes and systems with the potential for intermediate and high consequences are inspected within some periodicity, regardless of perceived risk significance. The team also suggested the development of additional guidance associated with reviewing and using the summaries of facility modifications and licensee ISA updates in support of inspection planning. Such additional guidance could also focus specific inspections on these analyses, with the intent of verifying the continuing validity of the technical bases and assumptions of the analyses.

For the operating experience program, the team identified for further evaluation the need to improve the framework and guidance for the flow of information from this program to the licensing and inspection programs. Related to the fuel fabrication facility operating experience database, the team suggested enhancing access to the database so that the information is more readily available to the licensing review staff and inspectors and to include legacy and international operating experience so that the database is more complete.

For the area of roles and responsibilities, the team suggested for further evaluation improving the guidance related to using the licensee's annual submittal of summary descriptions of facility modifications and ISA update summaries in inspection planning, setting the expectation to gain inspector facility knowledge and experiences within the licensing process, and providing rotational opportunities between the licensing review staff and inspectors to foster a better understanding of the diverse roles and responsibilities.

Finally, the need for improving knowledge management within these regulatory organizations is pertinent to all the above aspects. The team specifically identified for further evaluation the need to improve the qualification programs for the

licensing review staff and inspectors, to implement continuous knowledge management activities, such as regularly scheduled seminars and debriefings on topics of interest, and to periodically perform systematic reviews of the licensing and inspection programs to identify gaps and support continuous improvement.

5 CONCLUDING COMMENTS

The NRC created an action plan to guide and track the evaluations of the recommended improvements identified by the lessons learned team and their subsequent implementation, as appropriate. Some activities, such as the operating experience database, had previously been identified as needing to be improved and were already in the early implementation stages. Other activities involve additional considerations (e.g., priority, schedule, budget, and potential benefit) and are being evaluated and implemented, as appropriate. Through these efforts, the regulatory programs should improve, be more effective and efficient, and enhance the assurance of safety of the facilities.

Risk management for a particle therapy accelerator: The MedAustron experience

R. Filippini & P. Urschütz
EBG MedAustron GmbH, Wiener Neustadt, Austria

ABSTRACT: The Austrian facility MedAustron is one of the most advanced centers for ion beam therapy and research in the world. The MedAustron Particle Therapy Accelerator (MAPTA) is a CE-certified Class IIb medical device. Safety is the core attribute to be achieved, assessed and maintained during the entire system lifecycle. This paper tells about the experience of certifying a large particle accelerator as a medical device, from the risk management point of view. Examples of the different risk management activities are given, in order to explain the way the risks have been analyzed, controlled and evaluated.

1 INTRODUCTION

The MedAustron Particle Therapy Accelerator (MAPTA) is a CE-certified Class IIb medical device in compliance with the Medical Device Directive MDD 93/42/EEC [1]. The facility consists of four irradiation rooms, three for clinical operations (two horizontal and one vertical beam lines, one Gantry) and one for non-clinical research (one horizontal beamline). The layout of the accelerator complex is shown in Figure 1. The beam particles are generated in the ion source(s). They are pre-accelerated in the Linear Accelerator (Linac) and accelerated to the requested energies in the 80 meter-circumference Synchrotron ring, before being extracted and delivered into the irradiation rooms.

The maximum beam energies for patient treatment are 250 MeV/u and 400 MeV/u for proton and carbon ions respectively. For non-clinical research, beam energies up to 800 MeV/u can be generated. Compared to conventional radiotherapy with photons (gamma rays, X-rays) or electrons, the treatment with protons and carbon ions has a more precise dose distribution (i.e. the Bragg peak) and reduces damage to the adjacent healthy tissues significantly. This makes it possible to deliver much higher doses, with greater benefits for the patient, but also presents safety concerns, which have to be addressed by risk management.

Figure 1. MAPTA layout.

In general, the risk management for particle therapy accelerators and particle accelerators has relatively little literature, for several reasons. First, this depends on the size of the accelerator; only at high energies the consequence of a malfunction becomes relevant for costs and human lives for non-medical applications. Secondly, the particle accelerators are often research facilities, and this allows a larger degree of freedom of addressing safety without a risk management process. As a third reason, even if risk management is in place, there are restrictions that limit the dissemination of results. Because of that, most of the existing studies deal with reliability and availability, which are related to uptime and performance, and only a few of them included safety and risk in scope. The CERN Large Hadron Collider is within these exceptions. The LHC operates at very high beam energies (7TeV) and it is designed to deal with potentially catastrophic scenarios, e.g. beam losses and quench of the superconducting magnets with damage to equipment and interruption of operations for several months [1]. Several reliability and safety studies have accompanied its design and realization [3, 4, 5, 6]. Within the domain of particle therapy accelerators, a few studies exist, which are of great interest. A Probabilistic Risk

Assessment (PRA) has been performed for the PROSCAN proton therapy accelerator of the Paul Scherrer Institute [7] and similar analyses for radiation sources can be found in the IAEA report [8].

This paper presents the risk management for the particle accelerator MAPTA of MedAustron. The content of the paper is organized into five sections. Following this introduction, Section 2 contains the functioning principles and the safety architecture of MAPTA. The risk management framework is in Section 3, including the regulations and standards, the hazards of concern, the risk metrics and the acceptability criteria. Section 4 contains the description of the risk assessment activities, as well as several examples. A few concluding remarks are contained in Section 5.

2 MAPTA SAFETY ARCHITECTURE

2.1 *Functioning principles*

MAPTA produces ions beams of a given energy and intensity for the irradiation of the tumor, as specified in the patient treatment plan. A complete patient treatment consists of between 20 to 40 sessions, each with a total duration of about 30–40 minutes including a few minutes of irradiation time, depending on the tumor indication.

A treatment irradiation session starts after MAPTA has been handed over to the user (medical physicists and doctors), who has the responsibility of supervising the operations from the control room of the irradiation room. The entire irradiation process is automated. The MAPTA Medical Frontend (MF) system administers the irradiation according to a predetermined timing sequence. The scanning of the tumor target volume and the dose delivery is conceptually simple: the MF system switches on the chopper kicker magnet and actuates the switching dipoles to let the beam travel from the synchrotron into the irradiation room and then through the nozzle into the target volume. The beam scanning is done in "iso-energy slices", in order to deposit the required radiation dose at different positions and depths (higher energy = deeper penetration). During the irradiation, the MF system supervises the functioning of all components and monitors the beam parameters (intensity, position, energy, dose, etc.). Any possible malfunction, deviation out of tolerable limits or unauthorized action, triggers the interruption of treatment for safety reasons.

2.2 *Safety architecture*

The safety architecture in MAPTA covers three different domains: 1) access protection, 2) interoperability of the irradiation rooms and 3) patient treatment.

The MAPTA access protection system guarantees the "safe access and stay" in the accelerator areas and irradiation rooms for technical and medical personnel. Two states, "Green" and "Red", are defined. When the state is Green, the respective area/room is accessible. All radiation sources are turned off and the beam stoppers (or equivalent devices) prevent the beam from reaching the accelerator area or the irradiation room. When the state is Red, the beam can be sent into the respective area/room, and the accesses are locked. The violation of the Red state (e.g. unauthorized access) triggers an interlock which activates the Green state for the respective area or irradiation room, immediately stopping the beam and shutting down all radiation sources.

The second safety domain covers the risks that are caused by the simultaneous use of the irradiation rooms. Two operation modes per room are defined: 1) physics and accelerator (e.g. for commissioning, maintenance, and test) and 2) medical (for clinical operation). For safety reasons, certain combinations of the operation modes are not allowed and they are vetoed. Moreover, certain activities cannot be executed when in clinical operation. For example, if one irradiation room is in medical mode, none of the others irradiation rooms may be in the physics and accelerator modes. In case of violation of the veto, an interlock is triggered with subsequent beam stop and interruption of the treatment.

The third safety domain covers the risks during patient treatment. The goals are to guarantee that 1) MAPTA is correctly configured for the treatment plan, 2) the beam physics characteristics (energy, intensity, position, width) are within acceptable limits and 3) the dose is correctly delivered (i.e. the correct dose at the right time, into the right irradiation room). Most of the risk control measures are implemented in the MF system or other systems that assure an equivalent safety level. In case of detected errors, the beam is sent into the beam dump and the treatment is interrupted.

2.3 *Safety principles*

The architecture of MAPTA meets the "single fault safe" principle, which states that "a combination of two independent errors must not lead to a life-threatening situation" for the patient [9]. This principle requires a number of design features to be implemented in MAPTA, e.g.:

- Fail-safe behavior,
- Independency of risk control measures,
- Acknowledgement of a safety action,

- Alternative means or independent back-ups,
- Integrity of risk control measures.

The fail-safe behavior makes it impossible for a failure to develop in an unsafe way. For example, the selection of an incorrect source is fail-safe because it is impossible for the synchrotron to accelerate an ion species different from the one for which it is configured (e.g. protons instead of carbon ions and vice versa). A power supply failure is fail-safe for all MF components, e.g. it causes the demagnetization of the chopper magnet and the resulting beam dump. A pressure leakage in the beam stopper cylinders drops the shutters into the beam line by gravity, which again is fail-safe. The logic levels of the electronics are fail-safe in the case of loss of signal, and so forth.

Another important design feature is the independence of the risk control measure and the supervised system. This is guaranteed by hardware separation and/or software segregation, to avoid possible common causes of failure.

The result of the execution of a risk control measure is acknowledged and, in case of a fault, other risk control measures are triggered to complete the safety action, e.g. if the beam is still detected after the actuation of the chopper magnet, or if the position of the beam stoppers is still out of the beam path. The functioning of risk control measures is also verified before the start of every patient treatment session. This is guaranteed by functional tests and internal self-diagnostics. In addition, periodic checks are performed for the integrity of the risk control measure, e.g. by discovering dormant faults in redundant components.

2.4 *Hazardous situations and reaction times*

The majority of the hazardous situations in MAPTA develop in the order of milliseconds to a few seconds, depending on the causes and the circumstances. As a consequence, every risk control measure must have a suitably fast reaction time. All risk control measures are implemented in electronics and electro-mechanical components, including the back-up measures, which intervene in case of failure. The operators and the users are seldom called upon to respond to hazardous situations, unless they have a longer time of development for which the human reaction time is compatible and effective.

3 THE RISK MANAGEMENT FRAMEWORK

3.1 *Regulations and standards*

Medical devices have to comply with a complex and articulated sets of regulations, norms and standards. The Medical Device Directive MDD 93/42/EEC stipulates the manufacturers' responsibilities to consider all safety aspects and to be able to address them.

The Directive states that: *"the (medical) devices must be designed and manufactured in such a way that, when used under the conditions and for the purposes intended, they will not compromise the clinical condition or the safety of patients, or the safety and health of users or, where applicable, other persons".*

It continues: *"the solutions adopted by the manufacturer for the design and construction of the devices must conform to safety principles, taking account of the generally acknowledged state of the art. In selecting the most appropriate solutions, the manufacturer must apply the following principles in the following order:*

- *eliminate or reduce risks as far as possible (inherently safe design and construction);*
- *where appropriate take adequate protection measures including alarms if necessary, in relation to risks that cannot be eliminated;*
- *Inform users of the residual risks due to any shortcomings of the protection measures adopted."*

The above stipulations are extensively explained in the EN ISO 14971:2012 [10] regarding what concerns risk management. The safety requirements are defined in medical device standards, such as the general standard IEC 60601–1 [9], the safety standard IEC 60601–2-64 [11], the medical software standard IEC 62304 [12], the standard for medical IT networks IEC 80001–1 [13] and the IEC 62366 [14] for usability engineering. Industrial safety standards that are applied for MAPTA are the IEC 61508 with the derived IEC 62061 and ISO 13489 [15, 16 and 17]. The list is not complete and many other standards apply, which focus on a particular technical domain, e.g. the ÖVE/ÖNORM E-8001 [18] for electrical hazards.

3.2 *Scope of the risk management*

The risk management is performed throughout the entire life cycle of MAPTA, from the design to the decommissioning. While safety is the main goal, the manufacturer shall also take into account reliability and uptime, which eventually affects the performance, i.e. uptime and the patients' throughput. This is a well-known trade-off in safety engineering. Risk management also takes into account the interdependencies of MAPTA with the systems at the interface, such as the patient positioning system, the technical infrastructure and the IT network. The user activities related to the preparation of the treatment plan, accommodation of the patient, imaging, and supervision of treatment are out of scope.

The risk manager is responsible for the risk management process. The outcomes of the risk management process are reviewed by a team of experts, which includes representatives of the top management, accelerator technologists, medical physicists, and radiation oncologists.

3.3 *Hazards and categories of risk at MedAustron*

The EN ISO 14971 defines the applicable hazards and the categories at risk for MAPTA. The categories of risk are the patient, the user of MAPTA, the technical and medical personnel, the equipment, the environment and third persons (i.e. anybody not involved in the patient treatment, operation and/or service of MAPTA). The goal is to assure that all applicable combinations "hazard versus category of risk" are in scope of risk management. Table 1 provides an excerpt of the list of hazards (radiation, electrical, etc.) that apply to the categories of risk patient, personnel/user and environment for MAPTA, including the applicable standards.

3.4 *Risk metric and acceptance criteria*

The risk metric for MAPTA is the Risk Priority Number (RPN) [10]. The RPN is the product of the probability P and the severity S of a hazardous situation, i.e. $RPN = P \times S$. Six frequency intervals for P are defined in MAPTA:

- P = 1: Incredible;
- P = 2: Unlikely;
- P = 3: Seldom;
- P = 4: Occasional;
- P = 5: Often;
- P = 6: Frequent.

and five severity levels for S:

- S = 1: negligible;
- S = 2; minor;
- S = 3: moderate;
- S = 4: severe;
- S = 5: catastrophic.

Table 1. Hazards and categories of risk.

Hazards	Patient	Personnel/user	Environment
Radiation	ISO 14971	IEC 61508 IEC 62061 ISO 13489	UVP (RP)
Electrical	n.a.	ÖVE/ÖNORM E-8001	n.a.
Software	IEC 62304	n.a.	n.a.
IT	ISO 80001–1	n.a.	n.a.
Mech.	ISO 14971	ISO 14971	n.a.
Use	IEC 62366	IEC 62366	n.a.
…			

The frequency intervals for P and the levels for S are chosen in agreement with the risk management standard and the current state-of-the-art [10, 19, 20].

The acceptability criteria are applied by defining two risk thresholds. A risk is acceptable if $RPN < 10$, while it is not acceptable if $RPN > 12$. Risks with RPN between 10 and 12 (inclusive), and that cannot be reduced further, are evaluated by risk-benefit analysis. These risks are acceptable if the benefit for the patient outweighs the residual risk.

4 RISK ASSESSMENT FOR MAPTA

4.1 *Scientific rationale*

The risk assessment includes the activities of risk analysis, risk control and the risk evaluation. These activities are performed in sequence, one after the other, as shown in Figure 2. The Failure Mode, Effects and Criticality Analysis, FMECA, is the methodology for risk assessment [21] for all systems and components in MAPTA. The only exception is the access protection system, for which a

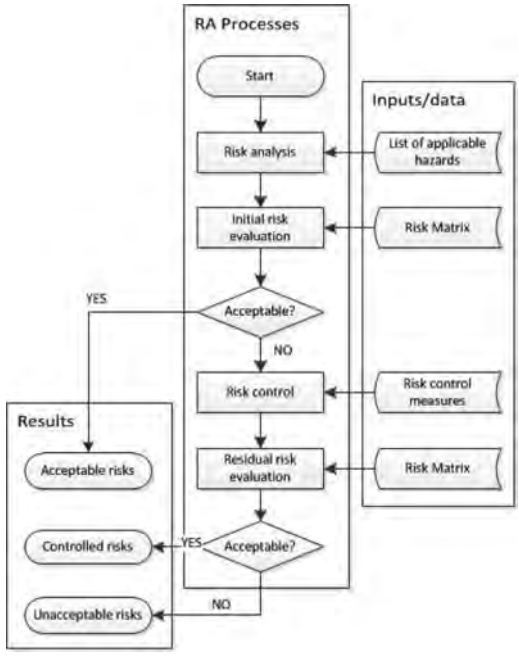

Figure 2. The risk assessment process workflow.

different method applies, as well as a different risk metric, the Safety Integrity Level (SIL) [15] instead of the RPN.

The FMECA is an inductive system analysis method. It uses the natural language to describe the hazardous situations, which has the advantage of facilitating the communication between the risk analyst and the system experts. Another advantage is that the analysis with FMECA is semi-quantitative, i.e. instead of precise failure statistics, probabilities are chosen within predefined intervals. This feature makes the risk assessment relatively easy, but also turns out to be a limitation in comparison with other methods of system/risk analysis, e.g. fault tree, which is more accurate. Another limitation exists for the analysis of common causes of failures. These drawbacks are known and have been addressed in MAPTA by ad-hoc risk assessment guidelines that assist the analyst during the compilation of the FMECA. The guidelines provide a comprehensive methodological approach and guarantee the correctness and consistency of the results.

4.2 *Risk analysis*

The risk analysis consists of three activities: definition of the hazardous situations, risk estimate and risk evaluation.

The first activity describes the failure dynamics as a causal chain of events, "initial cause → error → fault → failure → malfunction" that, together with the circumstances, lead to the hazardous situation. The more accurate the description of the causal chain is, the more effective the apportionment of the risk control measures.

The second activity makes it possible to estimate of the initial RPN. The estimate is done without considering the risk control measures. The MAPTA risk assessment guidelines provide empirical look-up tables with intervals of probabilities for the different classes of faults or errors (e.g. HW/SW faults, human errors, etc.). Analogous tables are also available for the severity. The analyst chooses the initial RPN within the suggested probability and severity intervals, for the worst case scenario. The last activity of the risk analysis is the evaluation of risks against the acceptability criteria. Those risks that are non-acceptable, i.e. RPN > 10 shall be mitigated by risk control measures.

4.3 *Risk control*

The EN ISO 14971 defines three types of risk control options: 1) inherent safety, 2) preventive/protective and 3) information for safety. Each of these risk control options has a different effectiveness, e.g. by avoiding, preventing or stopping a hazardous situation, see Table 2. Inherent safety is the most effective among the control options. It prevents the hazardous situation from developing. Preventive measures intervene while the hazardous situation is developing, while protective measures intervene when the hazardous situation has already developed and for example, it represents a real harm for the patient. Information for safety is the least effective of the risk control options. It includes organizational measures such as instructions for operators and users of MAPTA.

Table 2. Risk control options in MAPTA.

Risk control measure	*Effect to the hazardous situation*
Inherent safety (physical)	Make it physically impossible
Inherent safety (logical)	Make it logically impossible
Inherent safety (failsafe)	Turn it into failsafe
Preventive	Detect and stop development
Protective	Detect and stop at occurrence
Information for safety	Contribute to prevent/avoid

The MAPTA guidelines contain the rationale for the application of the risk control measures and the estimate of the risk reduction. This rationale follows a few general recommendations from the risk management standard and best practice. The risk control measures have to be applied altogether and not in isolation (EN ISO 14971). Secondly, a risk control measure has to be associated with the respective failure event (as identified in the causal chain). In addition, they have to be applied in the right sequence, i.e. inherent safety first, then organizational measures, preventive and protective measures. Finally, failure dynamics and the risk control measures have to be considered (and analysed) as interrelated processes. The model that supports this description is an event sequence diagram. An illustrative example is shown in Figure 3 for a hazardous situation with three risk control measures.

A risk control measure is "successful" if it prevents the hazard from developing and leads to the "end state", while it is "unsuccessful" if the hazard can develop further. In terms of P and S this means:

- Successful: P does not change, S is lower:
- Unsuccessful: P is lower, S does not change.

The amount of reduction of P depends on the type of risk control measure. The reduction of the severity S depends on the instant at which the risk control measure intervenes. If this is before the hazardous situation becomes a real harm, then the severity drops down to S = 1 (no harm), see End

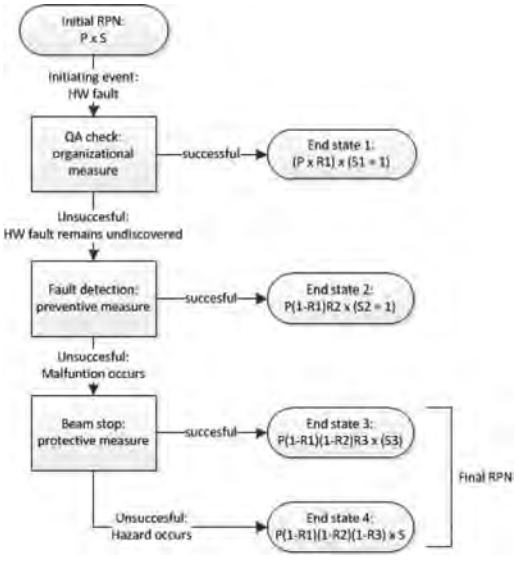

Figure 3. The risk reduction model.

states 1 and 2 in Figure 3. On the contrary, if it occurs at a later stage, then the residual severity could be higher, which is the case of End state 3.

The residual risk (i.e. the final RPN) is the risk after all risk control measures have been applied. Because the risk is reduced by a certain amount after the execution of a risk control measure, the residual risk is the highest RPN associated with the end states of the last risk control measure, e.g. End states 3 and 4 in Figure 3. In the example, End state 3 has a residual severity related to the extra dose deposited, before the beam is stopped by the protective measure. The estimate of the residual severity shall take into account: 1) the type of particles (e.g. carbon ions are heavier than protons), 2) the detection threshold of the protective measure, and 3) the reaction time, up to the complete beam stop. The limits for the maximum extra dose are defined in the standard IEC 60601-2-64, both under normal and fault conditions [11].

The amount of risk reduction is calculated in the risk assessment guidelines of MAPTA by look-up tables for every risk control measure. Figure 4 shows the risk reduction table for a preventive risk control measure. The calculation of the risk reduction is straightforward. The initial RPN = P × S identifies the cell in the table with the residual risk after the application of the risk control measure, e.g. RPN with P = 4 and S = 5 becomes RPN = 2 × 5. If more risk control measures apply, then the output of one risk reduction table becomes the input of the next risk reduction table and so forth.

Probability	Severity 1	2	3	4	5
6	3x1	3x2	3x3	3x4	3x5
5	3x1	3x2	3x3	3x4	3x5
4	2x1	2x2	2x3	2x4	2x5
3	2x1	2x2	2x3	2x4	2x5
2	1x1	1x2	1x3	1x4	1x5
1	1x1	1x2	1x3	1x4	1x5

Figure 4. The risk reduction table for preventive measures.

4.4 *Risk evaluation*

The risk evaluation is the final activity of the risk assessment. All individual risks are evaluated on the basis of the acceptability criteria. After this is done, the same individual risks are re-evaluated together in order to account for statistical cumulative effects. According to the risk assessment guidelines of MAPTA, the cumulative statistical effects are estimated by counting how many individual risks are in the same cell P × S. For every N individual risks in the same cell P × S, one cumulative risk is added in the cell (P+1) × S. The threshold N depends on the order of magnitude of the interval P. The P intervals in the risk matrix correspond to orders of magnitude 1 (P = 3, 4 and 5) and 2 (P = 1, 2), which is N = 10 and N = 100. As an example, 12 individual risks with P = 3 and S = 3 would be statistically equivalent to two individual risks in 3 × 3 and one cumulative risk in 4 × 3.

4.5 *A few results*

Figure 5 shows the results of the FMECA based on the functional description of MAPTA. The scope of this FMECA is the patient treatment session. A patient treatment session consists of four phases: 1) request and allocation of the accelerator components and the irradiation room, 2) activation, 3) irradiation, and 4) termination of treatment. In total, 132 individual hazardous situations have been identified and the respective risks have been analyzed, controlled and evaluated. The analysis also includes 26 risks related to common causes of failure. All residual individual risks (and the cumulative statistical effects) have been evaluated and they are acceptable i.e. all RPNs < 10. This result is obtained by applying 90 different risk control measures in MAPTA including:

- 22 inherent safety measures,
- 39 preventive risk control measures,
- 9 protective risk control measures,
- 20 organizational measures.

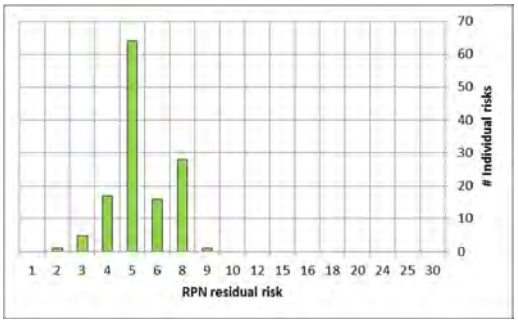

Figure 5. Distribution of the residual risks.

Another seven risk mitigations have been identified and transferred outside of MAPTA for their implementation.

The analysis of the risk control measures provides interesting insights on the MAPTA architecture for the patient safety. A risk control measure is often called for in more than one hazardous situation. Therefore, by counting the times this is required, it is possible to deduce its importance. The following statistics are obtained: the preventive measures are called for 143 times, the inherent safety measures 111 times, the organizational measures 49 times and the protective measures are called for 39 times. The preventive measures are the most required, followed by inherent safety, while the protective measures are the least required. This result is in good agreement with the general recommendation of the medical device standard, which states that hazardous situations shall be either avoided by design or prevented. Indeed, only a smaller percentage requires the intervention of protective measures.

The FMECA, based on the functional description of MAPTA, is completed by other FMECAs, which deal with risks at the system and component level. In total, more than 1700 individual risks have been analyzed and controlled in MAPTA. The overall residual risks have been evaluated and they are acceptable.

4.6 *Final reports and post-production*

The outcomes of the risk management activities and the verification by tests of the risk control measures are included in the MAPTA risk management report, which accompanies the declaration of conformity for the CE certification as a medical device. All documents produced by the risk management are organized in the respective file, which is periodically inspected by external auditors.

The risk management also covers the post-production activities, such as product changes, maintenance, commissioning and project development. These activities often require the update of the existing documents or new risk analyses, and because of that, they are constantly monitored. Reporting adverse events, errors and near misses is also within the scope of risk management. This includes the validation of the risk estimates and the estimate of MAPTA uptime, based on the operational data, as it was done, for example, in [22].

5 CONCLUSIONS

This paper presented an overview of the risk management for the particle accelerator MAPTA of MedAustron. All activities in scope of the risk management have been discussed, with several examples regarding the methodologies for the risk analysis, the risk control techniques and the outcomes of risk assessment. In total, more than 1700 individual risks have been identified, analyzed and controlled in MAPTA. The residual risks have been evaluated and they are acceptable.

The depth of this work is such that it can be barely summarized within these pages. Nonetheless, it is worthwhile sharing a few lessons learned. The first lesson learned is related to the complexity of the particle therapy accelerator on one hand, and the demanding requirements of risk management for medical devices, based on an all hazards approach, on the other hand. Complexity has been managed by the definition of different frameworks, focused on a specific domain e.g. intended use and patient safety, access protection and radiation hazards, industrial safety, etc. The second lesson learned concerns the development of the know-how. Standards for medical devices are general encompassing different applications. It is under the responsibility of the manufacturer to interpret the standard clauses, and organize risk management accordingly. A lot of groundwork has been done in this respect, with the preparation of scientific rationales, guidelines and safety concepts. Another lesson learned regards the safety culture. Risk management is a discipline that cannot be performed in isolation, and requires competencies of specialists from various fields. An essential requisite is to build adequate safety responsiveness within the different groups (engineers, accelerator and medical physicists) to be able to anticipate rather than react to potential adverse events. In order to attain these goals, risk management promotes regular exchange and dissemination of information, including training and team work. The fourth lesson learned is about the CE certification process itself. The MedAustron particle accelerator stands out among the majority of the existing particle therapy accelerators, and one of the reasons is that

risk management was part of certification process. Besides the illustration of the methodologies and the results, there is the unique experience of having dealt with a particle therapy accelerator of this size, which has challenged and possibly improved the state-of-the-art in this subject. This is one of the added values of the "MedAustron experience" in the domain of particle therapy accelerators.

Risk management was executed successfully during the phases that accompanied the certification of the particle accelerator as CE medical device, and it is presently looking after post-production activities for clinical operations with irradiation rooms IR2 and IR3 (horizontal beamlines, protons), and non-clinical operation in IR1. The vertical beamline of IR2 will be active in Spring 2018, while carbons ions are still under commissioning for a future use. The proton Gantry is planned as the last step in the commissioning sequence.

ACKNOWLEDGEMENTS

The authors are grateful to the colleagues Peter Gruebling, Gregor Kowarik, Maarten Schokker, Andreas Weinfurter and Marte Fjelland for their contribution in the risk management activities of MAPTA.

ABSTRACT: Onsite real-time video streaming of traffic accidents covering condition of inflicted person can help overcome problem of under and over-triage by emergency services. A network of Rescue Emergency Drones (REDs) that could transmit live video to emergency services is proposed to be mounted at the sites prone to frequent accidents in Denmark. A risk mapping for placement of RED docking stations at suitable places of southern Danish city, Esbjerg and its outskirts has been designed using Geographical Information System (GIS) tools ArcMap, and ArcGIS 10.5.1. The result demonstrates the robustness of RED into emergency services by providing high quality footage that helps to assess the scene of crash faster than the standard existing procedure.

1 INTRODUCTION

Lack of clarity of the condition of patients or injured persons can lead to wrong decision taken by Emergency Medical Dispatcher (EMD) and Emergency Medical Service (EMS). For instance, in Denmark 'Unclear Problem' of level B-E emergency was the chief complaint involving 66 deaths in period between 2011–2012. Because in many cases appropriate resources were not dispatched to handle the emergency which leads to degree of over-and under triage. (Andersen et al 2014)

Under and over-triage is a major problem that costs not only financial losses but also human lives. For instance, in Denmark 18 deaths could have been prevented if EMD had dispatched a targeted response. (Andersen et al 2014)

Drones have many applications in emergency services. For instance, drones can reach at the scene of the road accidents faster than conventional means of transportation. The aim of this study is to explore the potential benefit of a drone system to transmit live video footage covering the condition of the inflicted/patient that may improve the decision making of EMD. For application of drones in this regard, this study considered traffic accidents, because traffic accidents top the list of human casualties' statistics of non-natural cause of fatalities. Around 1.25 million people lost their lives and 20–50 million people suffered injuries due to traffic accidents. (WHO 2017)

Although Denmark is relatively safe country for commuters, there were 211 people killed, 1,796 suffered serious injuries and 1,432 suffered slight injuries in traffic accidents in 2016. (Statistics Denmark 2017)

Emergency medical dispatcher finds it difficult sometimes to comprehend the situation and condition of the emergency. First responders usually rush to the emergency sites with limited information that can sometime jeopardize the rescue operation. Therefore, if EMD and EMS can see and assess the severity of injuries of an inflicted person in traffic accident, it will facilitate a targeted response via live video footage.

The Danish Emergency Medical Communication Center (EMCC) receives medical emergency calls to respond and rescue patients and injured persons. EMCC staff responds the calls according to the Danish index care into five categories. Category "A" represents a life-threatening or potentially life-threatening condition; therefore, it requires immediate response. Category "B" means that a patient or injured person requires urgent help, but his/her condition is not life threatening, whereas category "C" requires an ambulance in a

non-urgent condition. Under "D" category EMD needs to send a patient transport while under "E" category no ambulance is dispatched instead taxi or other transportation is advised.

Category "A" has a pre-hospital time of 08:12 minutes, but sometime EMD can make a wrong decision in dispatching targeted response. In one of the case of an audit study, it was found, that EMD categorized an emergency as category B, however, when the ambulance arrived at the scene, a Mobile Emergency Care Unit (MECU) was summoned due to the severe condition of the patient. The life of patient would have been saved if the ambulance along with MECU could have been dispatched. (Andersen et al 2013) Therefore, fast response with right resources dispatched in saving human lives is crucial. The Danish pre-hospital median time for all emergencies is 10:27 minutes. (Andersen et al 2013) The average minimum response time of fire and rescue services (FRS) is 10 minutes and it could be 15–20 minutes depending on the location of accident sites. (Sydvestjysk Branvæsen 2015)

Rescue Emergency Drones (REDs) can reduce time of onsite assessment of the condition of inflicted person by reaching to the patient/injured person faster than the conventional means of transport and transmitting 'live video' that can help to cope with the problem of under, and over-triage.

2 RED NETWORK IN DENMARK

Providing visual aids by a drone will improve the prehospital process in case of a traffic accident this aim of the project will meet the need to reduce fatalities.

There are many potential benefits of incorporation of RED into emergency services and their improving the decision making as follows,

- Real time visual feed from the scene of crash will assist in better assessment of severity of the emergency by dispatcher.
- The sufficient of amount of resources will be saved by emergency services by overcoming problem of over and under-triage.
- A targeted and quick response will increase survival rate of inflicted persons.
- A targeted response will improve the quality of life by decreasing the severity of injuries of causalities and thereby saving them to live without physical impairments.
- Dispatcher would be able to better guide caller to handle emergency properly while the ambulance is on its way.
- Dispatcher can calm down the panicked caller.

Denmark map is developed in GIS based on the data of traffic accidents in Denmark between 2012–2016.

In Figure 1 the black dots represent the accidents, which are more frequent in populated areas of the country. There were 87,787 total accidents in Denmark recorded between 2012 to 2016 (Danish Road Directorate 2017). Majority of the accidents are reported in bigger cities for instance, Copenhagen, Odense, Aarhus and Aalborg.

Based on the audit study it is assumed that the onsite live video streaming aid would help to mitigate the consequences of accidents. For visual aid, network of REDs is proposed for Denmark. For RED network Esbjerg municipality is considered as a case study with the broader application for the rest of the country.

2.1 *Esbjerg municipality*

This study is carried out in Esbjerg municipality, which covers a total area of 794.5 km² (Sydvestjysk Brandvæsen 2015). The total population of Esbjerg municipality is 115,905. (Statistics Denmark 2017) The density of the population is 116 (individual/km²). The municipality consists of both rural and urban areas. Esbjerg municipality observed 2,515 total number of traffic accidents between 2012 and 2016. The accident data is extracted from the Danish Road Directorate and accidents coordinates are shown in the following Esbjerg municipality map.

Most of the accidents were recorded in the residential area. A total *of n* = 2515 cases of traffic accidents were reported in Esbjerg municipality between 2012 to 2016. The traffic accident casualties during this period are given in Table 1.

Table 1 shows that in 2016 total 63 casualties were recorded, among them six persons were killed, 38 injured seriously and 19 were injured slightly. One death due to traffic accidents costs Danish society up to 17.3 million DKK. (Transportministeriet 2010). To avoid such a huge loss, it is necessary to improve the pre-hospital response

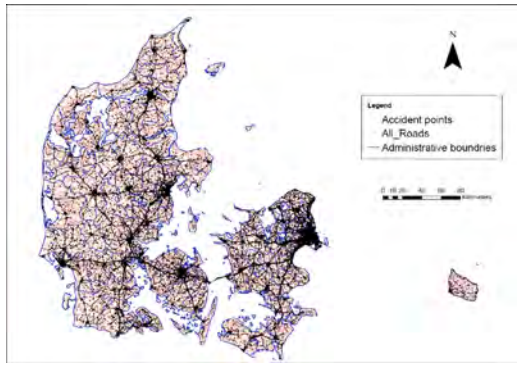

Figure 1. GIS mapping of traffic accidents coordinates on Danish roads.

Table 1. Traffic accidents casualties in Esbjerg municipality.

Years	Casualties, total	Killed	Seriously injured	Slightly injured
2012	102	7	49	46
2013	61	1	32	28
2014	83	2	47	34
2015	86	7	42	37
2016	63	6	38	19

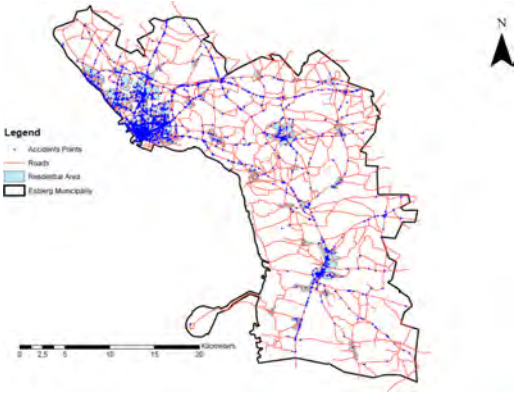

Figure 2. GIS mapping of traffic accidents coordinates on Esbjerg municipality roads.

time. There is a robust evidence for an association between short response time and survival rate for traffic accidents. (Sánchez-Mangas 2010)

Currently in Denmark, total pre-hospital median time for category "A" is 08:12 minutes whereas for B, it is 13:27 minutes. For "C" category, it is 16 minutes and 5 seconds. Similarly, for "D" category the time is 19:46 minutes. The Danish pre-hospital time median time for all emergencies is 10:27 minutes. (Anderson et al 2014). The detail of prehospital time is given in Figure 3.

Moreover, fire and rescue service (FRS) has also a crucial role in saving human lives as first responder along with EMS. As far as fire and rescue services are concerned in case of Esbjerg municipality, their time to reach at the site of accident in the municipality is depicted in the Figure 4.

Fire and rescue station of Vibevej 18, 6705 Esbjerg Ø is mainly responsible for urban area of the Esbjerg municipality. The emergency team is comprising of 7 rescues workers on 3 vehicles that is incident commander vehicle, fire truck and rescue truck. (Sydvestjysk Branvæsen 2015)

The green area of the map shows a response time of 10 minutes while yellow area represents 15 minutes of response time and rest of the area represents 20 minutes of response time. (Sydvestjysk Brandvasen 2015)

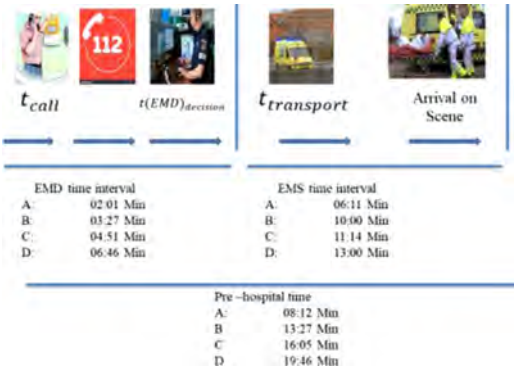

Figure 3. Current pre-hospital emergency time.

Figure 4. Esbjerg fire station response time to emergency calls.

RED can assist in emergency operations by reducing the FRS onsite assessment via video streaming by reaching faster than their time of 10 to 20 minutes depending on the location of accidents from FRS station.

2.2 *Identification of RED placement*

For optimal placement of RED networks, a spatial analysis was performed using geographic information system (GIS) tool ArcMap, and ArcGIS 10.5.1 to analyze and visualize the results. (Law & Collins 2015)

For application of RED network, DJI M210 Matrice drone is considered, which is one of the most advanced drone to date with broader industrial applications. The cruise speed of this drone with A mode is 82.8 kph. During vertical ascent, it has a speed of 5 m/s and vertical descent the speed is 3 m/s. (DJI 2017)

This drone can transmit footages with camera such a Zenmuse X4 and Zenmuse X5 s along with

Zenmuse Z30. The range of the drone is 7 km. Because of its agility, water proof and along with other specifications, it fits best to be considered as RED for building network to quickly assess the site of accident crashes and support EMD and EMS to make correct and quick decisions. RED can also assist fire and rescue team via video streaming.

Esbjerg municipality is considered for this explorative study. Esbjerg municipality is divided into urban and rural areas.

In Figures 5 and 6 optimal locations for placement of RED network are shown. To cover the urban area of the Esbjerg municipality five placements are identified to mount RED network. Similarly, five placements are also identified for rural area (Fig. 6). Each placement is the center point of the circle shown on the map. The drone range is 7 km; therefore, each circle represents 7 km of radius. The origin of the circle is for the docking station of the drone. As each UAV location covers a radius of 7 km, several traffic accident cases in the analysis are overlapping. A total *of* $n = 2515$ cases of traffic accidents were reported in Esbjerg municipality between 2012 and 2016. Out of these 2,029 were in the urban area and 486 were reported in the rural area of the municipality. For each location's (both rural and urban) median time, maximum time and minimum time is depicted in the following Tables 2 and 3.

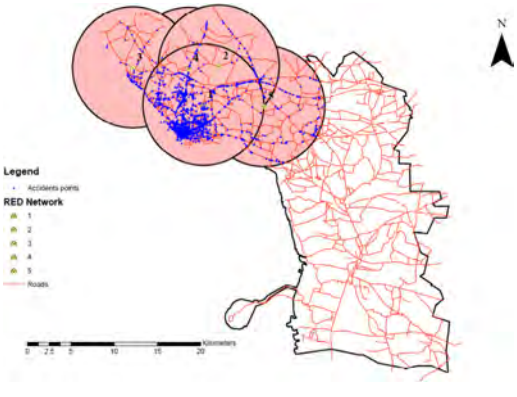

Figure 5. RED Network placement across Esbjerg municipality urban area.

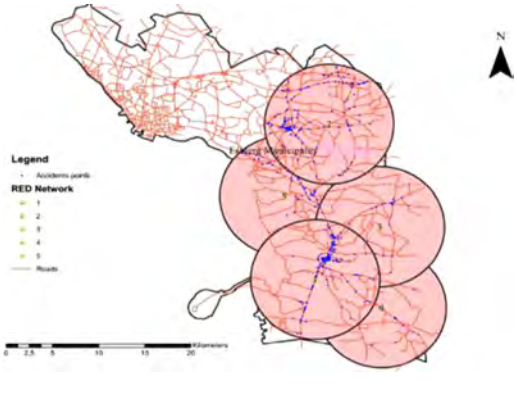

Figure 6. RED network placement across Esbjerg municipality rural area.

Each location is identified based on the number of accidents in the radius of 7 km of circle. The origin of the circle is the location for the drone placement. From drone placement to wherever accidents occurred in the circle, the distance is measured. The following formula is used to measure the distance between longitudinal and latitudinal coordinates.

$$d = \sqrt{(x_1 - x_2)^2 + (y_2 - y_1)} \tag{1}$$

Considering the speed of the drone total time between two locations is calculated and subsequently that total time is used to calculate the median time, maximum time and minimum time for each location. The preparation time for launching the drone is not considered, as this time is approximately 3 seconds. Claesson et al 2017) whereas airborne time of the drone is considered for median time calculation.

Maximum time for both urban and rural location is approximately 5 minutes 57 seconds, whereas minimum time and median time is varied across the locations.

Table 2. RED network median time to reach at the scene of accident in urban area.

Location urban	Median time	Maximum time	Minimum time
1	03:25	05:57	00:59
2	04:48	05:57	01:59
3	05:01	05:57	01:07
4	04:57	05:57	01:03
5	04:54	05:57	01:31

Table 3. RED network median time to reach at the scene of accident in rural area.

Location rural	Median time	Max time	Min time
1	03:21	05:55	01:05
2	04:22	05:56	00:53
3	04:53	05:57	01:39
4	04:03	05:56	01:01
5	04:05	05:57	01:47

3 DISCUSSION

Real time video from the scene of crash is powerful tool in supporting quick and right decisions. (Fig. 7) Due to many reasons bystander cannot clearly define the health status of the patient/injured persons. Danish medical staff supports the concept of live video streaming to deal with problem of over and under-triage. (Gerdstrøm 2017)

To have a safe operation of the live video streaming via RED, precautionary measures needs to be considered. There should not be any safety concerns for bystanders or any harm to the surroundings environment. DJI M210 has collision avoidance sensors, however, bystanders onsite must be informed of RED approaching to them. Moreover, rotors of RED should be shut down once the EMS or FRS reach at the site of accident.

Building and integrating RED Network in Denmark may bring new challenges for the emergency services to get training and implement the system as well as the interaction among EMD, bystander or inflicted persons at the site of crash.

There are some risks associated with this novel idea of RED network such as public perception of the drone technology, differentiation (colour/appearance) between the emergency drones and other drones for the public, risk of falling of a drone, risk of drone docking unit stolen or damaged, risk of data/information stolen, charging issues with the drone, bad weather and environmental effects of the drone technology etc.

Nevertheless, the pre-hospital phase of emergency services would benefit from RED due to live mutual visual inspection of the emergency. The real time video feed will help cut down the costs of the resources that are not needed at the site of crash. For instance, a procedural protocol to respond to a traffic accident alert involves dispatching of fire truck, incident commander vehicle and a rescue truck that may or may not be needed. Inter departmental and intra departmental communication of emergency services is expected to be improved. Another worth mentioning benefit of RED networks is that the implantation of the system to traffic accidents will pave the way to scalability and application of it to other emergencies.

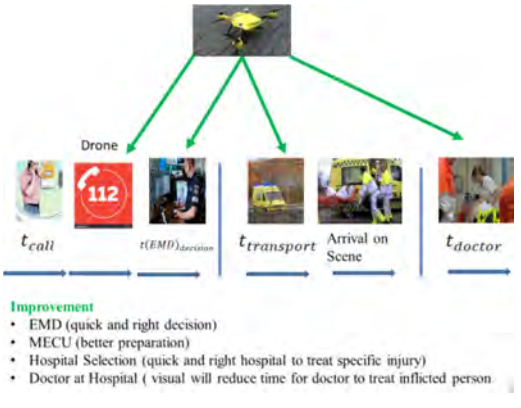

Figure 7. RED network assessment of emergency scene via live video.

4 LIMITATIONS

Beyond Visual Line of Sight (BVLOS), flight operations of drones are not allowed in Denmark.

It is important to know the acceptability of drone technology in local population, for which a there is a need to have comprehensive risk perception study.

DJI M210 drone was considered having a range of 7 km with area of network coverage of 14 km; many accidents in the analysis are therefore overlapping. The configuration of the drone along with range would have resulted different results if we would had considered another drone.

The real test flights are yet to be performed.

5 CONCLUSION

The application of GIS model results in the identification of appropriate placement of RED networks across Denmark. The real-time video transmission via RED networks can enable emergency services to take immediately right decision and dispatch a targeted response to treat injured persons. Therefore, RED could be the key to overcome the problem of under-triage and over-triage in saving lives besides cutting budgets.

Swedish multi-level planning system for critical infrastructure protection: The regional core

C. Groβe
Mid-Sweden University, Sundsvall, Sweden

P.M. Olausson
Mid-Sweden University, Östersund, Sweden

ABSTRACT: With its growing dependence on electricity, modern society faces the risk of cascading failure of interconnected societal functions. To protect societal functions during an event of power shortage, Sweden has implemented a multi-level planning process called *Styrel*, which involves national-, regional—and local-level actors. As part of the Swedish crisis management system, the regional body operates as a co-ordinator that organises co-operation and interaction between private and public actors. This study examines the role of the regional hub in *Styrel* and the collaboration and co-operation between planning levels. It focuses on the co-ordinator's perspective and presents evidence from interviews and a survey among planners at County Administrative Boards, entrusted with the supervision and execution of *Styrel* within their regional area of responsibility. This paper indicates that the regional co-ordinator lacks the awareness, knowledge and resources to fulfil its core function in the national planning for critical infrastructure protection.

1 ELECTRICITY AND THE SWEDISH CRISIS MANAGEMENT SYSTEM

1.1 *Background*

Electricity is a vital resource in today's society, which largely depends on electricity for maintaining critical social functions. It can be argued that the reliable distribution of electricity is crucial for private households, businesses, and public operations to function and survive (Cohen 2010, Ghanem et al. 2016, Rinaldi et al. 2001). This dependency is likely to increase over time due to the continuous developments in important infrastructure such as railways and electric cars (Cedergren et al. 2015).

The power grid is vulnerable to various types of events, such as extreme weather conditions (e.g. storms and floods), technical failures due to outdated infrastructure and aging components, cyber-attacks and destruction. Disturbances in the grid can have severe consequences for society (Gheorghe et al. 2006, Pescaroli & Alexander 2016). For example, in Sweden, the storms Gudrun, Per, Dagmar and Ivar caused major problems that in some cases lasted for more than a month (EA 2006, 2007a, 2007b).

In the future, there is a risk that such extreme conditions will increase in number and magnitude due to the changing climate (Birkmann et al. 2016). Given the serious effects of such events on society, creating the necessary conditions for sustainable power supply during a crisis is an important function of the Swedish Energy Agency (EA). In order to ensure undisturbed power supply to important users in society, i.e. critical infrastructure (CI), the EA has developed a planning process called *Styrel* (an acronym for *control of power supply to prioritized electricity users*), to provide critical infrastructure protection (CIP) against short-term power shortages.

1.2 *Aim of the study*

The County Administrative Board (CAB) plays a central role in the Swedish *Styrel* process as co-ordinator (EA 2014). The aim of this paper is to examine the role of the regional hub of *Styrel* and the collaboration and interaction between planning levels that are included in the process. The focus is on the differences between CABs regarding their performance as co-ordinators in *Styrel*.

1.3 *The Swedish crisis management system*

The Swedish crisis management system depart from three principles: The first one is *the principle of responsibility*, which implies that actors who are responsible for an activity or a process in everyday life are also responsible for it during a crisis. Next, *the principle of parity* implies that societal functions

during a crisis should as far as possible be carried out in the same way as they are during normal conditions. The third *principle of proximity* states that actors closest to the event handles the crisis when it occurs; this means that a municipality or county/region should primarily handle a crisis. If local resources are insufficient, the state can act through the CAB (MSB 2014, Pramanik et al. 2015, Tehler et al. 2012). In practice, this means that the CAB is responsible for co-ordinating between relevant actors in their county (MSB 2014). The co-ordinating role may involve some problems, as there is no explicit process for resolving possible conflicts within the Swedish crisis management system.

A study of the Swedish defence directors at the 21 CABs in Sweden has revealed what the problems are (Wimelius & Engberg 2015). According to the study, clearer governance, improvement in network management and increase in resources are measures that can help to improve co-operation among the various players in the county. Several defence directors expressed the view that the Swedish crisis management system is characterised by weak governance and lack of continuity (Wimelius & Engberg 2015). A study of the river groups in Northern Sweden further substantiated this view. The river groups exchange information in events such as floods and high flows through co-operation via networks. However, vague instructions from the Swedish Rescue Services Agency have resulted in the different river groups working differently, having different objectives, and involving different actors (Olausson & Nyhlén 2017). All these reports point to the need for a more integrated and standardised system when it comes to crisis management in Sweden.

2 THEORETICAL FRAMEWORK

This study focuses on the planning process for power shortages, *Styrel*, which involves both public and private actors (Große 2017). Pierre & Peters (2000) consider the management of society as a continuum that extends from traditional top-down control, at the one end, to self-organisation (autopoesis) and networks at the other end. The concept of governance is the common element of the entire continuum. In social sciences, the concept of governance has no clear definition, in which regard Pierre & Peters (2000) note:

'…Sufficiently vague and inclusive that it can be thought to embrace a variety of different approaches and theories, some of which are even contradictory' (Pierre & Peters 2000: 37).

Governance can be regarded as a policy instrument in the context of institutionalism, rational choice, and network and policy communities, or it can be analysed based on neo-Marxist and critical theories. The concept of governance describes how a society is organized, governed and who is involved in dialogue, participation, and networking. According to both governance and public policy theories, networks are an important phenomenon (e.g. Christopoulos & Ingold 2011, Henry 2011, McGinnis 2011, Petridou 2014). In this study of *Styrel*, we use the definition of governance as a policy instrument and subsequently as a network for steering. *Styrel* can also relate to the concept of risk governance, which considers legal, institutional, social and economic contexts as well as the actors involved in each of these contexts (Renn 1998).

Governance or policy networks can be either self-organized or created and co-ordinated by the state (Sørensen & Torfing 2005). Individual organizations often use networks to achieve their strategic and operative objectives, to maximize their influence over outcomes or to avoid dependence on other actors in the system. From this perspective, governance involves managing networks (Rhodes 1996).

This study examines material from interviews and a survey of planners at CABs to portray the CABs' central role in the Swedish planning system. The analysis was based on the concept of complex systems governance, the aim of which is to ensure control, communication, co-ordination and integration of a complex system by several metasystem functions (Keating et al. 2014). In particular, the focus is on two functions of complex systems governance:

- *Policy and Identity*
- *Information and Communications.*

The aim of focusing on these two functions is to inform other functions of complex systems governance, such as learning and transformation and the operational performance of the Swedish crisis management system and its governance, i.e. the metasystem (Keating et al. 2015, Keating et al. 2017, Keating & Bradley 2015).

- Policy and Identity

The role of policies is to provide direction and identity to the system components, e.g. the planners in the Swedish *Styrel* process, and to represent the system to external constituents, e.g. the Swedish crisis management system and the wider public.

- Information and Communications

Secure and reliable information paths are particularly important in national planning for CIP. However, access to relevant information for decision-making is similarly vital for the performance

of the planning system, as is the consistent interpretation of available information throughout multi-level planning, such as in the case of *Styrel*.

This study examines the available evidence in light of these governance functions and highlights problems in the design, execution and evolvement of the Swedish multi-level planning system for CIP, in order to inform further development of this complex system and its governance.

3 METHOD AND SELECTION OF CASES

In this study, we use interviews with co-ordinators at the CABs in three counties in Sweden: one in the rural north, one including one of the three major cities in Sweden, and one including some heavy industry close to the capitol of Sweden.

This study further includes a survey with all the co-ordinators at the 21 CABs in Sweden, carried out in October 2017. Until today, 15 of these co-ordinators have responded to the survey, which means that the participation rate is 71.4%. These 15 participants provided answers to 34 questions on their perceptions of the effectiveness and efficiency of the planning in general and on the proceedings during the last planning process iteration within their area of responsibility in particular. The survey has an overall response rate of 62.2%; the answers to the remaining questions were *do not know (N/A)*.

A document study complemented the interviews and the survey and provided important background information, which allowed for data triangulation (Gerring 2007). The documents for study included a handbook for the planning process (EA 2014), evaluations of the pilot study in 2008 (Länsstyrelsen Blekinge 2009, Dalarna 2009) and evaluations of the first round of planning in 2010 at the national level (EA 2012) and in Stockholm County (Länsstyrelsen Stockholm 2012). Moreover, a report on the grid operator's plans for manual load shedding (MFK) completed the document study (Veibäck et al. 2013). We conducted the interviews after the document study, which deepened the information gained from the documents and allowed for verification of the evidence from the documents in the interviews.

4 SWEDISH PLANNING FOR CRITICAL INFRASTRUCTURE PROTECTION–*STYREL*

In Sweden, different actors are responsible for energy supply at the national level. The EA is responsible for creating the conditions for efficient, resilient, and sustainable energy use and cost-effective distribution of Swedish energy (EA 2012). The Swedish Energy Markets Inspectorate (EI) is responsible for supervision, regulation and licensing in the energy market. The Swedish Civil Contingencies Agency (MSB) bears the overall responsibility of the crisis management system and the measures taken before, during and after an emergency or crisis. Finally, the Svenska Kraftnät (SvK) is nationally responsible for the power grid. When a power shortage occurs, the SvK is responsible for MFK in as informed and socially efficient a way as possible. The mission is to ensure that local and regional power grid operators can perform such MFK within 15 min (EA 2012, Veibäck et al. 2013).

In order to enable the national, regional and local grid operators to run an MFK without affecting critical social functions, the four national-level actors (the EA, the EI, the MSB and the SvK) have developed the planning process *Styrel*. The planning and prioritisation process for power shortages has been used 2010 and then repeated in 2014. The next planning process iteration will take place in 2019. In *Styrel*, the CAB acts as co-ordinator between governmental agencies and municipalities, on the one hand, and the municipalities and power grid companies on the other, as Figure 1 depicts.

During the recent planning in 2014, the following multi-level process was agreed upon (EA 2014):

With the aid of an eight-digit scale for prioritisation of CI (see Table 1), national agencies identify and prioritise the CI that each of them operate.

In step (1) (see Fig. 1), each agency sends a portion of these ranked objects to the CAB of the regional area of responsibility in which the CI object is located. Each CAB merges the received

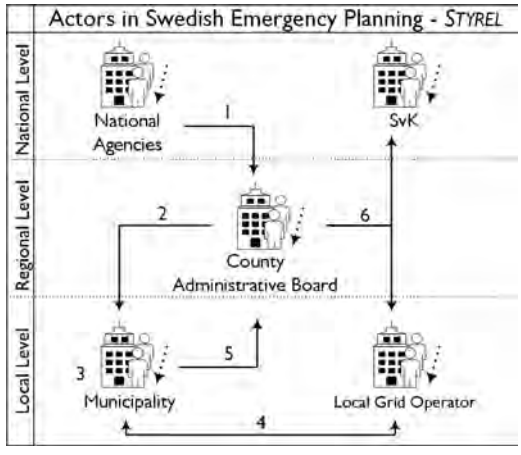

Figure 1. Actors and information paths in the Swedish multi-level planning process for CIP against power shortages.

Table 1. Priority classes of critical infrastructure.

Class	Description
Electricity consumers that have/represent:	
1	significant impact on life and health—short-term (hours)
2	significant impact on society's functionality—short-term (hours)
3	significant impact on life and health—long-term (days)
4	significant impact on society's functionality—long-term (days)
5	significant economic value
6	significant importance for the environment
7	significant importance for social and cultural values
8	others

lists of prioritised objects and divides them into portions that correspond with each municipality's area of responsibility. In step (2), the CAB forwards these portioned lists to each municipality. In step (3), the municipalities make an inventory of locally important infrastructure and prioritise the objects in accordance with the list in Table 1.

In step (4), the municipalities exchange information on the prioritised consumers with each locally operating power grid provider, which provides information on the technical feasibility of control. The CI objects merges into controllable power lines. Thereby, the used spreadsheet performs additive aggregation of the objects' ranking scores, which yields another list that contains the ranking of the power lines. After a final evaluation, the municipalities send this latter list back to the CAB in step (5). Each of the CABs merge these lists from the municipalities in their jurisdiction, resolve conflicts between lines that cross municipal or regional borders and make the final decision about the ranking of power lines. In step (6), the CABs send the final document to the SvK and dedicate portions of it to each power grid provider that operates in the region.

5 RESULTS OF THE STUDY

5.1 *Analysis of the reference process model*

The Swedish planning process for CIP involves actors from a large number of national agencies—all the CABs and municipalities and locally, regionally and nationally operating power grid providers. In Figure 1, the CAB makes two appearances as co-ordinator of the proceedings. The *Styrel* process can therefore be considered as a multi-agency planning process (Alexander 2015, Bharosa et al. 2010) that occurs at multiple hierarchical levels (Allouche & Berger 2011). This Swedish multi-level planning system consists of three hierarchical levels—the local, the regional and the national level.

The *Styrel* process can be decomposed into single problems at each level, at which responsible planners act on behalf of public or private organisations in sequential order, while the CABs play a central role as co-ordinators of the planning decisions. This role is directed top down and bottom up, but the latter role is incomplete because the procedure lacks co-ordination at the national level.

In the top-down part of the sequence (step (1) & (2)), a CAB receives information on an electricity-dependent CI that national agencies operate in the CAB's regional area of responsibility. The survey results in Tables 2 and 3 indicate that although the CABs perceived the collaboration with national agencies as good, 84.6% of the CABs stated the need for a more structured process for this activity, particularly for the consistent interpretation of priority classes. Further, on in the process, the CAB portions the information on national objects and sends them to each of the municipalities in its juris-

Cross-county lines	0.0%	30.7%	0.0%	58.3%

diction that host such assets. In addition, according to the reference process model, the CABs should provide training and guidance to their municipalities during subsequent planning at the local level. Since the questions on concrete proceedings had a low response rate of 57.5% during the survey, it is possible that the knowledge within the planning system is stunted. In addition, 58.3% of the CABs have not participated in the planning process before. This may influence their ability to co-ordinate the proceedings and to provide guidance to the municipalities. Nevertheless, the CABs' responses with regard to collaboration with the municipalities were slightly positive and indicated that they rather trusted the municipalities. However, the reference process did not provide any measures to evaluate the correctness of the planning decisions, so aside from communication, the CABs have no means of assessing the information they receive—neither in the top-down nor in the bottom-up phase.

In the second part of the sequence (steps (5) & (6)), the information flow is in the bottom-up direction. Information about local prioritisation also comprises the national CI assets, but they are masked. During the recent iteration of the planning process, information exchange was limited to power lines and the number of objects per priority class. Even though this reduction in information may ensure a certain level of information security, it makes regional—or national-level co-ordination impossible. The study results indicate that the CABs used meetings as a means to gain more information and to align the prioritisations in their area of responsibility. Nevertheless, 69.2% of the CABs stated that they require a more structured process for collaboration with municipalities. Moreover, each CAB must also merge the lists from the municipalities and then decide upon the regional ranking of power lines. Half of the CABs that answered this question decided to merge the lists entirely on their own. Further, one CAB performed the merging by itself and announced the changes to the concerned municipalities. The remaining respondents stated that they co-operated with the municipalities to align the results and to compile the final ranking list. Finally, the CAB divides this list into bundles of power lines that correspond to each local power grid operator in the region and sends this list to each of them. In addition, each CAB delivers a complete list to the national power grid provider. Interestingly, even though the process does not necessitate intensive collaboration of the CAB with the grid providers, 53.9% of the CABs stated that they required a more structured process anyway. This is probably because the CABs do not receive any feedback from the power grid providers about next-level planning for MFK because of national information security concerns.

Due to the immense information processing and process management involved, CABs bear a double burden—as participants in the process and as regional co-ordinators. Hence, the CAB represents the central hub in the current multi-level *Styrel* planning process in Sweden.

5.2 *Organisation and execution of Styrel*

Each CAB is responsible for co-ordinating work related to crisis management in its own county in Sweden. Therefore, the CAB is also responsible for co-ordinating the execution of *Styrel*, in which the CAB plays the central role in the planning approach, but with little influence on the quality of the process outcome. The evaluation after the pilot and the first round of planning showed overall, the CABs perceive *Styrel* as an important planning process for identifying CI. The survey substantiates this perception, as 92% voted on *agree*/*strongly agree*. However, due to the limited influence of the CABs on the outcomes of the *Styrel* planning and the subsequent MFK planning, the CABs expressed some doubt about the usefulness of *Styrel*'s outcomes for crisis management. Further, they expressed considerable doubt about whether *Styrel* can provide the intended protection for society during a power shortage.

The interviews show that the three CABs organised their work according to the reference model. All three CABs emphasise the importance of working within existing networks. In particular, the CABs used already existing networks, used

in ordinary work with crisis management and emergency response. No new networks emerged in the three regions. Evaluation of the first run in 2010 indicates that the CABs acknowledged the *Styrel* process' contribution to improved cooperation within existing networks (EA 2012). However, the organisation of these networks differs between the three counties, and the counties' size seems to be the main reason for the differences. The two smaller counties worked more closely together, e.g. meetings included representatives from all municipalities. The larger county also used existing networks meetings. In this case, the county divided into four or five different groups; northeast, north-west, southeast, south-west, and the large city. This division ensured a smoother planning process in the region, but it also made it difficult for the municipalities to have an understanding of the region as a whole. Instead, individual municipalities had only experienced the discussion in their part of the region, which could lead to differences in principles and priorities among the four parts. According to the evaluation of the first run in 2010, the major challenge was to find a common view on the prioritisations among municipalities in a region. Thereby, how to deal with the dependence chains and to which extent an analysis of these chains is appropriate seem unclear (EA 2012). In *the rural north county* and *the county close to Stockholm*, all municipalities participated in the discussions on principles and priorities.In the latter one, the municipalities made notes in the planning document, which made it easier for the CAB to identify the objects along the line. This could also have impact on the result: '*For the result then ... because we have a bundle of power lines, without knowing what is on them, it is extremely difficult. Because you could, in theory, cut off the hospital using a few ICA stores, or some water pumps*'. The notes made it possible for the CAB to identify such effects.

This study evinces that the CAB in general has followed the planning model as stated in the handbook for *Styrel*. However, there were some deviations from the model due to lack of time. Since some actors did not follow the predetermined schedule, the CABs ran out of time for their part of the process. Although the other actors in the process caused this delay, the three CABs perceive the initial plan as too optimistic. The co-ordinators argued that there was a risk that such a compressed schedule, which speeds up the work of municipalities and CABs, led to a widespread copy-and-paste behaviour in the municipalities: '*It may be necessary to give more time because it became very stressful when it became so delayed in the first line from government agencies*'.

Evaluation of the *Styrel* planning process in 2010 revealed that there were only a few, if any, contacts between CABs and private actors, except for contacts with the power grid providers (EA 2012). Due to time constraints, the interviews with the three CABs indicated that no other private actors or actors representing civil society have been involved in the current *Styrel* planning.

Between the two rounds of planning, the CABs' role in the process changed. In the first one, the CAB participated more actively in assessing and balancing the priorities of the CI objects at the county level, whereas in the second planning, the CAB only complied the results from the municipalities. One of the counties did not fully apply this change; instead, the municipalities, the region and the CAB made the final ranking list together. The participating municipalities were, according to the co-ordinator, unanimous about this departure from the official planning process: '*Yes, in what other way would we do? It's just like a damn long list*'.

5.3 *Integration and governance*

Styrel is an integrated part of the Swedish crisis management system. As stated, the three principles of the system are *responsibility*, *parity*, and *proximity*. The CAB is responsible for co-ordinating work with the system at the regional level. Critique from CABs against the *Styrel* process mainly includes problems with the process itself and the lack of feedback during the process in the multi-level system.

In the interviews, the co-ordinators at the CABs all agreed that it is important to identify CI objects, i.e. societally important objects, in advance in order to ensure that there is as much power supply as possible to these CI objects in the event of a power shortage. Therefore, there are certain elements of *Styrel* that are important for the functioning of society. However, all three CAB co-ordinators interviewed are critical about the design of the reference process model and process execution in the two rounds. They are also critical about, the limits of the usefulness of the planning process. Today, the process stands to some extend for itself; therefore, the co-ordinators regret the absence of a holistic, integrated view on *Styrel*. One co-ordinator envisioned that integration and transition of the planning process of *Styrel* would be an important pay-off to the Swedish crisis management system at subsequent planning levels, such as preparedness and contingency planning.

In two of the counties, the co-ordinator at the CAB described the process as smooth without any major conflicts between the included parties. The problem was primarily that the CAB, according to changes in the process in the second round of planning, could not access information about the objects themselves, but only the lines. All three co-ordinators at the CAB emphasised on the problems of this change. Since the co-ordinators did not get information about individual objects along high-

priority lines, there is a risk that important objects is down prioritised due to the process design. In all three cases, the co-ordinators preferred to have more information about the objects in order to ensure the quality of the process outcome.

There were solutions to deal with the problems. In one case, the CAB and the municipalities first discussed how to grade a certain objects. Then the municipalities made notes in the planning document indicating which objects are located along the line. In another case, the CAB, the municipalities, and the region made the final ranking together. In the third case, they only used initial discussions, but there were no discussions on individual objects. In theory, this could imply a down prioritization of the line for the major hospital in favour for other lines. Finally, before submitting the final ranking list, the CAB ensured that they were along one of the highest prioritised lines.

6 DISCUSSION AND CONCLUDING REMARKS

6.1 *Policy and identity*

From this study, it appears that *Styrel* is part of a reliable energy supply plan, even in the event of power shortages. However, the findings also indicate that the execution of *Styrel* does not follow on the process created by the EA. The risk of 'copy-and-paste' behaviour can particularly affect the prerequisites for reliable power supply during a power shortage. In accordance with the concept of resilience, this study on the co-ordinating function of the CAB highlights that there is a risk that society cannot maintain important social functions. The implementation of the process does not provide any guarantee for a resilient power supply. Further, any form of systematic co-operation between the system components, such as private and public actors, seems to be absent in the current *Styrel* process. Systematic co-operation, if any that occurs at the municipal level remains to study.

The importance of private-public co-operation in networks for enabling actors (i.e. the municipalities, regions, CABs and power grid providers) to identify and prioritise CI objects is further emphasised by the evaluation of the three pilot studies in 2009. The results from our current study reveal that none of the three CAB formed new networks for the process.

The findings signify the underrepresentation of private actors and actors representing civil society in the planning process and its reference model, developed by the EA. However, the deliberately vague definition of the reference model allows municipalities and CABs to include private actors to obtain as much information as possible for the ranking of CI objects. Thus, the system permits components to adapt to local regional commitment to improve the process. This means that the regional outcomes of a process instantiation can vary distinctly, which questions the national character of the planning. Particularly, since *Styrel* prescribes neither an over-regional nor a national alignment of CI and the power lines, it remains uncertain how local and regional proceedings during the planning affect CI objects of over-regional and national importance.

Although the policy is accepting alternative proceedings, the CABs used already existing networks, which only include public actors, mainly at the municipal level making the proceeding more effective. However, such an approach carries the risk that important information from private actors, such as private care providers, is lost ignoring proper risk communication to society.

6.2 *Information and communications*

This study implies that it is important that specific public actors, such as persons responsible for crisis management, have authorised access to crucial information on power lines that ensure power supply to CI objects, such as different care providers. It seems that there is no guarantee that the actors update available information, due to the earlier mentioned 'copy-and-paste' behaviour. Moreover, due the limited information content in the received lists, the CAB cannot control the correctness and completeness of the CI objects; instead, it has to rely on the performance and commitment of other actors.

Styrel can contribute to the maintenance of CI during power shortages, but there is no proof of its success in this role due to the absence of any assessable success factors. This presupposes that actors at the municipal level execute the planning in accordance with the national strategic objectives. However, the interviews in this study reveal that in some cases, individual interpretations of these objectives resulted in an adapted, time-saving behaviour, i.e. 'copy-and-paste' of local results from the first planning round. Since there is no way of ensuring that the available data on CI objects from the previous planning also applies four years later, there emerges a risk that the results of *Styrel* do not properly reflect the intentions and priorities of municipalities and agencies.

In addition, the absence of specific feedback from power grid providers on the planned proceedings during a power shortage hampers further reliable integration of *Styrel* in regional crisis management. These preconditions illustrate that the regional co-ordinator cannot rely on the results of *Styrel* planning for CIP in subsequent planning processes, such as preparedness and continuity planning.

7 CONCLUSIONS

Styrel as planning process does not necessarily contribute to the creation of a reliable energy supply as stated by the governmental guidelines of the EA. *Styrel* can contribute to the maintenance of CI and societally vital services, but it is difficult to gauge this in the absence of assessable success factors.

It appears that there are no integration of the *Styrel* process into the Swedish crisis management system. Such integration may further improve the effectiveness and efficiency of this complex multi-level planning system. In particular, such integration could facilitate the further development of co-ordinated information paths and directed communication. In turn, such development can assist with ensuring adequate national and international information security with regard to sensitive information about CI. Therefore, it is necessary for authorised persons to designate and monitor the necessary information with confidentiality, integrity and availability to fulfil strategic and operative objectives in the context of national CIP.

The present analysis shows that the results of the *Styrel* process, implemented in a Swedish multi-level planning system, rely on the commitment of the CABs as the co-ordinator for achieving a common understanding of the criticality of infrastructure and for mediating regional collaboration. The level of trust between the different levels of the planning system seems likely to further influence the resulting emergency response plan. Moreover, the planner's perceptions regarding the significance of the planning task, the likelihood of a power shortage situation and the crisis management capability of a county can have an impact on the effectiveness of the complex multi-level planning system in a crisis.

This paper also indicates that there is a lack of awareness at the regional level about the function of core players in the Swedish *Styrel* approach. In addition, the regional hub lacks the knowledge and resources to fulfil adequately its dedicated function in the national planning process for protecting CI objects from the consequences of a power outage.

With insights from the Swedish case, this paper highlights the regional core of *Styrel* and contributes thereby to international discussions on the identification, prioritisation and protection of CI objects.

Identifying hazards to include in risk analyses

M. Leonhardsen & O.E. Olsen
University of Stavanger, Stavanger, Norway

A.S. Nilsen
UiT Arctic University of Tromsø, Tromsø, Norway

ABSTRACT: A risk analysis should provide decision makers with information regarding relevant hazards. The initiating phase, where the risk analysts identify hazards to be included in the risk analysis, lays the foundation for the rest of the analysis. This phase is, therefore, of great importance. In this paper, we examine how risk analysts in a municipal setting identified potential adverse events and how they chose which ones to analyse in the risk analysis. The municipalities under study had important similarities with respect to exposure to hazards and government regulation. With these similarities as a starting point and studying how the initiating phase took place, the paper focuses on impact regarding the uniformity of adverse events. Looking at events included in the Comprehensive Risk and vulnerability Analyses (CRAs), seems to reveal a predominance of uniformity. This is reasonable given the previously mentioned similarities. It is arguably also a result of many risk analysts using the same sources to retrieve ideas of potential hazards. The latter is alarming when considering risks not listed in these sources, like emergent or local risks.

1 INTRODUCTION

Communities at different levels of society strive to attain safety and security. To do so, they try to identify hazards and threats that pose a risk. This is a starting point in preparedness for emergency response and risk and vulnerability reduction (Perry & Lindell 2003). Risk Analyses (RAs) are the prominent methods in which risks and vulnerabilities are identified and assessed. They are formal and analytical (Renn 1998; Rausand & Utne 2009) and used by organizations to prepare for misfortune. They do so by providing decision makers with information about relevant hazards and threats, the likelihood of these adverse events and their potential consequences. RAs enable decision makers to make informed decisions regarding reduction of risks and vulnerabilities (Aven 2011).

The mission of RAs is in other words (Rausand & Utne 2009):

- To figure out what kind of adverse events might happen
- To figure out the likelihood of the events
- To figure out the consequences of the events
- To describe the risks (Aven 2015)

The bulleted list clearly illustrates that beneficial outcomes of RAs depend on the initiating phase, which is identifying the adverse events of relevance to the RA.

"This is one of the most important steps in the risk analysis. If a hazard source or an adverse event is not detected, it will not be included in the analysis" (Rausand & Utne 2009, p. 86).

Likewise, Cameron et al. (2017, p. 53) describe the identification of hazards as "the first and most crucial step in any risk assessment". According to Renn (2008), stages of risk assessments vary depending on risk domains and risk sources. Regardless of that, hazard identification is one of three core elements in risk assessment (Renn 2008). Not being able to identify hazards properly can result in accidents or adverse events (Cameron et. al 2017).

Risk analysis has received a lot of academic attention. A December 2017search for "risk analysis" in the Academic Search Premier database, resulted in approximately 58800 academic articles. Comparatively, searching for "hazard identification" or "identification of hazards" resulted in 1100 and 1250 hits. This paper is a supplement to the studies of this highly important element of risk analysis.

This paper focuses on the initiating phase of RAs. It presents how risk analysts in 12 municipalities identified and chose hazards to be analysed in greater detail in their RAs. These municipalities had several similarities (they are presented in section 3). With these similarities as a starting point, can we categorise the risk analysts who carried out

the work as either copycats at one end of the scale, or explorative analysts at the other?

The main focus, though, is the impact of the approaches used in the initiating phase. This impact is identified and discussed, restricted to uniformity of risks included in the RAs. To be more precise: we have studied the processes when conducting so-called Comprehensive Risk and vulnerability Analyses (CRAs).

Municipalities are exposed to both hazards and threats. The nuances between the two terms are not of importance in our study. So, for convenience, we use "hazard" as a common term for both. Further, we use the terms hazards and adverse events in an interchangeable manner, even though hazards do not necessarily lead to adverse events.

1.1 *The CRAs*

The objective of the Civil Protection Act 2011 and secondary law is to ensure that municipalities safeguard the safety and security of the population (Directorate for Civil Protection 2017). According to these legal requirements, the Norwegian municipalities must have CRAs.

The objective of the Civil Protection Act 2011 and secondary law is to ensure that municipalities safe-guard the safety and security of the population (Di-rectorate for Civil Protection 2017). According to these legal requirements, the Norwegian municipali-ties must have CRAs.

The secondary law lists a few minimum requirements for the CRA. Two of them are of importance for the initiating phase of CRAs (Directorate for Civil Protection 2017):

- First, a CRA must address both existing and future risks in the municipality, as well as external risks of relevance to the municipality.
- Secondly, critical functions in society and critical infrastructure must be addressed. Loss of electricity or water can be examples.

Beyond that, the legal requirements do not specify what kind of adverse events be included in CRAs. Risk analysts in the municipalities must identify the potentially adverse events based on idiosyncratic risks in their communities.

There is a variety of methods for risk analysis (Rausand & Utne 2009). Analysts in the municipalities are free to choose, but preliminary RAs are the common method in the municipal domain. In preliminary RAs, potential adverse events are identified, then the identified events are analysed separately regarding causes, likelihood and consequences (Aven 2006).

In addition to the requirements in the Civil Protection Act focusing on the risks from a holistic perspective, the municipalities face regulation at the sector-level.

2 THEORETICAL APPROACH

Several elements are of importance in the initiating phase of RAs. Based on our point of interest, we focus on some theoretical considerations related to the method of risk/hazard analysis, supplemented with some perspectives when suited.

Due to the framework for the paper, elements of importance are excluded, though. For instance, risk perception, i.e. peoples' judgement of hazards (Renn 2008), is not explicitly addressed. Neither is safety culture addressed, even though culture can contribute to focus the attention to some specific hazards, while other hazards are not taken notice of (Pidgeon & O'Leary, 2000, Pidgeon 1998; Douglas & Wildavsky 1983).

2.1 *Method and regulation*

A preliminary risk analysis is suited for both major and minor hazards. However, risk analysts might be restricted by a decision that the process of identifying hazards should be limited to regulatory requirements (Baybutt 2014). Such restrictions could, in extreme cases, result in a CRA of rhetorical value, symbolizing control (Clarke 1999), risking that hazards of importance or interest are omitted from the analysis.

2.2 *Imagination*

Cole (2012, p. 12) uses the phrase "broaden the mind-set of responders" as an argument for surprise scenarios in exercises. It is also requisite to broaden the mind-set of risk analysts when identifying potentially adverse events.

Imagination and creativity contribute to the identification of scenarios that would otherwise not necessarily have been identified. Hence, imagination and creativity are required, but analysts might lack these characteristics (Camerona et al. 2017). Besides, even if risk analysts are imaginative, it is not a guarantee for identifying all hazards (Baybutt 2014).

A boundary for imagination might be the ontological status of hazards and risks. They are not fixed. Risks can be viewed in different ways; as objective properties or as socially constructed (Aven & Renn 2010). Risks pre-exist in the former view, and risks can in principle be identified and measured (Lupton 2013, p. 13). Socially constructed risks, on the other hand, are the product of rhetorical processes (Lupton 2013, p. 46). Potentially this induces discussions or interpretations among risk analysts about which hazards to consider in the initiating phase of CRAs.

2.3 *Cognitive biases*

Thinking can be divided into two systems; fast and slow (Kahneman 2011). The fast mode is instinc-

tive and the slow is deliberate. The risk analysis method presupposes deliberate thinking. However, risk analysts are humans. Therefor they are not necessarily as rational as could be expected (Aakvaag 2008).

Cognitive biases are results of heuristics (Kahneman & Tversky 1982). The biases stem from the unconscious influence on human judgements and decisions (Baybutt 2016). They are deviations from the rationality of thinking (Meissner & Wulf 2013, p. 802). Researchers have found many cognitive biases, e.g. the availability bias, group thinking or the framing bias, to mention a few. We will not go into details in this paper. The point here is that cognitive biases among risk analysts can result in missed hazard scenarios (Baybutt 2016). Therefore the negative effects of cognitive biases need to be addressed. This is very difficult due to the unconscious processes involved (Baybutt 2016). However, knowledge, information and awareness can reduce biases. Another strategy is to use a devil's advocate in the risk analyst team. An appointed devil's advocate can initiate debates that might challenge the mind-set of others (Baybutt 2016). Additionally, scenario planning can alter biases (Meissner & Wulf 2011).

2.4 *Filtering risks*

There must be a limit to the number of adverse events to analyse in the CRA. It is simply a matter of resources. This implies that the number of identified adverse events in the brainstorming process must be reduced. Rausand & Utne (2009) argue that hazards where the risks are small, due to low likelihood and/or insignificant consequences, could be filtered here.

Power and interest are also important. Interests can be invested in which adverse events should be emphasised and de-emphasised (Aven 2011; Dekker & Nyce 2014). This also applies to the brainstorming phase. Being able to handle interests requires the capacity to exercise power. There are several sources of power, e.g. information, expertise, control over agenda and resources (Antonsen 2009).

2.5 *Standardization and uniformity*

Recipes and checklists can be beneficial. They provide advice and save time for risk analysts (Hale & Swuste 1998). Checklists can also mitigate a lack of imagination among risk analysts (Baybutt 2014).

The purpose of recipes of how to do things is to do the same. Ergo, uniformity is reasonable (Brunsson 2000). However, standardization can cause blindness to possible adverse events unsuited to the recipes (Hale & Swuste 1998). For instance, Baybutt (2014) holds that elements unlisted in checklists might be left out.

3 METHODS

Data were gathered in twelve of nineteen municipalities in a county in Arctic Norway. The main criterion for including municipalities in the study was location. They are all located in the same geographical region, and therefore to a certain extent exposed to the same hazards. Another criterion was time. The Civil Protection Act came into force in 2011. Requirements in the law set a new framework for CRAs. The CRAs and CRA-processes included in the study are from the timespan 2011–2017, ensuring that the municipalities had been subject to the same legal requirements. Their geographical location also meant that they had been subject to the same supervision by the same County Governor. A third criterion was the availability of the informants during the data collection period.

The data was collected via interviews and analyses of the CRAs, a qualitative approach. Twelve semi-structured interviews were conducted; one informant per municipality. A question guide with open ended questions was used. The informants all played pivotal roles in the CRA process in their respective municipalities. All of them had participated actively in the process of making the CRAs which this paper focuses on. Hence, they had first-hand knowledge of the process and the choices that were made.

The contents of interviews and CRAs were analysed and compared, so data coherence could be checked.

In a Norwegian context, the municipalities spanned from small to medium population size.

Next, we will present findings from the processes of brainstorming and filtering.

4 THE BRAINSTORMING PROCESS

The identification of potential hazards in the municipalities is called the brainstorming process in this paper. The term here refers to a process of creativity, imagination, structure and mapping. Next, we will present the "who's" and the "how's" in this process.

The municipalities had their own unique brainstorming processes. However, there were similarities. Aggregated, the processes either involved

- municipal representatives (M)
- a combination of M and external representatives (E)
- consultants who involved either M or M+E

In eight of the municipalities, both internal and external representatives participated.

It is hard to conclude unambiguously in what way the legal requirements and other regulative

attempts to influence affected the process of identifying hazards. For some it seems as if regulative involvement broadened the scope of hazards to consider. The internal focus in one of the municipalities was not motivated by legal compliance. The intention was to heighten organizational competence in this area of municipal responsibility. A contrast is the municipality with the lowest involvement in this study. Here the primary objective was a "good enough" CRA.

A devil's advocate formally appointed to challenge assumptions or stimulate ideas was not used. Ascribing such a formal role to a participant in the processes seems to be unfamiliar to the risk analysts. However, in two of the municipalities, the risk analysts responsible for the local processes deliberately sought counter-arguments. They were self-appointed informal devil's advocates.

A common trait for the municipalities is that they based identification of hazards on a combination of information sources. In some cases, their imagination was not sufficient, and other sources provided valuable inspiration and ideas. Nobody referred to checklists etc. as means to save time or resources.

In addition to their own previous municipal CRAs, most analysts used regional or national sources to assist them when identifying hazards: typically, national and regional RAs and a government guideline for CRAs. The analyses and the guideline served as checklists. At the local level, other municipal CRAs were sources of information too, but to a lesser extent than for instance the regional RA.

Another influence was the urge from national and regional government to take specific adverse events into consideration, for instance deliberate adverse events in schools etc. (threats, use of weapons), and quite recently, arrival of refugees in large numbers.

Media-coverage was also a source of information and inspiration to some risk analysts.

The informants also referred to a recently established regional arena for risk analysts. Here the analysts could exchange ideas. For instance, the hazard related to cruise tourism had been addressed by one of the municipalities. This was also relevant for some of the other municipalities. The influence from this arena will probably be apparent in future CRAs.

Arguably, these sources facilitate uniformity if not reflected on.

Interestingly, in two of the municipalities, representatives from residents were invited to participate in the process, potentially providing a local focus. Representatives from the municipality and external actors who had been invited to contribute could, of course, also add a new perspective.

The analysts were asked about the usefulness of external information sources and potential negative effects. The majority found such sources very helpful, providing ideas and serving as some sort of quality control as to the content of CRAs. The potential negative effects seem to be eliminated by the usefulness of such sources.

5 THE FILTERING PROCESS

After having identified potential hazards, the municipalities chose which hazards to include in the CRA. In this paper, this process is called filtering. Some of them had identified many potential adverse events, others had few. Most of the municipalities structured the identified events by merging related events, thus reducing the number of events. In addition, the approach of filtering out small risks was applied in several municipalities.

One of the municipalities in fact included all of the identified hazards in the CRA as they were, without filtering.

All in all, the filtering processes passed without much controversies, according to the risk analysts. Issues for debate were the severity of hazards, not their ontological status. The participants in the process came to an agreement. External actors without representation in the CRA work, such as representatives from local industry, showed no interest in trying to influence this, or other, processes. This lack of interest is interesting per se, but beyond the scope of this paper.

6 IMPACT

Looking at the type of risks included in the CRVs, there is a high degree of uniformity regarding events that are mandatory to address; e.g. critical infrastructure.

However, the analysts have not analysed all types of critical infrastructure. They have chosen the ones relevant to them. Electricity and electronic communication are the focus of attention, followed by water supply. Transportation is also addressed in some of the CRAs. Here, local circumstances are obviously of importance. E.g. municipalities with only one main road are more vulnerable than those with several.

Pandemics, nuclear accidents and extreme weather, the transboundary risks, are also included to a high degree in the CRAs. Fires, accidents, emissions or spills of dangerous substances are also addressed to a high degree. These are events of relevance to all municipalities, regardless of location. However, the detailing and the objects at risk vary from one CRA to the other. Municipali-

ties with a coastline have analysed accidents at sea, for example.

Several of the above-mentioned hazards are regulated in sector legislation: e.g. water-supply, fires and nuclear accidents.

There is also high uniformity at an aggregated level regarding deliberate adverse events. They are included in the CRAs. The types of adverse events differ, though. Events like threats and "minor" violence are addressed by almost everybody. Terror, a disastrous event, is covered in fewer CRAs. Here, analysts have varied between the events, most likely based on their assessment of relevance to their municipality. Only two CRAs include Cyber-attack. This type of hazard has not been on the public agenda for very long, and the two CRAs have recently been revised.

In addition, the CRAs encompass a few adverse events of a strictly local character: flooding and the breaking of dikes.

Finally, a few of the CRAs contain unique adverse events; such as substance abuse among municipal employees, animal diseases, violence and sexual abuse against children and breaches in information security.

Identifying adverse events is a challenging task, taking uncertainty about what the future holds into consideration. In two of the municipalities this was addressed by including "the unknown event".

7 DISCUSSION AND CONCLUSION

7.1 *Discussion*

The preliminary risk analysis method and the legal requirements per se are neutral regarding the number of people involved. The variety among the studied municipalities is vast with respect to involvement of personnel. At one end of the continuum only the consultant and a single municipal employee took part in the process. Here the rhetorical value of the CRA was the primary objective, i.e. having a CRA in compliance with regulations (Clarke 1999). At the other end of the continuum a bottom-up approach was applied with all municipal departments being mobilized. The variety of involvement does not seem to have a bearing on the number of adverse events included in the CRAs.

If other parameters were considered, like how well founded the CRAs are in the municipality, or reduction of risk, then the verdict regarding choice of processes might shift. Important hazards might be missing in the CRA (Clarke 1999).

There is a predominance of uniformity in the events that were included in the CRAs. Obviously, this can be ascribed to legal requirements and that the municipalities face the same hazards to a relatively large degree. In addition, the formal framework for CRAs confers some uniformity. The brainstorming processes also induced uniformity, because many risk analysts in the study used the same sources to retrieve ideas of potential hazards. With recipes and a framework like this, some uniformity is reasonable (Brunsson 2000).

Still, we would argue that this is alarming with regard to hazards not listed in these sources, like emergent, novel or local hazards. They might be left out, as implied by Baybutt (2014) and Hale & Swuste (1998). For instance, fish diseases were not included in one of the often-used sources, the County-RA. This hazard might be of relevance in several municipalities because fishery is a prominent part of the industrial base in these communities. Only one CRA included this hazard. Using sources to retrieve ideas, the risk analyst might miss out hazards if the process resembles copying and has a lack of imagination (Cameron et al. 2017; Baybutt 2014).

Most of the processes took place without major disagreement. A devil's advocate was not used in most of the municipalities. Hence, the processes lacked a participant who systematically could have challenged the mind-set of others (Baybutt 2016). Given the uncertainty about future adverse events and local susceptibility, the processes could have benefited from critical voices challenging both the premises for analysing risks, i.e. the formal framework for CRAs, and the local processes.

This could perhaps have provided more diversity in novel or unique adverse events. However, diversity is not an objective per se. The CRAs were in fact diverse in having variations within types of hazards. For instance, some included car accidents, others included bus accidents.

Having argued in this paper that uniformity can be alarming, a final reflection should be added regarding crisis management. Even if all hazards have not been identified and analysed, in crisis management many of the same features occur regardless of the hazard involved (Nilsen 2017). Therefore, uniformity need not be too serious in that respect. The disadvantage of uniformity is the decreased possibility of reducing or eliminating unknown hazards in advance, making crisis management redundant.

7.2 *Conclusion*

The initiating phase of any risk analysis, where adverse events are identified and filtered, is very important. This paper has addressed how risk analysts in 12 municipalities have carried out this phase and the impact of uniformity of adverse events analysed in municipal CRAs. The main conclusion is that there is a predominance of uniformity in CRA-events, as could be expected due to the circumstances and the brainstorming-processes.

Diversity is not an objective per se. However, the chance of identifying the unknown adverse event is lessened by copycats. That is alarming, and awareness needs to be raised.

ABSTRACT: Design documentation, safety and security analysis, environmental studies, studies on organizational factors, product characterization, etc., constitute the knowledge base each process plant, with a higher or lower detail, uses for plant management.

Most of this knowledge is often lost inside an accumulation of formal documents that are not made available for practical use, while it should be disclosed and exploited within a living model of the plant (updated in real time), to which the various actors should refer to make their decisions throughout the lifecycle of the installations.

How to give a shared representation of the factory (state, history, behavior), in order to improve the reliability and flow of decision-making, investment, prevention, protection, crisis management? A Risk monitoring systems and knowledge management to be integrated in the architectures of the company IoT has been proposed, developed and tested in French national institute for industrial environment and risks (INERIS).

The initial risk modelling embedded in the knowledge management systems, based on the bow-tie methodology to identify the barriers for critical sequences to the Major accidents and to assess their availability, to be used for decision making, has been here integrated with the Integrated Dynamic Decision Analysis in order to obtain the critical sequences of events, that include the operator contribution (in terms of errors and recovery), the barrier effectiveness and the plant behavior.

The representation of the plant in the shape of sequences allow a more user-friendly management of the information and thus a simplified control of the coherence of the risk assessment modelling with the real plant behavior, and an enhanced decision-making support in the definition of plant control measures, both technical and operational. It also allows an easier integration of the data coming from the field, with traditional or new technologies, as virtual and augmented reality.

The proposed solution is exemplified through the application to an ammonia storage plant.

1 INTRODUCTION

In this paper a risk monitoring systems and knowledge management tool proposed, developed and tested in INERIS is described, named MIRA (Monitoring Intégré des Risques Actualisés, Integrated Risk Monitoring Updated). The MIRA system was developed in the Virtualis projec, update in the TOSCA projec and test in different company. It was developed with the purpose of making the risk assessment in major hazards process plants a living analysis, making available for the different actors—operators, managers, control authorities—the information from the risk assessment and management to support the risk-based decision making along the plant life cycle.

The tool is developed to be used by two main users—the plant managers and the authorities in charge of the inspections and authorization for plant activities—in order to make available all the information about risk management and to guide the decision making with reference to major accidents prevention.

As discussed in Demichela et al. (2004) and De-michela & Piccinini (2006), the strict correlation between the risk assessment and the safety management systems allows summarizing their relations and the links with the inspections activities as in Figure 1. According to this view, the tool developed in French national institute for industrial environment and risks (INERIS) manages the following set of data:

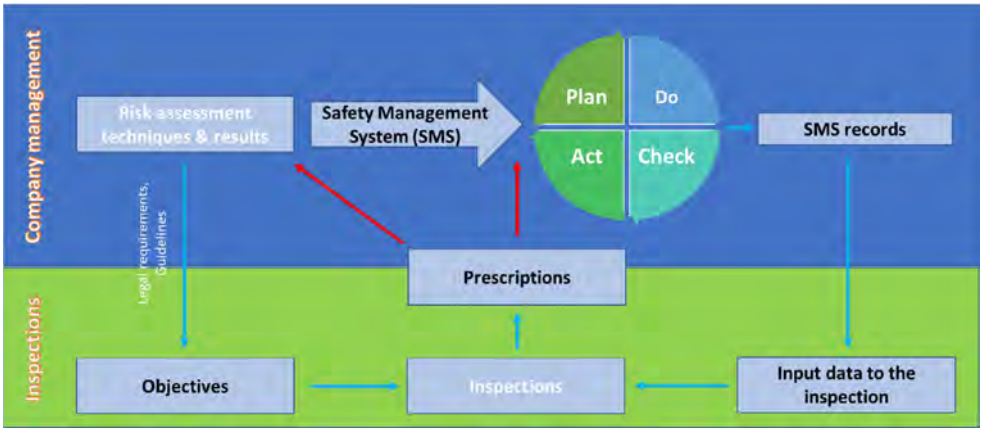

Figure 1. Processes included in the tool.

- The risk analysis data, both the probabilistic and the consequence analysis—in order to allow checking the hypotheses, the methodologies and the results;
- The prescriptions descending from the safety management system inspections, both internal and of the local authorities, that can affect the risk analysis and the related decision making;
- The operational control of the plant and its risks, designed also on the risk results that allows maintaining a tolerable the level of risk, through the safety management system;
- The records of the safety management system procedures and instructions;
- The results of the inspections and the consequent plans for improvements.

2 THE KNOWLEDGE MANAGEMENT SYSTEM

The heart of the knowledge management system is the management of the "living risk assessment", based on the updating of the risk analysis according to the modification of the processes—production processes, procedures and tasks—impacting on the possible accident sequences—probabilities of occurrence, accident scenarios, impact assessment.

The initial level of risk estimated in the "safety case" or "safety report" required by the Seveso Directive—Seveso III (Directive 2012/18/EU) –, when tolerable, should be maintained in time, maintaining the conditions that brought to the level of the risk assessed: process hazards, potential accidents sequences and barriers.

The safety management performance control allows a retrospective updating of the initial level of risk. According to Figure 2, the updating of the risk assessment will take into account the following aspects:

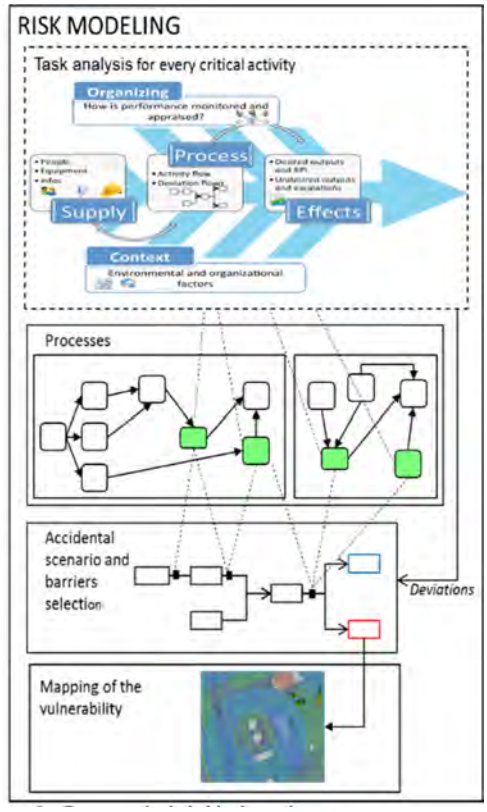

Figure 2. Risk modeling.

- The critical tasks. As an example, through task analysis, missing operational controls on criti-

cal equipment or protection systems can be traced, affecting reliability and availability of the systems.
- The analysis of technical failures and occurred accidents or near-misses. The analysis of the failures and of their treatment allows identifying the unavailability of a system or a missed critical task. Summing up the unavailability days over a given observation period allows estimating the actualized availability, e.g., of a safety barrier.

The calculation of the "level of confidence" of the system under study is carried on according to INERIS methods.

Comparing the initial risk level and the actualized one allows the inspectors to verify if the hypothesis made during risk assessment by the company management are realistic, given the real plant behavior.

In case of a difference, the plant management can revise the safety case, improve the management of the critical tasks and of the critical activities.

During inspections, the plant management has to make available the input data to the inspections, both from the risk assessment and from the operational management. The inspectors have to control the coherence of the different elements.

3 THE CASE STUDY

The case study refers to a company whose activities can be assimilated to those carried on at the AZF company, where the 21st September 2001 an explosion of ammonium nitrate killed 31 persons, together with thousands of injured (Paltrinieri et al., 2012).

In this case, the company produces and stores different types of solid fertilizers, using for their production raw materials, with different hazardous properties controlled by Seveso Directive:

- Flammable gases (natural gas and ammonia);
- Toxic gases (ammonia);
- Oxidising liquids (ammonium nitrate);
- Flammable liquids (oil);
- Toxic liquids (oil);
- Gas under pression (acétylène);
- Substances dangerous for the environment (oil, ammonia);
- Oxidising solid (fertilizers).

Within the risk assessment exercise, the company developed all the bow-ties needed to represent the possible accidental events and the barriers available for their protection (Aneziris et al., 2017). The barriers, whose availability has to be kept under control during time, being critical systems, could be technical or operational (Ahmad et al., 2015).

In Figure 3 one of the bow-ties developed for the ammonia piping system is shown as a demonstration. It refers to the release of a toxic cloud of ammonia (NH_3) and takes into account all the possible initiating events, internal and external, identifying the barriers, operational and technical, that should interrupt the possible event sequences towards an accident.

The barriers numbered in Figure 3 are:

1	Protection against lightning
2	Security guard
3	Design of the rack against earthquakes
4	Rack lay-out design
5	Site firefighting system
6	Manual decompression of the line
7a	Line section isolation for low pressure
7b	Building isolation for low pressure

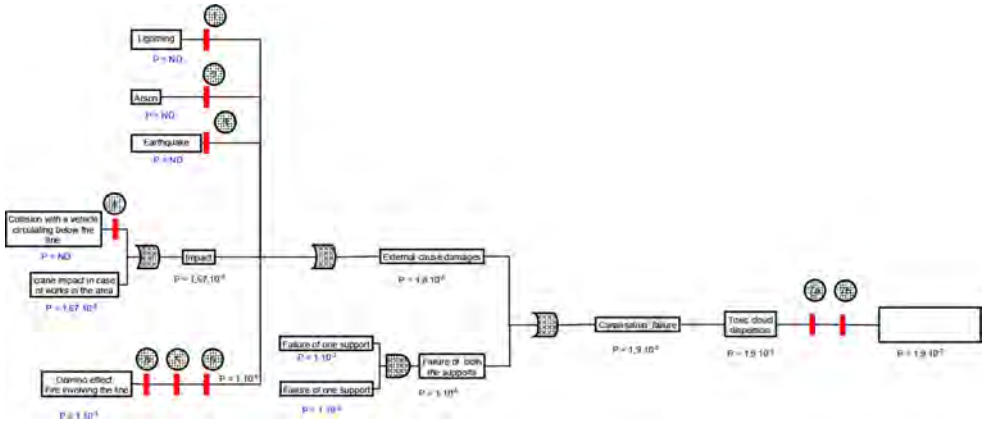

Figure 3. Sample bow-tie for the ammonia release case.

The value of barrier availability is justified in the safety case—not detailed in this paper—and can be updated according to the maintenance tasks records and the inspections' results thanks to the knowledge management system adopted.

The systematic adoption of this approach allows both the plant managers and the inspectors to easily identify the critical items and the protection systems that has to be taken under control in order to maintain in time the availabilities speculated in the risk assessment.

4 ONE STEP BEYOND

The present version of the tool, despite allowing a retrospective risk update, does not allow the risk to be updated in real time. Some experiences towards a similar purpose can be found in Paltrinieri et al. (2012), where the early warnings analysis is discussed and in Villa et al. (2016) where the dynamic risk assessment is introduced. In Raoni et al. (2018) the integration of probabilistic analysis and process simulation is also discussed and exemplified.

In general terms, to reach the goal the knowledge management tool should be interfaced with the control system of the process unit in order to collect the field data and update run time the risk figures.

In this way it could constitute an overarching real-time optimization and scheduling system, controlling and monitoring the operations of the whole plant together with the optimization of analytical tasks and the interpretation and the enhancement of the data used for risk assessment and control.

At the moment the representation of the potential accident through bow-ties does not allow this kind of integration, thus, in this seminal work, an attempt has been made of shifting toward the representation in "stories" – sequences of events—allowed by the Integrated Dynamic Decision Analysis (IDDA).

Originally developed by Galvagni, the method was tested on process case studies several times: by Demichela & Piccinini (2008) on a simple case study of a tank overflow; by Turja & Demichela (2011) and Demichela & Camuncoli (2014) for the risk-based design on an allyl-chloride production plant, where it allowed to carry on the risk analysis in a dynamic way, taking into account process time dependent occurrences; by Baldissone et al. (2016) to the analysis of competing technologies for the VOC treatment; by Gerbec et al. (2016) that compared the result of the IDDA analysis on a LPG tank cold water pressure test procedure to the results obtained with the Bayesian network.

The IDDA methodology, that can be seen as an enhanced event tree, is built on the interaction between a logical—probabilistic model and a phenomenological model of the plant under analysis.

Its use as a decision-making supporting tool in risk assessment is summarized in Figure 4, as also discussed in Baldissone et al. (2017).

The logical—probabilistic model is a logical description of the plant behavior (integrating human and technological aspects, where the case) based on the general logic theory.

In particular, when the operational aspect is relevant, a good starting point to build the logical—probabilistic model is the Task Analysis, or a

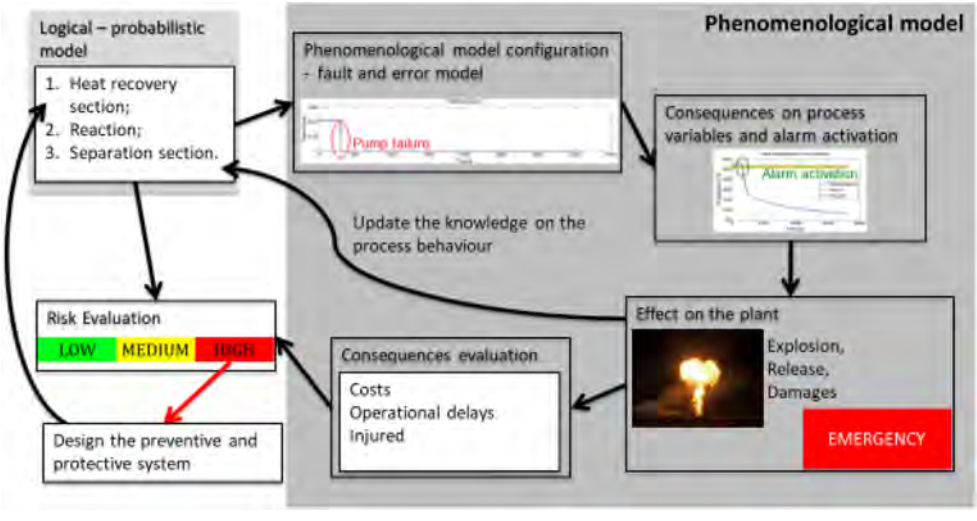

Figure 4. Conceptual scheme of the IDDA use as risk based decision-making support tool.

Table 1. Sequence n. 133 from the IDDA logical-probabilistic model elaboration.

Level	Answer	Prob.	Cumulative prob.	Description
1	1	1.00e-03	1.0000e-03	Operational error? Yes
2	1	9.00e-01	9.0000e-04	Enough space available? No
3	1	1.00e-01	9.0000e-05	Pump trip failure? Yes
10	1	1.00e-01	9.0000e-06	Level transmitter failure? Yes
20	0	1–1.00e-01	8.1000e-06	Extraction works? Yes—diluted cloud
101	0	1–1.67e-05	8.0999e-06	Crane falling down? No
102	1	1.00e-03	8.0999e-09	Fire below the pipe (Domino effect)? Yes
103	1	1.00e-02	8.0999e-11	Safety valve works? No
105	0	1–1.00e-01	7.2899e-11	Manual decompression? Yes
120	1	1.00e-03	7.2899e-14	Pipe support 1 failure? Yes
121	1	1.00e-03	7.2899e-17	Pipe support 2 failure? Yes
125	#1		7.29e-17	Both Supports fail? Yes
150	#1		7.29e-17	Pipe leaks? Yes—NH3 release
200	#2		7.29e-17	Result of the case 1? Overload—release managed
201	#1		7.29e-17	Result of the case 2? Toxic release from the pipe

Sequence probability: 7.28988e-17.

functional analysis for the technological part, as in Balfe et al. (2017).

The logical—probabilistic model elaboration brings to the development of all the possible sequences the system could undergo, with an accuracy dependent on the level of knowledge disclosed in the model itself.

Each sequence of events is coupled with its probability of occurrence, dependent on the occurrence probability of each event contained in the sequence, and on the logical and probabilistic constraints.

The phenomenological model is the mathematical description of the physical behavior of the system, assessing the status and trend of each relevant process variable with reference to the failure sequence identified and allows for a more realistic scenario both in probabilistic and in phenomenological terms; it allows the description of not only the unwanted events, but also of the resilience capacity built in the system (recover possibilities).

The full set of alternatives allows for the complete spectrum of possible probability-consequence conditions to be used as a basis for decisions in risk reduction and control with a compound knowledge encompassing system description.

The IDDA logical probabilistic model has been developed for the bow-ties related to the ammonia involving accident scenarios and returned a set of sequences the system could undergo.

The events represented in Figure 3, described through IDDA, brought to the generation of 220 alternative sequences, 90 of which bringing to a toxic release. The probability of occurrence obtained for the Top Event is comparable to the one obtained through bow-tie.

In Table 1 a sequence ("story") is represented according to the IDDA elaboration, as example of the results obtainable.

The representation in stories, coupled with the phenomenological behavior of the system allows comparing the data collected from the field—from different data sources: e.g. from the plant DCS/PLC or smart distributed sensors; from the registration of the maintenance activities, as through a Risk Register, as the one proposed in Leva et al. (2017) - with the sequences possibly occurring in the plant, thus allowing to follow up run-time the risk in the plant.

The application of the enhanced method has also identified some dependencies among events that can hardly be caught through the bow-tie approach adopted, thus bringing possibly to not conservative evaluations.

5 CONCLUSIONS

The risk assessment in process plants has often been regarded as a static document to be prepared for authorizations more than a living document for the day-to-day decision making in process plants.

The seminal work here described would like to overcome this view and include in a knowledge management system—already developed at INERIS—a way to trace the behavior of the plant towards an accident in order to guide the maintenance, inspection and even emergency preparedness in a living system.

The opportunity has been obtained integrating in the model the representation in sequences of the Integrated Dynamic Decision Analysis, that

could be used to compare the plant management and behavior and its model contained in the risk assessment.

It was demonstrated that including this approach allows some interdependencies among event to be identified—identification otherwise impossible—and that this constitutes a good support for the further developments above described.

AKNOWLEDGMENT

This knowledge management tool is one of the results of the European Project TOSCA—www.toscaproject.eu—that allowed the initial development of the Computerized Safety Barrier Management system and the company wide Risk Register.

ABSTRACT: Social interaction is regarded central in prevention, planning, handling and evaluation of unforeseen (UN) events. Hence, the social interaction factors may vary in different phases and conditions. This is also the case even when conditions are unpredictable compared to situations of low or without risk. We therefore apply an UN-oriented «Bow tie» model that focuses on three main stages related to the development of a serious event;

- Phase 1: Preparation/ identification of hazard signals and barrier development
- Phase 2: Occurrence of an unexpected event/accident
- Phase 3: Measures/ stabilization

The purpose of this paper is to investigate social interaction, the term and phenomenon at risk, and how social interaction factors behave under such conditions. How do social interaction factors relate to the different phases given by the «Bow tie» model? And, of what significance can this have related to education and training as well as the competence of a complex and interdependent organization? We will in this paper argue that social interaction plays a crucial role in meeting the unforeseen and discuss this accordingly.

1 INTRODUCTION

Organizations increasingly rely on their ability to adapt to and manage multifaceted, demanding situations (Herberg et al., 2018, Brozus, 2016, Roux-Dufort, 2007 Weick, 2015), particularly when facing sudden and unexpected risk events (Barnett, 2004, Bechky & Okhuysen, 2011, Cunha et al., 2006, Fornette et al., 2016). Little is known regarding how an organization can methodically identify relevant factors that influence the outcome of an event (Kaarstad & Torgersen, 2017). The current paper is based on the work of Torgersen (2018a) and Torgersen (2015). The starting point is the Norwegian/Nordic concept of *social interaction* (interaction). Traditional perceptions of the concept of *social interaction* are challenged and new models are introduced with the questions: What are the basic structures of the concept of interaction under/during risk, and further, how can interaction be created when the conditions are unpredictable? This scientific anthology "Social interaction" (Torgersen, 2018a) may be of relevance to anyone who works with warning signs, handling and stabilizing unforeseen events within most professions in society and emergency management, as well as students, teachers and researchers in education, strategy, human resources and organizational management subjects. The work was started by Torgersen & Steiro (2009). In 2015, the term unforeseen (UN) was introduced and defined as:

> "*Something that occurs relatively unexpected and relatively low probability or predictability for those who experience and must deal with it*." (Kvernbekk et al., 2015:30).

In this article we will provide an overview of the research and explaining the importance of social interaction linked to the unforeseen. We will argue that social interaction plays a crucial role in handling the unforeseen and can provide useful and applicable knowledge to the field of risk management and may add do the dynamic capabilities (Eisenhardt et al. 2000) of the organization.

2 THE DEFINITION OF SOCIAL INTERACTION

Based on a study of 15 organizations (Torgersen & Steiro, 2009), this definition of social interaction is developed:

> "*Social interaction is an open and mutual communication and development between participants, who develop skills and complement each other in terms of expertise, either directly, face-to-face, or mediated by technology or by hand power. It involves working towards common goals. The relationship between participants at any given time relies on trust, involvement, rationality and industry knowledge.*" (Torgersen & Steiro, 2009:130).

Social interaction is primarily a way to work or "act. Central to interaction is "action", first and foremost a targeted action. This action is shared or exchanged expertise—often extensive, specialized, and used in a complementary manner (Torgersen & Steiro, 2018, Steiro & Torgersen, 2013, Torgersen & Steiro, 2009). The focus on complementariness can also be seen in the work of Miles & Watkins (2007), supporting the notion that interaction is more than the sum of its parts. For *social interaction* to occur, one must also be aware that each participant contributes with their unique situational understanding ("shared situational awareness") or *shared repertoire of practice* (Wenger), based partly on their own perspective and position in the organization, and their experiences, culture, knowledge, attitudes, emotions and job satisfaction, including recommendations to the interaction process (Torgersen & Steiro, 2018, Sandeland & Boudens, 2000).

3 THE THEORETICAL FOUNDATION FOR SOCIAL INTERACTION AND RISK

In the previous paragraph, complementary elements was pointed out as important. An illustrative example of joining force a playing complementary roles is the Duomo in Firenze, Italy. Another illustrative example is the foundation of the dome of the Florence Cathedral, designed by Filippo Brunelleschi between 1417–1434. Brunelleschi had the bricks laid in a herringbone pattern to support the inner dome (Illustration 1). King (2000) explains this as an action and reaction between the bricks. We can argue that they are the same bricks but assigned different roles, and that the action and reaction creates interaction, redistributing the forces of pressure outwards and downwards. This prevents the dome from collapsing inwards (Torgersen & Steiro, 2018). It can be illustrated in the illustration below.

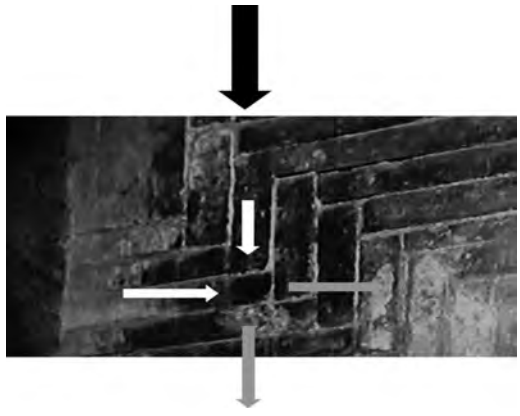

Illustration 1. The herring-bone pattern of brickwork designed by Filippo Brunelleschi (1377–1446) (Photo: Trygve Steiro, 2017).

The herring-bone pattern of brickwork designed by Filippo Brunelleschi (1377–1446), for the inner dome of Florence Cathedral, which effectively divides the pressure downwards and outwards, avoiding an inward collapse (grey arrows). The white arrows symbolize action and reaction, thereby creating an interaction, and an illustration of social interaction as something happen in the action. It also illustrate complementary aspects (Miles & Watkins, 2007).

The bow-tie diagram has been used extensively for risk management and is based on and modified after Primrose, Bentley, van der Graaf & Sykes (1996) model (Torgersen, 2018 b).

The bow—tie diagram modified after Primrose et al. (1996) in order to understand the interplay between the risk of the unforeseen through different phases and the importance of social interaction. The closer to the impact, the more demanding social interaction will be because of the actions required. However, Carlström (2018) stresses that social interaction can occur vertically, horizontally and synchronous. Scholtens (2008) emphasizes that operative staff, in most cases, make the right decisions and act in an optimal way, if they are allowed to act autonomously. Martin et al. (2016) have investigated crisis management and underlined the importance of the fours Cs; Communication, Cooperation, Coordination and Collaboration. Building on this work, we also put social interaction closest to the action.

The illustration is based on the work of Scholtens (2008), Torgersen & Steiro (2009), Martin et al. (2016) and Carlström (2018). Carlström (2018) further argue for in times of uncertainty, flexible and decentralized solutions should be sought. The same was claimed by Torgersen & Steiro (2009)

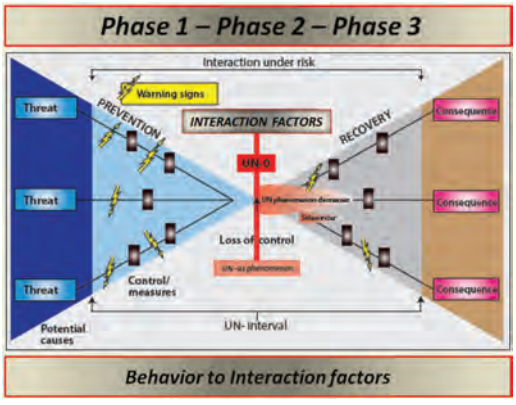

Figure 1. (Torgersen, 2018).

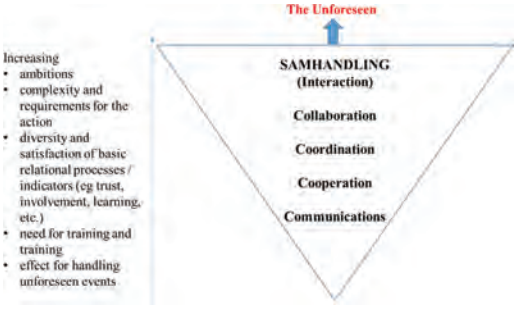

Figure 2. 4Cs plus social interaction in order to meet the unforeseen (Torgersen & Steiro, 2018).

building on the classical work by Burns & Stalker (1961). Carlstöm uses the military concept "auftragstachtik" as an example. For a further and elaborated discussion see Carlstöm (2018), Bergh & Boe (2018) Krabberød & Jacobsen (2018). Brady (2011) has looked into the Battle of Stalingrad and stressed that while the German commander Paulus sticked to the plan and doctrines too rigidly, the opponent Russian General was improvising and allowed improvising by the Russian over commando Stavka. New technology has been said will contribute to more decentralized chain of command (Zuboff, 1988; Albert & Hays, 2003). Albert & Hays introduced the term "strategical corporal". On the use of plans and military doctrines, also see Carlsten, Torgersen, Steiro and Haugdal, 2018. We are not claiming that plans are not important, since they obviously are. When foreseen interruptions occur, plans can be followed more strictly. However, when an unforeseen event appears they need to be uses as a framework and theory, but local action is apparently more important. An illustrative example on plans and social interaction are the Hudson River landing in 2009 with no fatalities (Eisen & Savel, 2009). On the 15th of January 15 in 2009, US Airways Flight 1549 hit a flock of geese shortly after takeoff from LaGuardia Airport (New York, NY), causing both of the engines to lose power. The first officer were in control of the aircraft. Captain Chesley Sullenberger took control of the airplane and the radio-communications, and then instructed the first officer to run an engine restart checklist, which was unsuccessful. Without engine power, Sullenberger decided that he was unable to reach either LaGuardia or the Teterboro airport in New Jersey. The flight crew then decided that an emergency landing in the Hudson River was a viable option. Pariés (2011) points out that a bird strike hitting and destroying both engines was thought of on beforehand. However, nobody had seem to predict or foresee the effect of losing both engines below an altitude of 800 meters. This was the case of Flight 1549. Below is excerpts of the communication of Flight 1549 and the air control of LaGuardia.

Based on National Transportation Safety Board senior official Kathryn O. Higgins's account and based on a transcript of the communication (Federal Aviation Administration, 2009). It is also worth noticing that within the cockpit, Captain Sullenberger orders *"My aircraft"*. First officer Skiles replies: *"Your aircraft"* (Eisen & Savel, 2009). Eisen and Savel (2009) write that this is according to the

Time	Event
1524:54	Tower cleared flight 1549 for takeoff
1525:51	Pilot informs control tower that they were at 700 feet
1527:01	Radar detected that 1549 hit primary targets
1527:36	Pilot, "Ah, this is Cactus 1539 hit birds, we lost thrust in both engines. We're turning back towards LaGuardia"
1527:49	Controller advised LaGuardia to stop departures
1528:05	Controller, "Cactus 1529, if we can get it to you do you want to try to land runway one three?"
1528:11	Pilot, "We're unable. We may end up in the Hudson"
1528:50	Pilot, "I am not sure if we can make any runway. Oh, what's over to our right anything in New Jersey; maybe Teterboro"
1529:02	Controller, "Do you want to try and go to Teterboro"
1529:03	Pilot, "Yes"
1529:25	Pilot, "We can't do it"
1529:28	Pilot, "We're going to be in the Hudson"
1530:30	Touchdown in Hudson River

Table 1. The terms 7T in Norwegian and the English translation.

Trust (Norwegian word *tillit*)
Assurance (Norwegian word *trygghet*)
Well-being (Norwegian word *trivsel*)
Belonging (Norwegian word *tilhørighet*)
Clarity (Norwegian word *tydelighet*)
Time (Norwegian word *tid*)
Tolerance (Norwegian word *toleranse*)

Table 2. Sources of influence and competencies for "samhandling" or "social interaction".

Competencies for samhandling	Sources of influence
Trust	Torgersen & Steiro (2009)
Assurance	Torgersen & Steiro (2009)
Well-being	Torgersen & Steiro (2009)
Belonging	Torgersen & Steiro (2009)
Clarity	Weick (1987); LaPorte & Consolini (1991); Weick & Sutcliffe (2001); Løfdali (2014); Steiro, Johansen, Andersen & Olsvik (2013); Fredriksen & Moen, (2013); Eggen & Nyrønning (1999); Simensen (2005); Leitao (2010)
Time	Weick (1993); Steiro et al. (2013)
Tolerance	Kant (1795/1991); Derida (2005a; 2005b; 2000); Torgersen & Steiro (2009); Steiro et al. (2013); Steiro & Torgersen (2018)

procedures and also accordance to Crew Resource Management Training, that is a well established concept to foster interaction within aviation crews. When Sullenberger gave the order, "*Brace for impact*," the flight attendants chanted repeatedly, "*Brace, heads down, stay down*" (Eisen & Savel, 2009:912). Pariés (2011) further reports that captain Sullenberger was very focused on the tasks. The Air Traffic Controller reported also after the accident: "*During the emergency itself, I was hyper focused, I had no choice but to think and act quickly, and remain calm. I was flexible and responsive. I listened to what the pilots said, and made sure to give him the tools he needed. I stayed calm and in control*" (Pariés, 2011:16).

All this communication can be seen as precise communication, that is so important for effective social interaction and particular when time is of such shortage (Torgersen & Steiro, 2009). The relevance of competence skills brings us on to further findings regarding competence for social interaction. Torgersen & Steiro (2018) have identified the following central competencies as important for social interaction. The first four was identified in Torgersen & Steiro (2009) and in Norwegian it was "tillit, trygghet, trivsel and tilhørighet", which was summed up in the 4Ts. In the study of Torgersen & Steiro (2018), "tydelighet" (English; clarity, both in role and communication) and "toleranse" (English; Tolerance) and "Tid" (English; time) was added. That would for Norwegian readers then be the 7Ts (Table 1). This point is not important in itself other that for educational reasons. To a not Nordic reading audience, this has no relevance.

In the following Table 2, the theoretical and empirical sources of influence to the 7T model is presented.

4 MEASURING SOCIAL INTERACTION IN RELATION TO THE UNFORESEEN

Herberg et al. (2018) found that social interaction combined with general self-efficacy and social support can account for a considerable proportion of the variance in preparedness for the unforeseen in different organizations. The study was performed using a self-completion questionnaire answered by personnel from the Norwegian Armed Forces during a three-month period in the winter of 2016 & 2017. The personnel were from all branches of the military, including commissioned and non-commissioned officers, military academy students and conscripts participated in the study. The study results are based on a survey carried out. The questionnaire was distributed to 16 units, departments and military academies throughout Norway. A total of 624 personnel participated in the study and the response rate was 77%. The sample consisted of 525 males (85%) and 92 females (15%) respondents with a mean age of 25.7 years and with the average military experience was 5.5 years (Herberg et al. 2018). Social interaction was found to be the most important predictor of preparedness for the unforeseen. The results in the study indicate that it is possible to prepare for unforeseen events by implementing measures that improve social factors in particular Herberg et al. (2018). Organizations should develop a work environment where managers and colleagues provides both moral and emotional support. Furthermore this environment where peoples communicating is recognized by their listening to each other and creating trust. The authors further suggest to create an environment of common understanding of the situation, have useful routines (and relevant) with partners and focusing on exchange and complement employee skills and knowledge (Herberg et al., 2018).

These findings lend support to the factors suggested by Torgersen & Steiro (2018) and listed in Table 1. However, Herberg et al. (2018) points to a need for more research to better understanding the relations between these factors.

5 TRAINING AND EDUCATING FOR SOCIAL INTERACTION

We have seen from paragraph 4, that social interaction plays an important role. In another study, by Nyhus, Steiro & Torgersen (2018), mentoring and coaching was studied for a joint operation course held at the Norwegian Defence College. Personnel form all weapon branches participated (Air, Army and Sea). The purpose of the course was to increase understanding of joint operations (Andersen, 2016; FHS, 2015). Since conflicts and wars rarely follow a familiar pattern, unpredictable factors are tried to be put into the education (Heier, 2015). The course is executed by more experienced officers, guiding less experienced officers and soldiers with given military cases and scenarios that are often based on experiences from actual events. The theoretical framework applied was therefore "apprenticeship learning". Apprenticeship is rooted in sociocultural learning theory (Saljø), which emphasizes that knowledge is constructed through social interaction (social interaction) in a context and not primarily through individual processes (Lave & Wenger, 1991, Maguire, 1999, Dysthe, 2001). 10 hours of observation was conducted in the sessions. In addition five group interviews were conducted with a total of 23 informants (out of a number of total 100 students). After a sufficient number of data was obtained (saturation), the interviews were stopped. A thematic analysis was adopted when interpretating the interview material. This is a suitable method for identifying, analysing, and reporting patterns within the data analysis (Braun & Clarke, 2006). The analysis reveals that some supervisors emphasize mainly on the product, and others more on how the group reached the result, i.e. the process. The product said something about the specific deliveries that the group arrived at. Furthermore, the product, among other things, referred to the supervisors who made sure that the group followed certain structured patterns of action and worked towards a goal that was embodied in doctrines and drills. Nyhus et al. (2018) found further that mentors who focused a lot on the product in the preparation phase did not take the unforeseen into account. A process-oriented supervisor with authority enough to create a shared commitment and understanding of situations. By the virtues of experience and competence, the supervisor can pave the way in preparation for meeting the unforeseen.

In the impact phase, we see how some mentors successfully combine equality with such results focus. It is seen as an advantage if the supervisor allows to focus on the result, but at the same time dares to move away from the role of an instructor who is going to make a correct or wrong answer.

In the final consequence phase, the supervisor should represent a counterweight to pure instruction, where logical conclusions about results control the conversation. Nyhus et al. (2018) found that the supervisor should not maintain a tight structure with a given focus on a blueprint product. The supervisors should investigate, challenge and test the group's knowledge and understanding, and she should ask follow-up questions where they, together with the group, assess the answers. The supervisor occupies a coaching role (Nyhus et al. (2018). The authors further suggest that guided student groups within the apprenticeship learning tradition is an alternative to traditional education, one that provides insights and valuable learning experiences.

6 CONCLUSION

We have demonstrated in this paper that social interaction offers something different than collaboration, co-operation. In a world facing the unforeseen, rather than insisting on the prediction of unexpected events, organizations should therefore investigate how to deal with unanticipated and learn from such events and how this can be developed. A change in focus and mind-set should highlight the relevance of social interaction as a basic and generic core competence. We have defined social interaction and explain underlying elements that makes it unique. At the same time trust, assurance, well-being, clarity, time and tolerance are, as we have argued, is central elements in order to establish and develop good social interaction. It does not come for free, but the potential benefits are expected to be large. We have also argued that social interactions plays key roles during risk and meeting with the unforeseen as demonstrated in paragraph 4. We have used the Bow-tie diagram to distinguish between social interaction before, during and after an incident or accident. We need further research that can contribute to the analysis of incidents and accidents within this framework. It would also been interesting to examine the developments of social interaction and to follow up on social interaction in different organizations.

ABSTRACT: Existing resilience management and assessment frameworks for Critical Infrastructure (CI), as well as resilience indicator indexes, define categories and methodologies that provide useful conceptual models. However, there is a lack of specific guidance on how to implement such conceptual models in practice, thus enabling stakeholders to conduct assessment, auditing, and consulting initiatives in a consistent manner. In this paper, we use an existing CI resilience management framework—based on the ISO 31000 risk management process–, and present guidance for implementing such a framework, based on generalized COBIT5 best practice. This is done by illustrative demonstration with a defined risk scenario that includes Information and Communications Technology (ICT) aspects, using a specific process from an existing CI resilience assessment framework.

1 INTRODUCTION

Assessing and managing the resilience of Critical Infrastructure (CI) present many conceptual and implementation problems, that CI operators, regulators, assessors, auditors, and consultants must address. High conceptual complexity kicks-in when hybrid threats, dependencies, and time-variable cascading effects are considered. Practical implementation issues arise, as crisis may span interdependent sectors and sovereign border, calling for frameworks and standards that promote interoperability and facilitate communication, cooperation, and collaboration among diverse stakeholders. Finally, the growing importance of the cyber dimension calls for an integrated people-cyber-physical approach to help solve the social-technical challenges of resilience management.

Significant research and development investments have been made in recent years to address such challenges (IMPROVER 2017, CIPRNet 2017, DRIVER 2017, FORTRESS 2017, PREDICT 2017, SmartResilience 2017, ERNCIP 2017).

In this paper we use the term resilience as defined by UNISDR (2017), i.e. "*The ability of a system, community or society exposed to hazards to resist, absorb, accommodate, adapt to, transform and recover from the effects of a hazard in a timely and efficient manner, including through the preservation and restoration of its essential basic structures and functions through risk management*". From this definition of resilience, three important aspects may be highlighted:

- The concept of resilience goes beyond the domains of security and safety – related to protection–, to include additional goals and functions related to crisis management – such as response, recovery, and adaptation;
- Risk management is an important function to ensure achieving the desired ability, towards a defined optimal level;
- Since UNISDR defines resilience as an *ability*, resilience management models and frameworks may take the point of view of optimizing sets of *capabilities* and *capacities*, as well as to assess resilience based on related indicators and measurement models.

Existing resilience management and assessment frameworks for Critical Infrastructure (CI), as well as resilience indicator indexes, define methodologies and categories that provide useful conceptualizations. A recent review of such resilience methodologies and frameworks can be found in Rød et al. (2017), Lange et al. (2017a, 2017b), and

IMPROVER (2016). Such conceptual models help address complexity, since they are simplified representations of the systems, intended to promote understanding within the relevant domain of discourse.

However, there's a lack of specific guidance on how to implement such conceptual models in practice, thus enabling stakeholders to conduct assessment, auditing, planning, and implementation initiatives in a consistent and effective manner.

Due to the growing importance of the cyber dimensions, it is important to note that security and resilience of CI requires consideration and integration of cyber and physical aspects, therefore a cyber-physical approach is needed (Choraś 2017, NIST 2014).

For addressing the government and management aspects of the cyber dimension, COBIT5 provides state-of-the-art conceptual models and guidance. COBIT5 is used e.g. in the NIST Cybersecurity Framework, for providing governance and management best practice (NIST 2014).

In this paper, we provide implementation guidance for resilience management and assessment of critical infrastructure, by developing, integrating, and demonstrating the two functional aspects:

- *Resilience management*: we reuse an existing CI resilience management framework from Lange et al (2017a, 2017b) –based on the ISO 31000 risk management process–, and present guidance for implementing such a framework, based on generalized COBIT5 best practice. By itself, the COBIT5 framework only addresses part of the problem, namely the enterprise governance of information and related technologies. However, as we propose and demonstrate in this paper, some of the key concepts, models, methods, and guidance of the COBIT5 framework may be generalized to encompass the broader scope of CI operator objectives, activities, and supporting technologies. Such an approach allows for a holistic solution to the resilience management problem, ensuring—by design—that the cyber dimension is integrated using a state-of-the art governance framework for information and related technologies.
- *Resilience assessment*: based on the resilience assessment framework from Cadete et al (2017), we define generic requirements for resilience assessment models, to enable seamless integration with the COBIT5 assessment and measurement models.

To illustrate the proposal, we provide a demonstration that uses a risk scenario that includes information and communications technologies (ICT) aspects, using as an example the resilience assessment framework from Cadete et al (2017).

2 RELATED WORK

In Rød et al (2017), a selection of existing resilience assessment methodologies is described and evaluated in the context of the IMPROVER project (IMPROVER 2017). The authors conclude that there is a need for a CI resilience assessment framework that is sufficiently well defined, but at the same time may be flexible to account for idiosyncrasies of the different types of CIs and their operators. Also, such a framework should remain compatible with the current guidelines for risk assessment of the European Union (EU) Member States and should integrate the paradigm of resilience into the risk assessment process according to ISO 31000.

Lange et al (2017a, 2017b) addressed those needs, proposing a framework for resilience assessment of CI, which integrates the resilience paradigm into the risk assessment (RA) process according to ISO 31000, while maintaining compatibility with the current European guidelines for national RA applied by the EU Member States (Fig. 1). Starting from definitions used in ISO 31000 for risk assessment, the authors propose a conceptual framework that maps these risk concepts to the resilience assessment domain:

- **Resilience assessment:** Resilience assessment is the overall process of resilience analysis and evaluation.
- **Resilience analysis:** Resilience analysis is the process of determining the level of resilience.
- **Resilience evaluation:** Resilience evaluation is the process of comparing the results of resilience analysis with criteria or objectives to determine whether resilience level is acceptable and identify areas for improvement.
- **Resilience treatment:** the process to modify resilience, focusing on the absorptive, adaptive or restorative capacity.
- **Resilience management:** Coordinated activities to direct and control an organization regarding its resilience, including the above processes.

According to these conceptual mappings, the authors propose that some of the expected outputs of a risk analysis could contribute to some of the indicators required to carry out a resilience analysis, i.e. the outputs may be utilized in the form of a single/multi-hazard engineering analysis to provide input to suitable resilience analysis methodology.

Dependencies (of other CI and suppliers) accounted during the risk analysis stage, may be used in the CI resilience analysis. The authors also propose that the maturity of organizational processes (see Fig. 1) may be used to provide more input to the resilience analysis methodology.

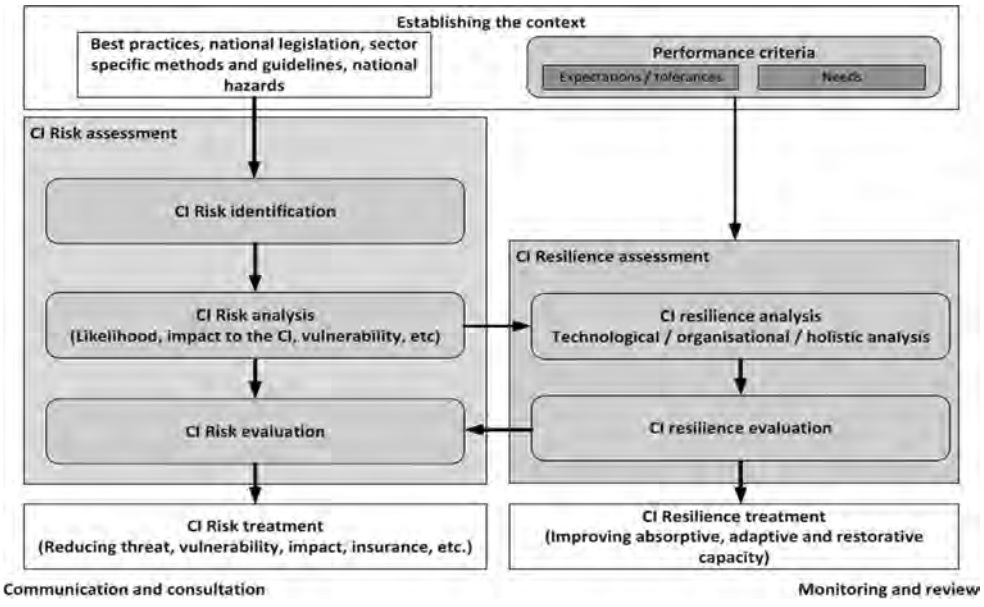

Figure 1. CI risk assessment (RA), incorporating CI resilience assessment. Taken from Lange et al (2017b).

The "*establishing the context*" activity (Fig. 1) provides input to the overall CI risk assessment process, requiring e.g. knowledge about best practices in the industry in question, national legislation, sector specific methods of RA, as well as relevant hazards identified in national RA standards.

However, the authors conclude that future work is needed to implement the proposed framework, namely to develop "*a resilience evaluation methodology which is compatible with a resilience analysis methodology and which allows a comparison between the results of a resilience analysis and real performance objectives based on the needs and tolerances of the society or community which relies on the service provided by the CI*".

Regarding resilience assessment models, Cadete et al (2017) propose a resilience assessment framework, based on rating the capability levels of organizational processes, that allows for a direct comparison between the capability levels that result from an assessment and the desired capability levels–thus enabling CI resilience evaluation. Both sets of capability levels (i.e. assessed and desired) are determined using the same goals cascade methodology, thus allowing for straightforward CI resilience evaluation, i.e. for:

- comparing the results of resilience analysis with criteria or objectives to determine whether the assessed resilience level is acceptable, and;
- identify areas for improvement.

The proposed framework consists of the following components:

- A **Goals Cascade Methodology (GCM)**, for ensuring that stakeholder needs are met, as well as for tailoring the framework usage for each CI organizational setting. This methodology is consistent with the COBIT5 goals cascade, thus enabling consideration of ICT concerns, which are increasingly important for all CI sectors. The proposed goals cascade methodology is derived from the COBIT5 goals cascade. This method allows for customizing the framework for different organizational settings, recognizing that each critical infrastructure organization has its own objectives and context. The goals cascade corresponds to the COBIT5 framework principle of meeting stakeholder needs. It provides value-based discernment for decision-making at several management levels, namely the discernment criteria for assessing risk, as well as for selecting risk indicators. Similarly, in this framework, the stakeholder needs translate to a cascade of inter-related goals at different levels, starting from high-level governance goals, cascading through all required management levels, down to relevant operational levels. Therefore, the GCM allows for tailoring the assessment rationale to any sector-specific, country-specific, as well as disaster-specific scenarios. Interestingly, the recently released *NIST Community Resilience Planning Guide for Building and Infrastructure Systems* (NIST 2015) also

approaches resilience planning activities based on understanding individual and social needs, which are then mapped to community goals and desired recovery performance goals, in recognition that "*the community's social and economic needs and functions should drive goal-setting for how the built environment performs*" (NIST 2017).

– A **Process Reference Model (PRM)**, is a set of interrelated processes that enables the governance and management of CI organizations, from a disaster risk management viewpoint. This reference model is integrated in the broader governance and management of the organization, thus embedding disaster risk management concerns in business-as-usual activities. The proposed model presents a disaster risk management viewpoint, and includes relevant concerns from the COBIT5 and the NIST Cybersecurity Framework (NCF). The NCF provides a common language for enabling communication and cooperation in cybersecurity risk management, for the information technology (IT) and industrial control systems (ICS) environments. The NCF core defines a set of relevant activities that help in the analysis, prioritization and implementation of cybersecurity countermeasures. Security functions are defined at the highest level of abstraction, helping to express activities for management of cybersecurity risk, and defined as follows:
– Identify: develop the organizational understanding to manage cybersecurity risk to systems, assets, data, and capabilities;
– Protect: develop and implement the appropriate safeguards to ensure delivery of critical infrastructure services;
– Detect: develop and implement the appropriate activities to identify the occurrence of a cybersecurity event;
– Respond: develop and implement the appropriate activities to act regarding a detected cybersecurity event; and
– Recover: develop and implement the appropriate activities to maintain plans for resilience and to restore any capabilities or services that were impaired due to a cybersecurity event.

A diagram of the PRM from Cadete et al. (2017) is shown in Figure 2. The governance and management enabling processes are aggregated in three interconnected groups:

1. *Cisis management*: a central process group for enabling specific disaster management functions, following the NCF terminology: identify, protect, detect, respond, and recover.
2. *Generic enablers*: a process group for cross-functional (generic) enablement, improvement, learning, and adaptation, for continuously enhancing disaster management capabilities, including generic governance and management capabilities.
3. *Risk*: processes for risk governance and management, conveying the idea that risk management should be continually performed on all other enabling capabilities for disaster management, thus promoting a clear disaster risk reduction perspective. Note that the risk-related processes refer to organization-wide processes (i.e. are not specific to disaster management), thus ensuring that disaster risk management concerns are embedded in the broader enterprise risk management (ERM) activities.

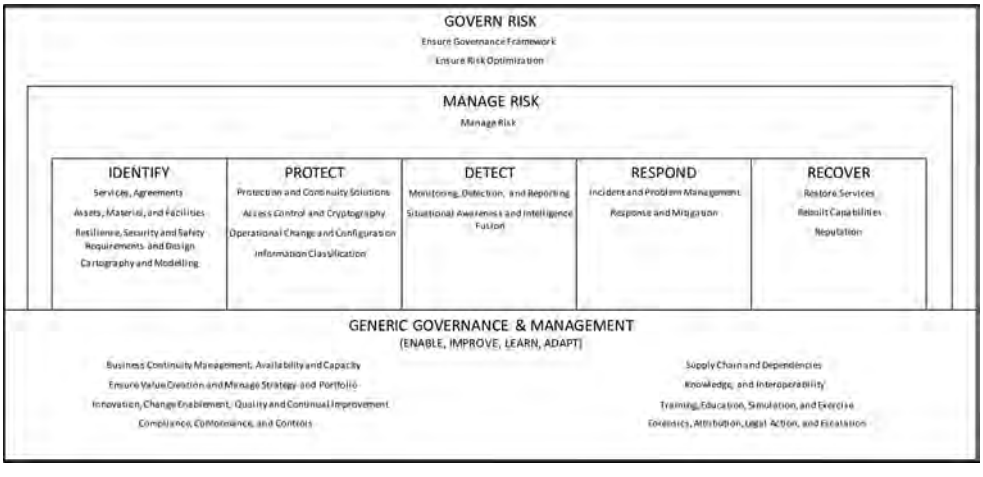

Figure 2. Process Reference Model (PRM), for the 26 disaster risk management processes. These organizational processes cover risk management (govern risk and manage risk), disaster management (identify, protect, detect, respond, and recover), as well as generic governance and management processes. Taken from Cadete et al (2017).

– A ***Process Assessment Model*** **(PAM) and a** ***Process Measurement Model*** **(PMM)**. These models are based on the ISO/IEC 33000 series guidelines. Like in COBIT5, the assessment results are expressed according to the capability level ratings achieved for each enabling process. Note that a certain capability level rating "*does not guarantee that an organization will perform its processes at any given process capability level, simply that it is capable of performing its processes at that level*" (ISO 2015). The capability levels follow the ISO/IEC 33020xx definitions, ranging from "*Incomplete*" to "*Innovating*" (the latter maps to the "*Optimizing*" COBIT5 capability level, based on ISO 15504).

The authors discuss why process assessment and measurement models are useful for conducting risk and resilience assessments, noting that risk is defined, in generic terms, as "*the effect of uncertainty on objectives*" (ISO 2009) and that processes "*have clear business reasons for existing, accountable owners, clear roles and responsibilities around the execution of the process, and the means to measure performance*" (ISACA 2012a). Note also that the first process capability level is named "*Performed*" and addresses precisely the achievement of organizational objectives in a certain process area, thus serving as a useful indicator for risk and resilience management. The achievement of higher capability levels provides stronger assurances regarding risk reduction, although generally implying higher implementation costs (Cadete et al. 2017).

3 RESEARCH PROBLEM

Although Lange et al (2017a, 2017b) proposes a CI risk assessment process model incorporating CI resilience assessment, and the resilience assessment framework from Cadete et al (2017) allows for establishing a link between resilience analysis and resilience evaluation—based on measuring and comparing capability levels of disaster risk management processes–, we currently lack a methodology for guiding the implementation of such conceptual models in practice.

Without such guidance, stakeholders will not be able to conduct assessment, auditing, and consulting initiatives in a consistent manner. Also, results from different CI assessment initiatives (e.g. different sectors, operators, auditing and consulting companies) will hardly be comparable, hindering the effectiveness of enterprise, policy, and regulatory initiatives.

4 PROPOSAL

In this paper we seek to provide a contribution to this problem, by providing guidance on how to manage, assess, and measure resilience-related capabilities which are expressed in the form of capability levels of organizational processes. As stated before, this approach is important because risk may be defined as "*the effect of uncertainty on objectives*" (ISO 2009c), and that processes "*have clear business reasons for existing, accountable owners, clear roles and responsibilities around the execution of the process, and the means to measure performance*" (ISACA 2012a). It is also important to clarify that governance and management processes have an overarching role in risk management, as stated in CISM guidance (ISACA 2016): "*most security failures can ultimately be attributed to failures of management, and it must be remembered that management problems typically do not have technical solutions*."

To this end, we propose to use generalized COBIT5 guidance for risk management, based on COBIT5 for Risk (COBIT 2013c) best practice. Note that COBIT5 provides a framework that assists enterprises in achieving their objectives for the governance and management of enterprise information technology (IT). As such, its IT scope is narrower that what we need to address the broader CI resilience assessment and management problem. However, the framework fundamentals may be easily generalized towards creating higher-order generic governance and management frameworks.

The COBIT5 extensive body of knowledge is based on the following objectives and principles (ISACA 2012b):

– *Governance objective*: enterprises exist to create value for their stakeholders. Consequently, any enterprise, commercial or not, has value creation as a governance objective. Value creation means realizing benefits at an optimal resource cost while optimizing risk. Note that, in COBIT5, IT risk is treated as business risk, therefore the COBIT5 recommendations may be generalized to other risk types.
– *Principle 1*: Meeting Stakeholder Needs: the purpose of risk governance and risk management is to help ensure that enterprise objectives are achieved throughout the goals cascade. Optimizing risk is one of the three components of the overall value creation objective for an enterprise. Note that this principle is aligned with NIST guidance, that approaches resilience planning activities based on understanding individual and social needs, which are then mapped to community goals and desired recovery performance goals, in recognition that "*the community's social and economic needs and functions should drive goal-setting for how the built environment performs*" (NIST 2017).

– *Principle 2*: Covering the Enterprise End-to-end: COBIT 5 for Risk covers all governance and management enablers in its scope and describes all required phases of risk governance and risk management. COBIT 5 does not focus on only the IT function, but treats information and related technologies as assets that need to be addressed like any other asset, by everyone in the enterprise. Also, governance of enterprise IT is integrated into enterprise governance. This principle is relevant to ensure that resilience management and assessment frameworks are able to cover all cross-sector concerns engaged in crisis management (especially due to CI interdependencies).
– *Principle 3*: Applying a Single Integrated Framework: COBIT 5 for Risk aligns with major risk management frameworks and standards, such as ISO 31000, ISO/IEC 27005, and COSO ERM (COSO 2017).
– *Principle 4*: Enabling a Holistic Approach: COBIT 5 for Risk identifies all interconnected elements of the enablers that are required to adequately provide risk governance and management, presenting a holistic and systemic approach towards risk.
– *Principle 5*: Separating Governance from Management: COBIT 5 distinguishes between risk governance and risk management activities. Good governance means that risk optimization is part of the governance arrangements that are put in place and risk information is included in the decision-making process, at the highest levels of leadership and related accountability.

A benefit of using a risk management approach that applies generic COBIT5 rationale is that the cyber and informational dimensions of CI are directly mapped to the information and related technologies content of COBIT5. Addressing the full people-cyber-physical challenge requires the seven categories of enablers of COBIT5, as per Principle 4:

– Principles, Policies and Frameworks;
– Processes;
– Organizational Structures;
– Culture, Ethics and Behaviour;
– Information;
– Services, Infrastructure and Applications;
– People, Skills and Competencies.

An adequate process reference model, such as the one presented in Figure 2, covers the "*Processes*" enabler dimension directly. Since COBIT5 is a holistic body of knowledge, the other six enablers are covered indirectly:

– The people dimension is covered by the enablers "*People, Skills, and Competencies*", "*Culture, Ethics, and Behaviour*", and "*Organizational Structures*", as well as informed and enforced by the enabler "*Principles, Policies, and Frameworks*".
– The enablers "*Information*" and "*Service, Infrastructure, and Application*" should be understood in the broad informational and technological scope of CI operator activity, i.e. including IT, operational technology (OT), material, facilities, and other infrastructural and technological artifacts.
– The enablers "*Information*", "*Service, Infrastructure, and Application*", and "*People, Skills and Competencies*" correspond to organizational resources. This entails that the concept of capability should include measures of (resource) capacity.

Considering the above COBIT5 guidance, as well as COBIT5 for Risk (ISACA 2013b), we may provide implementation guidance for CI resilience management, as described in the following sub-sections. In the remainder of this section we assume that GCM and PAM/PMM models are used—such as the one proposed in Cadete et al (2017).

4.1 *Establishing the context*

Using the GCM, we can translate stakeholder needs into specific, actionable, and customized goals cascade, from high-level enterprise goals, down to enabler goals.

For risk assessment, these enabler goals will later be associated with best practice, standards, and compliance requirements from relevant areas of concern.

During this risk management activity, the external and internal contexts should be established, and risk criteria—i.e. terms of reference against which the significance of a risk is evaluated—should be developed (ISACA 2013b).

4.2 *CI Risk Identification*

COBIT5 recommends an approach based on risk scenarios. A risk scenario is a description of a possible event that, when occurring, will have an uncertain impact on the achievement of the enterprise's objectives.

Risk scenarios can be identified and developed using two different mechanisms (ISACA 2013b):

– A top-down approach: starting from the overall enterprise objectives, identify business objectives and scenarios with highest impact on achievement of business objectives.
– A bottom-up approach: a list of generic scenarios is used to define a set of more relevant and customized scenarios, applied to the individual enterprise situation.

Note that using risk scenarios, as a specific method for identifying risk, does not exclude using other risk techniques e.g. from ISO 31010, to assist risk identification, as well as risk analysis activities.

4.3 *CI risk analysis*

In this activity, the frequency and impact of risks are estimated. Risk factors should be considered, i.e. those conditions that influence the frequency and/or business impact of risk scenarios. They can also be interpreted as causal factors of the scenario that is materializing, or as vulnerabilities or weaknesses.

Scenario analysis may be based on past experience, known current events, and also possible future circumstances (ISACA 2013b).

4.4 *CI resilience analysis*

Using a PAM and a PMM as assessment and measurement models, the analyst can relate the risk scenarios with current and forecasted organizational capability levels (including resource capacities), to calculate current risks and residual risks (equal to current risks with additional risk responses applied) (ISACA 2013b).

4.5 *CI resilience evaluation and treatment*

In this activity we compare the results of resilience analysis with criteria to determine whether resilience level is acceptable and identify areas for improvement. The purpose of defining a risk response (avoidance, acceptance, sharing/transfer, or mitigation) is to bring risk in line with the defined risk appetite for the enterprise (ISACA 2013b).

4.6 *CI risk evaluation and treatment*

The CI risk and resilience risk responses should be integrated in a common decision-making process and contribute to a single security, safety, and resilience strategy, although the implementation of specific resilience controls may be realized by specialized initiatives or projects, within a coherent portfolio.

5 DEMONSTRATION

To illustrative how to implement the proposed guidance, for conducting resilience management and assessment, we will address the ERNCIP Project Platform concerns (ERNCIP 2017) and adapt a demonstration from Cadete et al (2017).

- *Establishing the context:* we situate ourselves in the context of the ERNCIP Project Platform, addressing the concerns of the *Thematic Group (TG)* on *Chemical and Biological (CB) Risks to Drinking Water*. Adopting the framework from Cadete et al (2017) as our reference model, we use the GCM and define that the enabling process area "*Monitoring, Detection, and Reporting*" should achieve capability level "*Innovating process*" (ISO 33020), given the ERNCIP requirements for high levels of risk control and innovation.
- *Communication and Consultation:* note that the ERNCIP Project Platform itself provides a forum for communication and consultation purposes, i.e. addresses "*continual and iterative processes that an organization conducts to provide, share or obtain information and to engage in dialogue with stakeholders regarding the management of risk*" (ISO 2009).
- *CI Risk Identification*: using a top-down approach, we address the ERNCIP TG work programme goals and choose e.g. a bio-terrorism risk scenario.
- *CI Resilience Analysis:* using the PAM/PMM from Cadete et al (2017) as assessment and measurement models, we assume that the analyst (we may also assume external auditing validation) assessed the current capability level of the "*Monitoring, Detection, and Reporting*" process as "*Established process*". Note that this means that the current capability level is below the desired capability level of "*Innovating process*".
- *CI Resilience Evaluation and Treatment:* mitigation is proposed as risk response, meaning designing and executing a project to move from "*Established process*" to "*Innovating process*", to meet risk appetite criteria. Using ICT best practice from COBIT5, this project entails achieving a capability level of "*Innovating process*" for the COBIT5 processes "*DSS01 Manage Operations*" and "*DSS02 Manage service requests and incidents*". Further detailed guidance can be found in COBIT5 documentation (ISACA 2013a).
- *CI Risk Evaluation and Treatment:* finally, after designing the project and estimating related implementation costs, the plan is submitted to the approval of top management. A decision is made to include the new project in the ongoing organizational security programme, with a mandate to address all possible portfolio synergies, as well as to report to governance bodies accordingly, for *monitoring and review* purposes.
- *Monitoring and Review:* as assumed in the previous paragraph, monitoring and review should include the governance bodies, for the purposes of ensuring that controls are effective and efficient in both design and operation, obtaining further information to improve risk assessment, analyzing and learning lessons, detecting changes

in the external and internal context, and identifying emerging risks (ISO 2009).

6 CONCLUSION

The main contribution of this paper is to provide implementation guidance for resilience management and assessment of critical infrastructure, using the resilience management framework from Lange et al (2017a, 2017b). Also, we demonstrated practical implementation of this guidance, to facilitate understanding and provide validation, using the context of a real-world resilience initiative (ERNCIP 2017), a fictional risk scenario, and addressing ICT concerns using a state-of-the-art governance and management framework for information and related technologies (ISACA 2012b).

The ultimate goals of this contribution are to facilitate conducting assessment, auditing, and consulting initiatives in a consistent manner, as well to enable comparing assessment results from initiatives performed in different CI settings (e.g. different operators, sectors, or countries), using a standards-based approach.

Note that the resilience assessment framework discussed in the paper (Cadete et al. 2017) is not essential to the proposal, and may be replaced by another similar framework if the following generic requirements are met:

1. Approach: is aligned with the ISO 31000 risk management process, adopts a cyber-physical approach, and provides direct or indirect coverage for the seven COBIT5 enablers.
2. Governance: is aligned with the governance objective and principles, as described in the proposal.
3. GCM: provides a goals cascade methodology, so that risk may be address as "*the effect of uncertainty on objectives*" (ISO 2009), and we can translate stakeholder needs into a specific, actionable, and customized goals cascade.
4. PRM: provides a reference model based on organizational processes, covering all relevant resilience management and assessment areas of concern.
5. PAM/PMM: is aligned with ISO 33020 or a similar standard (such as ISO 15504).

Regarding limitations, note that this paper does not claim that the proposed guidance is the best approach for resilience management of critical infrastructure, instead assuming the framework from Lange et al (2017a, 2017b) is a reasonable approach. However, we have demonstrated that the framework from Lange et al (2017a, 2017b) can be used to derive an approach that is consistent with ISO 31000 and COBIT5 principles. Also, we have demonstrated that it can be used consistently with process-based resilience assessment frameworks.

Impact of human factors on threats in sewage treatment plants

M. Łój-Pilch, A. Zakrzewska & E. Zielewicz
Institute of Water and Wastewater Engineering, Faculty of Energy and Environmental Engineering, Silesian University of Technology, Gliwice, Poland

ABSTRACT: Physical, biological and chemical process take place during wastewater treatment. Any, even the smallest, disruption of any process may pose a risk in operation of the treatment plant. For each type of wastewater, an appropriate method for their purification is established. It depends on the type of sewage, the population equivalent and the type of receiver The paper compares the threats that may pose a risk in municipal sewage treatment plants. Selected, for risk analysis, sewage treatment plants are located in the same city. They were designed in the same technological chain due to similar Population Equivalent (PE) and comparable conditions of discharge purified wastewater to the receiver. Previous risk analyses have shown the importance of the human factor, in the form of management, work organization, documentation and databases, technical knowledge and staff training. Employees of sewage treatment plants in their daily work can prevent negative events or cause them to occur. The location of the selected wastewater treatment plant in the same city area causes that they are managed by the same person and operating in the same way. This ensures a similar response to the same events, similar risk elimination during the operation and quality of databases. These condition allow for the unification of the human factor when comparing the treats at the municipal sewage treatment plants.

1 INTRODUCTION

Man can influence the environment in which he lives and all processes that take place in his surroundings in both positive and negative ways. His decisions and actions during exploitation of technical objects may contribute to the emergence of potentially dangerous situations and events which result in losses, both material and immaterial, or in other words may cause risks. Therefore, the human factor can be seen as one of risk factors. It affects the effectiveness of business management, work organization and keeping of records and databases. It is also worth considering in terms of risk for occupational safety, which is caused by low level or total lack of employees' knowledge in this field, their reluctance to change and improve the work process and their unfamiliarity with OSH rules [1]. Speaking about the risk in terms of the human factor the authors want to focus on the human impact on municipal sewage treatment plants operation process.

The basic stage of risk analysis is its identification and classification, which enables its management in the company [2, 3, 10]. Obtaining reliable results depends on the accuracy of conducting the process and the professionalism of the person who identifies threats. Of great importance are also exactness and diligence in maintaining a database. In other words, reliable risk identification also depends on the human factor.

2 HUMAN FACTOR IN A MUNICIPAL SEWAGE TREATMENT PLANT

Sewage treatment plants are specific technical objects in which physical, biological and chemical processes take place. Constant supervision of the technological process and introduction of monitoring and control systems are not able to exclude the emergence of failures and malfunctions of individual devices [4, 5, 11]. This happens because adverse situations are fortuitous events and it is impossible to predict when and where they may occur. Correctly conducted threat identification and competent risk management in the object allows the elimination of adverse events before they may arise, and the development of operating instructions for dealing with a given phenomenon [12]. Yet the effectiveness of these activities depends on the employees who will execute them. Therefore it can be stated that proper functioning of a treatment plant is largely dependent on the human factor.

3 CHARACTERISTICS OF EXAMINED TREATMENT PLANTS

Risk identification was performed for two municipal sewage treatment plants in the Upper Silesian Industrial District (GOP). The examined objects are characterized by similar technological lines, PE

Table 1. Characteristic of examined treatment plants.

	Plant A	Plant B
Population Equivalent—PE	52 000	62 500
Treatment technology	Activated sludge	
Elements of technological line	Expansion chamber Bar screens	Sifters
	Horizontal grit-removal tank, aerated, two-chamber	
	Biological dephosphatation chamber	
	Activated sludge chamber	
	Secondary settling tanks, radial	
Difference in the quantity of technological line elements	3 secondary settling tanks	2 secondary settling tanks
Possibility of sewage delivery with the use of sewage truck	Yes—cast station present	
Industrial objects in the catchment area	Meat processing plant, electro-plating plant	None
Receiver	Watercourse	

value and the method of sewage discharge to the receiver. The characteristics of plants in question are presented in Table 1.

The analyzed sewage treatment plants are supervised by the same manager, so they both have identical treatment plants' worksheets, in which all works carried out during the shift and any failures or adverse events are recorded. This should standardize one of the human factor components in threats identification.

4 METHODOLOGY

First step in identifying threats of analyzed sewage treatment plants was the thorough familiarization with the technology and the way of operating objects, based on submitted operating instructions. The recognition of adverse events was preceded by a thorough interview with the manager of the object and shift managers. Researchers got acquainted with current operating problems and previous methods of their elimination. Operating instructions [6,7] for the treatment plant obligate the staff to carefully keep the operating log, which consists of:

- Worksheets of the treatment plant—it is required to record all work carried out during the shift, failures and observations;
- Equipment repair and maintenance cards—contain records on repair and maintenance works and failures;
- Technological notebook—contains results of analyzes of laboratory tests and information about the amounts of waste generated in the treatment plant; and therefore further stages of work are based on these documents.

Next, after analyzing the worksheets, a list of risk factors was prepared together with the frequency of their occurrence. Any doubts and inaccuracies in the records were verified with the operator's personnel. The next stage was to get acquainted with the equipment repair and maintenance card in order to determine risk factors being eliminated during maintenance of individual objects. This allowed identification of latent risk.

The final stage of the work was to determine which of adverse events actually cause a risk in the operation of a sewage treatment plant. For this purpose, records of laboratory tests results of treated sewage at the outflow during and after the occurrence of a potential threat were checked with the use of technological notebook. In the case of incorrect values of any quality indicator, the occurrence of a given adverse event was treated as a threat causing losses—an emergence of a risk.

Identification of threats in the examined treatment plants was performed for a period of 3 years of object's exploitation. This period fell on the years 2014–2016.

5 THREATS IDENTIFIED IN MUNICIPAL SEWAGE TREATMENT PLANTS

5.1 *Identified risk factors [4]*

Risk factors in municipal sewage treatment plants may be divided into:

- internal—caused by the impact of treatment plant objects,
- external—caused by the influence of factors from outside the treatment plant,
- ordinary—easy to predict, often occurring during current operations,
- extraordinary—unpredictable fortuitous events, unusual situations,
- explicit (existing) – occurring in the past, often appearing periodically,
- latent—potentially possible, but not yet occurred (in a given object).

5.2 *Identified risk types [4]*

During the risk identification process of municipal sewage treatment plants one can distinguish the following types of risk:

- qualitative—results in lowering the level of sewage treatment or in digestibility of individual devices,

- operational—results in a decrease of the efficiency of technological line cleaning, and in extreme cases even in a breakdown of the process,
- ecological—results in a negative impact on the receiver and environment,
- financial—results in a financial outlay which must be borne by the sewage treatment plant as a consequence of the arisen threat.

6 SEWAGE TREATMENT PLANT "A"

In the analyzed three-year operational period of the sewage treatment plant, a total of 36 different threats were identified. Some of them were isolated events, others occurred several times. It was stated that a total of 111 situations could have been risk-causing events. Table 2 presents the identified threats for individual objects of the treatment plant.

The percentage share of risk-posing events (Figure 1) indicates that devices exposed to the highest risk are the bar screen and activated sludge chamber. Description of the most frequent events and specification of type of factors and type of risk they cause are presented in Table 3.

Table 2. Identified risk-posing factors for individual objects of treatment plant "A".

Device	Number of events
Cast station for delivered sewage	1
Local sewage pumping station	1
Bar screen	30
Grit chamber	18
Dephosphatation chamber	15
Activated sludge chamber	23
Clariffer	17
Sewage treatment plant	6
Total	111

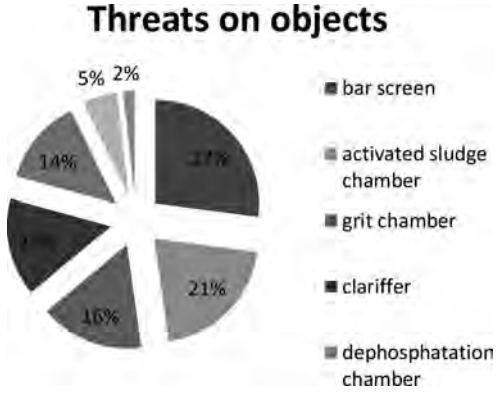

Figure 1. Percentage share of events that may cause risks in individual devices of the A plant's technological line.

Table 3. Examples of risk factors for selected elements.

Device	Event	Factor	Type of risk	Effect	Action taken/proposed
Bar screen	clogging of bars	external	qualitative	impeded sewage flow	cleaning of bars
Bar screen	large fat and meat dump	external	qualitative, operational, financial, ecological	greasing and clogging of bars, greasing of grit-removal tank	removal of excess fat, cleaning of bars
Bar screen	failure of bar screen automatics	ordinary	qualitative	closing of bar screen channel	repair of bar screen controlling automatics
Grit-removal tank	failure of grit-removal tank	ordinary	qualitative	increased amount of sludge in regulation chambers	repair of failure
Grit chamber	dump of greasy wastewater	external	qualitative	large amount of fats in the flotation area	pumping-out of fats
Dephosphatation chamber	sludge floating on the surface of dephosphatation chamber and activated sludge chamber	internal	qualitative, operational	bad sedimentation of sludge	lime dosage

(*Continued*)

Table 3. (*Continued*).

Device	Event	Factor	Type of risk	Effect	Action taken/proposed
Activated sludge chamber	freezing of activated sludge chamber surface	external	qualitative	ice formation on sludge coat	breaking the ice
Activated sludge chamber	formation of ice blockage	external	qualitative, operational	inability to draining of sewage	removal of blockage
Activated sludge chamber	problems with sludge draining, sludge putrefaction	internal	qualitative, operational	formation of scum layer	removal of scum layer and removal of putrefied sludge
Activated sludge chamber	emergence of filamentous bacteria	internal	qualitative	formation of scum layer	breaking the scum layer and bacteria removal
Secondary settling tank	freezing of the settling tank surface	external	qualitative, operational	formation of ice layer	breaking the ice layer
Secondary settling tank	auxiliary devices failure	ordinary	qualitative, operational	minor disturbance in the settling tank operation	repair of auxiliary devices
Sewage treatment	electrical power outage	external	qualitative, operational	lack of power for electrical powered devices	connection to the emergency power supply

Table 4. Identified risk-posing factors for individual objects of treatment plant "B".

Device	Number of events
Cast station for delivered sewage	2
Inflow to the plant	1
Sifters	9
Grit chamber	10
Activated sludge chamber	72
Clariffer	18
Sewage treatment plant	2
Total	114

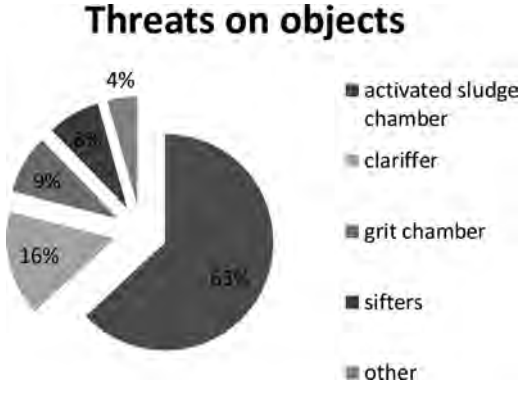

Figure 2. Percentage share of events that may cause risks in individual devices of the B plant's technological line.

7 SEWAGE TREATMENT PLANT "B"

Over the same time period, 32 different threats that could have caused risks were identified in treatment plant B. The number of risk-posing events was 114. Table 4 presents the identified threats and the number of their occurrences in individual objects of the "B" treatment plant.

Figure 2 shows that the most risk-posing device in the B plant was activated sludge chamber. The reason for this situation may be the attempt to improve the effectiveness of sewage treatment in the year 2015 and incursion in the technology used, as a result of which filamentous bacteria and scum layer appeared in activated sludge chamber. The most frequent threats are shown in Table 5.

8 COMPARISON OF THREAT IDENTIFICATION RESULTS IN THE EXAMINED TREATMENT PLANTS A AND B

Among the identified threats, 9 events occurred in both sewage treatment plants with different intensity (Table 6).

Large discrepancies in quantities of individual phenomena occurring in examined treatment plants may be caused by various circumstances, for instance:

Table 5. Examples of risk factors for selected elements.

Device	Event	Factor	Type of risk	Effect	Action taken/ proposed
Sifters	sifter scraper failure	ordinary	qualitative	clogging of sifter	repair of scrapper
Grit chamber	large dump of greasy sewage	external	qualitative	clogging of grease chamber outflow	unclogging the outflow
Activated sludge chamber	emergence of filamentous bacteria	internal	qualitative, operational	formation of scum layer	breaking the scum layer and actions aimed at stopping bacteria development
Activated sludge chamber	momentary change in quality of inflowing sewage	External ordinary	qualitative, operational	high concentration of ammonia in aeration chamber	turning on mammoth rotors
Activated sludge chamber	steering malfunction	ordinary	qualitative, operational	incorrect readings from activated sludge chamber	manual steering and repair of automatics
Activated sludge chamber	freezing of activated sludge chamber surface	external	qualitative	formation of ice layer	breaking the ice layer
Secondary settling tank	malfunction of discharge flume cleaning brush	ordinary	qualitative	cleaning of discharge flume impossible	reapair, cleaning of flumes
Secondary settling tank	auxiliary devices failure	ordinary	qualitative, operational	minor disturbance in the settling tank operation	repair of auxiliary devices
Sewage treatment	electrical power outage	external	qualitative, operational	no power for electrical powered devices	connection to emergency power supply
Sewage treatment	failure of devices visualization	ordinary internal	qualitative, operational	automatic steering of all devices impossible (aeration chambers operate in manual mode)	repair of visualization system

Table 6. Frequency of the same phenomena occurrence in sewage treatment plants A and B.

Device	Event	Treatment plant "A"	Treatment plant "B"
Cast station for delivered sewage	No flow	1	1
Grit chamber	Freezing of grit chamber elements	6	1
	Large dump of greasy sewage	8	1
Activated sludge chamber	Emergence of filamentous bacteria	1	41
	Freezing of activated sludge chamber surface	5	5
	Mammoth rotor malfunction	4	3
	Power cut of operation sensors	1	5
Secondary settling tank	Auxillary devices failure	15	7
Sewage treatment	Electrical power outage	6	1

- dump of greasy sewage was influenced by meat-processing industry in the catchment area of treatment plant A;
- the emergence of filamentous bacteria was the effect of attempts to improve the efficiency of treatment plant B, i.e. technological changes;
- momentary power outages in treatment plant A were caused by earthworks near the main power cable; treatment plant A was in five out of six situations notified beforehand.

Repetitive occurrences of only 9 adverse events in both analyzed objects does not mean that the remain-

ing events are distinctive for a given treatment plant. The same situations may be variously described in the worksheets depending on who makes the record on a given day. During the identification process, efforts were made to unify the records in operating logs, but this was not always possible.

The main operational problem of both treatment plants are fibrous substances not included in the above list. In treatment plant A, the cleaning of probes (activated sludge chamber, secondary settling tank) from fibers was called "a maintenance of individual objects". Due to the occurrence of this problem, initially assumed period between inspections was shortened from 6 to 3 months. On the other hand, in treatment plant B every 3 months on average the event called "removing of rags" has been recorded on individual objects (active sludge chamber, secondary settling tank). Only after conversation with the manager and employees of the sewage treatment plant it was found out, that it is all about the same operational activity.

The above examples show that the human factor is of great importance during identification of threats.

9 CONCLUSIONS

In both treatment plants appeared phenomena that under unfavorable conditions may be risk factors. In the analyzed period there were no exceedances of indicators examined at the outflow, so it can be concluded that potentially risk-posing situations did not adversely affect the process of sewage treatment. Employees' behavior, their decisions and actions taken when a risk-posing factor emerges have an impact on the level of sewage treatment attained by each treatment plant.

The human factor plays a decisive role in risk identification. Actions aimed at standardization of this factor (comparison of threats in two municipal sewage treatment plants with similar PE and a similar technological lines), have emphasized its role not only in the identification process but also in risk management. The methods of dealing with a given threat depend on the training and expertise of the staff.

ACKNOWLEDGEMENT

Field operations in the high arctic—experienced feedback and tacit knowledge as key tools for safety management

M. Indreiten
The University Center in Svalbard

E. Albrechtsen
The University Center in Svalbard
The Norwegian University of Science and Technology, Trondheim, Norway

S.M. Cohen
The University Center in Svalbard

ABSTRACT: The paper demonstrates the importance of tacit knowledge to cope with various situations during field work in the high arctic. Two cases from field work at the University Center in Svalbard (UNIS) are shown to exemplify this: one boat trip and one snow mobile trip with researchers and students. Successful field operations depend heavily on technicians from the UNIS Field Safety Section that have the responsibility to assist in the planning and execution of every type of field work. Due to rapidly changing conditions, local variations, extreme weather conditions, lack of access to infrastructure and communication, successful safety performance is accomplished by individual's ability to adapt to situations. The paper demonstrates that this ability to a large extent is a function of the tacit knowledge of the technicians. To improve the tacit knowledge of each technicians, systems and practices of experience feedback must be run to ensure individual and organizational learning from both failures as well as successes. This is in particular important in systems with great variability in climatic conditions and systems with organizational changes.

1 INTRODUCTION

The University Centre in Svalbard (UNIS) has been operating in Longyearbyen, Svalbard since 1993. Longyearbyen is a small town located on the west side of Spitsbergen, a part of the Svalbard archipelago in the high arctic at 78 degrees north. UNIS educates more than 800 students and supports close to one hundred research projects on an annual basis. In total UNIS has close to 12 000 field days per year. The education and research is field based and the season lasts from January to December.

Operations in the high arctic prove to be challenging. Challenges encountered include, but are not limited to: lack of infrastructure, harsh and variable weather, darkness, and rapidly changing natural hazards. These are conditions that have to be handled from day to day to ensure safe operations for students and scientists.

In the last five years natural hazards have been changing at such an increased rate (e.g. avalanche danger, melting sea ice, high levels of precipitation, rapid fluctuations in air temperature etc.). For UNIS this implies that established operational procedures based from many years of experience are no longer valid. The practitioners responsible for planning and guiding students and scientists in the field often experience that the plan deviates from the performance. They have to choose deviation "constantly" to maintain a safe performance of the activity. A challenge is thus to have a system or process that secures feedback to the decision makers.

To keep up with the changing risk picture, experienced feedback and tacit knowledge are getting more and more important to maintain safety management and safe operations.

The purpose of the paper is to exemplify how experienced feedback and tactic knowledge are used to manage safety for operations in the high arctic and discuss how experience feedback can ensure organizational learning for field operations.

2 EXPERIENCE FEEDBACK

Safety management is based on the principle of experience feedback, i.e. the process by which information about the results of an activity is fed

back to decision makers as new input to modify and improve subsequent activities (Kjellén and Albrechtsen, 2017). Kamsu Foguem et al. (2008) have a similar interpretation: experience feedback is a process whereby experience at an operational, tactical or strategic level is disseminated in such a way that the knowledge is used to improve the organization's performance.

The purpose is to use information about experienced or expected safety performance as a basis for decisions that prevent accidents and reduce accident risk.

Experience feedback is based on principles from quality management such as Juran (1989) persistent feedback control and Deming's (1993) cycle. Kjellén and Albrechtsen (2017) present a safety information system based on principles of experience feedback that consist of collection of data about experienced and expected safety performance; analysis and storage of the data; distribution of analyzed data to decision-makers; and decision-making and implantation of safety measures. This system facilitates systematically improvement of safety based on experiences (incidents, non-conformities, observations, etc.); identification of current performance (inspections, audits); and excepted safety performance and challenges (risk assessments).

Another important principle of experience feedback is organizational learning and knowledge sharing. The process of organizational learning involves an organizational unit changing itself or its knowledge base as a result of experience (Cyert & March, 1963). The unit can learn directly from its own experiences, or from the experiences of other units (Levitt & March, 1988). Argyris and Schön (1996) claim that organizations learn only if the product is a change in behavior and governing variables in the organization.

Although the literature differs between individual and organizational learning, there is a clear relationship between the two (Crossan et. al, 1999). Nonaka and Takeuchi (1995) demonstrates how transitions of tacit and explicit knowledge lead to organizational knowledge (Figure 1). Through these processes, knowledge is converted from individual knowledge to shared knowledge that can be utilised by the whole organisation. The transitions are continuous processes that lead to a learning spiral. Nonaka & Takeuchi (1995) propose four basic processes whereby knowledge is converted:

- Externalisation takes place when tacit knowledge is made explicit, for example when an unwanted occurrence is observed and reported by a worker at the sharp end.
- Combination takes place when explicit knowledge is combined with other explicit knowledge, for example when a reported unwanted occurrence is compared with other reported unwanted occurrences in an effort to identify similarities.
- Internalisation takes place when explicit knowledge becomes tacit knowledge. The point is to see the importance of making practical use of knowledge through converting the explicit to practical, effective and correct actions.
- Socialisation takes place when tacit knowledge is spread as tacit knowledge to other members of the organisation, who learn over time through seeing what others do.

Principles of organizational learning implies that safety management based by experience feedback is dependent on both formal and informal processes of knowledge sharing among practitioners, safety staff and managers.

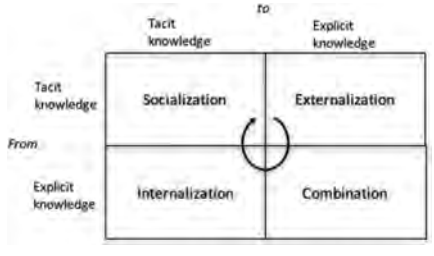

Figure 1. Knowledge creation in organizations (Nonaka and Takeuchi (1995).

3 SAFETY CHALLENGES IN FIELD OPERATIONS AT THE UNIVERSITY CENTRE IN SVALBARD

Every person going through the UNIS system expects access to teaching, learning or research in the field. Safety technicians at UNIS have the responsibility to assist in the planning and execution of every type of field work. This includes the safe transport of groups to their desired field locations, and then further technical assistance and general safety at the field site. Safety technicians at UNIS benefit from the experience of years of living and working in the Arctic. This includes hundreds of hours of work in the field on an annual basis.

At UNIS there are two distinct field seasons. Winter field season normally runs from January-May, while summer field season extends from June-October. November and December are typically slower, due to lack of snow and light.

Winter field season is characterized by snow mobile travel. Other forms of transportation may include travel by beltwagon or larger sea going vessels. Typical hazards encountered during winter season include: snow mobile driving, avalanche

terrain, sea ice, glaciers, harsh weather conditions, and polar bear encounters.

Field operations in the summer season is mainly done by boat travel. A variety of vessels are used including: zodiacs, polar circles, tourist boats and large cruise vessels. Typical hazards encountered during summer season include: harsh weather, rough ocean conditions, camp challenges, polar bear encounters, and hazards encountered when travelling in steep mountainous terrain.

The top priority in both winter and summer field seasons for the technicians is to ensure the group has safe transportation from Longyearbyen to their field location. In winter season this is controlling a group of 10–30 students and teachers on snow mobiles as they drive through variable terrain to their destination. In summer this is transporting up to 12 students and teachers at a time by polar circle to their destination.

Ideally the technicians should only operate under favorable conditions, where there are few hazards and thus low risk. Due to the environment and related hazards and challenges, all activities involve some kind of risk, and the plan often deviates from what is expected.

Two examples will be presented which illustrate the challenges associated with field travel in both winter and summer

3.1 *Case 1: Boat travel, summer season*

The objective of the field travel was to drop off one group to Colesbukta, drop off camp equipment and perform water sampling in Dicksonfjorden, see map in Figure 2. The two trips were originally scheduled to take place on different days, but this had to be changed when an attempt to drop off the first group in Colesbukta the day prior was unsuccessful. Technician A had taken three scientists, plus a boat full of field equipment towards Colesbukta the previous afternoon. The group had traveled for approximately one hour in bad conditions, heading straight into the oncoming waves which were crashing over the bow of the boat at a height of over two meters. The technician decided to turn around for several reasons:

- If the technician maintained the same speed, an hour long round trip would have taken two to four hours in conditions which were not supposed to improve
- The wind direction was not favourable for landing in the desired location
- The scientists had a lot of heavy equipment which would take a long time to unload
- The desired drop off point was extremely shallow, with lots of known objects in the water. With heavy waves and wind, chances of either grounding the boat, or hitting the propeller/engine on an object were increased
- The boat was heavy and had a broken anchor winch, making it not ideal for shore landings, especially with the given conditions

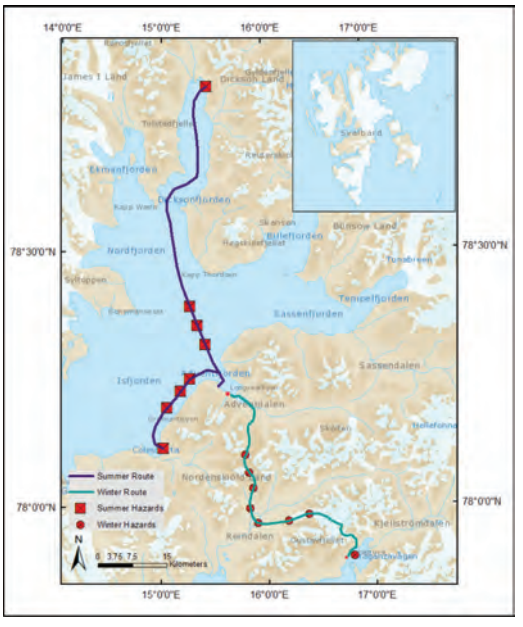

Figure 2. Map showing the routes described in the following tasks. Summer hazards are where shallows and rough seas are normally encountered. Winter hazards are where avalanche, glacier, sea ice and open water hazards are normally encountered. Basemaps © Norwegian Polar Institute.

If the technician only encountered one of the before-mentioned factors, the trip would probably have been completed. A combination of all of the factors, which the technician was able to identify during the trip, forced the decision to turn around. There was no protocol for this, but due to past experiences the technician was able to determine that in this particular situation, the risk was not worth the potential consequences.

The next day the winds and sea had calmed making it realistic to complete both trips. Due to a combination of factors it was decided that two technicians and two boats were needed to make this a successful operation. A request was made by Technician A to Technician B for assistance. Factors which were considered for this trip included:

- Colesbukta and Dicksonfjorden are in opposite directions, so if only one boat went, the trip would take a significantly longer amount of time
- The drop-off spot for the camp in Dicksonfjorden is dependent on tides. A lot of gear needed

to be unloaded which is time sensitive in order to not ground the boat
– The boat going first to Dicksonfjorden needed to pick up scientists from the camp for sampling
– Wind was coming from east, making the travel to Dicksonfjorden fine, but more challenging on the way back to Longyearbyen when heading directly into the wind

The plan was then executed safely and successfully. The two boats left at the same time, with Boat B heading first to Colesbukta to drop off scientists and gear, and then bring the rest of the gear to Dicksonfjorden to meet Boat A in time to drop off equipment before the tide started falling. Boat A went straight to Dicksonfjorden and was able to complete the sampling and drop off the other equipment. Boat A and Boat B were then able to drive back to Longyearbyen from Dicksonfjorden together, which was optimal because the winds began to pick up creating unfavorable conditions for driving alone. Boat B has a covered cabin, making it more favorable for driving in big waves. Boat A could then drive in the wake of Boat B, as to not get as many waves into the boat on the way back to Longyearbyen.

This task ended successfully for several reasons. The two technicians had combined experience from driving boats in Isfjorden. They both knew the challenges with landing in the two areas, and were able to understand the implications that the weather conditions and tides would have on the locations they needed to get to and tasks they needed to complete. Flexibility played a huge part in that both technicians were willing to change plans when it proved necessary in order to complete a safe and successful trip. The challenges and potential hazards encountered during this scenario are not uncommon or unknown. Shallows, tides, waves, wind, boat problems, etc., are all encountered by boat drivers in Svalbard. The challenges can be anticipated, but only the knowledge one needs to be equipped to deal with them, and to operate around them are only gained through experience.

Figure 3. Example of vessel used during field trips, UNIS Polaris beached.

3.2 *Case 2: Snow mobile travel, winter season*

The objective of the field travel was to transport a group of students and professors from Longyearbyen to Svea (a small mining settlement located 60 km away from Longyearbyen) in early February by snow mobiles. Travel between Longyearbyen and Svea is common during the winter and spring months by snow mobile. Transporting a group of up to 25 students and professors to do work on the sea ice close to Svea is normally not challenging. However, in recent years, Svalbard has experienced more precipitation, higher temperatures and less sea ice. This leads to more challenging conditions for winter field work. The technicians anticipated the following risk factors for this particular task:

– 25 people with little to no snow mobile experience must drive over 60 km through challenging conditions
– Driving through avalanche terrain
– Driving in places with open water
– Driving over terrain which is icy and rocky
– Driving over glaciers with crevasses
– Working on sea ice

Therefore, special precautions had to be taken, and here it is the job of the technicians to use their knowledge and expertise to ensure the group can travel and work safely in Svea. One should always expect and be prepared to encounter hazards doing this kind of work, but in this particular situation there were several risk factors which needed special attention from the technicians to ensure safe and successful travel:

– The season up to this point had brought unusual conditions which included: a lot of snow, followed by heavy rain and temperatures up to +7°C. Temperatures then quickly fell to well below 0°C.
– The normal route to Svea includes traveling through narrow valleys surrounded by steep mountains which leads to both avalanche hazards and water hazards
– The route also includes travel across a wide open valley which is vulnerable to wind which can blow all of the snow away leading to icy and rocky conditions
– The route includes a glacier crossing which creates a potential crevasse hazard
– Due to the decreased activity in Svea, the route which is normally well maintained is much more unknown and unpredictable

– Sea ice which is normally forms close to Svea is affected by warmer air and sea temperatures. Extra precaution must be taken when working on this ice.

Instead of the normal procedure of sending out one technician to follow the group as would be necessary, several scouting trips were undertaken in order to identify all of the possible hazards the group might encounter, and to confirm that safe travel was possible. Three separate scouting trips were completed until the technicians were satisfied that they were comfortable sending the group through the terrain and had identified all possible hazards and deemed them manageable for the group. The technicians identified open water, avalanche conditions, blue ice and rocks. They were able to deviate slightly from the normal route, in order to find a route which was as safe as possible for the students and staff.

On the day when the students and staff were supposed to travel to Svea, two technicians joined to ensure safe travel. The trip was completed successfully and the students and staff were able to do their work in Svea.

4 DISCUSSION

4.1 *Adaptation and flexibility*

Both field trip examples described in the previous section were successful in terms of safety because the technicians were able to anticipate the risks of the trips and thus adapt to the situation of the trips. Rankin et al. (2014) present a framework for understanding coping mechanism (adaptions) to respond to variations in a dynamic environment, see Figure 4. Adaptions are a function of 1) objectives, i.e. the outcome that the adaption aims at achieving and is related to identifying demands, pressures and conflicting goals; 2) the context in which the adaption is carried out; and 3) necessary resources and conditions for successful implementations of the coping mechanism, including both "hard" and "soft" conditions such as availability of knowledge. The adaption in itself consists of 1) the four cornerstones of resilience (Hollnagel et al., 2007) anticipating, monitoring, responding and learning; and 2) interactions between sharp-end and blunt-end.

Figure 4. Snow mobile travel to Svea.

The successful adaptions among the technicians at the field trips can be described in such a framework. Their adaption is a function of the context of the action that consist of their ability to monitor and anticipate the situation. The technicians' tacit knowledge is a key contributor to their ability to adapt to the situation, not least because the success of the actions depend on the decisions made at sharp end due to lack of communication infrastructure with the blunt end.

The tacit knowledge among the technicians and their ability to adapt to the situation are essential in both cases for maintaining safe travels in continuously changing variable conditions. Scenario 1 has several elements which made it more difficult than a normal to drop off or pick up in the field. Tacit knowledge from the technicians which is acquired through multiple seasons and hundreds of hours of driving boats around the Isfjorden area was vital to complete this task in a safe and effective way. The snow mobile trip in scenario 2 was successful for many of the same reasons that the boat trip was successful. The technicians were able to use their past experience and knowledge to anticipate the hazards and then act accordingly. Flexibility plays an important role. The technicians were able to put in much more work than is normal for this kind of trip. When many different hazards exist and combinations of hazards are not always predictable, tacit knowledge and experience are essential.

The two scenarios also show the connection between the sharp end—the practitioner, and the blunt end—the management. For both scenarios a key word is flexibility. Based on the experience in the sharp end from similar operations, the management can see the need for flexibility and use of extra time to adapt to the situation. Experience in the sharp end is building situational understanding in the blunt end.

4.2 *Experience feedback at an organizational level to improve coping mechanisms*

The available knowledge among the technicians at sharp-end during field trips could be improved by principles of experience feedback as illustrated in Figure 5. The framework by Rankin et al. (2014) is rooted in principles of resilience engineering.

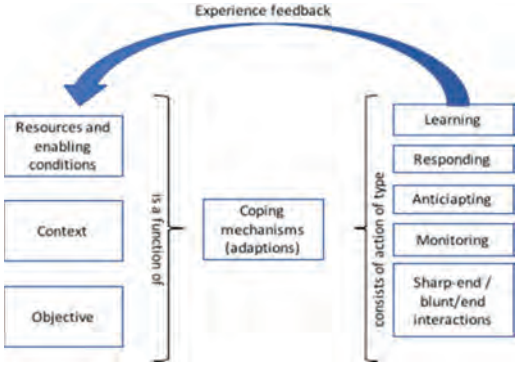

Figure 5. Framework for analysis of coping mechanisms (based on Rankin et al. 2014) and the importance of experience feedback.

Resilience engineering is centred around four main abilities: to respond, to monitor, to anticipate and to learn. The ability to learn from both failures and success is a key to improving the knowledge among sharp-end practitioners. By learning from experiences at field trips both individually and among colleagues, resources that contribute to adaptions will improve.

The technicians who participate in fieldwork with students and employees acquire new experience every day and thus maintain and develop their tacit knowledge. In addition, their tacit knowledge is generated when the they continuously close nonconformities during field trips as shown in the two cases in the prior chapter.

The individual learning is important learning for the organisation. Feedback from experiences related to everyday tasks should be shared in the organization; what works and what does not work in order.

Nonaka and Takeuchi (1995) emphasize how different transitions of tacit and explicit knowledge create shared knowledge in organizations. Socialization (from tacit to tacit knowledge) is one of the transitions that contributes to organisational learning. The technicians at UNIS start each morning with a meeting to go through the tasks/duties to be performed on that day. Ekman (2012) highlights the importance of informal conversations in making tacit knowledge visible in the organisation, and facilitating arenas that encourage small talk. The morning meetings involve a set agenda where events from the day before is discussed and the technicians inform each other of changes related to snow conditions, weather, etc. The technicians generally meet up for a cup of coffee together before this meeting. A lot of information is shared during this five-minute period that should be raised during the formal meeting. As a result, important information is not raised at the meeting with the management because it has already been shared during the small talk over coffee before the meeting. Tacit knowledge among those talking is improved, but there is potential for organizational learning in addition if this knowledge is share among more people.

Transition from tacit knowledge to explicit knowledge (externalization) will also contribute to organizational learning (Nonaka and Takeuchi, 1995). Within safety management, systems for reporting of unwanted occurrences is an important contribute to externalization of tacit knowledge, but also to combination of explicit knowledge as well as internalization (from explicit knowledge to tacit knowledge) (Kjellén and Albrechtsen, 2017).

Such learning among technicians wil happen in communities of practise (Wenger, 1998). Communities of practice is a group of humans that has a mutual engagement, common goals and activities and a common repertoire of actions and resources (Wenger, 1998). Among the primary parts of learning in communities of practice we find social participation, sharing stories, apprenticeship learning, and that learning is a complex social phenomenon dependent on context.

How can one use and systemise the informal "coffee break" to strengthen learning in the organisation? Ekman (2012) refers to the importance of horizontal meeting places for the tacit knowledge where every day experiences can be shared. It is also possible to learn from conversations about a completely normal day. It provides an opportunity to test out the prevailing knowledge and create new learning. A traditional view in the field of safety is that one learns from mistakes and incidents. However, in more recent times, it has become more common to focus on learning from successful tasks (Hollnagel, 2014), which after all is most of the tasks one performs during a working day. By learning from everyday events, it is possible to test the prevailing knowledge and, in doing so, uncover practices that are unsafe, even though no accidents have occurred. "Learning from successful operations is not only about identifying and promoting good practice, it is also about detecting the instances where no accident occurred in split of unsafe practices or unsafe systems" (Rosness et al., 2016).

4.3 *Contextual change that affect experience feedback*

UNIS experience increased student production and rapid changes in the natural environment. Ashby´s (1961) law of requite variety states that control of a system is achieved only when the variety of countermeasures matches the variety and changes of

the system. This implies that the field technicians must acquire new knowledge and put this into effect to deal with the contextual changes of their field activities. Systems and practises for experience feedback would enable improved knowledge to handle new situations.

Growth is not only a matter of increasing staffing to deal with the increased activity. One must also make structural changes to ensure that the environment for learning from tacit knowledge and making this visible is as favourable as possible. If one looks at organisations that manage to exploit tacit knowledge, facilitating communication is a key factor. Structurally, one can facilitate the rapid spreading of knowledge and spend time on systematic training and review the composition of the work group to attain a mentor effect.

5 CONCLUSION

Successful field operations at the University Centre in Svalbard depend heavily on safety technicians that have the responsibility to assist in the planning and execution of every type of field work. Due to changing conditions, local variations, extreme weather conditions, lack of access to infrastructure and communication successful safety performance is created by individual's ability to adapt to situations. This paper has demonstrated that this ability to a large extent is a function of the tacit knowledge of the technicians. To improve the tacit knowledge of each technicians, systems and practices of experience feedback must be run to ensure individual and organizational learning from both failures as well as successes. This is in particular important in systems with great variability in climatic conditions and systems with organizational changes.

Automation of the rail—removing the human factor?

T.M. Stene
SINTEF, Trondheim, Norway

ABSTRACT: Automated vehicles will be increasingly used as transport in the future. However, it is unclear if this imply full autonomy or different levels of automation. A unified definition of autonomy in transport is missing. The SAREPTA project (Safety, autonomy, remote control and operations of industrial transport systems) is established in 2017, and cover safety challenges of future intelligent transport systems that are autonomous, remotely controlled and normally not manned. The project covers both road, sea, aviation and rail. This paper focuses on issues related to rail transport, including both metros and railway. The purpose of the paper is to describe current rail accidents as a basis for questioning whether future digitalisation will improve safety. The paper will discuss the autonomy concept in relation to grades of automation. Relevant questions are: What is automation and which accidents may be prevented by automation? To what degree do automation and remote control imply removal of the Human Factor? And from a safety perspective—What is the safety potential of future automation, and how can humans contribute to safety in future intelligent transport systems?

1 INTRODUCTION

Digitalization is a global change affecting a variety of social conditions and businesses. In addition to changing products and services in businesses and the labour market, digitalization will also create radically new business models in many industries (Stene et al 2017).

1.1 *Safety and automation of transport systems*

Safety and environmental challenges of future intelligent transport systems are addressed in a newly established project founded by the Norwegian Research Council for 2017–2021. The SAREPTA (Safety, autonomy, remote control and operations of industrial transport systems) project focuses on systems that are autonomous, remotely controlled and/or periodically not manned.

In the project, four thematic areas of autonomous systems are central: (1) Risk identification and risk levels, (2) Infrastructure vulnerabilities and threats, (3) Technical, human and operational barriers to mitigate system risks, and (4) Organizational and human factors, and regulatory measures. The project includes road, sea, aviation and rail. This paper focuses on the rail. The purpose of the paper is to describe current rail accidents as a basis for questioning whether future digitalisation will improve safety. Relevant questions are: What is automation and which accidents may be prevented by automation? To what degree do automation and remote control imply removal of the Human Factor? And from a safety perspective—What is the safety potential of future automation, and how can humans contribute to safety in future intelligent transport systems?

1.2 *Current rail transport safety—fatal and frequent accidents*

European railways are the safest mode of land transport and the safety level has improved over the last decades (EU ERA (European Railways Agency) 2016). However, accidents have heavy impact on confidence in the system. Further, every accident represents a significant business cost in a highly competitive environment. It is argued that emphasis needs to be on human factors as well as on new technology which can be both an opportunity and a threat.

Compared to other transport modes, the fatality risk for an average train passenger (0.12 per billion km) is at least twice as high as commercial aircraft passengers (EU ERA 2017). However, the risk is higher for passengers traveling by bus/coach (one third of the risk) and sea vessels (nearly three times as high). Further, using individual transport means on the road is most risky. Car occupants have at least 20 times higher likelihood of dying compared to train passengers.

Even if rail transport statistically is safer than road transport, some large rail accidents have occurred. The rates of fatal train accident (five or more killed: totally 362) have fallen substantially from 1980 to 2009 on Europe's main line railways (Evans 2011). Fatality risks per million train-km (system risk) in the period 2010–2014, based on persons involved,

was 0.28 killed per billion train-km at the EU level (EU ERA 2016). For rail passengers, this was 0.14 killed passengers per billion train-km.

Although rail transport safety has steadily enhanced over the years, the number of accidents started increasing in 2014 and 2015 (Eurostat 2017). Still, the number of victims (killed or injured persons) continues to decline. Table 1 shows the number and persons killed and injured in rail transport accidents in Europe 2016. Two types of accidents are dominant – (1) Rolling stock in motion and (2) Level-crossings—followed by (3) Train collisions and (4) Derailments.

The majority are accidents to persons caused by rolling stock in motion. These are either hit by a railway vehicle or an object attached to it. Persons that fall from railway vehicles are included, as well as persons that fall or are hit by loose objects when travelling on-board vehicles.

Fatal level crossing accidents are more numerous and account for more fatalities than fatal train collisions and derailments (EU ERA 2016). Further, in contrast to collisions and derailments, the rate per train-kilometre remained unchanged in 1990–2009. Thus, level crossing accidents represent an increasing proportion of serious accidents.

The estimated accident rate in 2016 is 1.07 fatal collisions or derailments per billion train-kilometres, which represents a fall of 73% since 1990 (Evans 2011). This gives an estimated mean number of fatal accidents in Europe in 2016 of 4.7. In contrast to fatal train collisions and derailments, the rate per train-kilometre of severe accidents at level crossings fell only slowly and not statistically significantly in 1990–2016. There are statistically significant differences in the fatal train accident rates and trends between the different European countries.

Totally, the most common cause of fatal accidents is signal passed at danger, followed by signalling/dispatching errors and violation of the speed limit. Further, small numbers are train fires and groups of persons struck by trains, mostly track workers.

Table 1. Number and persons killed and injured in rail transport accidents by type of accident in Europe 2016 (Eurostat 2017).

	Number of persons		
Type of accident	Killed	Seriously injured	Total
Collisions	44	77	121
Derailments	11	27	38
Accidents involving Level-crossings	256	220	476
Accidents to persons caused by rolling stock in motion	651	438	1089
Others	2	16	18
Total	964	778	1742

The causes of level crossing accidents differ from train collisions and derailments. The most frequent cause of fatal train collisions (2) and derailments (3) is signals passed at danger. The majority of level crossing (1) accidents are caused by errors or violations by road users. Most major crossings in Europe have automatic warnings (lights, barriers and bells) operated by approaching trains. Most minor crossings have fixed warning signs only, with no indication when trains are approaching. The primary responsibility for operational safety thus rests with road users, either in obeying warnings or checking that no train is approaching before they cross.

1.3 *Animals along the track—a current challenge*

Less severe accidents and incidents strongly outnumber fatal accidents (EU ERA 2016). However, these occurrences are not collected at the EU level, and great benefits could be made from reporting them to identify and manage risks.

While the number of people killed or injured in rail accidents is well-documented, little research has been done to analyse the number of animal casualties on international railways (Gray 2015). High-speed trains often cut through sensitive wildlife habitats. Accidents involving various species are detrimental to local wildlife, are costly and a danger to travellers.

In Norway, nearly 2000 collisions with animal are recorded on the railway each year, which is a doubling of the frequency over 20 years (Roaldsen et al. 2015). Reduction of crashes—even by a few percent—can contribute to significant socio-economic savings and reduced conditions for both humans and animals.

From 1991–2014, the Norwegian National Rail Administration registered nearly 26 000 events with one or more animals (near 36 000 animals) being hit by train. Over 90 percent involve moose (57%), roedeer (15%), sheep (9%) and domesticated reindeer (8%). Topography and landscape influence the existence of animals in areas near the rail, thus increasing the accident risk. Important factors are related to food, shelter, visibility and animal corridors. Further, weather conditions as snow and rain affect where the animals are.

2 TRANSPORT TECHNOLOGY INNOVATION

2.1 *Digitalization of the rail*

Digital technology may be defined as the use of ITC (computing capacity + telecommunication)

to gather, transfer and process data to provide the communication backbone for all users of the network (BearingPoint 2017).

Rail 4.0 may be considered a parallel concept to Industry 4.0 (Stene et al 2017). The concept refers to four industrial revolutions starting at the end of 18th century with the introduction of (1) mechanical manufacturing, and continues with (2) mass production, (3) computers and automation (also labelled digital revolution) and (4) Internet. Four key components in Industry 4.0 are: CPS (Cyber-Physical Systems), IoT (Internet of Things), Smart Factory (e.g. traffic management sites) and IoS (Internet of Services).

Further, Davidsson et al (2016) divide the digital period in four waves: (1) introduction of computers in the 80s, (2) Internet in the 90s made it easy to access and share information, (3) mobile Internet making this possible regardless of where you are, and (4) is represented by Internet of Things (IoT). In addition to people, different types of entities (vehicles, machinery) may also have access to and share information.

In the rail sector, ERTMS (European Railway Traffic Management System) is a common signalling system that is to be introduced in all EU countries by 2030. A standardized system will improve the interoperability between networks and systems. ERTMS includes ETCS (European Train Control System), GSM-R (Global System for Mobile Communication-Railway, which is radio communication between train and signalling), and common European traffic regulation. A common trans-border railway transport allows trains to travel in any European country which has the ERTMS system implemented both in the rail infrastructure and in the train itself.

ERTMS has many similarities with CBTC (Communication-Based Train Control), which is the preferred signalling solution for automated subways and metros. One difference is that ERTMS is standardized, while CBTC is supplier specific. CBTC is a signalling system making use of telecommunication between train and track equipment (wayside) for traffic management. By making more exact positions of each train, the system makes it possible reduce time intervals between trains. The main objective is increased capacity.

2.2 *Automatic Train Operation (ATO)*

Generally, autonomy is often related to attributes like self-government, freedom to act or function independently. For vehicles, autonomy is generally understood as the ability to make decisions about actions to take, e.g. course or speed, independent of a human operator. Levels of autonomy or automation describe the successive shifting of responsibility from the driver to the vehicle. Different concepts are used to describe vehicle automation in each transport mode/ domain.

In addition to concepts used in each domain, Ponsard et al (2017) present a comparative over-

Table 2. Comparison of automation levels at road, rail and air. Based on Ponsard et al (2017).

Railway	Road	Aircraft	Resp.	
Grades of automation	SAE levels	Levels of automation		
GoA-0 Sight train operator	**L0** No automation	**Level 1** Raw data, no automation at all	All time	Warn Protect
GoA-1 Manual train operation Automated train protection	**L1** Driver assistance Park assist/cruise control	**Level 2** Assistance Flight director Auto-throttle	Drivers	Guide Assist
GoA-2 Semi-automated train operation (STO). Autom. train op. (ATO)	**L2** Partial automation Traffic jam assist	**Level 3** Tactical use Autopilot	Monitors all time	Manage movements within limits
GoA-3 Driverless train operation (DTO) Automated control (ATC) Some control by attendant (operating doors, emergencies)	**L3** Conditional automation	**Level 4** Strategic Flight management system	Ready to take back control	Drives itself, may give back control
	L4 High automation Highway traffic jam system	Uninterrupted autopilot project (Boing) Drones (unmanned)	May not take back control	Drives itself with graceful degradation
GoA-4 Unattended train op (UTO) Automated doors Platform screen doors	**L5** Full automation (all situations)		Not required	All time

view of the responsibility between system vs human (driver/pilot) at different levels of automation (see Table 1). In rail, the concept Grades of Automation (GoA) is used. Notice the double line in the table; this marks a shift from GoA-3 in responsibility from the driver to the system.

Rail and airplanes have already achieved much higher levels (Ibid). However, this is only true for some rail line types. Several fully autonomous metros exist. The next two sections in this paper goes more into this.

2.3 *New technology on the main line railway*

The difference between signalling and control systems in European railway is significant, and until 1980 14 national standards were in practical use (Tao & Jing 2014). ETCS (European Train Control System) is designed to replace these incompatible safety systems, and the first version was published in 2000.

As mentioned above, the GoA concept describe levels of automation in rail. Figure 1 illustrates the existence of a driver at different grades. Further, the operations are described at each grade, i.e. management agents and actions to be taken.

Implementation of ERTMS at GoA-1 implies that signal information is shown on a panel inside the cabin. The driver may use the signal as a replacement of a traditional light outside at the track. The signal tells whether the driver may drive into the next block or not. At GoA-2 the train is operated by automated control based on signals from sensors along the track. In addition to be responsible for monitoring the speed and position, the driver may take control in case of any incident or emergency.

A lot of literature on transport autonomy focus on train automation, i.e. the interaction and responsibility between vehicle—driver (see Figure 2). The inner control loop is responsible for executing the production plan (Rao & Montigel 2017), and the focus is on driving performance by

Figure 1. Levels of automation (Brodeo 2016).

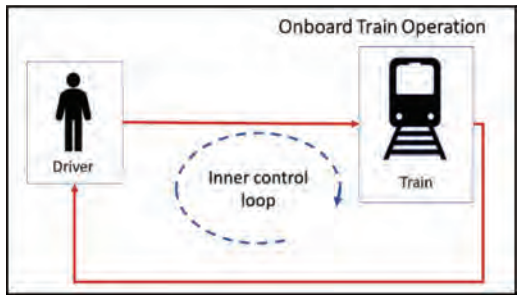

Figure 2. Train automation—Control of onboard train operation.

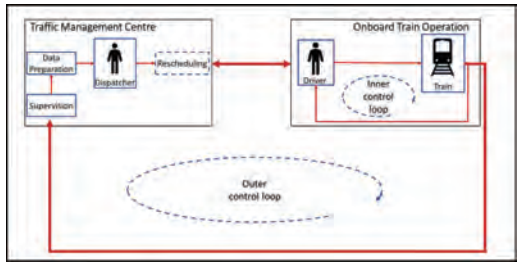

Figure 3. Traffic management—Control of traffic and infrastructure. (Based on Rao & Montigel, 2017).

providing driver assistance or introducing train automation.

Rao (2015) presents a holistic approach to the main line railway. In addition to (1) train automation, the focus is also on (2) traffic management, and the relationship between the two areas (see Figure 3). The outer control loop supervises the status of traffic and infrastructure, detects deviations and conflicts, and develops a new schedule (rescheduling) and transmits it to train operation.

Automation depends on two supports: Onboard support (as the Automatic Train Protection—ATP) system to provide train's overspeed protection and to keep a safe headway between trains, and infrastructure support (as Automatic Train Supervision—ATS) to provide dynamic traffic regulation to avoid traffic conflicts (Rao et al 2016).

Even at GoA-4 trains on are not autonomous in the sense that no control is needs. Traffic management focus both on the outer control loop (improving efficiency for the dispatcher by providing resolutions for traffic conflict) and the inner loop (improving driver performance or assisting the driver). Thus, reducing human failure are central in both control loops.

ETCS (European Train Control System) is a signalling, control and train protection system used on the main railway lines. The train detection

equipment sends the position about speed limitation, signal status etc. (Venticinque et al 2014). Three levels define the use of train control system; communication from track to train (level 1), continuous communication between the train and the Traffic Management Centre (level 2), and future implementation of a moving block technology (level 3). Several main rail tracks operate at level 2, including two main subsystems: (a) a ground system collects and transmits track data to (b) an onboard subsystem.

ETCS-2 uses digital radio transmission of signals along the trackside (Tao & Jing 2014). With its onboard positioning equipment, the train can automatically report its exact position and direction of travel at regular intervals, in addition to motion (stop/go) signals. Balises on the tack detect trains and send the position to the control centre (Venticinque et al 2014). Based on the position of all trains, the centre determines the new movement authority (MA) and sends it to the train. The onboard computer calculates its speed profile from the MA and the next braking point. This information is displayed to the driver.

2.4 *Autonomous metros*

In metro systems, automation refers to the process by which responsibility for operation management of trains is transferred from the driver to the train control system (UITP 2017).

The experience period with automated metros is over 30 years. The first was high capacity, but today we also see a trend of increase in mid-capacity trains. Between 2014 and 2015 Europe will lead in terms of growth (Hernández 2014). Asia and Europe together hold 75% of the km of fully automated metro lines.

For metros, many use the term CBTC synonym as an automated driverless system. However, at its most basic form the system provides automatic protection (ATP) only. Fully automated systems also include ATO (Automatic Train Operation) and ATS (Automatic Train Supervision).

A semi-autonomous train (GoA-2) may manage movements, but a human need to be onboard to start the train, open doors etc. (Lufkin 2015). There are also trains that can fully operate completely free of humans. Only 6% of the world's transit rails operate those trains. Several cities are aiming for automation.

There are 55 fully automated metro lines in 37 cities around the world (UITP 2016a). Fully automated metro lines, defined as those metro lines in which trains can be operated without staff onboard—a defining characteristic is the absence of a driver's cabin on the train. This type of operation is also known as Unattended Train Operation (UTO), or Grade of Automation 4 in standard IEC 62267.

2.5 *Metro automation and safety*

The positive experience of decades of automated operation highlights one of the major elements to consider in this success story: safety (UITP 2016b). There have been no significant accidents, in particular none involving casualties, in any automated metro line in the world.

Copenhagen Metro is one example of a system running fully automated, consisting of automatic train protection, operation and supervision. Although no serious accidents have occurred, incidents and accidents may point out some risk areas. The station area is strongly marked. The safety of the platform/track interface is crucial for fully automated metro lines.

The dominant safety measure is installation of platform screen doors (detection systems) preventing persons and objects from falling on the track. Currently, near 80% of stations in fully automated metro lines in operation in the world are equipped with such doors (UITP 2016).

Platform and track incidents aside, there has only been one operational incidents with UTO systems; in Osaka at the end of the 80s a train did not stop at terminus and hit a bumper stop, provoking injuries in a few dozen passengers (UITP 2017).

2.6 *Open surroundings—challenging the main railway*

Since the main railway has much more complicated infrastructure situations, currently train automation is mainly applied in metro railway (Rao et al 2016).

The open surroundings of current main rail traffic challenge safety. Rails with driverless trains are generally run on closed off networks, i.e. run underground. Thus, no one can fall onto the tracks, and there are no points where the trains cross with others.

3 DISCUSSION

3.1 *Rail 4.0 – Opportunities and challenges?*

The purpose of intelligent systems is to make the human environment more "people-friendly" technologies (Tokody & Flammini 2017). This means that infrastructural systems should be sustainable, safe, economic and easy-to-use. The development of intelligent, autonomous systems may ensure sustainability and safety.

Future IoS (Internet of Services) in a rail context will focus on offering services to the general public or specific target groups as passengers. For example, a dynamic system for Copenhagen metro, will automatically optimize trains frequency

depending on numbers passenger and changes of numbers (Razeto & Corsanego 2017). Likewise, in Switzerland, a new Trip Planner app using voice control will let customers compare, combine and book a journey with multiple modes of transport including taxi (SWI 2017b).

Integrated mobility is an example of Smart Management. According to the Federal Railways in Switzerland, integrated mobility is a central field of innovation, and thus they are developing a door-to-door service to the general public ("SBB Green Class").

One example of utilizing IoT, is goods transport in Switzerland installing various sensors in carriages. Instruments will measure temperature, vibrations and the wagon's position. Customers may get information of goods status, location and time for arrival. In Japan high-speed rail use in-ground sensors in quake-prone zones, that immediately activate emergency brakes seconds after the initial quake waves are detected.

However, one of the future challenges is related to telecommunication and traffic management. ITS includes telematics and all types of communications in vehicles, between vehicles and between vehicles and a fixed location (Brodeo, 2016). As even more transport is being digitalized, the use of radio frequencies for signalling systems may be conflicting or overloaded. Several EU countries already use radio communication systems in the same range, all on a limited duration licensing scheme.

3.2 *Scenarios – Can automation prevent future rail accidents?*

For more than three decades, rail transport safety has improved generally and presumably due to a wide range of safety measures like automatic train protection, improved signalling systems and improved operational management. The question is whether new technology may contribute to prevent the most serious and frequent accidents; (1) Rolling stock in motion, (2) Level-crossings, (3) Collisions, (4) Derailments and (5) Animals along the track.

1. The engine (rolling stock) is heavy, and as such needs a long distance to stop in case of an incident or unexpected objects on the track. A driverless train needs to have equipment that detect obstacles and stops automatically. Rail research and innovation in Europe include safety related technology development; automatic obstacle-detection systems for railway vehicles, regenerative braking, monitoring systems and satellite based positioning systems (Tokody & Flammini 2017).

   However, passenger comfort is also highly valued. An efficient and powerful breaking system may cause great discomfort and passenger injuries. This is true for passenger trains, but should be a less problem with freight trains. Even though automated trains may still include some staff onboard.

   Even though capacity is the main objective of CBTC systems used at automated metros, maintaining safety is a major requirement. In addition to distance, calculations cover speed, curves and position. Thus, controlling acceleration, retardation and stops at stations. At slower speed, the distance may be shorter. A challenge is to calculate the block length for max capacity while ensuring safety.
2. Level-crossings. Road user errors or violations contribute to most of fatal accidents, either in obeying warnings or checking that no train is approaching before they cross (EU ERA 2016). The authors point out countermeasures like those for road accidents, particularly education and enforcement. However, more autonomous vehicles may also contribute to prevent rail accidents.

   Autonomous obstacle detection systems may be beneficial for road and rail transport. The Germany SMART project focuses on rail freight and automation of railway cargo haul (Shift2rail 2016), including development of (1) a prototype of an autonomous obstacle detection system and (2) a real-time marshalling yard management system. The first system will use night vision technologies, multi stereo vision system and laser scanner to create fusion system for short (up to 20 m) and long range (up to 1000 m) obstacle detection during day and night operation, as well as during operation in impaired visibility. The second system will provide optimisation of available resources and planning of marshalling operations.
3. Collisions. Related technology development which may contribute to accident prevention are automatic obstacle-detection systems for railway vehicles, traction transformers, energy storage technologies, regenerative braking, monitoring systems, satellite based positioning systems, and smart railway technologies (Tokody & Flammini 2017).

   As mentioned in relation to rolling stock in motion, passenger comfort is highly valued, and unexpected intense breaking may contrast a safety measure. Acceleration and deceleration are essentially limited by the wellbeing and safety of the passengers (Gary 2016).
4. Derailments. One serious accident on a main line using ERTMS, was a derailment of a high-speed train in Spain in 2013. Initial reports cited driver error as the sole cause, but a deeper study of the accident says lack of a functioning onboard ETCS system was a crucial factor (Puente 2015). A high-speed train derailed trav-

elling at 180 km/h (speed limit 80 km/h) through a curve, resulting in the death of 79 people and injuring more than a hundred.

The line was equipped with ERTMS/ETCS Level 1, except for the first and the last kilometre, with a national signalling system used as a backup. However, the onboard ETCS system had been switch off in 2012 due to alleged operating problems. The train driver should manually have changed the speed, but when the train entered the low speed section the driver was speaking on the phone to staff at the train company (Johnsen 2015).

If onboard ETCS had been working, the following would have happened at the ETCS exit boundary 4km before the curve where the accident occurred (Puente 2015): (a) a text message announcing the transition would have appeared on the Driver Machine Interface (DMI) of the train, which was travelling at 200km/h, (b) the DMI would have shown a message with a yellow flashing frame and would have emitted an acoustic signal asking the driver to acknowledge the transition by tapping on the screen, and (c) if the driver failed to acknowledge the message within 5 seconds, service braking would have been applied continuously until the driver had acknowledged the transition or the train had stopped.

5. Animals along the track. Current countermeasures include building fences around the worst affected rail lines, removal of vegetation and warning systems (Roaldsen et al. 2015). The implemented strategies include installation of warning signs for train drivers, night patrols along the tracks and introducing staff to assist animal crossings. Warning signs are the most widespread accident prevention measure (Gray 2015). Most is human warnings, but acoustic signals creating fear in animals (preventing them from approaching the tracks) is also tried. As an example, Norwegian reindeer owners often warn about animals near the rail, implying that train drivers may reduce speed and the probability of incidents (Busengdal et al 2014). More general models have also been developed to predict the occurrence of animals (Gundersen & Andreassen 1998). Gray (2015) argue that manned assistance along high-speed tracks across the world is not a practical solution and better alternatives are needed. Deutsche Bahn Netz AG and OptaSense is one example of testing new warning technology. Distributed Coustic Sensing (DAS) technology uses heat and motion sensors in various areas of operation, including to detect and alert train drivers of animals approaching the tracks.

3.3 *Will automation remove the human factor?*

Automated systems are often designed to relieve humans of tasks that are repetitive. However, the more reliable the system, the more likely is it that humans in charge will "switch off" and lose their concentration, implying greater likelihood of unexpected factors and a potential catastrophe (Vedantam 2009). Technology replacing or assisting the driver can become crutches. Accidents happen when unusual events come together. No matter how clever designers of automated systems might be, they simply cannot account for every possible scenario, which is why it is so dangerous to eliminate human "interference."

The on-board personnel may be unprepared to take control and manually drive. Regular training exercises that require operators to turn off their automated systems and run everything manually are useful in retaining skills and alertness (Ibid). In addition to detect system failure, understanding how automated systems are designed to work also allows operators to recognize when it is on the brink.

As the system cannot cope with all situations, the driver must be ready to resume operations when instructed (Ponsard et al 2017). The author address issues as situational awareness (the system should make sure that driver's decisions are based on right mental pictures), human reaction capabilities (e.g. alarms may cause confusion, defect view of the entire situation, or panic), warning annoyance (trust in the system in case of e.g. frequent/inappropriate alarms) and task inversion (focus on monitoring alarm and lack of attention to real world situations). The authors claim that machine learning techniques can pay an important role for making sure the driver and the system are operating optimally together.

3.4 *How to cope with unexpected scenarios?*

The concept of black swans refers to rare and unpredictable events. Black swans are extremely rare, catastrophic, and unpredictable events that never have been encountered before (Taleb 2007). In principle, black swans cannot be anticipated. However, even though a catastrophe was not predicted, does not mean that the event could not have been prevented (Murphy 2016).

Implementing new technology and autonomous transport, black swans will occasionally occur. We have to prepare both to cope with alternative scenarios and to handle completely unexpected situations accompanied by high stress and emotions. Thus, in addition to training to identify clues of and handling anomaly situation, training should cover completely unexpected and catastrophically events with an extremely high emotional state.

Experiential training may be necessary for coping with unexpected events, especially to handle personal high stress and to communicate with others (Stene et al 2016).

Emergencies are events which happen suddenly and may destroy normal operations. Despite the presence of automated metro operation control system, the emergency management is still heavily dependent upon capabilities of dispatchers at the management centre (Wang & Fang 2014). The system may lose a part of automated safety protection function. Thus, human error behaviours during emergencies cannot be ignored. Competent humans in transport control centres may represent a safety barrier, preventing incidents and accidents (Stene et al 2017). Machines may be excellent in detecting signs and signals, but humans have to evaluate and decide action based on the context and complexity of the actual situation.

4 CONCLUSION

4.1 *Future automated trains and metros*

With more people living in urban areas than ever before, metro systems around the world will need to adapt (Lufkin 2015). The next generation of subways will develop from cities that are already at the cutting-edge, e.g. the super-fast speeds of Japan's shinkansen or the punctual, low-cost driverless trains of Copenhagen.

Self-driving trains are already being used in some countries, with varying degrees of autonomy. Autonomous driving on a complex rail system, with passenger trains and freight trains is more difficult than on a subway—but it is possible (Gary 2016). Several pilots are currently running. On a test field in Germany, trains will be fitted with cameras and other technologies to detect obstacles on the track and stop the train if necessary. The AutoHaul project in Australia, a long-distance railway system is intended to transport iron ore from 15 mines.

Switzerland will test self-driving trains on a main line without too many people, but still get a feel for how it would work in public (SWI 2017a). The trains will be fitted with sensors that should detect objects on the rails and bring the train to a stop. If rolled out, a system to automate train traffic is assumed to increase passenger and freight capacity by 30%.

4.2 *The human factor in future rail systems*

Technology can improve safety, but there may be examples where human interaction is necessary (Gary 2016). The main purpose of implementing a common European railway signalling system are: (1) Maintaining a safe distance between following trains on the same track, (2) Safeguarding the movements at junctions, and (3) Regulating the movements of trains according to the service density and the speed required (Abel, 2010).

The development relies too heavily on old inertia, meaning too much emphasize on technology. More attention should be paid to the organization, the passengers and the infrastructure (Malla 2014) and passenger evacuation procedures (Hernández 2014).

Factors contributing to the likelihood of catastrophic rail accidents are system complexity, a trend towards higher travel speed, growing infrastructure capacity constraints and the constant cost pressures on risk management activities (EU ERA 2017). Accident investigations should continue to report on both success or failure of systemic risk management methods, e.g. high-reliability organisations, redundancy, robust regulatory and enforcement regimes.

Based on experiences from operating both automated and conventional metro lines, one conclusion is that the human factor is that key for the success of an automated line. (UITP 2016b). The rail is far from being autonomous, in the sense of being independent of a human operator. Humans will still be a necessary resource to manage transport and cope with unexpected incidents.

Revitalization of risk management in the Norwegian petroleum sector

B. Heide & G. Ersdal
Petroleum Safety Authority Norway, Stavanger, Norway

ABSTRACT: The PSA has launched a risk management project. The purpose is to stimulate a revitalization of the risk management in the Norwegian petroleum sector. The project is ongoing, which means that no conclusions, findings or reports are final yet. In this paper we describe the reasons for initiating this project. We also describe the process, and the preliminary focus areas of the project. Three messages to decision makers are given special attention. First, that risk management has to be an integral part of all organizational processes, and part of decision making. Second, uncertainty is a main component in the risk concept, leading to a strong focus on the need for robustness. Third, the management culture at all times absolutely has to be characterized by a sincere wish to reduce risk. Finally, we describe our intention to provide examples of practical risk management challenges, as well as some ideas for how these challenges can be handled.

1 INTRODUCTION

1.1 *Background and the reasons to initiate this project*

The PSA (Petroleum Safety Authority Norway) has launched a risk management project in order to stimulate a revitalization of the risk management in the Norwegian petroleum sector. We aim to contribute to preservation and further development of the industry's risk management. We address key issues from the viewpoint of the PSA, based on input from the stakeholders in the industry.

The primary target group for the project is managers and decision makers. Other groups that have important roles in safety management will hopefully also benefit from the content.

The need to preserve and further develop risk management is described in several sources. This has resulted in the PSA's decision to initiate a project on risk management. The purpose of the project is both process oriented and goal oriented. The process shall give new and even more appropriate attention to risk management, and a memorandum on risk management shall be issued.

Several events and reports have led to the initiation of this project. A brief presentation of the most relevant of these are:

The annual report "Risk Level Norwegian Petroleum" (RNNP) attempts to contribute to a common perception of the risk level between the stakeholders. The RNNP indicates that there have been significant improvements in several areas over a number of years, but also opportunities for further improvement (PSA, 2017).

The Norwegian government appointed an expert group to assess the current safety regime. In the "Engen report" (2013) it was concluded that the current regime is well-functioning. However, the report also indicated that there was a need for further development of risk management, especially related to major accident risk.

The Deepwater Horizon accident in 2010 showed that there is a need to review the principles and methods of risk management, and also how they are carried out in practice. Following this accident, both the supervisory authorities and the industry have taken a number of initiatives in the fields of risk management, barrier management and management follow-up (PSA 2014, Norwegian Oil and Gas Association 2012). The PSA (2014) concludes that such initiatives must be subject to continuous development in order to achieve lasting effects.

A working group at the Norwegian Oil and Gas Association (2015) has reviewed today's practice to identify improvement areas within risk informed decision making. They pointed out that in many cases the information is not available soon enough, and identified possible paths for improvement. The Norwegian Oil and Gas Association also published a report "Black Swans" (2017), which points to the need for an expanded perspective on risk, where knowledge building, experience transfer and learning become even more central.

The risk concept in the regulations was clarified in 2015. Here, attention to uncertainty was made even more explicit, and the PSA issued a memorandum in 2016 describing what we aim to achieve regarding this topic. The memo from 2016 highlighted the risk term, while the project described in this paper highlights the management aspect of risk.

1.2 *Why is risk management essential?*

Good risk management will enable the industry to find a reasonable balance between safety and economic profit. The operators on the Norwegian continental shelf have been given a great degree of freedom to find efficient ways of doing business as long as a certain safety level is achieved, through a "functional based regulatory framework". This framework both encourages and requires a certain mindset. The intention is to both encourage and require that the nature of the operations is taken into account, as well as local and operating conditions. A prerequisite for a functional based regulation is that operators and duty holders take responsibility and implement suitable risk management processes. There are therefore requirements for risk management and reduction processes in the HSE regulations, including continuous improvement.

Good risk management should also provide an opportunity to use resources in a way that has the best effect on safety and value creation. This implies that the industry must integrate risk management in the decision making processes. Also, a proper understanding of how risk management can be performed well in practice is required.

1.3 *Limitations of this paper and project*

This paper should not be read as the viewpoint of the PSA. It is merely the viewpoint of the authors of the paper.

"Risk management" is here limited to the PSA's authority area, and is based on major accident risk. It may also be relevant for working environment, natural environment, health, security and so on. The project is not intended to introduce any new requirements.

We cover only selected themes, and the project should be seen in conjunction with other areas highlighted by the PSA. See for instance the Barrier memo, the "Book about learning" and the "HSE and Culture" pamphlet.

2 THE PROCESS

Members of the PSA's Risk management group have been running the project. In the planning phase of the project, some keys to success became clear for such an ambitious project. There was a need for discussions with the stakeholders, as well as professional experts. Such discussions between the stakeholders (regulators, trade unions and industry associations) are already a formalized part of the Norwegian petroleum safety regime. See for instance the Safety Forum (PSA, 2017). Therefore we have in the early stages discussed the project with the tripartite Safety Forum and the tripartite Regulatory Forum.

Furthermore, we emphasize that risk management is not a stand-alone activity for risk management experts. Instead, the various departments need to use risk management as an integral part of their activities. Therefore, we have taken great care making sure that the risk management project is not run solely by risk management experts. We are consulting with all the PSA departments to get their input on what is the key to successful risk management. This idea of consulting with different technical disciplines has also been applied while discussing with the industry.

We have had several meetings with operating companies, contractors, labor unions and risk management experts. In these meetings we have tried to make sure that the discussions are driven by the needs of the decision makers and managers in the industry, rather than the opinions of the risk management experts.

Additionally, we have had several meetings with the other relevant safety regulators in the Norwegian petroleum sector, the Norwegian Board of Health Supervision and the Norwegian Environment Agency.

Typically, the discussions have centered on topics such as:

- What is necessary for a well-functioning risk management?
- Which tools are useful?
- What are the conditions and principles that are necessary for risk to be managed as an integral part of the activities instead of a stand-alone activity after the main decisions are made?
- How can we make sure that there is sufficient agreement between short-term and long-term objectives in various areas (HSE, profits, project progress, departments), at various levels and between various participants in the activities?
- What are the main challenges?
- What are the necessary criteria of success?

The feedback from these meetings have been very valuable to gain an understanding of challenges and good practices. However, we need to emphasize that the conclusions in the project will be our conclusions, and not merely a summary of the statements of the parties.

A well-known challenge for any organization when dealing with major accident risk, is to make sure that even if you have a strong track record on safety you still must remain vigilant. This is very relevant for our project, since the stakeholders to a large degree have presented how they act when they are performing well. Hence, the intention is that this project can help in passing on such knowledge of best practice. Further, it is our intention

that the project also serve as a reminder that one major accident is one too many.

In the span of the project, our focus area has shifted slightly based on the meetings and discussions we have had. The project is not completed, so instead of any final conclusions we can only give an overview of how the project has developed so far. When the project started, the following main themes were identified:

1. Risk management as an integral part of the management processes
2. Risk reduction processes
3. Closing the "control loop" by learning
4. Risk analysis and—acceptance criteria

We identified theme number 1 above as the main theme, while there was no "ranking order" between the three other themes. At the time of writing, theme number 1 is still the main theme. As this paper will show, the others are still included but have been somewhat restructured.

At the time of writing this paper, we have identified three areas that are of importance to our target audience, where we believe that further development is necessary. In the next section we describe these three areas. We point out that being excellent in one of these areas is not sufficient. Instead, these three areas must complement each other.

3 PRELIMINARY FOCUS AREAS IN THE PROJECT

3.1 *Risk informed management*

ISO 31000 describes risk management as "coordinated activities to direct and control an organization with regard to risk". It is further stressed that risk management should be a holistic and integrated part of all processes in the organization.

The reality that we too often see is that risk analysis is done after the decisions already are taken, and used to justify decisions that are already taken, in contrast to the "direct and guide" role described in ISO 31000. This have been recognized by many organizations, and e.g. the Norwegian Oil & Gas Producers Organization (NOROG) have produced several reports (NOROG 2015) on the importance having risk information in time for the decisions and of how to produce the risk information in time.

Integrated risk management in ISO31000 implies that risk management is a (integrated) part of the organization's processes and activities. Further, that risk management is a part of the management's responsibility.

Holistic risk management in ISO31000 implies that the risk management is able to take into account how a decision will affect and interact with other related areas of the organization's activity, and how they relate as a whole. This will imply that there is a need to collate the risk information from all related parts of the organization and balance these in the decision. It is therefore essential that risk management becomes aligned and integrated with the strategic planning processes. Further, it should enable the involvement of all stakeholders, internal and external, capturing their opinions on the companies' operation and critical issues. Risk management according to ISO 31000 should equip upper management with tools to help taking better and more informed decisions.

The Petroleum Safety Authority in Norway do experience examples of what we perceive as good risk management. In these cases, the industry describes processes where appropriate risk information are available when the decisions are being made. Further, that the decision makers takes an active role in obtaining relevant information before making decisions, and that decision makers have fruitful discussions about the acquired information and the strength of knowledge in this information. In essence that they live according to the proverb that "Doubt is the key to knowledge". Finally, that they take the strength of their knowledge into account in the decisions.

These examples of holistic and integrated risk management in accordance with ISO 31000 is what we in this project and paper call "Risk informed management".

In a risk informed management, one must start by understanding the organizations activity as a whole and the goal in this specific activity and decision (what is to be delivered). Here it is important to understand the context in which this is done and what requirements are set for the activity. Furthermore, one need to identify risk and possible reasons for why things may go wrong and the consequences of this. The decision on how to perform the activity must consider this understanding. An evaluation of the robustness of these plans is needed, in case of disturbances and changes. Obviously, the decision makers need to be well qualified to make the decision.

The execution must be carried out as planned and it is important that those who perform the activity have the necessary understanding of the context as well as the procedures for the task. It is also important that they have understood the basis for decisions, consequences and uncertainties so that they can react properly if disturbances and changes occur.

To improve, it is important that one assesses the delivery and the execution. Any learning from this evaluation should be communicated to the organization.

3.2 *Uncertainty and robustness*

Before making decisions, the responsible party shall ensure that issues related to health, safety and the environment are adequately considered. The basis for decision-making must have the necessary quality, where different alternatives and consequences have been studied and relevant experts, departments and user groups have been involved. To consider uncertainty has to be included in this decision process.

How can uncertainty be considered adequately? This is a research topic that has been given quite a bit of attention the last few years, for instance in the previous ESREL conferences. We will not go into detail of the possible methods here, but we stress the following point that has been made in the literature.

Say that a decision maker concludes that it is unlikely that a particular event will occur within a given time frame. Such statements are typically based on data, information, testing, analysis, argumentation, theory, models, assumptions, discussions with stakeholders and more. These statements may be more or less strong, and taking uncertainty into account includes clarifying what this knowledge consists of and how strong it is. If the knowledge is weak, the decision will have a weak foundation.

Obviously, if the knowledge is weak, correcting measures are necessary. In our project we stress the importance of robustness as an important measure to provide extra margins, in addition to similar concepts like resilience and the cautionary approach.

Requirements for robustness are used because deviations, unexpected changes and surprises can occur. Robustness must be emphasized especially for events with high potential.

As unforeseen events may occur, robustness is needed to ensure that the business can be operated in a safe manner. This implies that the organization are still able to operate in the event of disturbances slightly beyond the stresses they are expected to be exposed to. Surprises, unexpected changes and disturbanses can happen, and events that are considered unlikely can still happen if the assessments are based on assumptions that are incorrect.

A high degree of uncertainty must lead to a cautionary approach, for instance through barrier requirements and robust solutions or application of principles such as reducing risk as far as possible without significant disproportion between cost and effect. If there is insufficient knowledge concerning the effects of a preventive measure, further measures should be taken according to the HSE regulations.

3.3 *Management and culture*

How can risk management become a good tool for reducing risk, rather than a documentation and reporting of risk? The attention and priority of the management greatly contributes to the culture. Risk management processes and systems are important tools to achieve good risk management, but humans and organizations are preconditions for success. *The management culture always must be characterized by a sincere wish to reduce risk*.

Further, knowledge, involvement and commitment must be a core value that forms the decision-making processes in every aspect of the organization, even in times of pressure on the industry such as delays, changes and increased cost consciousness.

Based on Reason (1997) we describe a good HSE culture as just, reporting, learning and flexible. There needs to be established a belief that you will not be met by sanctions when you report an issue. This trust is easily eroded, and is difficult to reestablish. A key to earning and keeping the trust is to display consistency between HSE promises and action, especially when finding the balance between safety and other priorities. Here, communication skills are important, as well as establishing dialogue with all stakeholders instead of solely managing by commanding. This facilitates trust, commitment and valuable knowledge into the risk management process.

3.4 *Examples of risk management challenges*

In the coming memorandum from this project, the PSA also intends to highlight some practical risk management challenges. This should include some ideas for how these challenges can be handled.

However, the PSA is careful to point out that the risk owner is responsible for their risk. Thus, it is neither possible nor advisable that the authorities give detailed requirements or solutions that can be interpreted as requirements. Therefore, the PSA is careful not to spell out detailed solutions, but instead we intend to nudge the industry in a certain direction when we see such a need.

In this paper we have highlighted the importance of considering uncertainties before making decisions. It has been discussed in the literature how uncertainties can be handled in practice when using Risk Acceptance Criteria and Risk Reduction Processes. Summarized, we note that the Black Swans report describes that Risk Acceptance Criteria are fulfilled if:

- The calculations are within the criteria while the knowledge is strong, or
- The calculations are within the criteria with a large margin, while the knowledge is not weak.

Similarly, the required risk reduction processes beyond the Acceptance Criteria (ALARP) might incorporate the effect of uncertainties in a manner where:

– If the cost is low, the proposal is implemented.
– If the cost does not present a significant disproportion to the risk reduction, the proposal is implemented.
– If there are other important aspects, the proposal is considered implemented. Other aspects can be significant uncertainty, need for robustness and barriers, and more.
– Furthermore, it is not possible to set specific regulatory requirements and established minimum solutions in the industry aside based on arguments about risk informed cost benefit assessments.

We note that these bullet points are well known in the literature and in the industry, but that uncertainties are not always systematically considered.

When successful, the decision makers are actively involved in and are observant as to whether the knowledge base is strong or if there is a need to obtain more information. In good examples, statistics constitute a necessary part of the decision-making basis, in addition to other sources of information.

Other typical management challenges includes:

– To balance the different needs. For instance, regarding ventilation, where working environment and avoiding gas collection should be balanced. Other examples include keeping aware of the possibility of conflicts between short-term and long-term objectives in various areas (HSE, profits, project progress, departments), at various levels and between various participants in the activities.
– The uncertainties we have discussed above leads us to conclude that risk assessments can often be "massaged" to provide a justification of decisions that are already made. That is not the intention behind the regulation, as it does not provide any incentive to improve safety.
– Placing great emphasis on identifying all relevant risk factors. Quality is ensured by considering specific aspects, local conditions and operational conditions. Involvement, local knowledge and broad knowledge are keys to success. The opposite would be generic hazard identifications. Generic lists of hazard situations can be used as a starting point for brain storming, but will not be sufficient to provide an overall and nuanced basis for decision making.
– To execute according to the decisions, with a good understanding of the risk while vigilantly detecting possible changes and deviations. Personnel on the sharp end need sufficient knowledge of the task and the risk picture, and to understand how the activity is planned and which surrounding factors that have to be taken into account. Furthermore, major accident risk is a natural part of the various forms of risk visualization, such as Safe Job Analyses and Work permits.
– To avoid that the plans are made without involving the personnel on the sharp end, and to ensure that the reasoning behind the decisions are communicated. If not, any adjustments that need to be made in the sharp end might not be considered and handled as a change. Another challenge is if the performance is rigidly performed according to the plan, but without understanding of the risk picture and possible changes in conditions. Rigid processes and procedures can also lead to a quietly accepted practice of non-compliance.
– Transfer of experience might be the most difficult part of the management loop, especially to make sure that the experience is accessible to anyone who needs the information later. In our "Book about learning" (PSA 2013), we emphasize that organizational learning is a prerequisite for safety. The book can inspire actors to find good learning solutions themselves. The report "Black Swans" (Norwegian Oil and Gas 2017) places great emphasis on better ways to learn, and can help actors find practical ways to close the control loop.
– The regulations require that one should improve safety by continuously identifying where it is needed. A typical pitfall is a "good enough" philosophy without being conscious about when and where improvement is needed.

4 CONCLUSIONS

We have described the need for well-functioning risk management to create a reasonable balance between safety and economic profit. Additionally we have described that several reports indicate a need to revitalize the risk management of the Norwegian petroleum sector.

Our project aims to contribute to these goals. The project is ongoing, and at the time of writing this paper our draft project report is subject to a hearing at several government agencies.

We have involved the stakeholders in the project, and aim to continue this approach in the coming phases.

The preliminary message is:

– There is a plethora of risk management tools available. These may seem intricate and difficult to use for management, which can create confusion and apathy. However, we note that all good tools are based on the traditional "Control loop" (Plan-Do-Check-Act) which is the standard way to operate for managers.
– Risk management is the responsibility of the decision makers, meaning that the role of a risk

management department is to give advice to provide the best possible knowledge background for the decision makers.

- Risk management must be an integral part of decision making, as described in ISO 31000. When "risk management" is performed separately from (and after) other processes, the intentions behind the regulatory regime will not be fulfilled. Instead, we note that when the stakeholders describe successful risk management, they describe a standard control loop where the necessary information about risk is available at the right time.
- Relevant information needs to be available at the time of decision-making. This can be challenging. We observe that the industry is currently focused on this topic, and possible improved methods are examined.
- Uncertainties needs to be acknowledged when making decisions regarding major accident risk. We note that success is contingent on decision makers that take an active role in requiring relevant information, including questioning the strength of knowledge. Due to uncertainties, there is a need for a cautionary approach where the industry ensures sufficient robust solutions.
- Decision makers need to be aware of the potential for conflicting aims. Examples include project progress, safety and department aims. To ensure balance between such various goals, a holistic approach is necessary.
- Finally, the framework described above is dependent on a management culture that at all times is characterized by a sincere wish to reduce risk.

In essence, the main findings so far from the project is that:

1. risk have to be managed by risk informed management,
2. decisions need to take into account the uncertainty, taking into account the proverb "Doubt is the key to knowledge".
3. robustness is a necessity and a prerequisite for providing margins for deviations, unexpected changes and surprises,
4. safety concerned leadership and safety culture is the foundation of risk management.

ACKNOWLEDGEMENT

We gratefully acknowledge the contributions to the project from all the project members and numerous other discussion partners.

TENVIRK Sp. z o.o., Chorzów. Poland

ABSTRACT: A system called SMARTD ID CARD employees location and working time registration systems. Among the others, the data obtained in this system allow one to monitor whether the employees use constantly personal protective equipment. The research aimed at verification of the effectiveness in detection whether a worker used personal protection means. To this end, a robot simulated some human movements. Comparison between Pearson, Kendall's Tau, Spearman's and BiSerial correlation detection algorithms has been performed. The results obtained proved that the system was highly effective in detecting the use of personal protective equipment. The system was more effective at detecting that the personal protective equipment had not been used, what was important from the safety point of view. Additionally, the detection time of the lack of personal protection was relatively short and taking about 2 minutes. Basing on the results obtained the Authors recommend the use of SPEARMAN or BISERIAL algorithm.

1 INTRODUCTION

With the development of new technology procedures, more and more efficient machines have been designed. Especially, the development of Information Technology (IT) and telecommunication techniques has brought about the possibility of intelligent manufacturing system design. In such systems a human factor contribution to production process has been significantly reduced in view of the automation of entire process. The computational capacity of these systems in the first place, is applied to monitor the manufacturing process. However, their usage in monitoring the level of safety of system operators has been increased significantly.

In modern systems, sensors devices are increasingly used to the implementation of safety functions. Such systems detect the position of special labels, which in turn allows for localisation of the objects on which these labels have been installed (Dzwiarek 2015, Reiner et al. 2013). An example of such equipment is the Real Time Location System (RTLS), which detects the position of the label (Gomez et al. 2013, Guyoun et al. 2013). RTLS systems employ a variety of location technologies, e.g., active identification using radio waves, optical location and ultrasonic location. A sample application of the location system to improve safety consists in using it in monitoring of employee activities is showed in (Seppa 2012). That is especially useful in detection of situations requiring medical attention (Sachs et al. 2014).

At the same time, the rapid development of electronic systems applications to working time registration is observed. Currently, most common are devices containing the radiofrequency identification (RFID) (Roberts 2006), bar code or magnetic strip card readers, in which the working time is registered after the card has come closer or been inserted into the reader. The major drawback of these systems consists in the fact that they display the information only at the moment of identification (card approach or insertion). Later, the user does not have the access to working time registration data until the card is used again.

2 MATERIALS AND METHODS

2.1 *SMART ID CARD system*

Advantages of location and time recording systems combines the system developed at TENVIRK Sp z o.o. called SMARTD ID CARD. The system consists of:

- control units forming a radio Mesh Topology Network (MESH) (Huang et al. 2008) and connected with the cloud computing called "eAttendace" via Ethernet or General Packet Radio Service (GPRS) (Walke et al. 1991),

- smart cards which can be pinned to the worker's clothing, equipped with a set of sensors, please find the items, which, at most, could form the aforementioned set:
  - two independent accelerometers,
  - magnetometer,
  - moisture sensor,
  - pressure sensor,
  - ambient light sensor,
  - temperature sensor,
  - measurement of battery voltage.
- system software of class Enterprise Resource Planning/Customer Relationship Management (ERP/CRM) (Møller 2005) in the cloud, which collects real time data.

Computer control system is called "eAttendence" and is available in the cloud Software as a Service (SaaS) model (Haolong et al. 2015). The data from sensors are collected in the radio MESH network (Fig. 1) and submitted to the cloud eAttendance by internet links. Then they are processed and stored.

The smart cards are located in the MESH network based on nearest router address. The values of card parameters of Link Quality Indicator (LQI) (Qinab et al. 2013) and Received Signal Strength Indication RSSI (Yanga at all 2015), are the basis of which the system calculates theoretical distance from the nearest router. Knowing the location of the router, one can specify the card position. Additional localisation functions employ the frame time-of-flight measurement/or phase shift. Location accuracy is estimated as 1 m.

The system provides:

- recording of all inputs and outputs automatically with no the need for any actions to be taken either by employee or employer,
- automatic detection and signalling of all misuses, such as fake presence at work of the absent employee, illegitimate absence at the workstation, work, improper exchanging of cards etc.,
- monitoring of the presence at work both inside and outside the building, e.g. on the construction site, with no need for installing control devices or construct additional input gates,
- prompt, real-time information about the working time; delivered not only to employers but also to employees,
- additional information about detecting any accidents at work;i.e., fall or impact,
- detection whether PPE is used,
- automatic registration of the working time devoted to specific tasks, projects and clients,
- prompt production of corporate employee cards,
- significant reduction of costs as compared to classic systems.

2.2 *Research aims and methodology*

Among the other, the data resulting from the SMART ID CARD allow one to, monitor whether the employees use Personal Protective Equipment (PPE) constantly. To this end the correlation between signals representing movements of cards used by workers and the signals from the cards installed at the centre of PPE (e.g., helmet, glove, mask, glasses, etc.) has been examined.

The purpose of the research consisted in effectiveness verification of the detection mechanisms used in the SMART ID CARD, showing whether PPE was used or not.

Specific objectives were:

1. To check which correlation algorithms most suitable for detection of the use of PPE.
2. Finding how the correlation determining parameters affect the determination efficiency.

The research conducted in the Laboratory for Safety Techniques in Control Systems has been implemented in accordance with the methodology of the research developed within the framework of the project "Principles of the use of monitor-

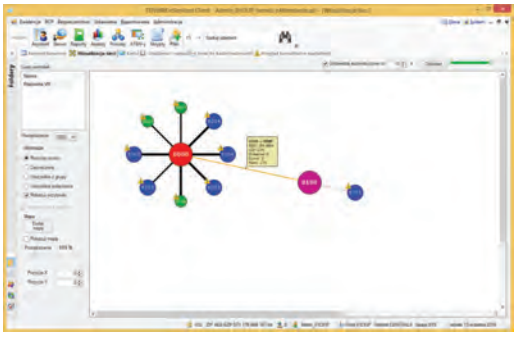

Figure 1. Sample visualisation of the network in eAttendance cloud.

Figure 2. Portal robot used in human movement simulation.

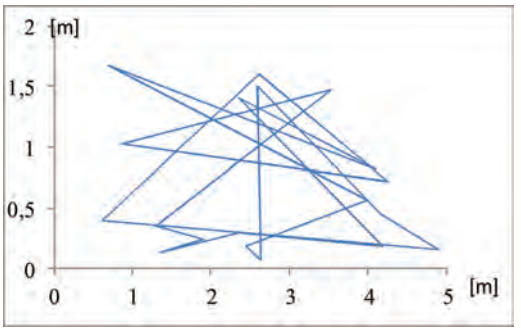

Figure 3. Robots head movement trajectory.

ing techniques for employee localisation with the use of ultra-broadband (UWB) communication to ensure machine safety" (Dzwiarek 2015). To simulate human movements the portal robot have been used (Fig. 2).

The displacements of robot working head represented human movements, as well as those of PPE. The card simulating men have been mounted on the robots head. The PPE use was simulated through a flexible connection of the second card, so that the movements of both cards were synchronised, but not identical. The robot head has been moved between consecutive points at a speed of 0.6 m/s. At each point of the trajectory the following sequence of movements was performed:

- 3 bottom-up movements,
- movement representing inactivity (a distance of 0.15 m along the Y axis, travelled at a speed of 0.01 m/s).
- 2 bottom-up movements,
- return movement to represent inactivity.

At the last point of trajectory the flexible connection of labels was broken and the smart card fell down (representing the PPE to be put away). The trajectory of robot motion that consisted of twenty randomly selected points is shown in Fig. 3. The experiment was repeated 3 times with the connection length 0.10 m, 0.50 m and 1 m, respectively.

3 RESULTS

In the course of experiment the signals from accelerometers situated in cards were registered. These were signals indicating:

- moving times,
- number of movments,
- motion sensitivity.

The data were stored in the cloud eAttendance. Sample data recorded during one experiment in the cloud eAttendance are shown in Fig. 4. The vertical line represents:

- start the experiment,
- connection fall,
- end of the experiment, respectively.

Then, the data obtained have been analysed. During the analysis effectiveness of the following correlation algorithms was compared:

- Pearson product—moment correlation coefficient (Buda &. Jarynowski 2004),
- Spearman's rank correlation coefficient, which is one of the non-parametric measures of statistical dependencies between monotone random variables (Kowalczyk 2015),
- Kendall's Tau coefficient (Kowalczyk 2015),
- BiSerial measure moment correlation coefficient (Linacre 2008).

The data were analysed basing on those registered by the Smart ID Card system, and written in the form of variables "quantity of movement" (IR), "time of movement" (CR) and "movement sensitivity" (CzR). During the tests they were compared with each other using different functions, which determined the value of the correlation coefficient:

1. The product of movement sensitivity and time of movement: CzR x CR.
2. The product of movement sensitivity and the logarithm of time of movement: CzR x log (CR).
3. The product of the logarithm of movement sensitivity and the logarithm of time of movement: log (CzR) x log (CR).
4. The product of movement sensitivity and quantity of movement: CzR x IR.
5. The product of movement sensitivity and the ratio of time of movement to quantity of movement: CzR x CR/IR.

To find the optimal values the Authors performed calculations for all control parameters:

a. width of the correlation window,
b. correlation coefficient threshold to identify the current situation,
c. type of correlation algorithm,
d. function of the measured data used as correlated variable.

During the experiment, we can distinguish two different phases:

1. Periods during which the both cards were attached to the robot head, i.e., their movements were correlated.
2. Periods during which one card remained motionless, so movements of the cards were not correlated.

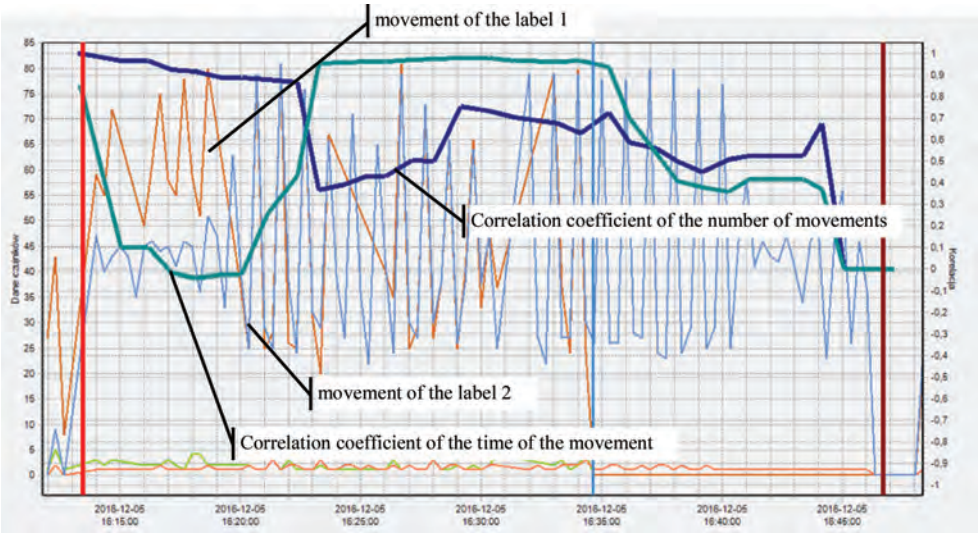

Figure 4. Example of experimental data obtained (Pearson correlation coefficient).

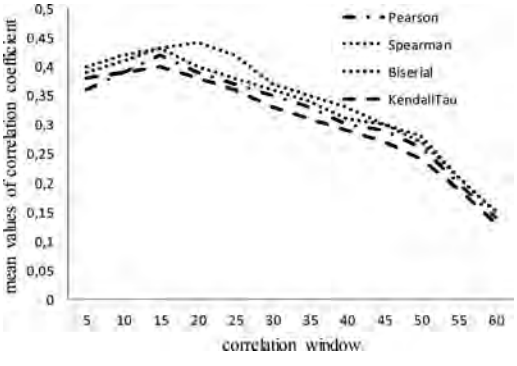

Figure 5. The averaged difference between the values for the correlate area and area without correlation depending on the correlation window width.

In the first phase, the values of correlation coefficients should be as high as possible (close to the unity), while in the second case, the correlation should not be observed, and the value of correlation coefficient should be close to zero.

To ensure that the detection of correlation loss was effective the following two functions of probability were determined:

- the probability that before the card release the correlation coefficient was not less than the assumed value 0.4,
- the probability that after the card release the correlation coefficient falls to zero after a certain period of time.

The results are presented in Table 1.

Table 1. The probability of an accurate indication of the PPE-lay-down obtained for each correlation algorithm.

Time after PPE put-away	Correlation algorithm			
	Pearson	Spearman	Biserial	Taukendall
0 (P(corrOFF > 0.4))	0.78	0.78	0.78	0.66
100 s (P(corrOFF < 0.4))	0.45	0.56	0.78	0.45
150 s (P(corrOFF < 0.4))	0.78	0.78	0.89	0.56
200 s (P(corrOFF < 0.4))	0.89	0.89	0.89	0.56
250 s (P(corrOFF < 0.4))	0.78	0.78	0.89	0.66

4 CONCLUSIONS

Test results have proved that the SMART ID CARD was highly effective in detecting the fact that PPE was worn, e.g., number of cases for which the value of the correlation coefficient has fallen below the threshold value reached 90%. System is much more effective at detecting that PPE was not used, what is important from the safety point of view. In addition, the time necessary for the detection of lack of personal protection is relatively short and reaches near 2 minutes. Taking

into account all the results obtained the course of research the use of SPEARMAN or BISERIAL algorithm for detecting lay down of the PPE is strongly recommended. Differences between these two algorithms are so small, that decision can be made depending on computational complexity the application involves.

An important innovation aspect consisted in the applied test procedure. On-line registration of all relevant test parameters in the cloud eAttendance allowed to both improve the conducted experiments, and significantly ordered their process. It is an excellent example of how the use technique of "Internet of things" can improve the research.

A Monte Carlo method for evaluating dependability of mission repairable items

H. Cheng, J. Huang & Y. Zhang
NAA, Beijing, China

ABSTRACT: When evaluating or predicting dependability of products in reliability engineering practice, we may face one kind of problems where product is repairable and mission time is flexible, i.e. repairs are allowed during mission process only if the accumulated delayed time is less than or equal to a specified time duration. The analytic solutions to this kind of problems are difficult or impossible to be derived. To solve this kind of problems, the relevant terminologies are listed and analyzed, firstly. Then, the occurrence processes of the probabilistic events corresponding to mission success or failure are analyzed. After this, a numerical method based on Monte Carlo simulation is proposed to compute dependability of repairable items when mission time is flexible. Finally, two examples are presented. The first one illustrates the use of the proposed method to assess or to predict dependability of an exponential distributed item. The second one shows the use of the method to compare two products in the dependability when mission time is specified, but repairs are allowed in the limited accumulated time during mission. Although, for simplicity, products in the two examples are assumed to follow exponential distributions, the method is available to any items with one or more failure mechanisms that follow the common distributions in reliability field, such as exponential distribution, normal distribution, log-normal distribution and Weibull distribution.

1 INTRODUCTION

Normally, mission reliability R_m is used to identify the probability for one product to finish a specific mission successfully (Zeng *et al* 2011, Murthy & Rausand 2008). Meanwhile, availability is used instead of reliability for reparable products. However, the conventional concepts and theoretical methods are not available for some special problems in reliability engineering practice (Porry 1973, Krivtsov 2000). One of these problems is to solve the success probability, namely, dependability of repairable product during mission (Yang 2007). In such case, some of the failures occurring during the mission process can be repaired by the operators, and the mission time is somewhat flexible, namely, maintenance that does not exceed specified time is allowed.

To solve this kind of problems, a Monte Carlo (Lemieux 2008) based method is proposed by considering the procedure of the probabilistic events, failure occurrence, down for repair, successful repair, unsuccessful repair, maintenance time exceeding limit.

Examples are presented to show the availability of the proposed Monte Carlo method in dependability prediction, dependability assessment, and dependability comparison for various products or design.

2 TERMINOLOGY

Before establishing the simulation process, it is better to review and study the terminology related. The dependability is related to reliability and maintainability of a product. Here, for that the issue studied is about dependability, i.e., success probability for mission, we just pay attention to the critical failures resulting in mission stop or mission failure. The notions related is described below.

1. Critical failure: the failures causing mission break off.
2. Mean Time Between Critical Failures (MTBCF): the ratio between accumulated operating time T and critical failure times r during a specific mission profile.
3. Mean Time To Repair (MTTR): The ratio between accumulated maintenance time and the failures times r during a specific mission profile.
4. Dependability: an item's ability to successfully finish an intended mission.

3 SIMULATION MODEL

The proposed method is useful regardless of the distributions of the failure and maintenance time.

But for simplicity, the exponential distribution is used to show the procedure.

Assume that one item with n kinds of failure mechanisms, all of which are followed independent exponential distributions with distribution parameters $\{\theta_i\}, i = 1, 2, \ldots, n$. The number of repairable mechanisms is k out of n, and n-k is the number of unrepairable mechanisms.

Let T be the time duration of mission. The item can be repaired during mission, but the accumulated maintenance time must be less than or equal to a specified time T_M, where $T_M < T$. For the item can be repaired T_M hours, the smallest operating time for item will be $T - T_M$ during the mission. Therefore, the item can conduct the mission successfully if the following events happen:

Event A: the item has never failed during the mission.

Event B: the item fails at t_0, but T-$t_0 \leqslant T$.

Event C: the item has failed l times during the mission, all are repairable, and the accumulated maintenance time is less than or equal to T_m.

Based on the analysis above, the Monte Carlo simulation algorithm is established and shown in Figure 1.

The simulation steps in Figure 1 are explained as follows:

Step 1: For one item with n types of failure mechanisms, every failure mechanism may follow different probability distribution. The distribution parameters for every type of failure should be obtained before to establish the simulation program. The parameters for failure distribution can be denoted by $\boldsymbol{\theta}_i$, $i = 1, 2, \ldots, n$, regardless of one-parameter cases, say exponential distribution, or multi-parameters cases, say Weibull distribution.

Step 2: Simulate failure time t_i for the ith failure mechanism with distribution parameter $\boldsymbol{\theta}_i$ described in step 1. Conduct the simulation for all the failure mechanisms to get the failure time series $\{t_i\}$ corresponding to $\{\boldsymbol{\theta}_i\}$, $i = 1, 2, \ldots, n$.

Step 3: Find out the minimum value t_k, $1 \leq k \leq n$, in $\{t_i\}$. Denote the minimum failure time t_k as $t_{\min}$ and $t_{k,0}$, and we will use them in the subsequent steps.

Step for judgement: Judge whether the failure mechanism corresponding to $t_{\min}$ is repairable or not in mission. Go on to conduct the next step for the case that the failure mechanism is repairable, and the mission fails for that it is unrepairable.

Step for judgement: Compare the values of $t_{\min}$ and T-T_m. If the result is,

$$t_{\min} \geq T\text{-}T_m \tag{1}$$

then the continuous operating time of the item can achieve the smallest operating time $T - T_M$, and the mission will succeed. Otherwise, go on to conduct step 4.

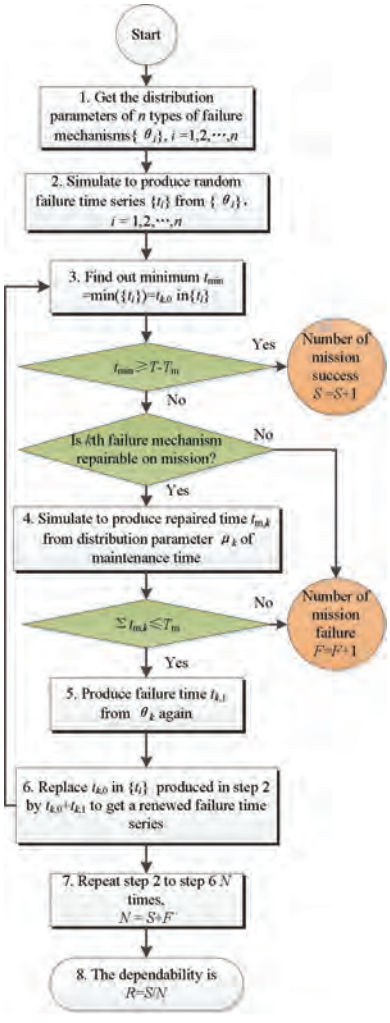

Figure 1. The Monte Carlo simulation algorithm for calculating dependability.

Step 4: Assume that the distribution parameter of maintenance time is $\boldsymbol{\mu}_k$ (the distribution of maintenance time could be any type normally used) corresponding to the failure mechanism of t_k in step 1. Simulate the maintenance time $t_{m,k}$ from distribution with parameter $\boldsymbol{\mu}_k$. The subscript "m" indicates "maintenance", and "k" indicates the kth failure mechanism**.**

Step for judgement: Compare the accumulated maintenance time $\Sigma t_{m,k}$ (Σ indicates cumulative sum) with the specified T_m, if,

$$\Sigma t_{m,k} > T_m \tag{2}$$

this means that the maintenance time used has exceeded the maximum maintenance time allowed. And mission fails.

if,

$$\Sigma t_{m,k} \leqslant T_m \tag{3}$$

then go on to step 5.

Step 5: Simulate the next failure time $t_{k,1}$ based on the distribution parameter $\boldsymbol{\theta}_k$ corresponding to the kth failure mechanism. In addition, for a prescribed problem in practice, we must know the performance of the repair that the item is repaired to new or is repaired to old first. Produce the next failure time $t_{k,1}$ based on this precondition.

Step 6: Get new failure time series by replacing t_k in $\{t_i\}$ produced in step 2 by $t_{k,0}+t_{k,1}$. And then denote the new time series with $\{t_i\}$, $i = 1, 2, \ldots, n$, as well.

Go back to step 3, continue to conduct the loop from step 3 to step 6 until that we can get a result that the mission fails or succeeds.

Step 7: Repeat the simulation procedure (from step 2 to step 6) N times, and N is determined based on the requirement of accuracy (Murthy & Rausand 2008).

Step 8: Compute dependability of the item based on the simulation result,

$$R = S/N \tag{4}$$

where N is the total number of simulated test shown in Figure 1, and S is the number of successful cases out of N times of simulation.

4 EXAMPLES

The Monte Carlo simulation method presented in section 3 could be used to predict or to assess the dependability of a specified item. Also, it is useful for comparing two items in the aspects of reliability and maintainability. Two examples are presented to show the availability of the proposed method. For simplicity, the failure time and maintenance time are both assumed to follow exponential distributions. The simulation processes are the same for the cases that the failure time and maintenance time corresponding to different failure mechanism follow different kinds of distributions.

4.1 *Example 1*

The mission time $T = 100$ h for item A. The maximum allowed accumulated maintenance time $T_m = 10$ h. There are four critical failure mechanisms which can cause mission pause for item A, and all the related parameters will be used in the simulation procedure are tabulated in Table 1. The first and second failure mechanisms are repairable during mission, and the third and fourth are not.

Calculate the dependability R of item A based on the simulation process shown in Figure 1. The change of R with simulation times N (the maximum number is 100000) is shown in Figure 2.

It can be seen from Figure 2 that the dependability R of item A converges to a somewhat stationary level with the increase of N. The maximum value of R is 1, and the minimum one is 0.5, corresponding to $N = 1$ and $N = 2$ respectively.

To show the change rule of R clearly, the abscissa scale is limited to the interval [0 10000]. The result is shown in Figure 3.

Table1. The distribution parameters for failure mechanisms of item A.

Distribution parameter of failure time θ_i	Repairable during mission	Distribution parameter of maintenance time μ_i
$\theta_1 = 400$	Yes	$\mu_1 = 2$
$\theta_2 = 500$	Yes	$\mu_2 = 3$
$\theta_3 = 1000$	No	/
$\theta_4 = 900$	No	/

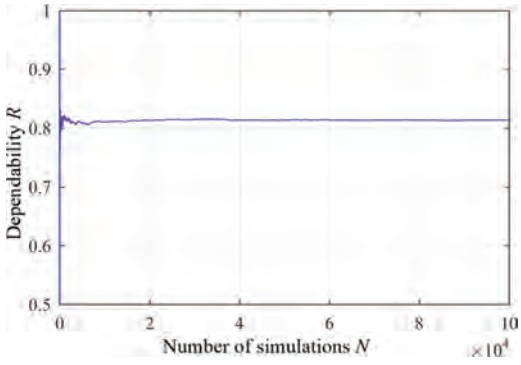

Figure 2. The change of R with simulation number N (global).

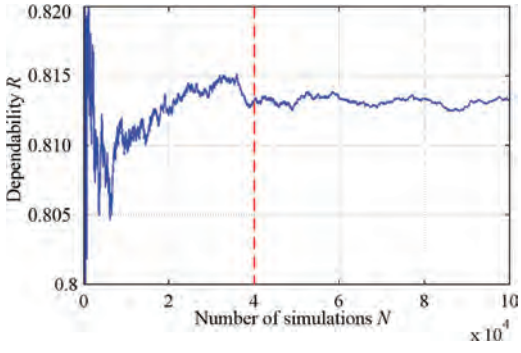

Figure 3. The change of R with simulation number N (local).

From Figure 3, it can be seen that R becomes stationary relatively when $N \geq 1107$. A step further, when N reaches 40000 and above, the result of R is very stationary, and the variation is acceptable.

To analyze the stationary property of the simulation based result, the change values of R corresponding to $N = 100000$ are divided into 1000sections with 100 continuous simulation results in each section. N' is used to denote the order of the sections. The coefficient of variation standard deviation to mean ratio, C (Ronald *et al.* 2007) of each section is calculated. The change rule of C with the section number N' is shown in Figure 4.

As shown in Figure 4, the maximum value of C is 0.1046. The coefficient of variation C converge quickly with the increase of N'. To show the result clearly, the ordinate axis is limited to the interval [0 0.0001] as shown in Figure 5.

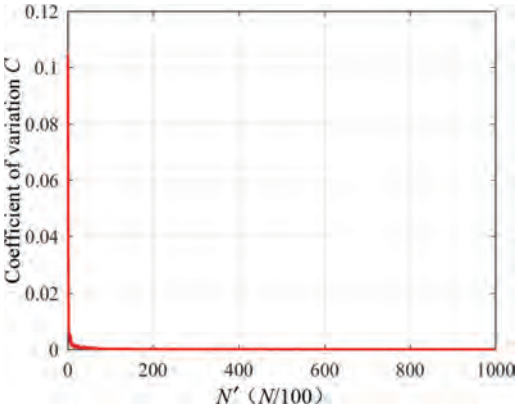

Figure 4. The change rule of coefficient of variation C of R with the divided section number N'.

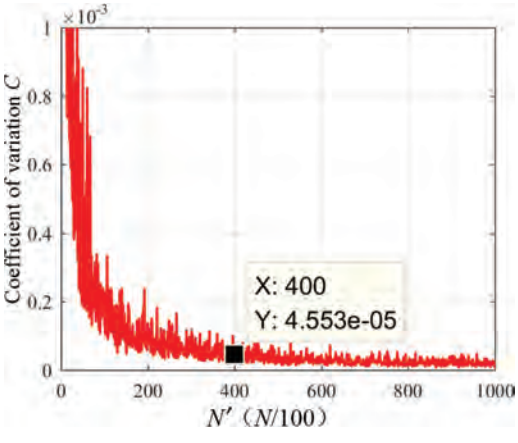

Figure 5. The change rule of coefficient of variation C of R with the divided section number N' (local).

Form Figure 5, we can see that the coefficient of variation C will be less than 10^{-5} when the simulation number N reaches $400 \times 100 = 40000$. This implies that the variation of R is extremely small already.

Based on all the analysis above, we accept the simulation results of R from $N = 40000$ to $N = 100000$ here in this example as shown in Figure 6.

The dependability of item A is shown in Figure 6, the mean value is,

$$\hat{R} = 0.8132 \tag{5}$$

4.2 *Example 2*

There are item B and item C to compare the dependability. The mission time is $T = 200$ h, and the maximum allowed accumulated maintenance time is $T_m = 12$ h.

There are four critical failure mechanisms which can cause mission pause for item B, and all the related parameters will be used in the simulation procedure are tabulated in Table 2. The first, second and third failure mechanisms are repairable during mission, and the fourth are not.

There are three critical failure mechanisms which can cause mission pause for item B, and all the related parameters will be used in the simulation procedure are tabulated in Table 3.

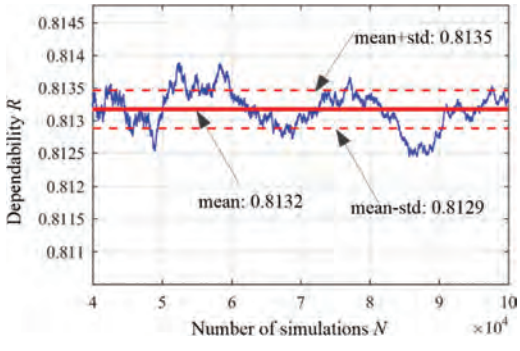

Figure 6. Simulation result of R of item A (N = 40000–100000) and its variation.

Table 2. The distribution parameters for failure mechanisms of item B.

Distribution parameter of failure time θ_i	Repairable during mission	Distribution parameter of maintenance time μ_i
$\theta_1 = 500$	Yes	$\mu_1 = 0.5$
$\theta_2 = 1000$	Yes	$\mu_2 = 1.5$
$\theta_3 = 1200$	Yes	$\mu_3 = 1.0$
$\theta_4 = 1300$	No	/

Table3. The distribution parameters for failure mechanisms of item C.

Distribution parameter of failure time θ_i	Repairable during mission	Distribution parameter of maintenance time μ_i
$\theta_1 = 800$	Yes	$\mu_1 = 3$
$\theta_2 = 1200$	Yes	$\mu_2 = 4$
$\theta_3 = 800$	No	/

Based on the data in Table 2, the MTBCF of item B through traditional method is,

$$MTBCF = \frac{1}{\frac{1}{500}+\frac{1}{1000}+\frac{1}{1200}+\frac{1}{1300}} = 217h \quad (6)$$

The MTTR of the mission repairable failure mechanisms of item B is,

$$MTTR = \frac{\frac{0.5}{500}+\frac{1.5}{1000}+\frac{1}{1200}}{\frac{1}{500}+\frac{1}{1000}+\frac{1}{1200}} = 0.8696h \quad (7)$$

Meanwhile, the MTBCF of item C is,

$$MTBCF = \frac{1}{\frac{1}{800}+\frac{1}{1200}+\frac{1}{800}} = 300h \quad (8)$$

The MTTR of the mission repairable failure mechanisms of item C is,

$$MTTR = \frac{\frac{3}{800}+\frac{4}{1200}}{\frac{1}{800}+\frac{1}{1200}} = 3.4h \quad (9)$$

Based on the analysis above, item C is more reliable than item B from the viewpoint of tradition method.

However, it is more reasonable to consider both the reliability and maintainability of a product when calculating its ability to finish a specific mission. The comparison of dependability of item B and of item C based on the proposed Monte Carlo method in Figure 1 are shown in Figure 7. The total simulation number N is 100000.

The simulation result becomes stationary when N is larger than 40000 as shown in Figure 7. A step further, we have analyzed the variation of the simulation results of item B and item C quantitively from N = 40000 to N = 100000 as shown in Figure 8 and Figure 9, respectively.

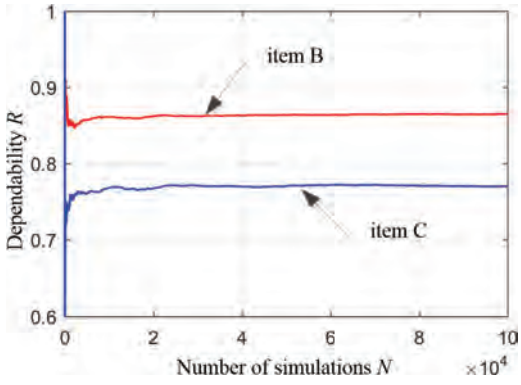

Figure 7. The comparison of simulation based dependability of item B and of item C.

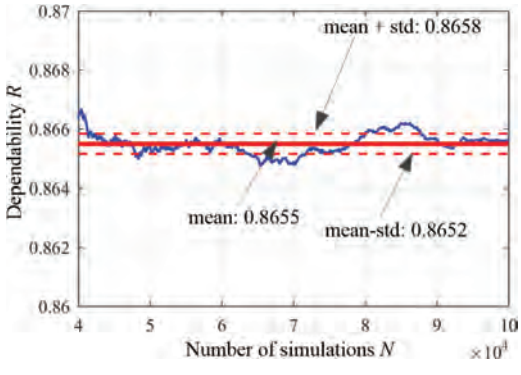

Figure 8. Simulation result of R of item B (N = 40000–100000) and its variation.

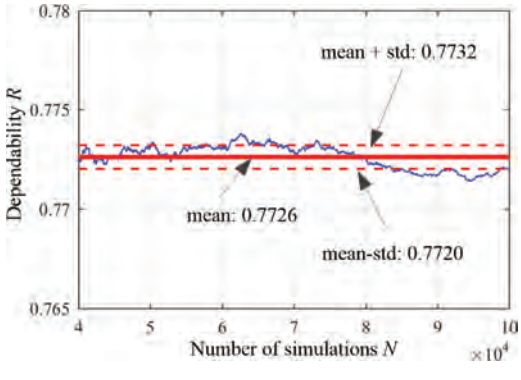

Figure 9. Simulation result of R of item C (N = 40000–100000) and its variation.

Table 4. The comparison of item B and item C in the aspects of reliability, maintainability and dependability.

Item	MTBCF (h)	Mission repairable proportion of critical failure	MTTR (h)	Dependability
B	217.27	75%	0.8697	0.8655
C	300.00	67%	3.400	0.7726

Based on the result shown in Figure 8, the dependability of item B is,

$$R_B = 0.8655 \tag{10}$$

The standard deviation of R_B is

$$S_{td}(R_B) = 3.4241 \times 10^{-4} \tag{11}$$

The coefficient of variation of R_B is

$$C(R_B) = 3.9562 \times 10^{-4} \tag{12}$$

The coefficient of variation is very small, this means that the result is stationary and believable.

Based on the result shown in Figure 9, the dependability of item C is,

$$R_C = 0.7726 \tag{13}$$

The standard deviation of R_C is

$$S_{td}(R_C) = 5.9918 \times 10^{-4} \tag{14}$$

The coefficient of variation of R_B is

$$C(R_C) = 7.7554 \times 10^{-4} \tag{15}$$

The coefficient of variation is very small; this means that the result is stationary and believable.

Based on the calculation above, the comparison of item B and item C in the aspects of reliability, maintainability and dependability is listed in Table 4.

As listed in Table 4, the inherent reliability of item C is better than item B. However, the maintainability design of item B is better comparatively. Finally, as shown in this example, the dependability (probability to finish the given mission) of item B is 12% higher than item C, although its MTBCF is 28% lower compared to the latter.

5 CONCLUSIONS

In this study, we focus on the issue calculating dependability of repairable item when the mission time is flexible, and get the following conclusions:

1. A Monte Carlo simulation algorithm is established based on the analysis of the occurrences of the random events during the mission where the item could be repaired with in limited accumulated maintenance time.
2. The use and availability of the proposed method in predicting or assessing the dependability of a product is developed and verified in the first example.
3. Based on the process and result in example 2, the dependability of one item during the mission scenario analyzed in this study is determined by both reliability and maintainability, and a better maintainability can even make up the disadvantage in the aspect of reliability.

Real-time work simulations of aircraft unit fuzzy reliability evaluator

Norbert Grzesik, Robert Czapla & Aneta Krzyżak
Faculty of Aviation, Polish Air Force Academy in Dęblin, Poland

Mariusz Zieja
Air Force Institute of Technology in Warsaw, Poland

ABSTRACT: In this publication, the authors presented a proposal to use fuzzy expert inference system for evaluating the selected aircraft on-board unit reliability. Under consideration is military aircraft gun. The article is continuation of 2015 ESREL publication. There were initial analysis and now work simulations is presented. The project ensures reliable work (selected unit reliability, in addition maintenance process and safety improvements). It was verified by practical simulations. The research confirm possibility of use fuzzy expert inference systems in aircraft on-board units reliability evaluation.

1 INTRODUCTION

Prof. Lotfi Zadeh, in 1965, proposed to use multivalent logic in inference systems. This technology was and is used in many branches of science, including reliability systems research. Used by people systems reliability analysis with traditional mathematical and statistical methods is difficult because of its complexity. Research centres from all over the world started to search alternative object reliability evaluation approaches. For example in automotive (ABS system Mauer, 1995), reliability analysis (Azadeh et al. 2009), aviation (Grzesik 2004, 2012), medicine and even in music. Selected unit was M61A1 gun mounted on F-16 class aircraft. Many different factors effect gun reliability. Some of them changing slowly and some dynamically (Wrona, 2013). It can lead to gun parts damages. Proper design fuzzy expert inference system may contribute to decrease the gun maintenance costs and time. In the publication (presented on ESREL 2015 Conference, Żurek, & Grzesik 2014) fuzzy expert inference system designing process in Matlab, Fuzzy Logic Toolbox software (Mrozek & Mrozek, 1998) and initial analysis were described. Dynamic system simulation of designed models with use of Simulink software is presented as the next steps of the project development. The scope of research is to increase the system reliable work.

Extensive literature analysis and preliminary studies about very wide range of fuzzy logic applications provide the authors necessary fundamentals to continue the project in aircraft on-board units like selected one. Moreover there are several available publications in web sites describing similar problems, but not in military aircraft.

And that is why the authors conducted further system work analysis to verify proper system work practically in dynamic system work simulations which are presented in the article.

One of the most important factor determine achieving the main goal is accurate selection of the knowledge base experts during designing process of such systems. The experts were responsible for the criteria and principles of operation of these systems determination (creation of inference rules). The general overview about expert selection process is presented in Żurek & Grzesik (2014).

That kind of reliability evaluation method supports classical methods Adamski (2006), Jasztal et al. (2007), Tomaszek et al. (2011) Jasztal et al. (2008), Zio (2009) and can be used when there is no statistical information or the information is not sufficient, prognostic parameters, describing the object, change and the changes are not well known, long term prognosis are determined with combined mathematic and heuristic methods Idziaszek & Grzesik (2014).

Typical fuzzy inference system consists of fuzzy sets (membership functions). Those sets and membership functions are characteristic for fuzzy logic and provide opportunity to use the data in fuzzy inference systems.

This publication is an integral part of the authors scientific researches.

2 FUZZY EXPERT INFERENCE SYSTEM FOR SELECTED AIRCRAFT ON-BOARD UNIT RELIABILITY EVALUATION

Project is Mamdani type non-adaptive fuzzy inference system with two inputs and one output (MISO—

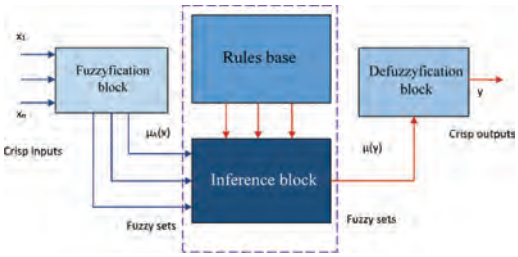

Figure 1. Fuzzy inference system (typical).

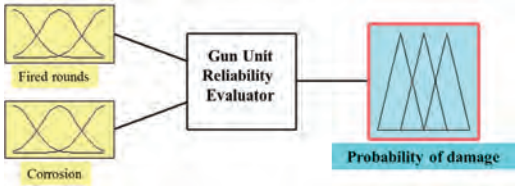

Figure 2. Fuzzy expert inference system for selected aircraft on-board unit reliability evaluation (first evaluator).

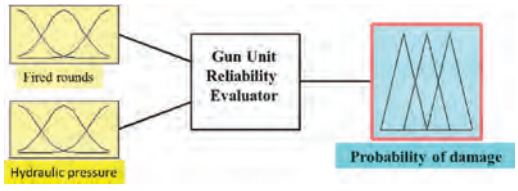

Figure 3. Fuzzy expert inference system for selected aircraft on-board unit reliability evaluation (second evaluator).

many inputs—single output), Wrona (2014). The project consists of two evaluator and is shown on Fig. 2 (first evaluator, presented on ESREL 2015 Conference) and Fig. 3 (second evaluator).

According to technical documentation, reliable gun system work depends on number of fired rounds, barrel corrosion (barrel reliability) and hydraulic pressure in the hydraulic drive. That is why authors analyzed the influence of those factors on gun probability damage.

3 REAL-TIME WORK SIMULATIONS OF THE SYSTEM

In order to carry out the simulation, the fuzzy expert inference systems designed in Matlab, Fuzzy Logic Toolbox software need to be transferred to Simulink software. The Simulink model consists of two signal blocks ("Signal Builder") and fuzzy inference system block ("Fuzzy Logic Controller", Fig. 4). In addition, each block is combined with a block showing the results of the simulation ("Scope"). Simulations were performed using the same, designed in Fuzzy Logic Toolbox models, because the structure of the test models is the same. To obtained results the simulation time is not relevant. It was selected that retrieving parameters from individual samples is easier. In the simulations, 11 samples were collected at intervals of every 10 seconds, so the simulation time is 100 seconds., Wrona (2014).

- M61A1 gun barrels evaluation damage probability simulation analysis

Three system simulations were performed in order to examine the proper project work. The input signals are: "Fired Rounds" expressed in number of total shots and "Barrel Corrosion". The output signal presents changes of gun barrels damage probability along with a change in input parameters. The input signal builders present the change of systems' input values.

Simulation I

The first simulation assumes that the input parameters are changing from the minimum to the maximum value in a linear way (Figs. 5, 6).

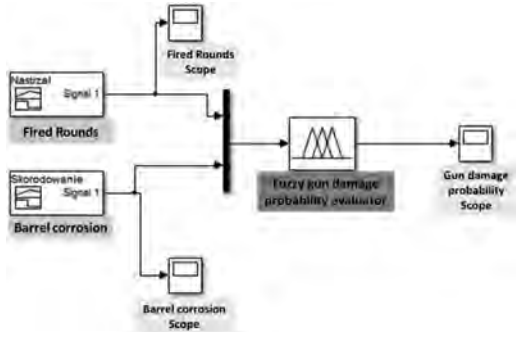

Figure 4. The Simulink model of fuzzy expert inference system.

Table 1. Signal samples parameters used in the simulation I.

Sample number	Fired rounds	Barrel corrosion [in]	Probability of damage [%]
1	0	0	3
2	5000	0,01	12,4
3	10000	0,02	21,8
4	15000	0,03	28,6
5	20000	0,04	33,3
6	25000	0,05	45
7	30000	0,06	52,4
8	35000	0,07	60
9	40000	0,08	63,4
10	45000	0,09	68,1
11	50000	0,1	97

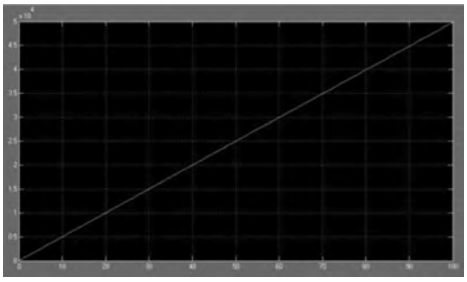

Figure 5. "Fired Rounds" linear input function in the Simulink signal builder.

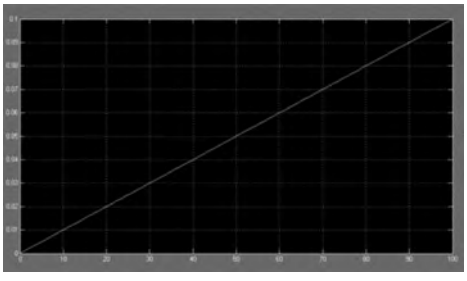

Figure 6. "Barrel Corrosion" linear input function in the Simulink signal builder.

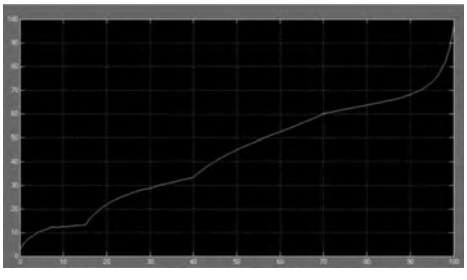

Figure 7. Gun barrels damage probability linear output function calculated in the Simulink.

The Fig. 7 shows that with simultaneous and proportionate input values increase the gun barrels damage probability increased almost linearly. From 90 seconds the damage probability increases sharply to 97%.

Simulation II

The input parameters of the "Fired Rounds" signal in the second simulation remained unchanged (Fig. 8) in relation to the parameters from the previous simulation. However, it was assumed that the corrosion parameters have changed very slightly and oscillate around a small value of 0.01 in (Fig. 9).

Taking into account the simulation II assumptions, the probability of gun barrels damage is kept

Table 2. Signal samples parameters used in the simulation II.

Sample number	Fired rounds	Barrel corrosion [in]	Probability of damage [%]
1	0	0,008	3,56
2	5000	0,0084	12,4
3	10000	0,0088	12,8
4	15000	0,0092	26,7
5	20000	0,0096	29,4
6	25000	0,01	29,7
7	30000	0,0104	30
8	35000	0,0108	33,5
9	40000	0,0112	49,6
10	45000	0,0116	61,5
11	50000	0,012	83,1

at a low level for 20 seconds (Fig. 10). Then for about 70 seconds the damage probability is averaging. From 70 seconds the damage probability rapidly increases and reaches a large level due to activate antecedents with high and very high fired rounds value.

Simulation III

The third simulation imitated the situation with the intense increase in barrels corrosion with relatively small fired rounds.

Table 3. Signal samples parameters used in the simulation III.

Sample number	Fired rounds	Barrel corrosion [in]	Probability of damage [%]
1	5000	0,06	29,4
2	6000	0,064	31,1
3	7000	0,068	32,7
4	8000	0,072	38
5	9000	0,076	44,4
6	10000	0,080	49,6
7	11000	0,084	55,4
8	12000	0,088	59,3
9	13000	0,092	49,6
10	14000	0,096	70,6
11	15000	0,1	83,7

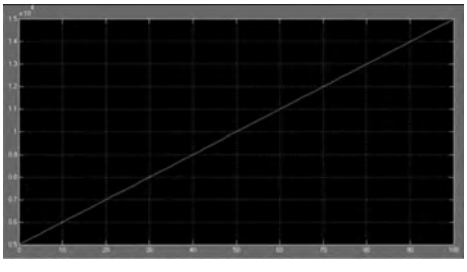

Figure 11. "Fired Rounds" linear input function in the Simulink signal builder.

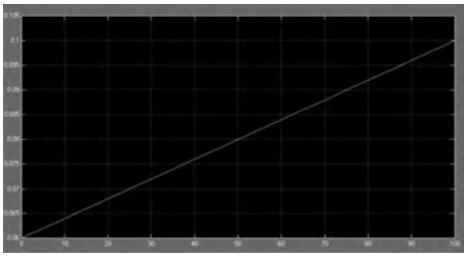

Figure 12. "Barrel Corrosion" linear input function in the Simulink signal builder.

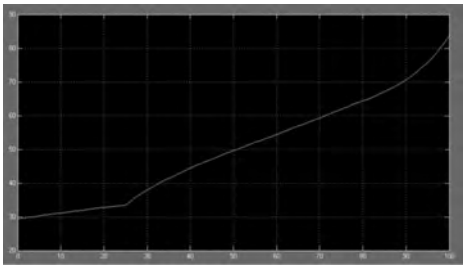

Figure 13. Gun barrels damage probability linear output function calculated in the Simulink.

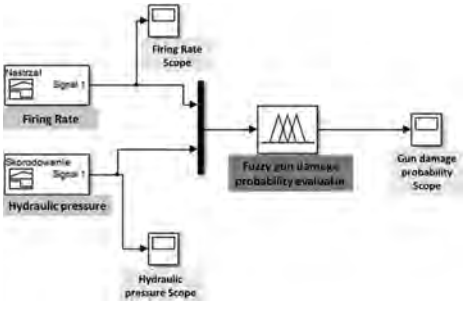

Figure 14. The Simulink model of fuzzy expert inference system.

Fig. 13 analysis of the gun barrels damage probability in the third simulation shows, that with a relatively small amount of fired rounds, rapid growth of barrels corrosion significantly increases the barrels damage probability.

- M61A1 hydraulic drive evaluation damage probability simulation analysis

Two system simulations were performed in order to examine the proper project work. The input signals are: "Firing Rate" expressed in number of shots per minute and "Hydraulic Pressure" (Fig. 14). The input signal builders present the change of systems' input values. The output signal presents changes of gun barrels damage probability along with a change in input parameters.

Simulation I

The first simulation assumes that the both input parameters are within the range of the optimal values.

According to performed simulations and taking into account project assumptions assessed that input parameters will be oscillated within the nominal system work parameters and the probability of gun hydraulic drive damage is small or very small (Fig. 17).

Table 4. Signal samples parameters used in the simulation I.

Sample number	Firing rate [rounds/min.]	Hydraulic pressure [psi]	Probability of damage [%]
1	5800	3000	3
2	5880	2900	8,3
3	5960	2800	10,6
4	6040	2700	11,8
5	6120	2600	12,5
6	6200	2500	12,9
7	6060	2560	12,7
8	5920	2620	12,4
9	5780	2680	12
10	5640	2740	11,4
11	5500	2800	10,6

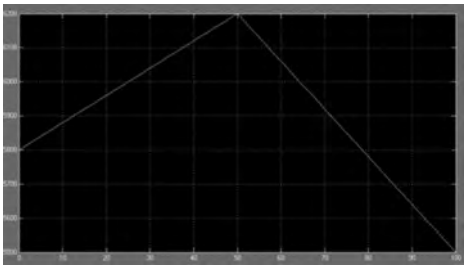

Figure 15. "Firing Rate" linear input function in the Simulink signal builder.

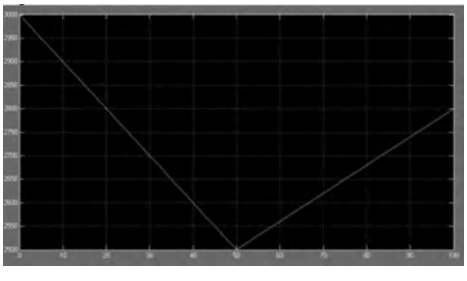

Figure 16. "Hydraulic Pressure" linear input function in the Simulink signal builder.

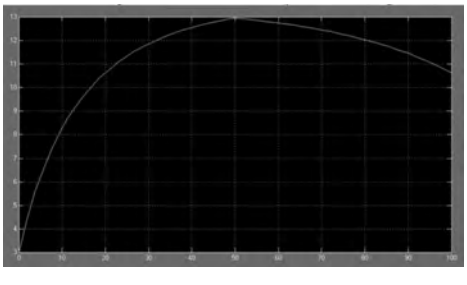

Figure 17. Gun hydraulic drive damage probability linear output function calculated in the Simulink.

Simulation II

Simulation number two assumes that gun drive supply pressure is continuously dropping to an unacceptable value. The firing rate remains the same for some time and then drops below the limit value.

Fig. 20 shows, that with the optimal gun firing rate the drop of gun hydraulic drive pressure does not affect its probability of damage. When the gun firing rate and the gun drive pressure are average, the probability of gun damage is also on average level. Dropping firing rate below 3,900 rounds/min

Table 5. Signal samples parameters used in the simulation II.

Sample number	Firing rate [rounds/min.]	Hydraulic pressure [psi]	Probability of damage [%]
1	6200	3000	3

leads to sharp increase the gun damage probability and when the pressure reaches a value of approximately 1000 psi, probability is at level of 97%.

4 DISCUSSIONS

Fuzzy expert systems are increasingly used as a tool to solve all sorts of scientific problems. These systems are characterized by high accuracy, while used mathematical simplicity and uncomplicated structure. In past and recent years, research are intensifying into the use of inference systems in the objects reliability and maintenance analysis and evaluation (lead to improvement, Kacprzyk & Yager 1985, Sergaki & Kalaitzakis 2002, Yager 2004). Moreover, these systems also are more and more used in the aircraft on-board systems. That is why authors decided to try to demonstrate the possibility of use fuzzy expert inference systems in aircraft on-board systems reliability evaluation (based on M61A1 gun damage probability evaluation systems). Some simplifying assumptions were used during designing process. However, it did not cover the benefits of use the technology in the complex objects reliability analysis.

The advantage of fuzzy expert inference systems is the fact that they can be used to assess the objects damage probability, that reliability depends on rapidly changing in time parameters (like: hydraulic pressure, firing rate), as well as on the parameters that changing during exploitations (like: fired rounds, barrel corrosion, Wrona 2013).

Another advantage the fuzzy systems is the ability to perform a simulation based on the real-time changing parameters of which it would be possible to determine when the individual maintenance procedures are necessary, and when it can be done later. Such action could lead to reduction in amount of unnecessary maintenance procedures and reduce operating costs.

5 CONCLUSIONS

The possibilities resulting from the use of fuzzy expert systems, are very flexible and depend on the creativity of engineers designing such systems. The results obtained in Simulink software are satisfactory at this level of designing process. The project development would require the M61A1 gun damages and malfunctions data collection.

The main contribution of the publication is that there is possibility of use the fuzzy logic (fuzzy expert inference systems) in selected aircraft on-board systems/units reliability evaluation. This approach is pioneer according to the systems reliability evaluation problems.

Selecting correct architecture for mission critical safe control systems

E.H. Dogruguven
Aselsan Inc., Ankara, Turkey

I. Ustoglu
Department of Control and Automation Engineering, Yildiz Technical University, Istanbul, Turkey

ABSTRACT: Developing safety critical systems require long years of planned investments, broad theoretical knowledge and domain experience. Data interchange between CPUs, synchronization, computation speed and diagnostic measures shall exhaustively be evaluated along with the effects of the parameters used in the reliability and safety calculations ex tunc. This study focuses on the effects of calculation parameters for different architectures. Special attention is paid for the architecture 1oo2D regarding its model and normative definition. It has also been revealed that there are correlations between some parameters which seem independent. An advising route map is created to distill what kind of methods can be applied to decrease the hazard rates. For concretizing some concepts and sharing field experience, railway domain is selected, however the study is fully applicable to other domains due to deeming the norm IEC 61508 along the entire paper.

1 INTRODUCTION

Murthy et al. (2008) mentions that regulatory requirements, customer requirements, and technical requirements are to be fulfilled when developing a safety instrumented system (SIS). For safety related systems in railway, automotive, nuclear power etc. the domain specific norms dealing with system, hardware (HW), software (SW) and transmission are derived from the core norm IEC 61508 (Functional safety of electrical/ electronic/ programmable electronic safety-related systems) as depicted below in Figure 1. CENELEC Norms are the railway norms derived from this standard.

The norm IEC 61508 defines in Part I four discrete safety integrity levels (SIL) with regards to the low demand and high demand or continuous. In case the yearly demand rate is lower than one, then the low demand mode is applied, else continuous mode should be considered. For the low demand mode, SIL is determined according to the Probability of a dangerous failure on demand (PFD) explained as safety unavailability of an E/E/PE safety-related system to perform the specified safety function when a For the high demand mode, SIL is determined according to the average frequency of a dangerous failure per hour (PFH) explained as average frequency of a dangerous failure of an E/E/PE safety related system to perform the specified safety function over a given period of time.

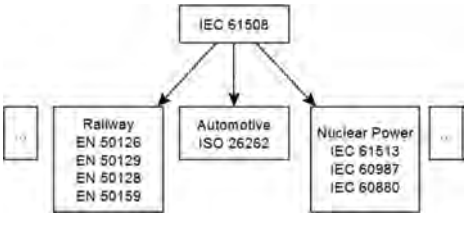

Figure 1. Derivation of standards from IEC 61508.

A similar approach is applied also in EN 50129 (Railway applications—Communication, signalling and processing systems—Safety related electronic systems for signalling). IEC 61508 and CENELEC norms describe both qualitative and quantitative requirements to be applied for these integrity levels (IL). Architecture is both relevant with qualitative and quantitative requirements. For instance, hardware fault tolerance (HFT) is defined as qualitative requirement and PFH_G is allocated as quantitative requirement for the pertinent IL. Here, the subscript "G" represents the group of voted channels which is also used in the remaining part of the paper in this manner.

Although several formulas are provided in the norms or stochastic processes can be utilized for the calculation of the PFH_G, it is not comprehensible to judge the effects of the parameters in these formu-

Table 1. SIL vs PFD_{avg} and PFH.

SIL	PFD_{avg}	PFH [h^{-1}]
1	1E-1 > PFD_{avg} ≥ 1E-2	1E-5 > PFH ≥ 1E-6
2	1E-2 > PFD_{avg} ≥ 1E-3	1E-6 > PFH ≥ 1E-7
3	1E-3 > PFD_{avg} ≥ 1E-4	1E-7 > PFH ≥ 1E-8
4	1E-4 > PFD_{avg} ≥ 1E-5	1E-8 > PFH ≥ 1E-9

las. However while developing on-board computer, it has been realized that such a study would be very useful to decide the design path. Chen et al. (2008) simulated RAMS of triple-modular-redundant system and a dual-modular-duplex-redundant system and compared using the estimates of actual hardware failure rates. King (2014) analyzed Hazardous Event Frequency per year with respect to demand rate. But, neither effect of the parameters in Table 2 nor the crucial dependent failures were discussed in these studies. Smith & Gruhn (1995) showed dependency of the safety system on some parameters at some level, however this study is not very detailed, the results were shown in bar charts with two only values. Moreover, the architectures 1oo2D and 1oo3 were not covered and high demand/ continuous mode was not evaluated, but the behavior of parameters in high demand mode are very different as the algebraic equations differ essentially from each other in low and high demand mode for the same architecture. There are some studies like the one from Liu and Rausand (2016) about proof testing effect or the one from Ilavsky et al. (2013) about ß factor effect, but no detailed work covering all parameters and all plausible architectures has been met in the literature. Therefore, it is believed that a study examining different architectures to find out the influences of parameters to reach very low PFH_G could be very beneficial and interesting. These very low challenging values are required since the result of a possible hazard at some systems like nuclear power plants, autonomous vehicles, high speed trains or air planes could be catastrophic. For instance, European rail traffic management system/European train control system (ERTMS/ETCS) defines the core hazard for ETCS on-board in Subset – 091 in clause 4.2.1.8 as exceedance of the safe speed or distance as advised to ETCS with tolerable hazard rate of $2 \times 1E\text{-}09$ (1/h) for the entire system which results in a PFH_G requirement of the vital train computer about less than 1E10–12 (1/h). A similar or even less quantitative target for the on-board vital computation unit is obtained for the metro lines considering the safety requirement in the CBTC standard IEEE 1474.1. It sets the requirement that the CBTC wayside and train-borne equipment located within any contiguous portion of a one-way route (including the maximum number of other trains that can be located in this contiguous portion of a one-way route under the specified peak operating headway) that can be traversed by a train traveling at the specified maximum authorized speed for one hour or less shall have a total calculated aggregate MTBHE (total of all critical and catastrophic hazards) of at least 1E-09 operating hours. This information shows that quantitative values that are thousand times better than SIL 4 are to be obtained for several constituents like vital train computer or vital wayside Automatic Train Protection computer. Another novelty of the paper is a route map providing structural information to develop safety critical constituent to reach very low dangerous failure rates.

This paper is organized as follows. The introductory part gives a brief information about the norms, functional safety and motivation of the study. Section II distills technical background of the architectures and the calculation methodologies. In Section III, the simulation results of PFH_G as a function of different parameters are described by highlighting the most interesting results in accordance with the pertinent architecture in the form of deductions. Furthermore, the architectures are compared in this part. Section IV provides a route map as a proposal to reach very low PFH_G ranges. Finally, some concluding remarks are conveyed.

2 SAFETY ARCHITECTURES

Karydasa & Brombacherb (1999) explain that architectural modeling deals with the development of a detailed block diagram of the programmable electronic system identifying each subsystem and the interconnections related to the safety function under consideration. IEC 61508 defines six architectures providing the formulas depending on the parameters defined in Table 2 to calculate the PFH_G. However, according to IEC 61508, part 2, Table 3, for SIL 4, the HFT must at least be one, if diagnostic coverage (DC) is over 99%, and two, in case DC is between 90% and 99%. The architectures 1oo1 and 2oo2 thereupon are eliminated for

Table 2. Parameters and their explanations.

λ	Total failure rate (1/h) of a channel in a subsystem	ß	The fraction of undetected failures that have a common cause
λ_s	Safe failure rate (1/h)	$ß_d$	Of those failures that are detected by the diagnostic tests, the fraction that have a common cause
λ_{sd}	Detected safe failure rate (1/h)	MTTR	Mean time to restoration (h)
λ_d	Dangerous failure rate (1/h)	MRT	Mean repair time (h)
λ_{dd}	Detected dangerous failure rate (1/h)	K	Fraction of the success of the autotest circuit in the 1oo2D system
λ_{du}	Undetected dangerous failure rate (1/h)	T_1	Proof test interval (y)
DC	Diagnostic coverage		

this analysis. Chen et al. (2008) points out that triple modular redundancy and dual-duplex modular redundancy are main architectures used for safety-critical computer systems. Furthermore, according to our investigations in the railway industry, 1oo2, 1oo2D and 2oo3 are the main vital computer architectures for Communication Based Train Control (CBTC) systems used in metro lines and ERTMS ETCS systems used in high speed lines. In case availability requirements are high, then redundant 1oo2 and 1oo2D architectures are selected. 1oo3 architecture is usually used in transmitters and electromechanical relays, but not preferred for computing units due to relative lower availability since the unavailability of the computing unit would result in the unavailability of the entire system.

Reliability block diagram paradigm is used for deriving the equations in IEC 61508. Another widely accepted and used method for sophisticated architectures is Markov Diagrams, a stochastic process. In this work, the formulas in IEC 61508 are utilized. Applying different paradigms will surely result in different algebraic outcomes, however as Zhang et al. (2003) shows the difference is not so crucial when applied correctly.

The calculation formulas and architecture explanations provided in IEC 61508 are distilled in following. In these algebraic formulations, ß-Factor paradigm is selected for modeling the dependant failures.

2oo3 Architecture: This architecture consists of three channels connected in parallel with a majority voting arrangement.

$$PFH_G = 6\left((1-\beta_D)\lambda_{DD} + (1-\beta)\lambda_{DU}\right)(1-\beta) \lambda_{DU} t_{CE} + \beta\lambda_{DU} \quad (1)$$

1oo3 Architecture: This architecture is similar to 2oo3. It consists of three channels connected in parallel with a voting arrangement such that one channel is enough to perform the safety function.

$$PFH_G = 6\left((1-\beta_D)\lambda_{DD} + (1-\beta)\lambda_{DU}\right)^2(1-\beta) \lambda_{DU} t_{CE} t_{GE} + \beta\lambda_{DU} \quad (2)$$

1oo2 Architecture: This architecture consists of two channels connected in parallel, such that either channel can process the safety function. It is assumed that any diagnostic testing would only report the faults found and would not change any output states or change the output voting.

Figure 2. 1oo2, 2oo3 and 1oo2D architectural descriptions.

$$PFH_G = 2\left((1-\beta_D)\lambda_{DD} + (1-\beta)\lambda_{DU}\right)(1-\beta) \lambda_{DU} t_{CE} + \beta\lambda_{DU} \quad (3)$$

$$t_{CE} = \frac{\lambda_{DU}}{\lambda_D}\left(\frac{T_1}{2} + MRT\right) + \frac{\lambda_{DD}}{\lambda_D} MTTR \quad (4)$$

1oo2D Architecture: This architecture consists of two channels connected in parallel. During normal operation, both channels need to demand the safety function before it can take place. In addition, if the diagnostic tests in either channel detect a fault then the output voting is adapted so that the overall output state then follows that given by the other channel. If the diagnostic tests find faults in both channels and a discrepancy that cannot be allocated to either channel, then the output goes to the safe state. In order to detect a discrepancy between the channels, either channel can determine the state of the other channel via a means independent of the other channel. The channel comparison/switch over mechanism may not be 100% efficient therefore K represents the efficiency of this inter-channel comparison/switch mechanism, i.e. the output may remain on the 2oo2 voting even with one channel detected as faulty. The parameter K will need to be determined by an FMEA.

$$PFH_G = 2(1-\beta)\lambda_{DU} + \left((1-\beta)\lambda_{DU} + (1-\beta_D)\right) \lambda_{DD} + \lambda_{SD}) t_{CE}' + 2(1-K)\lambda_{DD} + \beta\lambda_{DU} \quad (5)$$

$$t_{CE}' = \frac{\lambda_{DU}\left(\frac{T_1}{2} + MRT\right) + \left(\lambda_{DD} + \lambda_{SD}\right) MTTR}{\lambda_{DU} + \lambda_{DD} + \lambda_{SD}} \lambda_{SD}\frac{\lambda}{2} DC \quad (6)$$

Although this formula does not make a distinction regarding the DC between detected and undetected dependant failures, Hokstad (2005) showed how the DC is influenced when comparison of channels is applied as part of the diagnostic testing for multiple channel systems and suggests an alternative to define two betas, i.e. β for DU failures, and β_D for DD failures. Notwithstanding, this paper takes the formulation provided in IEC 61508 part 6.

3 SIMULATION RESULTS AND DEDUCTIONS

In this section, the effects of parameters are explained. At each step, one parameter and of

course the parameters derived from this parameter if there exist are varied while remaining ones are fixed. A table is provided to track the values of variables in the equation. The parameter of interests is shown as "PoI", variating value as "v". Having provided the simulation results, a deduction part is also provided to summarize the impact of the pertinent parameter. It is found that setting plausible values for fixed variables is essential. A particular importance should be given for the value K used for the calculation of the architecture 1oo2D. In IEC 61508, part 6, an example value for K is given 0.98. However, according to our field experience, it is possible to reach 0.9999 for K, and with this valuation, the results change for 1oo2D substantially. In the simulations, attention is drawn in case a change from 0.98 to 0.9999 for K has a great impact on the results.

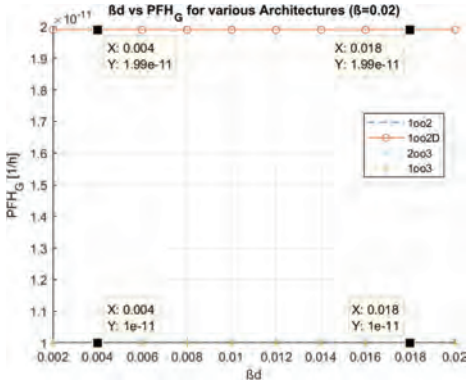

Figure 7. The influence of $ß_d$ while ß is 2%.

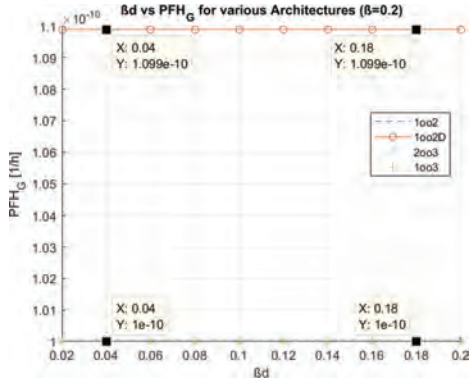

Figure 8. The influence of ßd while ß is 20%.

3.1 *The influence of λ (Table 3 and Figures 3 and 4)*

To compare 1oo2D with other architectures in a correct way, K is chosen firstly as 0.98 and then as 0.9999.

According to above parameters, the simulation re-sult is shown below.

Deduction: There is a positive correlation between λ and PFH_G for all architectures. 1oo2D is the most affected architecture. K should be selected correctly to judge the results and compare the architectures.

3.2 *The influence of ß (Table 4 and Figures 5 and 6)*

Deduction: To make an exhaustive effort for decreasing the ß ten times affects 1oo2, 2oo3 and 1oo3 almost linearly such that ten times better PFH_G can be reached. Similar is also valid for 1oo2D in case K is relative high (0.9999). If it is not the case, the effect of ß on 1oo2D is negligible.

3.3 *The influence of $ß_d$*

The influence of $ß_d$ is examined for two different ß factors to see the difference between the cases with relative high and low ß values. First, a ß value of 0.02, afterwards a ß value of 0.2 are handled.

3.3.1 *The influence of $ß_d$ for ß= 0.02 (=2%) (Table 5 and Figure 7)*

3.3.2 *The influence of $ß_d$ for ß= 0.2 (=20%) (Table 6 and Figure 8)*

Deduction: It is found that any change in the $ß_d$ fraction of ß does almost not affect the PFH_G which is very strange, because lots of effort is to be paid for increasing the diagnostics and the return of this endeavor is almost zero. Besides, when compared with DC, a measure for detecting independent failures λ, this behavior is found again too strange, since in this case, the failures are also detected which would cause a hazard if they would not be revealed. We believe this equation should be reconsidered from this perspective. According to this simulation result, we decided to scrutinize this issue in our next study in more detail.

3.4 *The influence of DC (Table 7 and Figures 9 and 10)*

Deduction: An increase of DC causes a decrease in the PFH_G for 1oo2, 2oo3 and 1oo3. In case the DC

1E-07	5E-08	4.95E-08	5E-08	4.95E-08	5.00E-10	0.99	0.995	0.02	0.01	8	8	0.98 < K < 0.9999	1

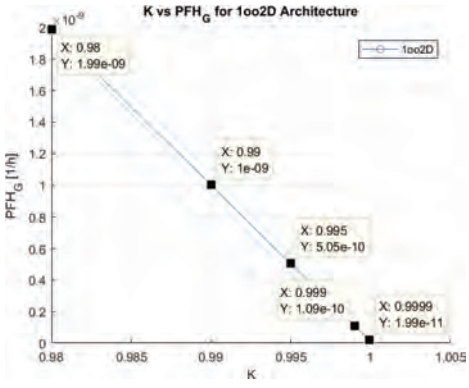

Figure 13. The influence of K.

is doubled from 0.5 to 0.99, then the PFH_G falls for these by half. For 1oo2D, the situation is observed again as strange. It is found that when K is 0.98, then there is a positive correlation between PFH_G and DC such that if DC goes up from 0.5 to 0.99, the PFH_G increases about 33%. However, the question arises here why DC would affect negatively the PFH_G. On the other hand, in case K is 0.9999, then the behavior is similar to the other architectures. It is unveiled that when K is about 0.99, then PFH_G is not influenced by DC. According to this simulation result, we decided again to scrutinize this issue in our next study in more detail.

3.5 *The influence of MTTR (Table 8 and Figure 11)*

Deduction: MTTR is usually selected not more than 8 hours. In this simulation, as the affect during the 8 hours was found as none, the time range is changed up to1000 hours. Even in this case, for all architecture, the MTTR has almost no impact on the PFH_G.

3.6 *The influence of T_1 (Table 9 and Figure 12)*

Deduction: T_1 can be selected from one day to many years according to the type of the unit. For vital computers it can be the life time such as 20 years. However, for both very short and very long time, the T_1 does almost not affect PFH_G. Besides, when doing proof tests, the effectiveness of the tests shall also be considered. Therefore, taken into account the effort needed for proof tests and also the effectiveness of such tests, the life time can be selected for proof test interval such that no proof test is required during the normal life time of the constituent.

3.7 *The influence of K (Table 10 and Figure 13)*

Deduction: The parameter K has an important impact on the PFH_G for 1oo2D. If it is increased from 0.95 to 0.99, five times better PFH_G can be obtained. And if it changes from 0.98 to 0.99, then two times, if from 0.98 to 0.999, then twenty times and if from 0.98 to 0.9999, then hundred times lower PFH_G could be obtained.

Beside the deductions mentioned above, the simulation results show surprisingly that the architectures 1oo2, 1oo3 and 2oo3 have very similar PFH_G values and similar characteristics although there are major differences for the HW/SW design and implementation of these architectures. At first glance, a hypothetical judgement would claim that 1oo3 should have much more better safety performance than 1oo2 as there exist one additional computation unit, however the results show this is not the case.

Taking into account the highlights for the architectural perspectives, we have eliminated 1oo3 architecture and decided to select 2oo3 architecture for ERTMS/ETCS on-board vital computer and 2 × 1oo2 (cold stand-by redundancy) value for CBTC on-board vital computer, since for the CBTC systems full redundancy for sensors and actors are given as requirement due to very high density traffic. We have favored 1oo2 over 1oo2D, because with this selection, the time and cost efforts needed to spend to reach for very high K values could be excluded. On the other hand, instead of developing two different systems and going through the exhaustive certification processes for two different systems, we have unified the requirements and decided to develop 2 × 1oo2D (cold stand-by redundancy) platform with relative high K value, since this effort has been evaluated as less than going through the second independent assessment process. We have chosen 1oo2D also for utilizing cross channel comparision. We have also come to conclusion for our projects that it is plausible to utilize diverse HW to reduce dependent failures and get better hazard rates while it helps to reduce systematic failures at the same time. Moreover, according to the analyses, hot stand-by design would cause additional failures in comparison to cold stand-by, its design would be much more

complex, and as cold stand-by can cover the availability requirements, too, the cold stand-by system is selected.

4 ROUTE MAP TO GET BETTER PFH_G WITH REGARDS TO THE RELIABILITY AND SAFETY PARAMETERS

As mentioned in the introduction, todays challenging technologies require a PFH_G of the computation unit about less than 1E10-12 (1/h). Regarding these though requirements, an ordinary development procedure would not be sufficient for reaching the quantitative requirements. According to the results and deductions provided in the previous section, a route map is developed for this purpose in this section. Note that ß factor is utilized for modeling dependant failures in this study, so these clauses are valid in case ß factor is used. If this is not the case, simulations are to be repeated to ensure the correctness and consistency of the results.

i. Decrease λ as much as possible; for each potential architecture. A linear relationship with a slope one is valid between λ and hazard rate. To decrease this reliability parameter, selecting higher quality parts, setting correct duty cycle, applying derating, consulting engineering experience to adjust data and using field data can be utilized. For instance, if the duty cycle is reduced from 100% to 75%, we experienced 23.47% better failure rates. Moreover, the reliability calculations can be performed using different methods such as MIL 217F, Bellcore, 217 Plus etc. Sometimes, ten times better results can be obtained as provided in the study of the RIAC (2010). At our experience, 217Plus developed by RIAC (2010) gave 5.29 times better results in comparison to MIL HDBK 217F N2 developed by USA Department of Defence (1995). If there is no special requirements, then the most effective handbook can be utilized. Besides, it has been observed for some COTS products in the industry that they are claimed to work at mobile and ground environments, however there is only one failure rate and one MTBF (Mean Time Between Failures) value provided. But, according to our calculations, if the environment changes from ground fixed to ground mobile, the failure rate increases 83.71%. As a result, if the constituent is designed to word at different environments, with different duty cycles etc., the quantitative values should be provided for these different operating conditions.
ii. Decrease common cause factor, namely ß as much as possible; for 1oo2, 1oo3, 2oo3 architectures, approximately ten times better ß results in ten times better PFH_G; however the effect for 1oo2D is very limited if K is relative low like 0.98 such that ten times better ß results in two times better PFH_G. Diversity is a very decisive character to get low dependant failures. Another approach would be trial modeling dependant failures with another method than ß factor. Fleming (1987) explains details of the dependant failure models such as binomial failure rate, multiple Greek letters, alpha factor etc. which can be alternatives to ß factor modeling.
iii. The effect of detecting the common cause failures, namely $ß_d$ has almost no effect on PFH_G for any architecture, hence do not spend much effort to detect common cause failures. On the other hand, as explained previously, we believe that some issues are overlooked for this parameter in the equations of IEC 61508 and we will investigate this issue in more detail at the next studies.
iv. Increase DC for all architectures except 1oo2D if K is less than 0.99. Similar to the previous item, the behavior of DC for 1oo2D with a K of less than 0.99 is also strange. Therefore, we recommend to bring up K at least to 0.99 to get plausible results.
v. Do not perform much effort to decrease MTTR for the safety performance as it has almost no effect on PFH_G for any architecture.
vi. Similar to the case with MTTR, do not perform much effort to decrease T_1 for the safety performance as it has almost no effect on PFH_G for any architecture.
vii. If 1oo2D is chosen, then increase K as much as possible. If K changes from 0.98 to 0.9999, then hundred times better PFH_G could be resulted.

5 CONCLUSION

In this study, the effects of calculation parameters for several architectures are simulated. Attention is drawn for surprising, interesting sides of the results while providing detailed deductions regarding the architectures for each parameter in the calculations. It has been observed that some parameters like K or DC for the architecture 1oo2D are crucial while some other parameters like MTTR or T_1 has almost no effect on the results of any architecture. The simulations can be utilized when designing safety critical systems, subsystems or equipment. The selected architectures for on-board computer to be used in ERTMS ETCS and CBTC domains are shared providing the most important judgements. An advising route map is newly created, including project

examples, to distill what kind of measures can be taken to decrease the dangerous failure rate which is at challenging low levels in today's high-tech mission critical systems like high speed trains or driverless vehicles performing vital safety functions.

ABSTRACT: We extend the equal load-sharing model of cascades to investigate the abrupt breakdown behavior of coupled distribution grids. In particular, we mimic the effects of the ever-increasing customer demand in a foreseen scenario where energy hubs interconnect the different energy vectors. In the load growth scenario we find evidence of first order transitions (i.e. abrupt breakdowns of the system) due to the long-range nature of the flows. Our results indicate that the foreseen increase in the couplings between the grids has two competing effects: on the one hand, it increases the safety region where grids can operate without withstanding systemic failures; on the other hand, it increases the possibility of total failure of all the interconnected systems at once.

1 INTRODUCTION

In this paper we will consider a simple mean-field model of cascading that applies both to single and to interdependent networks. To highlight the possibility of emergent behavior, we will first abstract *PNI*s in order to understand the basic mechanisms that could drive systemic failures; in particular, we will consider finite capacity networks where a commodity (a scalar quantity) is produced at source nodes, consumed at load nodes and distributed as a Kirchoff flow (e.g. fluxes are conserved) and introduce a simplified model that is amenable of a self-consistent analytic solution. Subsequently, we will extended such model to the case of several coupled networks and study the cascading behavior of such a model under increasing stress (i.e. flow magnitudes).

2 MODEL

Let's consider a weighted network $G=(V,E,\boldsymbol{c})$ where $V=\{1\le i\le|V|\}$ is the node set, $E\subseteq V\times V$ is the set of edges and $\boldsymbol{c}=\{c_{(i,j)}\}$ is the vector characterizing the capacities of the edges (i,j). We associate the nodes a vector $\mathbf{s}=\{s_i\}$ that characterize the production ($s_i>0$) or the consumption ($s_i<0$) of a commodity. We further assume that there are no losses in the network (i.e. $\sum_i s_i = 0$); hence, the total load on the network is

$$L=\sum_{i:s_i>0} s_i$$

The distribution of the commodity is described by the fluxes $\boldsymbol{f}=\{f_{(i,j)}\}$ on the edges $(i,j)\in\mathcal{E}$ and is supposed to respect Kirchoff equations, i.e.

$$\sum_j f_{(i,j)} = s_i \tag{1}$$

The relation among fluxes and demand/load is described by constitutive equations

$$\boldsymbol{f}=F(\boldsymbol{s},G) \tag{2}$$

where in general Eq. (2) is non-linear but satisfies Eq. (1).

More often, constitutive equation rely on a relation among fluxes on the line and the values of a physical field ϕ defined on the nodes. As an example, in networks transporting fluid commodities (e.g. gas, water) the constitutive equations take the form

$$f^{\gamma}_{(i,j)} \propto \phi_i - \phi_j \tag{3}$$

where $\gamma \sim 2$ and ϕ_i is the pressure at the *ith* node. In the case of DC currents, the relation is linear ($\gamma = 1$), $f_{(i,j)}$ is the electric current and ϕ_i the voltage; the same linear equations hold in the case of steady-state DC power flow in electric networks, where now $f_{(i,j)}$ is the power flow and ϕ_i the phase angle. For further details, see (Scala 2017) and references therein.

3 METHODS

Cascading failures represent a critical vulnerability in our world where network infrastructures grow both in complexity and interdependencies (D'Agostino and Scala 2014, DAgostino and Scala 2015). When detailed information about the topology are at hand, centrality measures can be used to identify vulnerable subsets of the infrastructural system (Scala et al. 2016). However, in this section we will concentrate on cascading due to the violation of the link capacities while disregarding the effects of shocks due to strong transients.

For the flow networks described in the previous section, the finite capacity $c_{(i,j)}$ of a link (i, j) constrains the maximum flux on such a link

$$\left| f_{(i,j)} \right| < c_{(i,j)}$$

while above such flux, the link will cease functioning. As an example, power lines are tripped (disconnected) when power flows go beyond a certain threshold. Since flows will redistribute after a link failure, it could happen that other lines get above their flow threshold and hence consequently fail, eventually leading to a cascade of failures. A typical algorithm to calculate the consequences of an initial set of line failures $\mathcal{F}^0 = \{(ij)\ failed\}$ is the alg.(1). Here $F(\boldsymbol{p}, G \,|\, \mathcal{F})$ calculates the flows subject to the constrains that flows are zero in the failure set of edges $(i, j) \in \mathcal{F}$.

Algorithm 1 Network cascading

```
Set initial failures F^0
t ← 0
repeat
  t ← t + 1
  Calculate flows f^t ← F(s, G|F^{t-1})
  Calculate new failures ΔF^t ← {(ij) : |f_ij^t| > c_ij}
  F^t ← F^{t-1} ∪ ΔF^t
until ΔF^t ≡ ∅
```

To develop a general model that helps us understanding the class of failures that can affect Kirchoff-like flow networks, let's start from rewriting Eq. (1) in matrix form

$$\mathcal{B}^T \boldsymbol{f} = \boldsymbol{s} \tag{4}$$

using the incidence matrix B that associates to each link $(i.j)$ its nodes i and j and vice-versa. B is an $|v| \cdot |\varepsilon|$ matrix where each column corresponds to an edge (i, j); itscolumns are zero-sum and the only two non-zero elements have modulus 1 and are on the *ith* and on the *jth* row.

The matrix B is related to the Laplacian B^TB of the system; in particular, it shares the same right eigenvalues and the same spectrum (up to a squaring operations); hence, it is a long-range operator since perturbation on a node of the system can be reflected on nodes far away on the network (Pahwa et al. 2014).

Due to the long range nature of Kirchoff's equations, to understand the qualitative behavior of such networks we can resort to a mean field model of flow networks where one assumes that when a link fails, its flow is re-distributed equally among all other links. Such model, introduced in (Pahwa et al. 2014), is akin to the fiber-bundle model (Peirce 1926, Daniels 1945) and has been considered in more details in (Scala and Lucentini 2016, Yagan 2015) for the case of a single system. In this model, each time lines trip, flows are recalculated, the lines above their threshold trip again, their flows would be re-distributed and so on, up to convergence; recalling that L is the total load of the system and assuming the each link (i, j) has an initial flux $f = L/|E|$, we can describe such a model by alg.(2).

Algorithm 2 Mean Field cascading

```
t ← 0
F^t ← 0 initial number of failed links
repeat
  t ← t + 1
  M ← |E| − F^{t-1} number of working links
  l ← L/M average flux on the working links
  F^t ← |{(ij) : l > c_(ij)}|
until F^t = F^{t-1}
```

Such algorithm can be cast in the form of a single equation in the case where the system is composed by a large number of elements with capacity c. In fact, in such limit we can describe the links' population by the probability function $p(c)$ of their capacities. Indicating with $M = |E|$ the initial number of links, we see that if we apply an overall load L to the system, all the links will be initially subject to a flow $l^0 = L/M$. Thus, a fraction of links $f^1 = \int_0^{L/M} p(c)dc$ would immediately fail, since their thresholds are lower than the flux l they should sustain. After the first stage of a cascade, there will be $M^1 = (1 - f^1)M$ surviving links and the new load per link is $l^1 = L/M^1$. The following cascade's stages follow analogously; we can thus write the mean field equations for the $(t + 1)^{th}$ stage of the cascade:

$$f^{t+1} = P\left(\frac{l}{1-f^t}\right) \tag{5}$$

where $l = L/M$ is the initial load per link and $P(x) = \int_0^x p(c)dc$ is the cumulative distribution function of link capacities; the initial conditions are $f^{t=0} = 0$. The fix-point f^* of Eq. (5) satisfies the equation

$$f^* = P\left(\frac{l}{1-f^*}\right) \tag{6}$$

and represents the total fraction of links broken at the end of the cascading stages (Pahwa et al. 2014).

The behavior of f^* depends on the functional form of $p(c)$. In particular, by defining $\pi(c) = 1 - P(c)$ and $x = l^{-1}(1-f)$, we have that

$$f = \int_0^{1/x} p(c)dc = 1 - \pi\left(\frac{1}{x}\right)$$

and can rewrite Eq. (5) as

$$lx^{t+1} = \pi\left(\frac{1}{x^t}\right)$$

(see Fig. (1)). This equation has a trivial fix-point $x^* = 0$ (representing a total breakdown of the system) since $\pi(\infty) = 0$. Such fix-point is unstable for $l \to 0$ and becomes stable for $l > \partial_x \pi(x^{-1})|_{x\to 0}$. We notice that if $P(c)$ does not change convexity

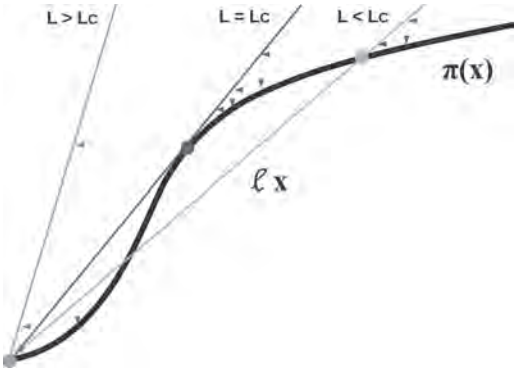

Figure 1. Graphical solution of the fixpoint equation. For $L = L_c$, there is only one solution corresponding to a critical point. For $L > L_c$, the stable fixpoint x^* corresponds to a small fraction of broken links f^*; in the limit of $l \to 0$, $f^* = 0$. On the other hand, for $L < L_c$ the only stable solution is $x^* = 0$, corresponding to the situation $f^* = 1$ where all the links are broken and hence the whole system has failed.

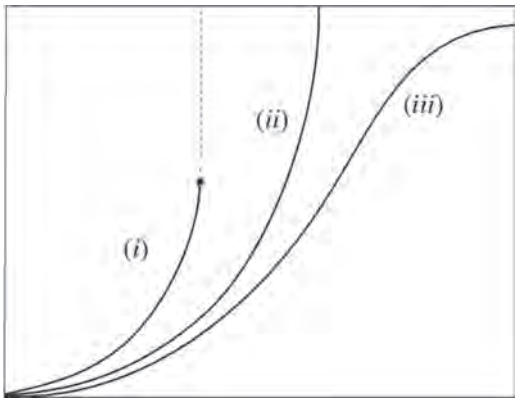

Figure 2. The behavior of the fix-point x^* depends on the tail of the distribution of link capacities $p(C)$ and is known to present a first order transition for a wide family of curves; in particular, when the cumulative distribution function $P(C)$ goes to zero faster than C^{-2}, we are in case *(iii)* where the transition is discontinuous, with a jump at a critical value L_c and a divergence of $dM/dL \sim (L - L_c)^{-1/2}$.

(i.e. has no bumps) and the transition is first order, the system will breakdown directly to the total collapsed state $f = 1$.

In general, the behavior of the fix-point x^* depends on the tail of the distribution $p(c)$ and is known to present a first order transition for a wide family of curves (da Silveira 1998) (see Fig. (2)); in particular, the fixpoint behavior is dictated by the behavior of $\frac{d\pi}{dC} = \frac{p(C)}{C^2}$ for $C \to \infty$, i.e.

- for $p(C) \sim C^{-\gamma}$ with $1 < \gamma < 2$, no transition occurs
- for $p(C) \sim C^{-2}$, the transition is continuous but there is a critical point L_c with a divergence of $dM/dL \sim (L - L_c)^{-1/2}$
- for $C^2 p(C) \to 0$ when $C \to \infty$, the transition is discontinuous, with a jump at a critical value L_c and a divergence of $dM/dL \sim (L - L_c)^{-1/2}$.

Depending on the functional form of $p(c)$, Eq. (6) could sometimes be solved analytically. Otherwise, the fix-point of Eq. (6) can be solved numerically either by iterating the Eq. (5) or by finding the zeros of Eq. (6) by Newton-Raphson iterations.

4 RESULTS

Commodities are defined substitutable when they can be used for the same aim; when commodities are substitutable, they can expressed in the same units. An example of such commodities are electricity and gas can, since be both used for domestic heating. Hence, an increase on the cost of the gas (as the one that has been recently experienced by

Ukraine) could provoke stress on the electric network of the country since most customer will possibly switch to the cheaper energy vector. To take account for such effects, we will extend the model described by Eq. (5) to the case of several coupled systems that transport substitutable commodities.

We will consider n coupled systems assuming that when a system a is subject to some failures, it sheds a fraction $T_{a\to b}$ of such the flow increase due to such failures on system b. In other words, upon failure system a decreases its load by a quantity $l_a f_a \sum_{b\neq a} T_{a\to b}$ and increases the load of all systems $b \neq a$ by $l_a f_a T_{a\to b}$. Thus, the n coupled systems are described by a set of n equations of the form of Eq. (5)

$$f_a^{t+1} = P_a\left(\frac{\tilde{l}_a^t}{1-f_a^t}\right) \tag{7}$$

$\tilde{l}_a^t$ is the load per link experimented by system a at the t^{th} stage of the cascade and $P_a(x) = \int_0^x p_a(x)\,dx$ is the cumulative of the probability distribution function $p_a(x)$ for the capacities of the a^{th} system. Equations (7) are not independent, since the systems' coupling is reflected by the dependence of $\tilde{l}_a^t$ on the fractions f_b^t of failed links in all the other systems, i.e.

$$\begin{aligned}\tilde{l}_a^t &= l_a\left(1-f_a^t\sum_b T_{a\to b}\right)+\sum_b T_{b\to a} l_b f_b^t \\ &= l_a + \sum_b \mathcal{L}_{ab} l_b f_b^t\end{aligned} \tag{8}$$

where $\mathcal{L}_{ab} = (1-\delta_{ab})T_{b\to a} + \delta_{ab}\sum_b T_{a\to b}$ has again the form of a Laplacian operator. Thus, the full equations for n coupled systems are

$$f_a^{t+1} = P_a\left(\frac{l_a + \sum_b \mathcal{L}_{ab} l_b f_b^t}{1-f_a^t}\right) \tag{9}$$

For simplicity, we will consider the case of two identical system with a uniform distribution of link capacities and solve the fix-point of Eq. (7) numerically. We show in Fig. (3) the cascading behavior of two coupled systems; we observe that—as in the single system case—transitions are in the form of abrupt jumps, i.e. are first order. Let's rewrite Eq. (9) in the case of symmetric couplings $T_{1\to 2} = T_{2\to 1} = 1$ and same probability distribution for the capacities

$$\begin{cases} f_1^{t+1} = P\left(\dfrac{l_1}{1-f_1^t}\left[1-T\left(f_1-\dfrac{l_2}{l_1}f_2\right)\right]\right) \\ f_2^{t+1} = P\left(\dfrac{l_1}{1-f_2^t}\left[1-T\left(f_2-\dfrac{l_1}{l_2}f_1\right)\right]\right) \end{cases} \tag{10}$$

If the two systems described by Eq. (10) are stressed at the same pace (i.e. $l_1 = l_2 = l/2$), we get the case

$$\begin{cases} f_1^{t+1} = P\left(\dfrac{l}{1-f_1^t}\left[1-T\Delta f_{12}\right]\right) \\ f_2^{t+1} = P\left(\dfrac{l}{1-f_2^t}\left[1+T\Delta f_{12}\right]\right) \end{cases}$$

from the symmetric solution $\Delta f_{12} = 0$ we see that the breakdown of both systems happen at the same critical load as the uncoupled systems. Such situation is shown in the left panel of Fig. (3).

In the general, only one of the systems will be the first one to break down (i.e. the fraction of broken links jumps to $f = 1$): correspondingly, also the other systems will experience a jump in the number of broken links. Let's consider the symmetric case described by equations (10) and suppose that $l_1 > l_2$, so that system 1 is the first to breakdown (i.e. $f_1 = 1$); hence, the equation for the fix-point of the second system becomes

$$f_2^* = P\left(\frac{l}{1-f_2^*}\left[1+T\left(1-f_2^*\right)\right]\right) = P\left(\frac{l^*}{1-f_2^*}\right)$$

i.e. the system behaves like a single system starting with a renormalized load $l^* > 1$. Thus, if $l^* < l_c$ the

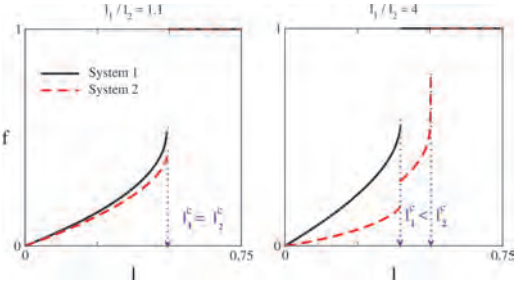

Figure 3. Behavior of the number of failed nodes respect to the total stress $l = l_1 + l_2$ of the systems. For simplicity, we present the case of two identical systems with a flat distribution of link capacities and symmetric couplings $T_{1\to 2} = T_{2\to 1} = 0.5$. We show the result of increasing the total stress l in the two systems along the lines $l_1/l_2 = const$. **Left panel:** we show the case $l_1/l_2 = 1.1$ where both systems are subject to a similar stress while increasing l. In such case both system break down together at the same critical load $l_1^c = l_2^c$; in the region $l > l_1^c = l_2^c$ both systems are failed. **Right panel:** we show the case $l_1/l_2 = 4$ where when increasing l systems 1 is more stressed than system 2. In this case, the break down of system 1 at the critical load l_1^c induces a jump in the number of failures system 2, but system 2 is still able to sustain stress and will break down only at higher values of l. Respect to the $l_1 \sim l_2$ case, there is now a region $l_1^c < l < l_2^c$ where only system 1 is failed.

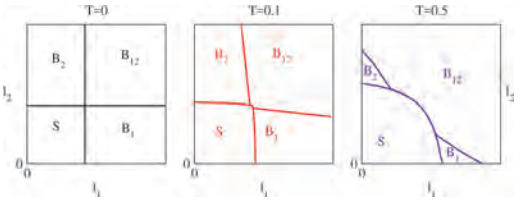

Figure 4. Phase diagrams of two identical coupled systems with symmetric interactions $\left(T_{1\to 2} = T_{2\to 1} = T\right)$. The plane of initial loads l_1 and l_2 is separated in four different regions by critical transition lines. The labels B_i (i = 1,2) mark the areas where only system i suffers systemic cascades ($f_i = 1,\ f_{j\neq i} < 1$), while the label B_{12} marks the area where both system suffer system wide cascades $\left(f_1 = f_2 = 1\right)$. The label S marks the (safe) area near the origin where no systemic cascades occur. **Left panel:** the case $T = 0$ corresponds to two uncoupled systems: thus, each system suffers systemic failure at $l_i > l^c$ (where l^c is the critical load for an isolated system); both systems are failed in the B_{12} area corresponding to the quadrant $(l_1 > l^c, l_2 > l^c)$. **Central panel, right panel:** when couplings are introduced, each system is able to discharge stress on the other one and the area S where both systems are safe increases. On the other hand, the area B_{12} where *both* systems are failed increases.

critical value of Eq. (5), system 2 will break down at higher values of the stress. Such situation is shown in the right panel of Fig. (3).

In Fig. (4) we show the full phase diagrams of two coupled systems while varying the coupling among them. As discussed before, due to the symmetry all the systems have a transition point $\left(l^c, l^c\right)$ along the $l_1 = l_2$ line, where l^c is the critical load of the single system. According to the initial loads, we can distinguish an area S near the origin where the system is safe and three separate cascade regimes: B_1, B_2 where either system 1 or 2 fails, and B_{12} where both systems fail. We notice that, by increasing the coupling among the systems, both the area S where the two systems are safe and the area B_{12} where they fail together grow; accordingly, the areas B_i where only one system fails shrink.

5 DISCUSSION

In this paper we have introduced a model for cascade failures due to the redistribution of flows upon overload of link capacities. For such a model, we have developed a mean field approximation both for the case of a single network and for the case of coupled networks. Our model is inspired to a possible configuration for future power systems where network nodes the so-called energy hubs (Geidl et al. 2007), i.e. points where several energy vectors converge and where energy demand/supply can be satisfied converting one kind of in another. Hubs condition, transform and deliver energy in order to cover consumer needs (Favre-Perrod 2005). In such configurations, one can alleviate the stress on a network by using the flows of the other energy vectors; on the other hand, transferring loads from a network to the other can trigger cascades that can eventually backfire.

By analyzing the case of two coupled systems and by varying the strength of the interactions among them, we have shown that at low stresses coupling has a beneficial effect since some of the loads are shed to the other systems, thus postponing the occurrence of cascading failures. On the other hand, with the introduction of couplings the region where not only one system fails but both systems fail together also increases. The higher the couplings, the more the two systems behave like a single one and the area where only a system is failed shrinks. Notice that our model in the present form does not apply to islanding strategies in power systems, where some sub-networks can even enhance their reliability upon failure of part of the remaining system (Mureddu et al. 2016); such subject will deserve further investigations.

6 CONCLUSIONS

It is worth noting that while fault propagation models do predict a general lowering of the threshold for coupled systems (Wang et al. 2013), in the present model a beneficial effect due to the existence of the interdependent networks is observed for small enough overloads, while the expected cascading effects take place only for large initial disturbances. This picture is consistent with the observed phenomena for interdependent Electric Systems. Moreover the existence of interlinks among different networks may increase their synchronization capabilities capabilities (Martin-Hernandez et al. 2014).

Optimizing terminal logistics and dimensioning

S.L. Isaksen & T. Lilleheier
Safetec, Oslo, Norway

N.J. Edwin
Safetec, Trondheim, Norway

ABSTRACT: Design and correct dimensioning of oil and gas terminal facilities is often a challenge due to a variety of operational uncertainties as well as the volatility in supply and demand. Various factors come into play to ensure smooth uninterrupted operation, as well as optimal and effective resource utilization. This paper discusses the challenges of optimization and presents an integrated approach to optimize terminal logistics and dimensioning, where parts of the objective function is solved by discrete event simulation. A case study of the new Veidnes terminal to be commissioned in the north of Norway, is also presented. This terminal shall serve as a central hub for export of oil from the already producing Goliat field and the upcoming offshore facilities in the Barents Sea, including Johan Castberg as well as the later producers Alta Gotha and Wisting. A variety of factors including weather disturbances, production profiles, shuttle tankers, jetties, etc. are included in the analysis to help provide a decision-basis on the number and size of tanks required at the terminal.

1 INTRODUCTION

Oil produced offshore is usually transported to terminals onshore either via pipelines or by oil tankers. These terminals typically have facilities for storage and export of oil, and some also have facilities for further treatment of oil, such as fractionation. Export of oil from the terminal can be done via pipeline, ship, train or trucks. In practice, an oil terminal represents a buffer in the middle of the supply chain, reducing the consequences of disturbances in the transportation.

During the design process of such terminals, important decisions are made. One such decision is related to the dimensioning, where the difference between good and bad decisions can be worth tens or even hundreds of millions of dollars. Dimensioning of these terminals is difficult as the required capacity may vary due to high volatility in supply and demand. Tank storage space is expensive in terms of CAPEX (Capital Expenditures) but too little storage can turn out to be much more expensive in terms of deferred production and delays in the supply chain. This can lead to the design of an extra buffer, which in practice is expensive overcapacity. Also, tank suppliers may have a tendency to recommend more volume than necessary.

Despite the expense of bad decisions in design, it is not uncommon to base such decisions on experience, general knowledge, and gut feeling. Experience is certainly always valuable, but is not sufficient since each terminal is unique. Some sort of simplified calculation is usually involved as well in the design or planning phase. However, a common misconception in the industry is that complexities and uncertainties make the problem impossible to fully approach mathematically.

This paper discusses how a mathematical model may be used to approach the optimization problem. It discusses an integrated approach involving an objective function and discrete event simulation. The paper also describes a specific case to demonstrate the application of the mathematical approach for a Norwegian oil terminal.

2 PROBLEM AND CASE DESCRIPTION

2.1 *The optimization problem*

Mathematical optimization constitutes a large area of applied mathematics. It includes finding the 'best' value of some objective function within a given domain. The 'best' value is depending on the context but will typically be the one which maximizes or minimizes the value of the objective function.

Terminal dimensioning can be viewed as such an optimization problem, where the aim is to minimize overall costs over a defined period. Both CAPEX (Capital Expenditures) and OPEX (Operational Expenditures) are important to include. Another

important aspect is the revenue from exported oil. Lost revenue due to deferred production as a consequence of shortage in storage capacity, can be regarded as an expense. Alternatively, the objective function can contain all revenue from exported oil, subtracting the CAPEX and OPEX, in which case the function should be maximized. In that case, the objective function would in a simplified form look something like this.

$$\max_{\bar{x}\in(0,\infty)} f(\bar{x}) - g(\bar{x}) - h(\bar{x}) \quad (1)$$

where f = revenue from exported oil; g = CAPEX; and h = OPEX. $\bar{x}$ is a vector of elements such as number and size of offshore tanks, number and size of shuttle tankers, pump capacities, etc.

CAPEX is usually the easiest function of the three, consisting of sums of unit costs multiplied by number of units. But it may be hard to express the cost as a continuous function, since e.g. tank producers offer a fixed selection of designs with a certain size. Uncertainties may also be present at an early stage, but these are quite small compared to the other parts of the objective function.

OPEX is more complex as these are running costs over a long period of time, i.e. the expected lifetime of the terminal, which in itself is a large uncertainty factor. On the other hand, OPEX may not be very largely influenced by the size of many of the elements in $\bar{x}$. I.e. maintenance of a 500,000 barrel tank is not necessarily much more expensive than maintenance of a 400,000 barrel tank. But for both, the Life Cycle Cost (LCC) is associated with high uncertainty.

The revenue from exported oil or the revenue loss from deferred export due to shortage in storage capacity, is the most difficult parameter to assess. There are many factors associated with large uncertainties. In order to understand what could cause deferral in oil production or export, we must understand the dynamics of the whole supply chain. These dynamics contain a lot of time-dependent and stochastic elements and are difficult to represent with equations.

Consider the following example: An oil tanker is on its way to an offshore installation to load oil. The approximate loading operation and sailing times are known. However, it turns out that the waves are too high for a safe loading operation and the tanker must wait. If we are unlucky, the bad weather period lasts for so long that the oil storage tank on the platform gets full and there is a forced production shutdown. By the time the weather improves, the tanker loads and heads to the terminal. This delay may cause a delay in the export, or export of off-spec oil quality because the export tanker was depending on the load from the shuttle tanker getting there in time.

One could say that the weather was the cause of two financial loss factors; the offshore disruption and the delayed or off-spec export load. However, this could have been avoided with e.g. larger tanks offshore and onshore. Weather is just one of several factors influencing the oil export, and as the example illustrates, the dynamics or timing is an important element. To express revenue as part of the objective function is thus a very challenging task. As will be discussed in the next chapter, discrete event simulation is a suitable way to solve the problem, since the dynamics are well captured and the objective function to a large part is reduced to drawing random numbers from given distributions.

2.2 *Case description*

2.2.1 *Veidnes terminal development*

Statoil are building a new terminal in Veidnes in the northern parts of Norway, which will receive oil from various offshore installations in the Barents Sea by a fleet of winterized shuttle tankers. Oil stored at Veidnes will be shipped by export tankers to various destinations in continental Europe. The sizing and number of tanks located at Veidnes is important, since overcapacity is expensive and insufficient storage may lead to expensive losses. Figure 1 contains an overview of the Veidnes terminal with associated offshore fields.

Optimal sizing and number of tanks is influenced by the sizing and number of shuttle tankers and export tankers, as well as several other parameters. In addition, exported oil is required to have a certain quality, measured in API (American Petroleum Institute) gravity value. The storage and mixing of different oil qualities, as well as requirements for a certain API value of exported oil, also influence the optimal size and number of tanks.

One of the biggest challenges is the volatile nature of supply. In the case of Veidnes, one of the offshore fields, Goliat, has just started producing. The plan for Veidnes is to start operation when also Johan Castberg, with larger oil reserves than Goliat, starts producing. Later, additional fields,

Figure 1. Location of the Veidnes terminal and associated oil fields.

Alta Gotha and Wisting, will start production and the winterized shuttle tankers will transport oil from four different fields to Veidnes.

In addition to the four fields starting production at different times, their production profiles are dynamic, and their forecasts are associated with a high degree of uncertainty. There are also other reserves in the area, which could be relevant for oil production and shipping to Veidnes at some point in the future. However, these factors are not considered in the first stage of designing the terminal.

2.2.2 *Phased development*

When the Wisting and Alta/Gotha fields begin production, the terminal needs to be expanded. For now, we consider the three phases listed in Table 1.

In a scenario like this, there are two main options. The first is to account for the highest supply somewhere in phase 3 (when the sum of all four fields reaches peak production) and dimension the terminal capacity accordingly from the start. In this case, there is excess terminal capacity in the first two phases. The second option is to build a smaller terminal at first and then expand capacity in the later phases. Which of the options is best also requires analysis, since it can be argued that building a large terminal from the start is cheaper than doing it in steps. But there is also a potential NPV (Net Present Value) gain in delaying some of the construction for later. This evaluation was already made on a high level, with the decision to construct in two phases, one for the first two phases and then add additional tanks and another jetty for the third phase. Since some decisions had been made already, the case study was both a verification, as well as an optimization study.

In other words, for larger planned increases in supply, such as the start-up of a new producing field or plateau production of fields, the existing structure can be increased. For smaller and highly uncertain increases in production profile, it is not feasible to add to existing capacity.

For predicted reductions in supply such as end of plateau production, reductions in capacity are of course not feasible either, as it hardly affects the costs, since the investment has already been made.

Table 1. Phases considered for the Veidnes terminal project.

Phase	Period	Involved fields
1	2022 Q4–2023 Q4	Goliat, Johan Castberg
2	2023 Q4–2024 Q3	Goliat, Johan Castberg, Alta/Gotha
3	2024 Q3–2030 Q4	Goliat, Johan Castberg, Alta/Gotha, Wisting

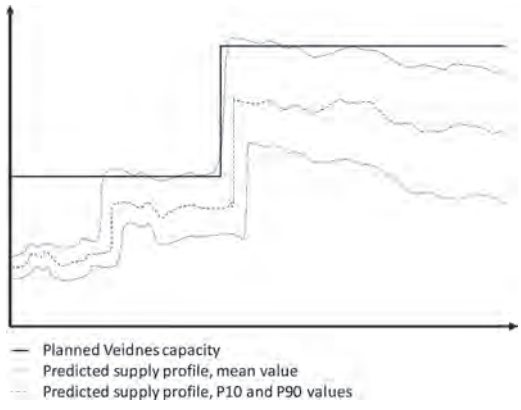

Figure 2. Illustration of supply, uncertainties and phased development.

Figure 2 illustrates the main elements as discussed. The planned capacity should account for the peak supply in all phases. But planned capacity must take uncertainties in supply into account. The optimization approach consists of finding the right balance between minimizing the risk and associated financial loss of too little capacity and the investment in sufficient capacity, even though overcapacity is inevitable in certain periods.

3 APPROACH

3.1 *Discrete event simulation*

As mentioned in Section 2.1, the dynamic nature of the terminal activities and resulting oil export, presents a significant challenge to express the $f(\bar{x})$ function from equation 1. Monte Carlo simulation, however, is suitable for dealing with dynamics. The progression of time is simulated and stochastic events can be dealt with by conditions implemented in the simulation algorithm.

Monte Carlo simulation has the advantage of simplifying a mathematical problem significantly. If a stochastic element is represented by a probability distribution function, the simulator draws just one number at a time from this distribution, making calculations much easier. But if this process is repeated a sufficient number of times, the numerical result still approaches the theoretical result. Hence, the challenge shifts from mathematical complexity to computational power in the case of Monte Carlo simulation. This challenge becomes smaller as the computational power in general keeps increasing.

Discrete event simulation is a branch of Monte Carlo simulation which is suitable for solving problems like these, because they are characterized by

events occurring at discrete points in time. Events are generated at simulation start or initialization. These are exemplified by the arrival of a shuttle tanker, the tank getting full or empty based on current loading/unloading rate, the shift from waves under the critical threshold value to above the critical threshold value, etc. These events are sorted in an event queue, according to time of occurrence. Instead of moving forward in time in pre-defined small incremental steps, which is the traditional Monte Carlo approach, the simulator skips to the next event in the queue. At the event, calculations are done and new events drawn from distributions, which might change the existing event queue.

In a case like this, there are elements of both discrete events and continuous flow. When e.g. a shuttle tanker offloads at Veidnes, there is a steady flow into the tank and the tank level increase is continuous in time. However, it is not necessary to monitor the tank level continuously. With a discrete event simulation model, the next event can be the time when the tank is full or the shuttle tanker is empty. If the flow rate varies in time, e.g. full flow at the start of the offloading operation and then slowing down when the tank approaches full, the point in time changing to a lower flow rate can be regarded as an event.

In models with both elements of continuous flow and discrete events, it is generally more efficient to create a discrete event simulation model and include the continuous flow elements, than vice versa.

The difficult part of the revenue function is twofold. It is expressed as a product of the amount of exported oil and the oil price. The problem with the oil price is simply the fact that it is highly uncertain, looking over a future 10-year period. It should be discounted as well and the discount rate adds to the uncertainty.

The difficulties about the amount of exported oil have been explained in Section 2.1. It is a time-dependent function which is difficult to express due to many parameters and high complexity. Hence, this part is covered by the simulation model.

In order to assess the amount of exported oil, it was important to consider the supply chain and evaluate all significant influencing factors. The simulation model includes the following parameters:

- Production profiles
- Capacity of pumps, tanks and tankers
- Number of tanks, jetties, and tankers
- Oil quality (API grade)
- Weather
- Criteria for critical wave heights and oil quality blend
- Travel speeds and distances
- Berthing and de-berthing times
- Export strategy (blended or segregated oil quality)

Some of these parameters are dynamic and change during the simulation. For instance, the number of jetties increase from one to two at a certain point in time, when more offshore fields start producing.

3.2 *Simulation tool and algorithms*

The simulation software, ExtendSim, was used to create and run the model of the Veidnes terminal. It belongs to the class of generic simulation tools, not specifically built for a particular industry or simulation paradigm. These are typically very flexible and can be used for almost any modelling of production, processing, logistics, resource management, etc. or combinations of these.

ExtendSim consists of different blocks, which perform various functions, e.g. drawing a random number from a distribution, creating an item, assigning an attribute to an item, performing an activity, acting as a storage tank, and even implementing a custom-made function. These existing blocks cover the necessary functionality for the basics of the model, i.e. producing oil offshore, loading shuttle tankers, transporting to Veidnes and offloading, storage at Veidnes, loading export tankers and transport it to various destinations. It also enables the specification of oil quality requirements and the inclusion of a weather model and its interaction with loading and unloading operations.

Despite much existing functionality, the custom-made function block has been used extensively for implementing algorithms for specific operational rules. For instance, rules must be implemented to determine which offshore field the next available shuttle tanker will go to and when. This requires some calculations and functions. In this case, it was decided that the next available shuttle tanker (the one that just finished offloading at Veidnes) goes to the offshore field that requires offloading first. Loading starts when the tank will be full in x hours, where x is a parameter that can be sensitized.

Another challenging issue which needed hard-coding of algorithms, is the rule-set of loading and offloading at Veidnes. In order to know if there is capacity to receive or even to know if an export tanker can be filled with the right API blend, it is necessary to keep track of the total volume of each API value and the used and potential volume for each tank at Veidnes. This is fairly straight-forward. However, with the introduction of a second jetty in phase 3, one can easily end up in a situation where e.g. an export tanker is about to load when the shuttle tanker arrives at the other jetty. Hence,

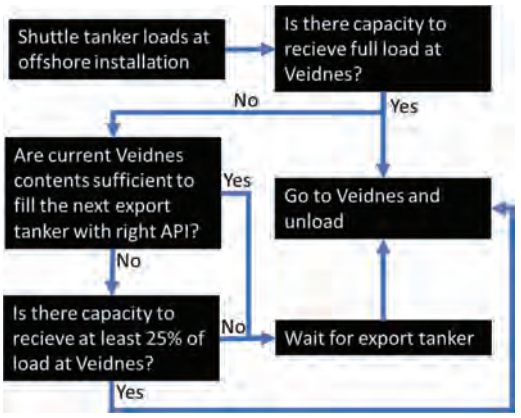

Figure 3. Algorithm for prioritization of shuttle and export tankers.

it is not enough to know the status at Veidnes, but also the remaining volume and API grade of a tanker at the jetty in the middle of a loading/offloading process. Operational rules implemented in the algorithm are illustrated in Figure 3.

Yet another operational rule must deal with the loading and offloading in case of bad weather. Critical wave height limits are typically established for given vessels. The critical limit for start of loading operation is lower than the limit for abortion, which may occur if the wave height increases during the operation. If the operation is aborted due to increased wave height during the operation, exceeding the critical limit, it must also be decided if one should take the current load to the destination or stand-by for a new weather window to complete the operation.

As for the weather itself, we obtained weather data for the last 25 years. There are several possibilities to apply these data to model the weather over the next 15 years. A common approach would be to fit the duration of the good weather and bad weather periods to probability distributions and draw a number from those distributions during the simulations. Good and bad weather would then be defined by the critical wave height limits. In the Veidnes project, another approach was used. The weather data are stored in a database linked to the simulation model. At the beginning of a new year in the simulation, a random historical weather year is drawn. Then the weather in the model replicates the weather in that particular year.

3.3 *Sensitivity cases*

In order to solve the objective function, $f(\bar{x})$ must be simulated, while $g(\bar{y})$ and $h(\bar{z})$ can be calculated. However, the vectors, $\bar{x}, \bar{y}$ and $\bar{z}$ contain many of the same elements, so they cannot be optimized independently. For instance, the amount and size of the tanks at Veidnes contribute to CAPEX, OPEX and revenue. Due to the fact that we simulate revenue rather than attempt to express $f(\bar{x})$ mathematically, it is more difficult to genuinely find an optimum, as we simulate rather than derivate the function. When simulating the oil export, a specific tank configuration must be selected. Hence, each simulation produces results for a specified vector, $\bar{x}$. In theory it can take an infinite range of values, making the task of finding an optimal value impossible by just selecting arbitrary values for $\bar{x}$ and running simulations. In practice, there are of course restrictions with regards to many of the parameters. Not only is the tank size restricted to a positive value, which cannot exceed the size of the largest tank available on the market, but the tank supplier usually has a finite set of products to offer.

Still, there are many parameters and thus a large amount of combinations of values, even if they can take finite values or at least values in a finite interval. Simulation thus impedes the calculation of an optimum value somewhat, but this is the price to pay in order to be able to realistically model the revenue from exported oil.

In the Veidnes case, sensitivity analyses are easily done, with all essential model input parameters listed in MS Excel with a link to the simulation model. Each Excel worksheet represents a unique sensitivity case. By changing parameter values and running sequential simulations for all cases, results are exported back to Excel for each case for comparison.

There are two main cases dealing with the different oil qualities. One alternative is to keep all API grades segregated. The other alternative is to blend them to a mix with a given API. There is also a question of how to blend, since it can be done either in the Veidnes tanks or in the export tanker. Only the second option has been considered in this analysis, i.e. the tanks at Veidnes never contain more than one oil quality and the blending is done when loading the export tanker from different tanks.

Except for the 'segregated' and 'blended' cases, all other sensitivity cases are defined by changes in parameter values. Thus, the model becomes a tool for Design of Experiments (DOE), to contribute to the economic optimization. That is, the model is suitable for analyzing the effect of changes in all the parameters listed in Section 3.1. The DOE includes all of these, as well as the timing for the time-dependent parameters.

With the objective function calculated for each sensitivity case rather than derivated, we obtain a

set of results. Of these we can select the one which gives the highest profit. If we are uncertain about this being the optimal value, new simulations can be run for values in the vicinity of the previous ones.

4 RESULTS

Detailed results of the case study are not presented in this section due to confidentiality. Also, only preliminary results have been produced so far, due to high uncertainties, especially in the economical parameters. Several interesting observations have been made, however. First off, it was observed that the assumed tank volume at Veidnes is sufficient and could even be somewhat reduced, thus reducing CAPEX, if one is willing to accept a few deviations. That is, in the segregated oil quality case, one must accept that a small fraction of export tankers is not fully loaded. For the blended case, one must accept that a small fraction of export tanker loads is off-spec with respect to oil quality. Due to variations in the production profiles for the different fields and the batch-like nature of the supply to Veidnes, situations like these are difficult to avoid entirely. If one has zero tolerance of these issues, the number of Veidnes tanks must increase significantly, which generally will result in over-capacity except for those few instances. In order to conclude, we need to obtain the cost associated with off-spec tanker loads.

A few offshore disruptions or so-called tank tops are also expected over a 9-year period. The simulation model verified that the planned number of shuttle tankers is sufficient and disruptions are not due to late arrivals, but solely long periods of bad weather. The only way to avoid these, is changes in design of shuttle tankers and loading facilities, enabling higher tolerance for waves. However, the number of disruptions seemed acceptable to the project.

In the base case, it was assumed that an increase to three shuttle tankers and two jetties were needed in phase three. This seems to lead to some over-capacity. For instance, average jetty occupation is right below 30%. It would seem sufficient with one jetty occupied 60% of the time. However, this average is calculated over the period, 2022 to 2030. In the peak year, 2026, the jetty occupation is close to 40%. With one jetty this would be 80% and lead to much waiting time.

5 CONCLUSIONS

This paper has demonstrated that mathematical optimization of terminal dimensioning and logistics is difficult but possible to a large extent. Drivers of production deferral in a complex supply chain are difficult to identify using analytical approaches, but discrete event simulation is a helpful tool as it is suitable for capturing the dynamics and reduce mathematical complexity. This does, however, require a flexible tool, allowing for algorithms to represent operational rules in a realistic way.

Even though results are preliminary, there are several key learning points for the project. E.g. optimum tank configuration depends on both the blending strategy and the size of the export tanker.

It has been demonstrated that results from simulation of DOE lead to very valuable insight by quantifying important parameters and reveal how they are influenced by changes in input values. Although a single optimum is difficult to conclude from these results alone, they provide valuable insight and a solid basis for cost-benefit evaluations.

An integrated bayesian network and cost-benefit analysis model for blowout preventer configuration selection in deepwater offshore fields

E.M. Enjema, M. Shafiee & A. Kolios
Cranfield University, Bedford, Bedfordshire, UK

ABSTRACT: Due to the capital intensive nature, limited supply quantities, infeasible and unviable prospects, among several other setbacks of other emergent energy sources, huge importance continues to be placed on Blowout Preventers (BOPs), the principal defense mechanism against blowouts during any drilling/workover operation in the oil and gas sector. Particularly so after the Macondo disaster, BOPs have been the center of regulatory change and sector development. BOP availability and reliability become even more important as drilling advances into deep and ultra-deep water offshore fields. The BOP configuration choice for such variable environments will have far reaching consequences. Reliability, though hugely important and vital, is one of the several criteria that operators must use for determining the most cost-effective configuration as the cost of accidents in deeper waters increases proportionately. In the current paper, an integrated framework for the selection of the most appropriate BOP configuration in deep and ultra-deep water conditions is proposed. The framework captures all evaluation criteria such as BOP reliability, handling/deployability, overall weight and CAPEX/OPEX ratio. Appropriate mathematical and evaluation tools such as Bayesian Network (BN) and Lifecycle Cost Analysis (LCCA) are employed to evaluate different configurations. The models are applied to a commonly used CLASS VII subsea BOPs in deeper waters. The results indicate that configuration 1 (with 2 annular, 2 pipe rams, 1 blind shear ram, 1 casing shear ram) is slightly less reliable than configuration 2 (with 1 annular, 2 pipe rams, 1 blind shear ram, 2 casing shear rams), however, the operation and maintenance (O&M) costs are higher for the latter configuration. Our framework can serve as a valuable decision making tool for BOP stakeholders as varying facets of information regarding the device are obtained.

1 INTRODUCTION

The increasing demand in world's energy consumption has made the Blowout Preventer (BOP) a crucial and indispensable complex technical system. Coupled with improved safety awareness and growing stringent environmental protection policies, the safe operation of the device cannot be overemphasized. However, depletion of shallow oil reserves has forced drilling and oil exploration into deeper, erratic sea environments. Such deep and ultra-deep water developments rely on new technology, which is yet to be field proven, hence, increased uncertainty related to occurrence of unforeseen events and higher capital expenditure, costs of production interruption and subsea intervention costs (Enjema *et al.*, 2017). A combination of unpredictable and erratic environmental conditions as well as increased associated costs is a major challenge in this sector.

Several studies have been carried out on different individual aspects of the BOP system, including its reliability (see, e.g. Cai, *et al.*, 2012; Holand & Skalle, 2011; Holand, 2001), cost analyses (see, e.g. American Petroleum Institute (API), 2015), etc. More so, aspects such as maintenance, repair and inspection, or configuration and classification are well regulated and documented by regulatory bodies. However, there exist great dependence and interconnectivity among these aspects and evaluating them holistically provides a better view of the entire system functioning and operation.

Given the above-mentioned research gap, this study proposes a framework that considers many of these factors simultaneously and the interrelationship between them. The model is comprehensive and built upon modern intuitive techniques such as Bayesian Network (BN) for technical reliability analysis, Cost Benefit Analysis (CBA) for economic analysis and eventually, a comparison scheme for selection of the best solution. The proposed approach is validated with a case study of a class VII BOP system and the results are subsequently discussed and evaluated. The generic nature of the proposed framework makes it applicable to various other complex engineering systems.

The rest of the paper is organized as follows. Section 2 presents the selection framework developed in this research. In Section 3, the model is applied to a case study and the results are analysed in Section 4. Finally, the research is concluded in Section 5.

2 PROPOSED FRAMEWORK

In this Section, a conceptual framework is developed for the purpose of analysing and selecting suitable BOP configuration for varying operational conditions. Comparative analyses of the reliabilities of various system configurations under these conditions and a cost-benefit evaluation of the configurations is performed. Decision making based on economies of scale and suitability for particular fields of operation is simplified. Information used in the concept development emanate from published literature in the offshore oil and gas sector, face-to-face semi structured interviews and correspondence with BOP experts. The proposed framework, as shown in Figure 1, consists of three main phases. Phase 1 is a preparatory stage in which the premise for selection is determined. The system requirements, functionality and safety levels are investigated. This provides further information on the related parameters involved in operating the system. Evaluating and discretising the operating condition(s) is achievable at this stage. All related correlations are then analysed and data is collected. Phase 2 is the core of the framework, in which mathematical and technical determination of all correlations related to BOP selection is performed. The final phase captures the comparative analyses and selection process. The entire framework will provide a modern comparative and selection tool, given several interrelated parameters. Key tasks in each phase are described in the following subsections.

2.1 *Preparation*

2.1.1 *Setting premise*

Setting the ground rules for the technical, operational and economic aspects is the first step. BOPs

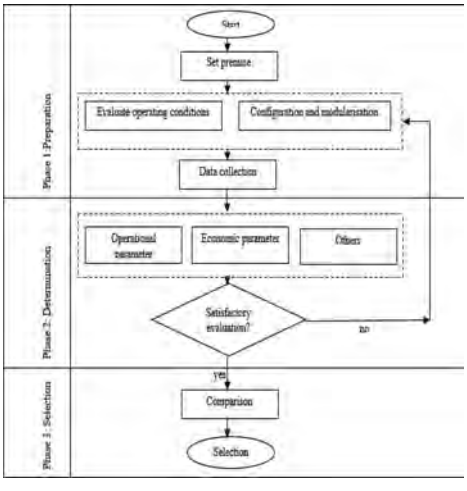

Figure 1. The proposed integrated framework.

are deemed the most safety critical component in a driller's toolbox but also the single largest agent of unproductive time (Sattler, 2013). BOPs are no doubt complex, multi-configuration and multi-phase devices, synchronising several individual components of hydraulic, electrical and mechanical nature. Aside the failsafe function of monitoring and maintaining well integrity, BOP system's primary functions are therefore:

- to confine or seal off well fluids in the well bore
- to provide means of adding or withdrawing controlled volumes of fluid to and from the well bore.
- to shut or 'kill' the well and seal the wellhead.

Typical BOPs are huge pieces of equipment with some current weighs of about 450 tons and 60 ft. in height (Tulimilli *et al.*, 2014). Principal factors affecting safety and reliability of BOPs particularly in high pressure high temperature (HPHT) operations include (Montgomery, 1995):

- Manufacturing specifications
- MIT (Maintenance, Inspection and Testing) techniques.
- Temperature and pressure (and corresponding fluid effects).
- Stack configurations.

Deep and ultra-deep water developments rely on new technology, which is yet to be field proven. The uncertainty related to occurrence of unforeseen events increases as novel technologies introduced for deep waters are not encountered in shallow waters. Deeper waters are also characterized by large capital expenditures with relatively high operational expenditures and high sustainable production rates – hence large losses for production interruption. Furthermore, subsea interventions become more expensive and are associated with longer waiting times for the required mobilization of intervention vessels. Subsea well system repairs and economic penalty for delayed/lost production also soar, characterized by long delays centered on availability, particularly in ultra-deep water environments.

Some BOP configurations have been shown to be more reliable than others (see, Cai *et al.*, 2012; Sattler & Gallander, 2010). Individual components' reliability affects overall system reliability due to variations in numbers, position and even type within stack configuration. Common-cause failures are popular within BOP systems, with a dominant impact on accidents (Cai *et al.*, 2012). Redundant components (control panels, control pods, annular preventers, ram preventer, valves and regulators etc.) may fail from a single event. Historically, multiple low frequency failures lead to blowouts (Whooley *et al.*, 2011). A failure in a BOP system with series-fashion connectivity will affect the entire system functionality. It is therefore obvious that reliability

is directly related to configuration, which intends to have a direct bearing on size/weight and hence total cost of operation and maintenance (O&M).

Safety Integrity Level (SIL) requirements for the BOP are specified in IEC 61508 and 61511standards which are widely accepted for the basis of operation and design of Safety Instrumented Systems (Pinker, 2012). The Norwegian Petroleum industry accepts a minimum SIL 2 requirement for the SIF (Safety Instrumented Function) of the subsea BOP systems (NOG 070, 2004).

2.1.2 *Evaluation conditions*

Technology progressed significantly and by the 1990s it was advanced into deeper depths. Deepwater drilling refers to water depth between 400 m – 1500 m. Depletion shallow water reserves coupled with huge advances in technology has seen many drilling companies venture into depth greater than 3000 m. Though the risks in shallow water drilling are considerably less, the economics of deep-water production are highly attractive and worth the risks (Latham, 2002). Areas such as the Atlantic Margin in Europe, Gulf of Guinea in West Africa, the Gulf of Mexico and the Compos Basin in Brazil are currently drilling and exploring deep-water environments of over 2000 m (Oyeneyin, 2009). These future oil and gas development regions are burdened with complex geological features and profiles. Conditions that affect the operation, maintenance and testing (MIT) of the BOP are also considered. These new adventure presents varying oceanographic and geological environments, flooded with high gas-oil ratios, HPHT regions, elevated tides and wave currents, difficult formations and even lack of experienced personnel (Skogdalen & Vinnem, 2012). Specific data based on some of these conditions provide some foundation in this study. Erratic conditions are limited to HPHT, where 'high' is defined based on API TR 1PER15 K-1, API 17TR8, and expert literature regarding current operating limits (Lehr & Collins, 2015):

- High Pressures ≥ 15000psi (~1000bar)
- High Temperatures ≥ 350°F (175°C)
- Water depths ≥ 5000 ft or 1500 m

Classification for HPHT wells are expected wellhead shut in pressure ≥ 10.000psi (690bar) or pore pressure gradient >1.81bar/10 m and high temperature when reservoir temperature or wellhead temperature > 150°C (Masi *et al.*, 2011).

2.1.3 *Data collection*

Data for analyses, particularly for safety critical technical systems in the oil and gas industry, is constant challenge (Khakzad *et al.*, 2014). The accuracy and integrity of the data is sometimes questioned. Expert judgements through rigorous elicitation techniques (see Clemen & Winkler, 1999; Keeney & Winterfeldt, 1991) are used and due to the dynamic nature of the proposed framework, updating is possible when new and coherent data becomes available. In a bid to overcome this problem, subject experts with extensive years of experience are selected to provide required information. More so, different types and forms of data is sourced from different systems, the trends are observed and aggregation is done where possible to eliminate and minimise ambiguity. In the second phase, different types of data about system design, component interaction and interrelationships and operational procedure are required. Primary qualitative data is obtained via questionnaires completed by subject experts. Slightly more precise and delicate qualitative assertions and quantitative information such as failure rates and conditional failure probabilities, load margins and corresponding effects are gathered. In order to control the quality and ensure specificity of the data obtained, interviews and questionnaires are employed. Specific primary data here provides greater confidence in the results obtained. Additional secondary data is also available within literature. However, greater focus is placed on primary data obtained from questionnaires.

2.2 *Determination*

2.2.1 *Operational parameter (Reliability)*

A few studies such as Holand (2001), Holand & Skalle (2011), Holand & Awan (2012) have considered the reliability of the BOP in deep-water conditions, using the fault tree analysis (FTA) and the reliability theory. Some other studies, e.g. Cai *et al.* (2012) and Cai *et al.* (2013) use a more contemporary technique called Bayesian Network (BN). The effects of inherent complex technical systems characteristics such as common-cause failures are considered, alongside important reliability attributes such as maintenance and repair can be captured with this technique. A Bayesian network (BN) is a compact representation of a multi-variate statistical distribution function (Langseth & Portinale, 2007). It has a qualitative side, portrayed by a directed acyclic graph with nodes (representing random variables) and arcs between the nodes (representing dependencies) which together define the joint probability distribution over all random variables (Boudali & Dugan, 2006). Nodes represent cause and effect in real-world situations and arcs connect the nodes. The quantitative part, made up of conditional probabilistic tables, could easily be ascertained by a domain expert (Langseth & Portinale, 2007).

BNs perform both predictive and diagnostic analyses and are now considered as a viable alternative technique (Khakzad *et al.*, 2013). Such predictive analysis is used to compute the reliability of systems in a process called marginalization. Qualitative and quantitative parameters, discrete and

continuous data, equations and data sets can be modelled into systems or processes through BNs. Erratic conditions such as extreme temperature and pressure and their immediate corresponding effects are easily incorporated into complex technical system analyses via this methodology. A simple step by step frame is presented in Figure 2.

2.2.2 *Economic parameter (cost-benefit ratio)*
Several factors influence the choice of BOP employed in any drilling or workover development and this is common with other complex technical systems which are associated with high turnovers and productivity. Cost-benefit analysis (CBA) as used in economics enables long-term decision making by comparing present value of costs with the present value of benefits. An activity is considered worthwhile when the sum of its benefits outweighs the sum of its costs, i.e. benefit/cost ratio is greater than 1. It becomes necessary to identify the associated benefits and costs. Based on experts' input, a summary of potential benefits and costs associated with BOP operation and functioning are shown in Table 1.

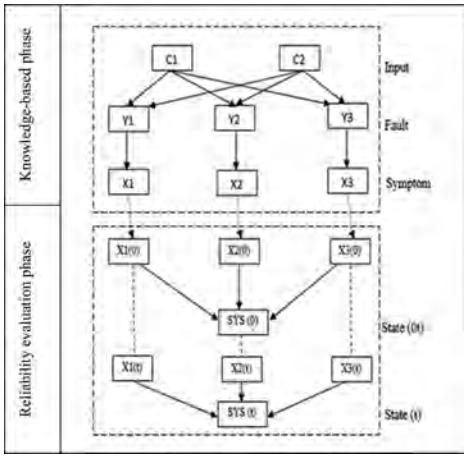

Figure 2. Bayesian network framework.

Table 1. Associated BOP costs and benefits.

Costs	Cost elements	Benefits	Benefit elements
Capital costs	Purchase Upgrades	Production	Revenue
Installation costs	Labour Logistics	Increased Safety	
Operating cost	Maintenance Royalties Taxes Logistics	Time savings	

2.2.3 *Others*
Given that the proposed framework is a living tool, stakeholder decision-making is facilitated as new data is obtained. Though reliability, of paramount importance, is the focus of the study carried out, other related factors which affect the selection process are compared. The economic benefits are determined in CBA whilst other criteria such as associated weight/size are obtained from varying available data sources and expert opinion.

2.3 *Selection*

In the case of different BOP configurations under study, the most appropriate option is chosen on the basis of a number of criteria such as reliability, cost, weight/size, technical handling/deployment issues, etc. For this purpose, a simple weighted decision matrix is used to rank options. Buying or rental and MIT expenses may be of utmost importance to an operator but reliability and availability affect several other stakeholders, the environment and beyond. Adding weights to these criteria will enable clear decision making and eventual optimisation.

3 APPLICATION AND RESULTS

In this Section, the proposed model is applied to a BOP of class VII. This class is typically used in deep water application and comprises of either a dual annular, five (5) ram arrangement or a single annular, six (6) ram configuration. The required data is collected from 4 BOP experts, two BOP vendors and supported by extensive literature review. Employing the proposed model, prior to setting the appropriate premise, the reliability for both Class VII configurations is calculated. The selected tool, incorporates a continuous discretised evaluation range for both temperature and pressure, considering one-year period, and the results are presented in Table 2.

The results indicate that the configuration 1 (with 2 annular, 4 pipe rams, 1 blind shear ram) is slightly less reliable (obtained with Bayesian Network analysis) than configuration 2 (with 1 annular, 4 pipe rams, 1 blind shear ram, 1 casing shear rams). Increase in reliability may be due to

Table 2. Reliability approximation of different configurations.

	Reliability	
Configuration	Temperature model	Pressure model
1) 2 annular, 5 rams	≈ 99.7	≈ 97.2
2) 1 annular, 6 rams	≈ 99.8	≈ 97.5

Table 3. Preventer type and overall configuration weight.

BOP Type	Weight (lbs)	Configuration 1 quantity	Total	Configuration 2 quantity	Total
Annular	40,632	2	81264	1	40632
Pipe (single)	23,300	4	93200	4	93200
Casing shear (single)	28783	–	–	1	28783
Blind shear (single)	28783	1	28783	1	28783
			Total = 203247		Total = 191398

Table 4. Final selective decision matrix.

Decision matrix			
Criteria	Weight/ Rating	Configuration 1	Configuration 2
A: Reliability	0.4	2	2
B: Weight/size footprint	0.2	–2	1
C: Technical feasibility	0.1	1	–1
D: Economic feasibility	0.3	1	–1
	Total = 1	0.8	0.6

Feasibility scale:
2 = better than average.
1 = slightly better than average.
–1 = slight worse than average.
–2 = worse than average.

the casing shear ram. Temperature models also seem more tolerance compared with their pressure counterparts as pressure has a direct bearing on the operation of the rams. Costs and benefits are also evaluated for each configuration. Approximate purchase prices for single annular, pipe, and shear preventers are $29500, $39500, and $105000 respectively. The Net Present Value (NPV) can be appropriately estimated by calculating the Net Cash Flow (NCF), depicted by Liu and Ford (2008) as:

$$NCF = Revenue - CAPEX - OPEX - Tariffs - Tax$$

The analysis captures most factors, parameters and risks involved in operating a complex technical system. Holistic analyses and suitability assessment of the individual configurations examined for the loading parameters involved is then made possible. As mentioned earlier, configurational changes affect the weight and size of the entire BOP stack. This has bearings on maintenance as number of components may have increased or reduced. More so, the larger the stack, the more complicated installation, deployment and decommissioning will be. Weight and size depend largely on the manufacturer and if the rams are studded, flanged or hub type. Table 3 provides the details on different BOP types available in the market.

Finally, based on expert opinions, the weights are assigned to the parameters and the best alternative, given the period and conditions considered is chosen.

4 CONCLUSIONS

This study developed a framework for BOP selection, particularly in deep and ultra-deep water environments. The model provided a powerful decision making tool for incorporating the effects of erratic/extreme loading conditions and selecting the set of system modules, considering several related factors. Application to a class VII BOP configuration was also shown and the results demonstrated the validity of the proposed framework. Correlating several aspects related to the selection process facilitated decision making and provided a better overview of the many intricacies involved in deep and ultra-deep water exploration and drilling. Simultaneously analyses and incorporation of technical, operational and economic selection aspects were incorporated. The entire framework, once completed efficiently resulted in varied forms of information relating to system operation, design (redundancy configuration), loading condition boundaries and even economic consideration. The proposed model can be applied to other modular complex technical systems in general as it is comprehensive, intuitive and dynamic. Its application to other operational conditions is a possible step in the future. Appropriate and more coherent data will also provide refined results in further analyses. The development of appropriate modelling tools to reduce uncertainty in cost assessment and the development of a software based selection mechanism after the evaluation of the necessary correlates are other future prospects.

The use of reliability simulation techniques in data-driven facility simulation

F. Reinecke & S. Bracke
Chair of Reliability and Risk Analytics, University of Wuppertal, Wuppertal, Germany

ABSTRACT: Simulation methods are widely used in different industrial sectors like economics, logistics and also in the field of reliability engineering. In general, simulation pursues the target of imitating the operation of a real-world system over time in order to gain knowledge of its behavior which is transferable to reality. It is especially applied when the testing of the real-world system is too expensive, risky or too complex. The aim of this paper is to present different simulation modelling techniques which are used in reliability engineering and other subject areas and to evaluate them regarding the specific application of Data-driven Facility Simulation (DFS). After presenting the techniques, important issues of DFS are discussed. Subsequently, the presented modelling methods are evaluated with respect to a wind park consisting of wind turbines as an illustrative example. They are discussed regarding different advantages and disadvantages as well as limitations.

1 INTRODUCTION

Simulation is widely used in different industrial sectors like economics, logistics and also in the field of reliability engineering. It pursues the target of imitating the operation of a real-world system over time in order to gain knowledge of its behaviour, which is transferable to reality (Banks 2005). It is especially applied when the testing of a real-world system is too expensive, risky or too complex (Kolonko 2008).

One of the first steps in performing a simulation study is to develop a (mathematical) simulation model, which consist of objects and their mutual relationships. It is expressed in a mathematical, logical or symbolic way and can either be static or dynamic (Banks 2005).

In reliability engineering, various simulation approaches have been used, i.e. for estimating performance characteristics of system components, the system availability and safety or the system's degradation. For example the Monte Carlo Simulation (MCS) as well as its specific application, the Discrete Event Simulation (DES), is used for the evaluation of reliability characteristics of multicomponent technical systems as well as for the estimation of the reliability of mechanical structures (VDI 1999). Gathered simulation results can be used for reengineering activities or for further improvement of the system.

The aim of this paper is to show selected and established simulation modelling methods, which are used in reliability engineering and other subject areas. The stated modelling methods are evaluated regarding the specific application of DFS. This is done by means of a wind park consisting of wind turbines as an illustrative example. They are discussed regarding different possibilities of application, advantages and disadvantages as well as limitations.

2 MONTE CARLO SIMULATION IN RELIABILITY ENGINEERING

The MCS is a well-known and established method for simulating stochastic systems. Within MCS, random numbers are used for solving or rather estimating solutions of a deterministic or stochastic problem (Law 2007; Zio 2013). It is often applied when it's too complex or impossible to evaluate a system by analytical methods. In reliability engineering, MCS is used for the determination of reliability characteristics of technical systems and can be performed by the following 3 steps (cf. VDI 1999):

1. Building a stochastic simulation model $y = \varphi(\underline{x})$, which contains random variables (i.e. component state variables x_i). The model should describe the behavior of the system under study in a sufficient way.
2. Implementation of the model in a computer program for simulating system failure processes
3. Simulate the model with a sufficient amount of simulation runs N. Within a simulation run,

input random variables $x_i, i = 1,...,n$ are generated with consideration to their determined distribution (i.e. by inverse transform sampling or rejection sampling, etc.) and the model output (the simulated state of the system y) is calculated. Lastly, statistical parameters of the generated output data $y_k, k = 1,...,N$ are calculated (i.e. mean value, variance, etc.)

According VDI (1999), the MCS can be performed at different types of models, which can be static or dynamic. In literature, the MCS is often associated with simulating only static models whereas for discrete dynamic models the terms of discrete event and discrete time simulation (DES and DTS) are used. However definitions of MCS vary in literature.

3 METHODS FOR SIMULATION MODELLING

This section deals with selected dynamic simulation modelling techniques, which are used in reliability engineering and are mostly based on MCS. The methods are presented and instances of applications in the field of reliability are shown.

3.1 *Discrete event simulation*

Discrete Event Simulation (DES) describes a technique of system modelling where the system's state variable can only change at discrete points in time (Banks 2005) when an event occurs which is defined according (Law 2007) *"as an instantaneous occurrence that may change the state of the system"*. After establishing a model, it can be run and an artificial history in form of generated data can be produced (Banks 2005).The DES can be seen as particular application of the MCS if events occur at random.

A typical application of using DES in reliability engineering is the simulation of a model (e.g. a block diagram model) over a specific operation time t. For each component, failure and repair events are generated from its time-to-failure or time-to-repair distribution. At each point of time an event occurs, the system state (success or failure) is determined. Moreover, in such simulations, different constraints can also be considered (e.g. repair strategies and capacities or operation phase-switching) (cf. VDI 1999). With a sufficient number of simulation runs N, reliability measures (e.g. MTTF) can be estimated. There are also other applications where DES is used. For instance, it is used for reliability and availability assessment of civil engineering structures (Juan 2009). Moreover, Sharda & Bury (2008) developed a DES model for understanding facility failure effects on a chemical plant's production capability.

3.2 *Discrete time models*

According Zeigler (2010), within discrete time models, the time advances stepwise in a discrete way (i.e. in a one-second interval). At each specific point in time, the model persists in a certain state. The model is executed at each point in time and the next state is determined for the subsequent time step. In this subsection, selected discrete time modelling methods are presented and discussed.

3.2.1 *Discrete-Time markov chain models*

Discrete-Time Markov Chains (DTMC) can be used for modelling and simulation studies (cf. Nfaoui, Essiarab & Sayigh 2004; Papaefthymiou & Klockl 2008; Sahin & Sen 2001; Shamshad 2005). A discrete time stochastic process $X_t, t \in \tau, \tau = \mathrm{N}_0$ can be described by a markov chain, where for all states $i_0,...,i_t \in I$ the following condition (1) is valid (Waldmann & Helm 2016).

$$\begin{aligned} &P\left(X_{n+1} = j \mid X_n = i, X_{n-1} = i_{n-1},..., X_0 = i_0\right) \\ &= P(X_{n+1} = j \mid X_n = i) \\ &= P_{ij} \end{aligned} \tag{1}$$

I denotes the state space and P_{ij} the one-step transition probabilities which can be represented in a one-step transition matrix **P**.

The simulation of the stochastic process is carried out for each time step and can be performed as follows (cf. Sigman 2007).

1. Select an initial value $X_n = i_0, n = 1$
2. Generate X_{n+1} by sampling from the conditional distribution $P(X_{n+1} \mid X_n)$ and set $n = n + 1$
3. Set $X_n = X_{n+1}$ and go back to step 2 until the desired number of n is reached.

Markov chain models are also used in the field of reliability. Skalny (2013) used Discrete-Time Markov Chains in combination with the MCS Method for estimating the failure probability of companies for satisfying an order to industrial partners. Markov chains were also applied in modelling reliability structures (cf. Koutras 1996).

3.2.2 *ARMA models*

Autoregressive Moving Average Models (ARMA models) (Box & Jenkins 1979) are used for time series forecasting and simulation (especially for wind speed time series (cf. Kamal & Jafri 1997; Sfetsos 2000)). In ARMA models, it is assumed that the present value of a variable is the result of a linear function of a specific number of past values and a random error term. It can be represented generally in the following form (see equation 2):

$$y_t = \sum_{i=1}^{p} \phi_i y_{t-i} + \sum_{j=1}^{q} \theta_j e_{t-j} + e_t \quad (2)$$

y_t denotes the actual value and e_t the random error which is assumed to be i.i.d. with mean of zero and constant variance σ^2 at time t. $\phi_i (i = 1,...,p), i \in N_0$ are the autoregressive and $\theta_j (j = 1,...,q), i \in N_0$ are the moving average model parameters, p and q are referred to as the order of the model. ARMA models can be used to model only stationary time series. If a time series, which has to be modelled, isn't stationary, it has to be differenced d times or transformed. The determination of the model (model orders p, d, q and model parameters θ_l and ϕ_l) can be performed by the Box and Jenkins methodology (Box & Jenkins 1979).

The simulation process can be done by performing the following three steps:

1. Select an initial value $y_t, n = 1$
2. Generate a value of e_t by sampling from the fitted normal distribution function for e_t with MCS
3. Calculate a new value of y_t by equation 2, shift all former values one step in the past and go back to step 2.

ARMA models are also applied in reliability engineering. For instance (Ho & Xie 1998) used ARMA models for repairable system failure reliability forecasting. Another application example is given in (Karki, Hu & Billinton 2006) and (Billinton, Chen & Ghajar 1996). They used an ARMA model for simulating wind speeds in combination with a power generation model for the reliability evaluation of wind power systems.

3.2.3 *Artificial neural network models*

Another technique for simulation modelling are artificial neural networks (ANN) (Kruse 2012). ANN's are used in a wide range of applications (i.e. wind speed forecasting). It is a technique for mapping input vectors to output vectors by learning from examples without implying a specific relationship between them (Li & Shi 2010). There are different types of ANN's available (i.e. feed forward, radial basis function networks or recurrent neural networks). This section deals only with the type of feed forward ANN models (FNN) (Kruse 2012). The mapping is realized by interconnected neurons, arranged in different layers called input, hidden and output layer and no feedback loops between the layers exist. The strength of each connection from a neuron j to a neuron i is expressed by a connection weight. Hereby an activation level v_i is calculated for each neuron i in the network as follows (Mohandes 1998):

$$v_i = \sum_{j=1}^{n} w_{ij} x_{ij} - w_{i0} \quad (3)$$

w_{ij} denotes the connection weights and x_{ij} the input values to neuron i. The bias value w_{i0} denotes the shift of the function $\varphi(v_i)$. This function determines the output of a neuron from a calculated activity level and is a nonlinear function (i.e. a sigmoidal function, see equation 4).

$$sig(x) = \frac{1}{1 - e^{-x}} \quad (4)$$

In order to get adequate results by the FNN for a given input, the connection weights of the network need to be trained (Welch 2009). For training, the well-known back propagation algorithm (BP) (Kruse 2012) can be applied. Hereby, an iterative training process minimizes the mean square error of the network output in comparison to the real output by adjusting the connection weights which are assigned with random values initially (Li 2010; Mohandes 1998).

Concerning time series simulation or forecasting, an ANN describes a nonlinear function $f(.)$ which represents the relation of past recorded values of a time series to future values (see equation 5) (Zhang 2003).

$$y_t = f(y_{t-1},...,y_{t-n},\underline{w}) + \varepsilon_t \quad (5)$$

ε_t describes the error term of the model, whereas $\underline{w}$ denotes the vector of the model parameters (connection weights between the neurons). After training the ANN, the simulation can be performed by selecting initial values of $y_{t-1},...,y_{t-n}$ and calculating a new value of y_t. Then all former values are shifted one step in the past and the simulation process is performed again until a specified number of simulation runs is reached. ANN models were also applied in reliability engineering. They are widely used in structural reliability analysis (cf. Chojaczyk 2015; Hurtado 2001). Moreover (Rajpal, Shishodia 2006) used ANN's for modelling and simulating the behaviour of a complex, repairable system (helicopter transport facility) under various constraints. Results can be used for optimizing the operation of the system.

4 MODELLING METHODS FOR DATA-DRIVEN FACILITY SIMULATION

In recent years the availability and functionality of condition monitoring and diagnostic systems regarding a wide range of technical facilities has

increased. The systems offer the ability to record field data of different variables during field operation which can be used for the identification of damages and the facility state history. The data are acquired by different sensors, which are integrated within a plant and are available in form of multivariate time series.

They can be used for prediction purposes like the estimation of the Remaining Useful Life (RUL) or the future facility state. However the amount of recorded data is often small in case of a short field duration time which hinder prognoses. Additionally, the gathered data often represent just a small time frame within the usage phase concerning the whole expected facility service life. Thus long-term predictions concerning the facility state can be afflicted with high error because aspects like changing of environmental conditions; degradation behavior as well as changing of the facility usage, which also leads to a change in the facility load scenarios, cannot be included. In order to address these problems, the behavior of the facility can be simulated over a desired period of time in form of generating synthetic operation data. Thereby the simulation process can be performed under assumptions (i.e. changing usage behavior after a specific operation time) based on expert knowledge which gives the possibility to perform more accurate predictions in case of the occurrence of changing conditions during the facility life.

4.1 *Important issues of data-driven facility simulation*

For performing DFS, several issues (i.e. requirements on data structure) have to be taken into account which are stated as follows:

Data structure and recording
For performing DFS, multivariate input time series data need to be recorded which fulfill requirements of a constant sampling rate and consistent time stamps at all variables. This is needed for instance for identifying cross correlation structures between the variables. Another important issue is the amount of recorded data. For instance, if a simulation model is built in form of a markov chain, the amount of recorded data needs to be sufficient for determining state transition probabilities.

Another important issue is the occurrence of incorrect measurements as well as missing values within the recordings. Therefore, it is recommended to treat implausible and obviously incorrect data as missing values. Missing values in time series can then be replaced with the help of data imputation methods within a data preparation process. On the contrary, outliers are treated as rare events by the simulation model and thus don't need to be rejected.

Data analysis
In order to perform a DFS, a profound data analysis has to be made. Results are serving as input for the simulation model building as well as for the evaluation process. The data which exist in form of time series can be analyzed among others in the following way:

Statistical parameters: Calculating general statistical parameters for evaluation purposes (mean, variance, percentiles, min/max, etc.)
Probability density functions: Fitting probability density functions (i.e. Weibull density function) to the time series data. This can be done either for the whole recorded time series (i.e. also for evaluation purposes) or within a system state (i.e. a specified range of wind speed) for modelling transitions into other system states.
Autocorrelation: An analysis of the autocorrelation structure of the recorded time series needs to be performed for considering the series chronology within the simulation process (Feijóo & Villanueva 2016). This can be done by the following equation given in Shamshad (2005) for a specified number of lags k

$$\rho_k = \frac{\frac{1}{N-K}\sum_{i=1}^{(N-K)}(x_i-\bar{x})(x_{i-k}-\bar{x})}{\frac{1}{N}\sum_{i=1}^{N}(x_i-\bar{x})(x_i-\bar{x})} \tag{6}$$

where $x_i,...,x_N$ is the analyzed time series and $\bar{x}$ is its mean. The autocorrelation structure describes the correlation of time series values with its past values at different lags. The calculated autocorrelation structures of simulated and real data can be compared and thus the simulation model performance can be evaluated.
Event identification: Technical facilities behave in a different way in various operation phases which also results in the data recordings which must be considered during simulation. For instance wind turbine data recordings clearly differ between starting up phases and shutdown phases as well as in idle time phases (i.e. during maintenance). Therefore it is important to label the recorded time series for allocating data to different operation phases in order to acquire better simulation results. Additionally, the occurrence of events needs to be analyzed regarding frequency, sequences and occurrence probability.
Dwell times and idle times: Another important issue within data analysis is the determination of dwell times in system states because in simulation the time duration within different load states of a facility which is an important factor for the degradation estimation needs to be reproduced in an adequate way. For increasing the accuracy of simulated data

and for better RUL estimation, the determination of idle time durations has also to be taken into account.

4.2 *Evaluation of simulation modelling methods for data-driven facility simulation*

The reviewed simulation modelling methods shall be evaluated regarding DFS by means of a wind farm as an illustrative example. The evaluation is based on a data set consisting of operational time series data of wind turbines located in the western part of Germany. The data set consists of 10 minute values. Its essential structure is shown in Table 1.

Discrete event simulation

The operational time series variables 3 to 7 and 12 (see Table 1) in the data set change at almost every point in time their value or remain just a short time in a value level. This leads to an enormous number of system changes which are not seen as events in the proper sense. DES is usually not applied here because a system change takes place at almost every discrete point in time and a system change can't be assigned to a specific reason. However with DES, sequences of clear specified events concerning a wind turbine can be modelled in which the behaviour of operational time series variables change. An example for such events are maintenance activities, facility shutdowns caused by shadowing or occurring facility failures. An advantage of applying DES for simulating a wind park on event basis is that it can help for evaluating maintenance and repair strategies of the plant or for estimating the plants availability. However, a major disadvantage is that a plant specified model has to be developed. The wind turbine data set includes high numbers of different types of facility states. If DES is applied, a complex model has to be established. For DFS, a DES model can be combined with an DTS model (cf. Cha & Roh 2010). This would take potential impacts from the facility states (e.g. maintenance actions) onto the operational time series data into account as well as their interdependencies. For establishing such a model, expert knowledge of the facility is an essential condition. DES models are usually very process specific which another drawback is.

Table 1. Structure of the wind farm data set.

No.	Variables	Available data
1	Timestamp	Date, hour, minute
2	Plant number	1 to 14
3	Wind speed [m/sec]	Mean, min, max
4	Rotor speed [1/min]	Mean, min, max
5	Active power [kW]	Mean, min, max
6	Reactive power [kW]	Mean, min, max
7	Nacelle position [°]	Mean
8	Blade angle A,B,C [°]	Mean
9	Rainfall [mm/min]	Mean, min, max
10	Visual range [km]	Mean, min, max
11	Ambient brightness [lux]	Mean
12	Temperature of machine parts [°C]	Mean
13	Facility status	Nominal status values

Discrete time models—ARMA models

The operational time series variables of the wind park data set (variables 1 to 12) show a strong autoregressive behaviour which is given by a slight decrease of the ACF function. This is a strong indicator that the time series are non-stationary which means that the series doesn't have invariant characteristics. Invariant characteristics of a (weakly) stationary time series would be a constant mean, a constant and finite variance over time as well as a covariance structure which is only dependent on the lag and not on time (Davies 2014). As with ARMA models only stationary series can be modelled, they are not suited to model operational time series variables of a wind park without stationarizing the series (e.g. by applying data transformation or decomposition). Differencing would lead to a stationary series, however the effect of a huge information loss leads to problems in simulating a time series which has similar characteristics as the observed one. With decomposition techniques, the time series can be divided into a trend-cycle component and a stationary component. The former still can't be modelled by ARMA in contrary to the latter component.

The advantage of ARMA is that just a few parameters for generating a time series with a specified ACF are needed. However, generally the probability density function differs from the measured data which can lead to wrong estimations (Papaefthymiou 2008). Furthermore, concerning wind turbines, it is assumed that ARMA models are not suited for simulating idle times of a facility within a variable (e.g. active power) as well as for instance dwell times (e.g. in specific temperature value level of a machine part) because the simulation of its trajectory is driven by sampling from an error distribution (see equation 2). Another disadvantage of ARMA models is reasoned by its linear nature which make them potentially not well suited for modelling operational time series data of wind turbines (cf. Chen & Yu 2014).

Discrete time models—ANN models

ANN Models are another way for time series simulation as described in section 3.2.3. They can be

used for approximation of various nonlinearities in data (Zhang 2003) in contrary to ARMA models. Moreover, they give the possibility to model a huge number of functions with high accuracy. They were successfully applied in wind speed simulation as well as in simulation of series of solar radiation (cf. Li 2010; Mihalakakou 2000). However, there is no rule available for determining the ANN topology and the number of needed neurons for modelling a function. This has to be examined for every different time series in a parameter study.

A disadvantage of ANN lies in modelling time series in which values persists a certain duration. For example, regarding the wind park data set: During an idle time no output power is generated. That means the future value of past zero values is also zero as long as the facility is in idle mode. However, after a while the facility is re-started which leads to future values different to zero. This can't be modelled solely by an ANN as described in section 3.2.3. The ANN would persist in the idle stage for the rest of the simulation duration. A possible way to face this problem is to use hybrid models. For example, the ANN model can be trained for just simulating changes of value levels and the dwell time within a level can be simulated by a Monte Carlo approach. Another way for applying ANN models in DFS is the usage for regression. For instance, the variables rotor speed and active power are highly correlated. After simulating one of these variables, the other one can be determined through modelling the relationship between the two variables. This gives the possibility for generating multivariate correlated time series.

Discrete time models—markov chains

Instead of ARMA models, Discrete-Time Markov Chains can be used to model operational time series data of the wind park. The methodology is suited for modelling non-stationary and nonlinear time series which are existent in the wind park data set. Moreover, the methodology considers the underlying ACF as well as the probability distribution function of the control sample series. It is also able to simulate dwell times (of temperature levels of machine parts of the wind turbine) as well as idle times associated with the belonging state. However, when applying this methodology, the stochastic process needs to be discretized by defining a number of states (Papaefthymiou 2008), which leads to a loss of information. According Papaefthymiou (2008), when applying MC, a tradeoff between the model accuracy and complexity (represented by the number of states and parameters) has to be made. With a high number of states the process can be better represented. However it is difficult to assess transition probabilities in case of a low data volume. Regarding wind speed series, in literature, MC of higher order are applied, which leads to more adequate results with better ACF and a better retention of the probability density function of the simulated series compared to the real data (Feijóo 2016). However, by using a higher order MC, the model complexity as well as the needed amount of data increases enormously which limits their usability (cf. Aksoy 2004).

The MC approach is also not able to simulate a trend. As the series of the data set don't show a trend over the observation time, this restriction is negligible.

5 CONCLUSIONS

In this paper, different simulation modelling techniques were reviewed regarding the field of reliability engineering. After discussing important issues of data-driven facility simulation, the presented modelling methods were evaluated regarding the specific applicability in DFS and in general. Its advantages, disadvantages and limitations were pointed out by means of a wind park as an illustrative example. The stated models (ARMA models, DES, ANN as well as Discrete-Time Markov Chains) can be seen as tools which can be used for establishing a comprehensive simulation concept for operational time series simulation of a technical facility. In future studies, the stated modelling methods shall be applied on the wind park data under consideration of the stated important issues of DFS. Furthermore, the methods shall be applied in combination for performing the DFS.

Safety for automated warehouse exhibiting collaborative robots

Rafia Inam & Elena Fersman
Ericsson Research, Ericsson AB, Stockholm, Sweden

Klaus Raizer, Ricardo Souza, Amadeu Nascimento Jr. & Alberto Hata
Ericsson Research, Ericsson Telecomunicações S.A., Indaiatuba, SP, Brazil

ABSTRACT: The trend of automation in industrial production has led to massive use of autonomous robots. In classical approaches, safety is usually guaranteed by isolating robots from humans. Collaborative robots, i.e., humans and robots working together, are expected to increase both productivity and performance. However, removing fences and putting the robot working in collaboration with humans causes new hazardous situations. Therefore, proper risk assessment should be performed to avoid those hazardous situations without compromising the productivity. We present an automated warehouse where autonomous robots load trucks with products while sharing the same environment with human workers. In this position paper we propose a safety strategy that is modeled based on dynamic safety fields around the robot, which is consistent with important guidelines in collaborative robotics (i.e., ISO15066). We propose three different safety levels of dynamic fields: red (critical), yellow (warning) and green (clear). Instead of completely stopping the robot in the presence of humans it can keep performing its operations with some enforced constrains for safety reasons. We also propose a risk assessment of hazardous situations based on proprioceptive and exteroceptive data. This evaluation generates different warnings or actions to be performed based on those safety levels and is responsible for changing the size of the dynamic fields.

1 INTRODUCTION

In the present phase of industrialization, automation represents an important role, that leads towards an extensive use of robots from factories and manufacturing industries to other business areas, like in large logistic systems and warehouses. The traditional safety strategy is to separate robots and humans completely by isolating robots behind fences, and stop the robot immediately if anything goes wrong, thus minimizing the contact between robots and workers, as in Kiva project (Guizzo 2008). *Collaborative robotics*, in which robots and humans collaborate to accomplish tasks, introduces new advantages in terms of productivity and efficiency, but also new hazards, like increased possibility of collision with workers.

Avoiding hazardous situations is an absolute prerequisite for autonomous robots. Due to elimination of barriers around the robot in this new collaborative situation, a robot should interact with other robots and workers at different levels. It is crucial to ensure the correct and safe operation of the robot so that it cannot cause injuries to the workers, other objects or to itself (Robla-Gómez et al. 2017). This issue is aggravated in the warehouse scenario, where mobile robots can move freely in the presence of other moving robots and workers. The regulations that incorporate robot related risks for workers include the international standard ISO 10218 (ISO 2011a, ISO 2011b). A recent technical specification ISO/TS 15066:2016 (ISO 2016) for collaborative robots introduces new concepts, such as *collaborative operation, collaborative work-space* (a shared space where worker and robot can perform tasks concurrently), and *collaborative robot*, which are a direct focus of this work. Please note that in the rest of the paper, we use human and worker synonymously.

Many safety approaches for collaborative warehouse rely only on sensor data (e.g., cameras and Li-DARs) to perform high precision detection and tracking of the workers (Krug et al. 2016, Sabattini et al. 2017). By knowing the position of the workers, robots simply deviate from them as they come closer. Although such reactive approach may be sufficient in some situations, there are other solutions in which robot actions can be determined from its proximity to the obstacle and the type and nature of this obstacle. This leads to the *safety field* concept which creates a virtual circle around the robot, where robot reaction changes according to the region of the circle that is occupied (Magnanimo et al. 2016, SafeLog 2017).

In this position paper, we present a two-fold safety strategy and a detailed architecture including all the required components to implement safety for collaborative operations within an automated

warehouse. We base our safety analysis on creating three-layered safety fields around the robot: red (critical), yellow (warning) and green (clear). It is based on *speed and distance monitoring* and *power and force limiting* approaches of the ISO/TS 15066:2016. An advantage of using different safety fields is the increased performance of the collaborative operation. Instead of completely stopping the robot in the presence of humans it can keep performing its operations with a decreased speed. Our two-fold safety strategy consists of:

1. *An offline safety analysis:* performs a simulation-based quantitative safety assessment of the scenarios. It evaluates the high-level plans (high-level task descriptions for the robots), generated by the system before sending it to the robots.
2. *An online safety analysis:* creates the safety field around the robots within the robot control loop at runtime. It uses the sensors' data and performs *risk assessment* to calculate the risks. Based on the calculated risk values, it generates 3-layered safety fields around the robot. These fields are dynamic in size, and its sizes are computed based on the risk assessments and on both environmental and operational context of the robot.

Paper Outline: Related work is presented in Section 2. Section 3 describes details of the automated warehouse, its scenarios and the proposed architecture. Our idea for three-layered safety strategy is presented in Section 4, and finally, Section 5 concludes the paper with a description of ongoing and future works.

2 RELATED WORK

The problem of robot safety in warehouses is a relatively recent issue, though the safety problem involving robots have already been discussed for decades (Robla-Gómez et al. 2017). One of the first initiatives in warehouse automation was the Kiva project (Guizzo 2008) which used omnidirectional mobile robots to load shelves and bring them close to workers. This enables workers to pick products from the inventory and accomplish the orders efficiently. In this scenario, humans are placed in a separate area from the robot and an alarm is triggered when someone enters the robot area. In comparison to this traditional approach, our approach allows collaborative operations inside the working space and hence the safety requirements are less restrictive than keeping the robot within a limited area.

The problem of automated picking and placing of objects using mobile robots is addressed in (Krug et al. 2016), in which the robots operate in the same area as the workers. The robots are equipped with a set of safety LiDARs and camera sensors for safety assessment. Workers use reflective vests (ANSI/ISEA 107-2004 standard) to facilitate the process of human detection and make it possible even in low light conditions. The robot determines the position, velocity and the body configuration (e.g., sitting, standing) of the worker through its sensors and uses this information for safe navigation. The mobile robot conforms with the EN 1525 standard (CSN 1998) which tolerates contact with a human. The robot solution for warehouse proposed by (Sabattini et al. 2017) relies on 3D object detection using the fusion of four LiDARs and two cameras. The LiDARs ensure coverage of 360° of the scenario. The object detection and tracking is performed by both camera and LiDAR. The outputs from these sensors are used by the robot to deviate from obstacles and workers during the navigation.

In both approaches of (Krug et al. 2016, Sabattini et al. 2017), robots share a collaborative workspace with humans and a safe distance is kept to avoid collisions with objects and humans. However, the distance is calculated based on sensor data only and no risk assessment or safety analysis is performed, as we propose in this paper.

SafeLog is a more recent initiative which deals directly with safety in a collaborative scenario between robots and humans inside a warehouse (SafeLog 2017). It uses three safety levels (A, B and C) which creates a three-layered virtual circle around the worker. The safety level A creates a virtual circle around the worker which repulses the robot in a similar approach as potential fields (Taquet et al. 2017). Robots should stop when entering region covered by level A, which is the closest one to the worker. In the safety level B, robots should send a notification to the worker about the risk and the travel speed can be limited. Finally, in the safety level C, the safety system re-plans the robot and human paths to avoid close encounters between them. Further, safety vests are also used to facilitate the localization and detection of humans.

Another collaborative scenario presents a two-level dynamic safety fields creation around the moving robot (Magnanimo et al. 2016). The protection field behaves like a cage; that is, the robot immediately halts when detecting a human inside this field, while detecting any object inside the warning field results in less rigorous action like reducing the robot speed. The sizes of the fields are changed dynamically based on sensor data.

Both SafeLog and the work of (Magnanimo et al. 2016) use collaborative scenarios and are more similar to our proposed approach. However, differently, we introduce a three-layered safety field which dynamically changes the sizes of each field based on 1) the environment conditions and 2) the results of the risk assessment performed on the captured data. We also present an offline safety analysis before sending plans to the robots. Moreover, in the approach of (Magnanimo et al. 2016),

their warning field is intended for human safety assessment and does not focuses on interaction with other robots, as done in our approach.

3 WAREHOUSE LOGISTICS MANAGEMENT USING COLLABORATIVE ROBOTS

The first part of this section presents details of our logistics use case within an automated warehouse and describes collaborative and non-collaborative scenarios to be performed safely inside the warehouse. The second part of this section describes the proposed architecture and its components.

3.1 *Collaborative scenarios*

Our use case is an automated warehouse where autonomous robots and humans work together in a shared environment to perform the logistics management operations. The high-level task is to load trucks with products. Multiple robots pick up products from the shelves and deliver them to conveyor belts, that in turn take the products to the trucks. Robots can move freely in the environment to perform the tasks and are equipped with a robotic arm for pickup operations. Humans interact with shelves by placing or moving products on them. Thus, the shelves and warehouse floor are shared among humans and robots, presenting a collaborative work-space and a collaborative scenario, as shown in Figure 1. Here, the human and the robot can come into close interactions with each other, thus leading to severe safety risks.

Other situations can include the human intervention when a product is dropped by the robot and human comes to clean up, or for the maintenance of a broken robot. Proper procedures must be adopted and safety must be ensured during this operation.

Figure 1. Illustration of robots in the warehouse and the dynamic safety fields. The blue cube is the recharging station, the small boxes in red, green and brown are products on the shelf, and a white square on the floor next to the conveyor belt is a way-point. The green (clear), yellow (warning) and red (critical) circles are the safety zones around the robot.

A robot can also come close to another robot in multiple situations. Encounters can happen during navigation from shelves to conveyor belts and when the robot is coming back to the shelf after delivering the product. Another encounter can occur when two or more robots are picking up products from a different row or column of the same shelf. Although the plan provided to each robot will ensure that two or more robots will not be at the same row and column at a particular time (using offline safety analysis), still a situation can arise when the products are placed closely and there is a chance of colliding with nearby robots.

3.2 *System architecture*

This section describes the basic architecture model with some core functionalities necessary to provide all the features of an automated logistics warehouse with collaborative robots. Figure 2 presents an overview of the basic architecture.

Some physical components of Figure 2 and their respective functions within the automated warehouse are described in Section 3.1, i.e., products at the *shelves*, *robots* picking up the products from the shelves and placing on the *conveyor belt*. A *human worker* is responsible for placing products on the shelves.

To fully automate the warehouse scenario and for simulation purposes, a digital representation of all these physical components/actors is required. We use *digital twins* for this purpose, which is a digital/virtual representation of an actor/component in the system. It provides a well-known communication interface and resource description, therefore, hiding all the specific complexity of heterogeneous devices/resources. A *Warehouse Controller* component performs the main control of the system. It is responsible to perform all initial configurations and discovery mechanisms setup. When a resource becomes online it will need to register itself to the system and that, in turn, will trigger the spawning of a digital twin associated with that resource, and from that point on, all interactions between the system and the actual resources are performed through the digital twin.

The system needs to perform task planning and monitor the execution of the tasks. Thus, a *planning service* is implemented, employing PDDL traditional technique (Mcdermott et al. 1998) to generate an overall plan for the whole system[1].

While dealing with the collaborative scenarios, there is a strong requirement of assuring human

[1]Please note that the details of the warehouse controller, planning service, and digital twins are presented to depict a complete picture of the architecture and are beyond the scope of this paper.

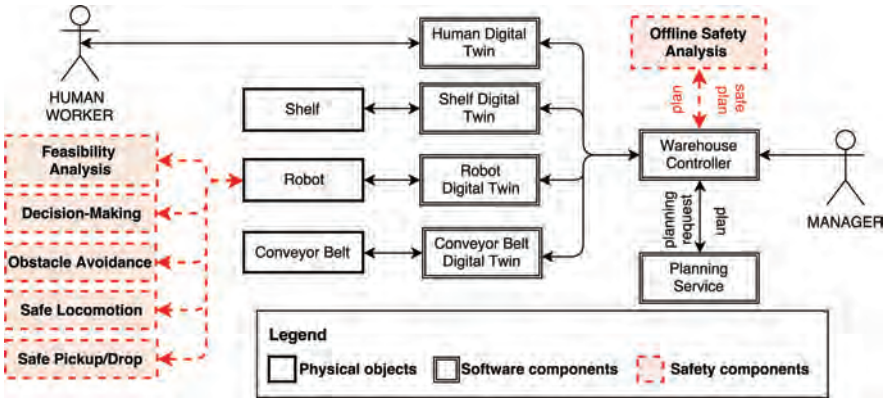

Figure 2. System architecture of the collaborative warehouse, the safety components are highlighted in red dotted boxes and arrows.

worker's safety aspects during operation. Our two-fold safety strategy is presented by dotted components and arrows in Figure 2. First, there is an initial assessment of the whole computed plan performed within the *Offline safety analysis* element. If the plan is deemed safe, the tasks are sent to the respective resources for execution. Second, during the entire operation, local *Online safety analysis* is performed within the robots to guarantee safety. It consists of multiple components namely *feasibility analysis, decision making, obstacle avoidance, safe locomotion and safe pickup*. All these safety-related functionalities are described in the next section.

4 SAFETY STRATEGY

A proper safety analysis is required for multiple collaborative scenarios in the automated warehouse (described in Section 3.1) where a robot can come close to humans, other robots or objects.

For collaborative scenarios, the ISO/TS 15066:2016 (ISO 2016) establishes a series of guiding points towards a situation where robot and human worker can share the same workspace. A first requirement on the technical specification enforces that the robots used in collaborative operations shall meet safety requirements defined in ISO/TS 10218:2011 (ISO 2011a, ISO 2011b). Secondly, the document restricts robots to have at least one of the following modes: *safety-rated monitored stop*, *hand guiding*, *speed and separation monitoring,* and *power and force limiting*. In the first method when the human is outside the collaborative workspace the robot can operate normally. For human and robots working together in the workspace, the robot must be at safety-rated monitored stop, resulting in a stop category 2 (actuators are still powered on) as defined in (IEC 2016). If any of previous conditions are violated the robot must issue a protective stop resulting in a stop category 0 (actuators are powered off). In hand guiding mode, the human must control the robot using a device located near or at the robot's end-effector. For the human to enter in the workspace, the robot must be in a stop category 2. The third method allows human and robots to be moving while both are inside the workspace, but the robot shall keep a protective distance from the human (ISO 2016). This distance varies based on some parameters (such as velocity, robot reaction time, robot distance to stop, operator velocity) and to keep that distance robot's velocity can be restricted. The power and force limiting method allows intentional and non-intentional contacts between robot and human. In this mode, the robot should keep values of force, pressure and energy transfer limited according to different parts of human body and contact situations.

Our proposed safety approach is based on both *speed and distance monitoring* and the *power and force limiting* methods. Although distance monitoring is performed throughout the process, during navigation most safety measures are based on limiting the speed of the robot. On the other hand, during the robotic arm operations, all the safety measures are done by imposing limitations on power and force.

The following sections present our main approach to achieve safety. Our key aim is to enhance safety through a dynamic system capable of adapting the robot's behavior based on its current context. To achieve this purpose, we present a *3-layered safety strategy* in Section 4.1. Sections 4.1.1 and 4.1.2 present how tactical and operational aspects of safety will be handled by different components at different moments. In the context of an automated warehouse where all devices are interconnected (i.e., share information),

make decisions and perform actions, a robust *safety analysis* should be performed. Section 4.2 briefly discusses the need of a real-time implementation of *risk assessment* approach to achieve a robust hazard management. Another important aspect to obtain effective and safe co-working in the automated warehouse is the human psychological state. This aspect of *establishing human trust* is discussed in Section 4.3.

4.1 *Three-layered safety strategy*

Our safety strategy is based on dynamic safety fields around the robot. The strategy defines three distinct levels of safety: *critical (red), warning (yellow)* and *clear (green)*. The levels classify the "degree of safety" in which the robot is currently operating in relation to outside elements such as humans and other robots while also taking into account the nature of the operation being performed by the robot itself.

The green level corresponds to a clear state, i.e., even if the robot is detecting obstacles (i.e., human, robot, warehouse infrastructure) those are at a safe distance from the observing robot. Therefore, the robot is clear to continue working with its current setup and parameters.

The yellow level is a warning state. Here, the robot has detected an obstacle closer than a certain threshold and has to *adapt its behaviour* to guarantee that it is operating in a safe state. The dimension and impact of this adjustment is dependent on its current operation and the nature of the detected obstacles. If the robot is moving inside the warehouse, it might be necessary to reduce its velocity, but if it is performing an operation with its manipulator it might be necessary to not only decrease the speed of the joints but also to change the areas within which the arm is allowed to move about.

Finally, the red level is the critical level. When the robot is at this level, a human or another robot is very close and it is under safety threat. Therefore, every action needs to ensure that neither the human, other robot nor the robot itself are injured or damaged. In most cases, the natural decision is to perform category 2 stop on the robot, i.e., stop the movement of the arm or the robot platform completely in a controlled manner.

To classify the safety state (green, yellow or red) and alter the robot's behavior accordingly, the nature of the detected object (i.e., human, robot, infrastructure) and the current context (i.e., operation being performed) should be taken into consideration. To help the human establish *trust* on the robot, it is also important to inform the close-by detected human about the robot's safety state. This can be performed through triggering a cue and/or even using augmented reality devices to get the alerts and detailed information of the robot, similar to the approach of (SafeLog 2017).

Additionally, in a truly collaborative scenario, there may arise situations where the human and robot will have to almost touch each other in order to complete some task. For instance, a scenario where a robot needs to give an item to a human or the other way around. Here, the human will most likely be very close to the robot and, based on the nature of the interaction, the decision to completely stop the robot might not be applicable. Although the robot needs to be allowed to perform some actuation to conclude the previously mentioned operation, other types of actuation should be extremely limited if not forbidden. E.g., the robot needs to be able to actuate the gripper and perhaps some other parts of the manipulator itself, but these movements should be performed under severe constraints, while the overall movement of the robotic platform should be forbidden.

We envision that an advantage of using different safety fields will be the increased performance of collaborative operations. Instead of completely stopping the robot in the presence of humans, it would be better if the robot could keep performing its operations in a constrained manner. Further, due to dynamically changing sizes of the fields based on the input data and calculated risk[2], the robot could maneuver efficiently even in small places, e.g., by reducing field sizes in the presence of no risk.

4.1.1 *Offline safety analysis*

To analyze the safety of the generated plan (generated by the planning service) from a tactical perspective, offline safety analysis is performed before actually sending those plans to robots. This analysis is implemented by running the candidate plan in a realistic simulated environment (i.e., using 3d physics-based robotics simulator such as V-REP (Rohmer, Singh, and Freese 2013) or Gazebo (2017)). The purpose of this step is to reduce the possibilities of unforeseen situations, e.g., robots moving too close to one another, which could lead to unnecessary recalculations by the planning service.

The simulation reproduces all objects, robots and other devices[3], and receives as input a starting state for the warehouse and a plan to be implemented. The offline safety analysis module returns a feasibility status (whether the plan is feasible/safe or not) and a level of risk associated to following the given plan. In order to calculate this level of risk the following measurements can be used: the number of robots crossing closely to other robots or obstacles,

[2]Risk assessment module will calculate the risk level for situations in real-time as described in Section 4.2.

[3]At this moment we are not considering modeling humans in the simulated scenario due to the complexity and unpredictability of human behavior. Future work could address this point to bring the safety evaluation closer to that of the real scenario.

the waiting time for other robots to move away in order to pick up or drop products and the number of times robots have to access the same shelf.

4.1.2 *Online safety analysis at robot*

While the offline analysis is responsible for dealing with safety at a tactical level, robots are responsible for handling most of the safety requirements at the operational level. The robots must be capable of not only detecting static and dynamic obstacles but also identifying the human workers. To detect the human workers, a variety of techniques and sensors can be applied. When a worker is detected within a minimal distance, the robot must enter a mode where its power and force are limited to a threshold to ensure no physical harm to the worker, but may still allow physical contact between them (ISO 2016). This method of operation avoids a complex tracking of all human movements and distances from the robot parts, yielding a simpler and more straightforward system.

Interactions that strictly happen among robots, have fewer safety requirements. In these situations, robots must be aware of their poses and collision avoidance techniques such as Singh and Krishna (2013) and Belkhouche (2017) can be applied. When dealing with static objects (such as shelves, conveyor belts, walls and non-interactive equipment), the robot can follow classical collision avoidance behavior like (Khatib 1986), since in those scenarios safety requirements are not so demanding.

Each robot in our scenario is modeled as an autonomous cognitive agent which is capable of highlevel decision-making[4], i.e., it has its own goals, perception, actuation and decision-making capabilities. Even though our control strategy contemplates a centralized planning service, which can perform planning at the level of the whole warehouse and send tasks to each robot, a minimum level of autonomy at each robot is necessary to deal with unforeseen events. For example, when the robot receives a high level task, its cognitive agent would then perform a local safety analysis for the received task/instructions. If the instructions are deemed unfeasible or too risky, the robot tries to find an alternative way of accomplishing the tasks. A diagram that illustrates the connection between robot, its cognitive agent, its digital twin and the environment can be seen in Figure 3.
