Each robot must be able to acquire information about its current environment from a multitude of sources, of both proprio- and exteroceptive nature, and be able to fuse this information to build a complete perspective of its state and the world around it.

[4]We are implementing the high-level control of robots as cognitive agents (Laird 2012), which are capable of reactive and deliberative decision-making. We believe such an approach can produce more resilient robotic agents that are able to adapt to unforeseen scenarios.

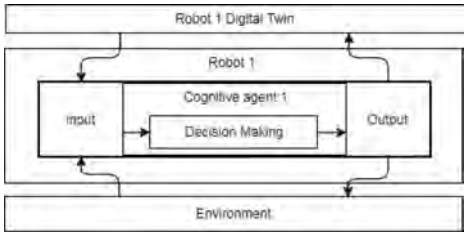

Figure 3. Cognitive control at each robot is responsible for monitoring the environment, with instructions from warehouse controller coming via digital twin. The robot then reasons about the most appropriate way to perform those instructions given what it knows about the local environment through its sensors' input.

For environment perception, we choose cameras and LiDARs to detect static and dynamic obstacles in the vicinity of the robot. Cameras can have additional application by capturing some special vests/tags on the humans (e.g., ANSI/ISEA 107-2004) to facilitate the process of human detection. Robots' set up also includes wheel encoders and IMU for self localization. As the position estimation is a key component to avoid close encounters between robots and workers, we consider the usage of radio triangulation, through technologies such as Wi-Fi, Bluetooth Low Energy, Ultra-Wideband, together with the encoders and IMU data (Jiménez and Seco 2017).

4.2 *Risk assessment*

We consider to implement a risk assessment algorithm (e.g., fuzzy logic, neural networks, or neuro-fuzzy as described in (Viharos and Kis 2015)) to calculate the risk level (i.e., high, medium, low) and then calculating the sizes of the dynamic safety fields based on the calculated risk level. The algorithm will be implemented within the cognitive agent's *decision making* module. Proprioceptive and exteroceptive data is input from the chosen sensors to the module, based on which the risk assessment algorithm will calculate the current risk level for the robot.

Depending on the level of risk calculated by the agent, module 1) changes/recalculates the sizes of the fields and 2) the robot's behavior is modified in order to increase safety accordingly, as shown in Figure 4.

For example, if no object detected within the warning or critical fields, and the area where robot has to move is narrow, then the size of the field can be reduced so that robot can move safely within the area. If a human/object is detected moving fast towards the robot then it should not only reduce the speed but also increase the size of the fields around it to avoid any hazardous situation.

For safety reasons, in our scenario the arm is not used while the robot's base is in movement. The arm

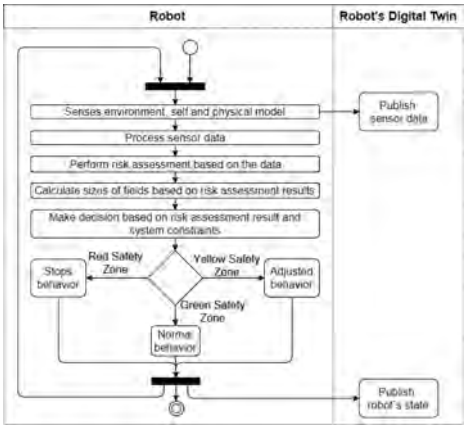

Figure 4. Workflow to execute the proposed safety strategy.

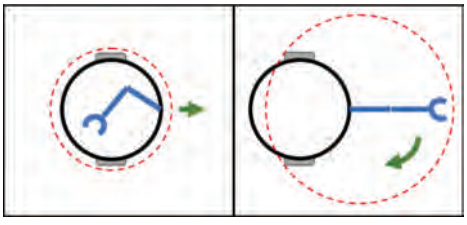

Figure 5. Difference in risk assessment for the cases when the robot is moving (to the left) and when it is standing still and moving its arm around (to the right). Green arrow indicates movement.

stands still at a position within the base's bounding box. When the robot's base is standing still, the robotic arm is then able to move for performing its pick-up and drop actions. This scenario is illustrated in Figure 5, where red dotted lines represent the areas considered to be critical for human interaction.

4.3 *Discussion on establishing human trust*

It is necessary to ensure that the worker feels comfortable and safe when cooperating with a robot, and that mental strains associated with such tasks are bearable. Three influential factors to assess the worker's mental strain (including distance, speed and warnings of motion) were varied in order to define design criteria to improve human worker comfort in (Arai, Kato, and Fujita 2010). Suitable training of the worker is reflected in the ISO/TS 15066:2016 (ISO 2016). Training clearly has an influence on his/her confidence and stress levels as well as their safety.

We propose that the robot informs the identification of human/other robot in its safety zones through a visual cue (a visual indication, for example a led panel on the robot), sound alert or augmented reality. To exemplify, if used visual cues, a red light can be displayed when human is identified inside the red zone, a yellow light for yellow zone and green light for the rest to specify that robot is performing its operation normally). In this way the human feels informed about the robot working and feels safe while performing collaborative tasks. The robot performs similar actions when another robot comes closer to it.

Most works often focus on the task of increasing trust of humans on machines. However, human trust on the automated system should not be blind. Excessive trust could be as harmful (or even more) as a lack of it. Therefore, the concept of "calibrated trust" should be explored (Lee and See 2004).

Calibrated trust tries to minimize the mismatches between trust and the capabilities of automated systems. Over-trust means poor calibration in which trust exceeds what the system is capable of delivering, and distrust means not trusting the system enough, thinking it is not capable of delivering what in fact it can. Both scenarios are undesirable because they could generate safety issues (e.g., over-trusting an autonomous car with level 3 autonomy to behave like one with level 4 autonomy *Automated driving* (...), see weblink in 'References' section) and reduced efficiency (e.g., a worker insisting on doing by hand something that is already automated).

With that in mind, we intend to increase the level of human-machine mutual understanding (Azevedo, Raizer, and Souza 2017), by making clear to the human user the intentions and motivations that led the automated system to make its decisions.

5 CONCLUSIONS AND FUTURE WORK

In this position paper, we have presented a detailed architecture to realize a safe collaborative automated warehouse scenario. We have proposed a safety strategy that combines the safety analysis performed globally by the warehouse controller (offline safety analysis) and locally by the robot itself (online safety analysis). The simulation-based offline analysis will check the safety of the high level plans for the robots at a higher level, and will ensure that collisions will not happen.

Considering the dynamism of the warehouse, unexpected changes in the robot and human plan may occur at run-time. To address unforeseen events, we have presented a three-layered safety field approach to be applied by the robots to adjust their behavior locally.

Currently, we are implementing the proposed architecture in a simulated scenario using V-REP simulator. For future works, we will extend the simulation with our proposed three-layered safety strategy. We will also implement it using physical

robots. It will consists of the implementation of the risk assessment module, and the three-layered safety strategy. Results will be evaluated using a set of Key Performance Indicators (KPIs) based on safety requirements, and the overall performance of the warehouse. We also intend to imbue each robot with learning capabilities, so it can adapt to situations that are particular to the warehouse. For instance, robot A is picking up a product at the shelf while robot B is waiting to do the same. Robot B could learn that pick up action at this particular shelf takes longer than at others, and adjust its behavior accordingly (e.g. should it keep waiting or should it move to another shelf?). Another future direction could be to extend the simulation with a human model and work on trust aspects to bring the safety evaluation closer to the real world.

A flexible simulation model of the operation and maintenance process of a complex technical system

J. Malinowski
Systems Research Institute, Polish Academy of Sciences, Warsaw School of Information Technology, Warsaw, Poland

ABSTRACT: The paper presents a versatile simulation model of the operation process of a complex technical system. Among other features, the model assumes dependencies between the system's components, and a priority-based maintenance/repair policy implemented by a limited personnel. Over the recent decades various maintenance models were investigated with the aim of optimizing the maintenance costs. Most researchers pursued analytical approach, hence the obtained results hold true under quite restrictive assumptions imposed for the purpose of analytical tractability (mutual independence of components, exponential time-to-failure and time-to-repair, no waiting time for repair, etc.). The model described herein is free from such limitations, as it is designed to compute the system's reliability or performance indices by way of simulation rather than analytically. The following features make it more realistic than many other models from the relevant literature: 1) the components are mutually dependent, i.e. a component's state change affects the failure rates of some other components, 2) repairs can be perfect, imperfect, or minimal, 3) due to a limited maintenance personnel, a failed component may have to await its repair in a priority queue, where the priority level depends on the component's importance, 4) a component state may be unobservable, in which case hidden failures are revealed by inspections. Using such a model, the optimal or near optimal parameters of an assumed maintenance policy can be found by repeated simulation. Any performance index expressed as a priori known function of these parameters can be subject to optimization. The author's main result is a non-trivial simulation algorithm encompassing the model's comprehensiveness. Clearly, the simulation approach, although time-consuming, allows to avoid elaborate analytical derivations which, in the absence of simplifying assumptions, become unreasonably complicated or impossible as the system's complexity increases.

1 INTRODUCTION

Over the recent decades numerous researchers investigated various maintenance models with the aim of optimizing the maintenance policies of the modeled systems. They mainly used analytical approach, hence most of the obtained results hold true under quite limiting assumptions imposed for the purpose of analytical tractability (mutual independence of components, exponential TTF/TTR, no waiting time for repair). See Couchan et al. (2013), Nakagawa (2008a), Nakamura et al. (2017), Sarkar et al. (2011), and Wang (2002) for surveys of more or less recent works on the subject.

The model presented in the current paper is free from such limitations, as it is constructed for the purpose of simulating the system's behavior rather than analytically computing its reliability or performance indices. This model assumes that the system is composed of two-state mutually dependent components, which means that the aging rate of a component may depend on the states of other components. When failed, a component is either replaced or repaired, depending on its wear-related age measured by integrating the component's changeable aging factor over time up to the moment of failure. A component is also replaced on reaching the age limit for its operation, even if it is still in operating condition (preventive replacement). Repairs and replacements are performed by a limited maintenance personnel, hence a failed component may have to wait in a maintenance queue for being serviced. There are multiple queues corresponding to various priorities assigned to individual components. The components waiting in a higher priority queue have precedence over those in the lower priority queue, and each queue is a FIFO sequence.

Based on the above model, a simulation framework for the reliability analysis of a complex technical system is constructed. By assumption, the simulation begins at time $t_0 = 0$, when all the components are new and operable. The simulation procedure produces a sequence of time instants at which changes of components' states occur, i.e. if

t_k is the time when a component changes its state, then t_{k+1} is the time of the subsequent state change of the same or another component, $k \geq 1$. More accurately, t_1 is the time of the first component failure, and either of the following events takes place at each subsequent t_i, $i > 1$:

- a component fails
- a component's hidden failure is detected
- a component's age reaches age limit for operation
- a component's repair or replacement is completed

Depending on a component, its failures can be self-revealing or hidden. In the first case a failure and its detection are simultaneous events; in the second case a failure can only be detected at the next inspection or preventive replacement, whichever comes first, and until then the component remains in the state of undetected failure. A binary vector defined in the next section is used to distinguish between the two types of components. Upon a failure detection, either the component's repair or replacement is started (if at least one maintenance team is available), or (if all the teams are busy) the component is placed in the respective maintenance queue, following the rules given in section 4.

The proposed simulation model has a number of changeable (adjustable) parameters. One of the key parameters is the age limit on a failed component's repair; if a component's failure is detected before its operating age has reached that limit, then the component is scheduled for repair, otherwise it is scheduled for replacement. Another key parameter is the age limit for a component's operation; when this limit is reached, the component is put out of operation and scheduled for replacement regardless of its state. Clearly, the value of the former parameter should be smaller than the value of the latter one.

Each failure, repair, and replacement incurs a cost, and so does a sojourn in a failed state. The system operator's aim is to minimize the overall operating cost over a certain period of time, or the average operating cost per unit time over an indefinitely long period. This aim can be achieved by appropriate adjustment of the aforementioned changeable parameters (decision variables). This can only be done by means of the trial-and-error method combined with the repeated simulation, as the model's complexity practically excludes analytical optimization methods.

2 ACRONYMS AND NOTATION

CDF – cumulative distribution function
PDF – probability density function
TTF – time-to-failure
TTR – time-to-repair
IFR – increasing failure rate
n – number of components
$e_1,\ldots,e_n$ – the individual components
Q – number of priority levels (maintenance queues) for maintenance scheduling
R – number of maintenance teams
D(i) – set of components whose states affect the aging rate of e_i; let us note that $i \notin D(i)$
$X_i(t)$ – the reliability state of e_i at time t; $X_i(t) = 1$ if e_i is in operation, and $X_i(t) = 0$ if e_i is failed or under repair
$Y_i(t)$ – the operational state of e_i at time t; $Y_i(t) \leq -1$ when e_i is awaiting repair, $Y_i(t) = 0$ when e_i is undergoing repair, $Y_i(t) = 1$ when e_i is in operation, and $Y_i(t) = 2$ when e_i is in the state of undetected failure
$a_i(t)$ – the aging rate of e_i at time t; $a_i(t)$ can differ during e_i's lifetime and, if $Y_i(t) = 1$, it is dependent on the states of e_j, $j \in D(i)$
$A_i(t)$ – the age of e_i at time t, defined as $\int_{[0,t]} a_i(s)\,ds$, where t is counted from the last moment when e_i was first put in operation or replaced;
$T_i(t)$ – the prospective sojourn time of e_i in the state $Y_i(t)$, as counted from t, provided that the aging rate after t is constant and equal to a(t). The prospective and actual sojourn times may differ, because e_i's aging rate may change before the prospective time elapses.
V[i] – age limit for e_i's repair, i.e. if t is the time of e_i's failure (or its detection) and $A_i(t) \geq V[i]$ then e_i will be replaced rather than repaired
W[i] – age limit for e_i's operation i.e. e_i will be replaced at time t, regardless of its state, when $A_i(t)$ reaches W[i]. Clearly, W[i] > V[i]
dtc[i] – a binary variable stipulating whether failures of e_i are self-revealing; if so, then dtc[i] = 1, otherwise dtc[i] = 0
S – time between consecutive inspections that are necessary to reveal failures of e_i for which dtc[i] = 0
A_i^* – age of e_i at its failure or preventive replacement, whichever comes first; A_i^* is simulated each time when e_i enters state 1, i.e. when new, replaced, or repaired e_i is put in operation
sim(i, 1, A) – a function simulating the random age of e_i at which its failure will occur, given that e_i is in state 1 and its already accumulated age equals A
sim(i, 0, A) – a function simulating the random duration of e_i's repair (A < B[i]) or replacement ($A \geq B[i]$), given that A is the already accumulated age of e_i
prt[i] – the maintenance priority level of e_i
len[q] – the current length of the repair queue no. q
ind[q, r] – the index of the component awaiting its turn in the r-th place in the q-th queue
avl_r – the number of currently available repair teams

$C_f[i]$, $C_{rpr}[i]$, $C_{rplc}[i]$ – the costs of e_i's failure, repair, or replacement respectively

$c_{und}[i]$ – the unit cost of e_i's sojourn in state 2 (undetected failure)

$C_{idl}[i]$ – the unit cost of e_i's sojourn in idle (≤ 0) state (awaiting or under maintenance)

c_{team} – the unit cost of employing one team

c_A – average total operating cost per unit time

3 A COMPONENT'S LIFE CYCLE

The functioning of a single component can be modeled by a stochastic process with the state-space $\{\ldots, -1, 0, 1, 2\}$. The assignment of individual states is shown below:

–1 or less: a component placed in a repair queue,
0: a component under repair,
1: an operable component,
2: a component with undetected failure.

If a component is in a "negative" state, then this state's absolute value of determines the component's place in the respective repair queue. Fig. 1 illustrates all possible inter-state transitions. Let us note that all the "negative" states are grouped into one.

The above diagram can be simplified if a component's failures are self-revealing, i.e. it never enters state 2. In such a case the node representing the state 2 can be deleted along with the adjoining links.

The diagram in Fig. 2 illustrates the transitions to or from the "negative" states, i.e. placements in the repair queue, forward moves in the queue, and repairs completions. It is assumed that multiple repairs are never completed simultaneously (simultaneous completion is an event of probability 0).

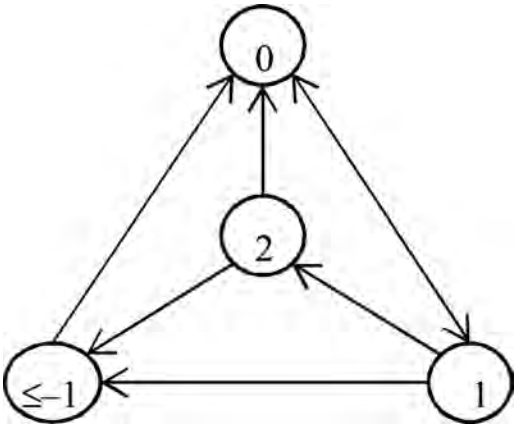

Figure 1. The diagram of a component's inter-state transitions.

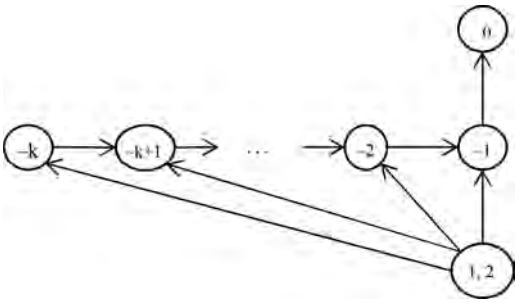

Figure 2. A diagram of transitions to or from the "negative" states.

Otherwise, transitions from – k to min(–k+s,0), where $k \geq 2$ and $2 \leq s \leq r$, would also be possible, which would increase the diagram's complexity.

4 THE MAINTENANCE POLICY RULES

A failure of e_i is revealed immediately if $dtc[i] = 1$. In turn, if $dtc[i] = 0$, then e_i's failure is revealed at the time of the next inspection. When this happens, e_i's maintenance is performed immediately provided that the maintenance personnel is available, otherwise e_i must wait for its turn. Furthermore, when the age of e_i reaches $W[i]$, it is either replaced or scheduled for replacement, no matter what its state is (if e_i is still operating, its operation is stopped). The components awaiting maintenance are placed in Q (logical) queues, corresponding to different maintenance priority levels. The levels assigned to individual components are stored in one-dimensional array $prt[\cdot]$, where $prt[i]$ is the level assigned to e_i. Components on priority level q are placed in the q-th queue, $1 \leq q \leq Q$. Each queue has the FIFO property, i.e. components with equal priority are placed in the respective queue in the order of their failure times—the recently failed one is placed at the end of the queue. The components in the q-th queue are scheduled for maintenance ahead of those in the (q+1)-st queue, $1 \leq q \leq Q–1$, i.e. the lower the component's priority level, the sooner its maintenance will start. Summing up, the component e_i awaits repair in the queue whose number is given by $prt[i]$, and the (negative) state of e_i determines its place in this queue.

If e_i is repairable and the time of its maintenance arrives, then e_i undergoes repair, provided that its age has not reached the limit $V[i]$. If e_i's age is greater or equal to $V[i]$, then it undergoes replacement rather than repair. It is necessary to be aware of the difference between $V[i]$ and $W[i]$. $V[i]$ is the age limit for e_i's repair. If e_i's age reaches or exceeds $V[i]$ and e_i fails, then e_i is only subject to

replacement. W[i] is the age limit for e_i's operation. If e_i's age reaches or exceeds W[i], then e_i will be replaced even if it is in the operating state.

5 THE SIMULATION ALGORITHM

According to the maintenance model presented in the previous sections, the following algorithm, simulating the system's operation, will now be presented. The core of this algorithm is the procedure generating the sequence $(t_k, k \geq 1)$ which, as indicated in the Introduction, is the sequence of time instants at which components change their operational states. The algorithm operates in a loop consisting of the following steps:

1. At $t_0 = 0$ all variables characterizing the maintenance process, defined in the Notation section, are given their initial values. The respective pseudocode is given below.

   k ← 0; t_0 ← 0; len[q] ← 0, q ∈ {1,…,Q}; avl_r ← R;
   for i = 1,…,n do {
   ··$Y_i(t_0)$ ← 1; $A_i(t_0) = 0$; A_i^* ← min(sim(i,1,0), C[i]); ··$T_i(t_0)$ ← $A_i^*/a_i(t_0)$
   }

   Since all components are in state 1 at t_0, their prospective sojourn times in this state are simulated with the use of sim(i, 1, 0). In order to obtain $T_i(t_0)$ the simulated age has to be divided by $a_i(t_0)$, as follows from the definitions of $A_i(t)$ and $T_i(t)$.
2. Increase k by 1
3. Compute t_k by taking the smallest $T_i(t_{k-1})$ over all e_i that are in non-negative states at t_{k-1}; the components in negative states, i.e. those awaiting repair, are irrelevant to the system behavior in the interval $[t_{k-1}, t_k)$. Also, add $a_i(t_{k-1})\cdot(t_k - t_{k-1})$ to $A_i(t_k)$ for each e_i that is not in state 0 at t_{k-1} (the aging rate of a component under maintenance equals 0).
4. Assign $Y_i(t_{k-1})$ to $Y_i(t_k)$ for each i, so that each component that does not change its state at t_k will remain in the same state in which it was at t_{k-1}.
5. Compute $Y_i(t_k)$ for each e_i that is in non-negative state at t_{k-1} and changes its state at t_k. Each such e_i is identified by checking if its sojourn time in the state $Y_i(t_{k-1})$, as counted from t_{k-1}, equals $t_k - t_{k-1}$.[1] For any e_i fulfilling this condition we have:

   1. if $Y_i(t_{k-1}) = 1$, then e_i changes its state to 2 at t_k provided that dtc[i] = 0 and inspection or preventive replacement does not coincide with t_k; otherwise (i.e. dtc[i] = 1, or dtc[i] = 0 and inspection or preventive replacement is performed at t_k) e_i is queued for maintenance, i.e. e_i enters an appropriate negative state at t_k.
   2. if $Y_i(t_{k-1}) = 2$, e_i is queued for maintenance at t_k,
   3. if $Y_i(t_{k-1}) = 0$, e_i's maintenance is completed at t_k, i.e. e_i changes its state to 1 at t_k.

   In case (3) one maintenance team is released, hence avl_r is increased by 1. Moreover, if e_i's age was greater or equal to V[i] when e_i entered state 0, e_i underwent replacement in state 0, hence its age is set to 0 at t_k. In view of the above analysis, step 5 is implemented in the following way:

   for each i such that $Y_i(t_{k-1}) \geq 0$ and $T_i(t_{k-1}) = t_k - t_{k-1}$ do {
   ··if ($Y_i(t_{k-1}) = 1$ and dtc[i] = 0 and $\lceil t_k/S \rceil \cdot S \neq t_k$
   ····and $A_i(t_k) \neq W[i]$)
   ··then $Y_i(t_k)$ ← 2
   ··else {q ← prt[i]; len[q] ← len[q] + 1;
   ····$Y_i(t_k)$ ← –len[q]}
   ··if ($Y_i(t_{k-1}) = 2$)
   ··then {q ← prt[i]; len[q] ← len[q] + 1;
   ····$Y_i(t_k)$ ← –len[q]}
   ··if ($Y_i(t_{k-1}) = 0$)
   ··then {$Y_i(t_k)$ ← 1; avl_r ← avl_r + 1;
   ····if $A_i(t_k) \geq V[i]$ then $A_i(t_k)$ ← 0}
   }
6. If avl_r > 0, set to 0 the states at t_k of at most avl_r components placed at the head of the repair queue, then update avl_r and the repair queue accordingly.
7. Compute the cost incurred during $(t_{k-1}, t_k]$ and add it to the total cost. The respective pseudocode is given below.
   C ← C + $(t_k - t_{k-1})\cdot R\cdot c_{team}$;
   for i = 1,…,n do {
   ··if ($Y_i(t_{k-1}) \leq 0$) then
   ····C ← C + $(t_k - t_{k-1})\cdot c_{idl}$[i];
   ··if ($Y_i(t_{k-1}) = 2$) then
   ····C ← C + $(t_k - t_{k-1})\cdot c_{und}$[i];
   ··if ($Y_i(t_{k-1}) \neq 0$ and $Y_i(t_k) = 0$) then
   ····if ($A_i(t_k) < V[i]$)
   ·····then C ← C + C_{rpr}[i]
   ·····else C ← C + C_{rplc}[i];
   ··if ($Y_i(t_{k-1}) = 1$ and $Y_i(t_k) \neq 1$ and fail[i] = 1) then
   ····C ← C + C_f[i];
   }

   Remark 1: The cost of repair or replacement is added when the respective action starts, because it is only then known whether ei's age has reached V[i].

   Remark 2: The last "if" adds C_f[i] to the total cost if e_i fails at t_k; fail[i] is defined in the explanation to step 8.

[1] Possible state changes at t_k of the components awaiting repair in the interval $[t_{k-1}, t_k)$ are secondary w.r.t. state changes of those which are in non-negative states in this interval. The former components' states at t_k are computed in step 6.

8. Determine $T_i(t_k)$ if e_i changes its state to a non-negative one at t_k, or e_i remains in state 1, but at least one e_j in D(i) changes its state. Otherwise assign $T_i(t_{k-1}) - (t_k - t_{k-1})$ to $T_i(t_k)$. The binary value fail[i] is set to 1 if e_i enters state 1 at t_k (e_i's repair or replacement is completed at t_k) and the age of e_i at its failure (simulated at t_k) doesn't exceed W[i] (e_i fails before or when it reaches its planned replacement age); fail[i] is used in cost calculation in step 7. Step 8 is implemented by following pseudocode:

```
for i = 1,…,n do {
··fail[i] ← 0;
··if (Yi(tk) ≠ Yi(tk–1) ) then {
····if ( Yi(tk) = 0) then
·····Ti(tk) ← sim(i, 0, Ai(tk));
····if (Yi(tk) = 1) then {
·····Ai* ← min( sim(i, 1, Ai(tk)), W[i]);
·····Ti(tk) ← (Ai* – Ai(tk))/ai(tk);
·····if (Ai* ≤ W[i]) then fail[i] ← 1
····}
····if (Yi(tk) = 2) then
·····Ti(tk) ← min( ⌈tk/S⌉·S—tk, (W[i]–Ai(tk))/ai(tk)
)
··}
}
```

Remark 1: cf. step 5 for the conditions of entering state 2.

```
··else if (Yi(tk) = Yi(tk–1) = 1
····and Yj(tk) ≠ Yj(tk–1) for at least one j∈ D[i] )
····then Ti(tk) ← (Ai* – Ai(tk))/ai(tk);
```

Remark 2: If any e_j, $j \in D(i)$, changes its state at t_k then e_i's aging factor also changes, hence $a_i(t_k) \neq a_i(t_{k-1})$ and $T_i(t_k) \neq T_i(t_{k-1}) - (t_k - t_{k-1})$, thus $T_i(t_k)$ must be calculated using the new aging factor.

```
··else
····Ti(tk) ← Ti(tk–1) – [tk – tk–1]
}
```

The function sim(i, 1, A) simulates, using a random number generator, the age of e_i at which its failure will occur, provided that e_i is in state 1 and its already accumulated age equals A. This function is called when e_i is put in operation, and then A = 0 for new or replaced e_i, or $0 < A < V[i]$ for a repaired e_i. The simulated value is used to calculate A_i^* which, divided by e_i's aging rate, yields the prospective sojourn time of e_i in state 1 from the moment when e_i enters state 1, provided that e_i's aging rate remains unchanged during e_i's sojourn in state 1. Since e_i's aging rate depends on the states of e_j, $j \in D(i)$, it is necessary to recalculate $T_i(t)$, using $a_i(t)$, at each time t when any e_j, $j \in D(i)$, changes its state during e_i's sojourn in state 1.

The function sim(i, 0, A) simulates the duration of e_i's repair or replacement depending on whether $A < V[i]$ or $A \geq V[i]$ respectively. If e_i enters state 2, i.e. $Y_i(t_{k-1}) \neq Y_i(t_k) = 2$, then $T_i(t_k)$ is calculated as $\min(\lceil t_k/S \rceil \cdot S - t_k, (W[i] - A_i(t_k))/a_i(t_k))$, because e_i must wait in state 2 until the time of the next inspection or until e_i's age reaches W[i], whichever comes sooner.

9. Go to step 2

For illustration, the algorithm's block diagram is shown in Fig. 3.

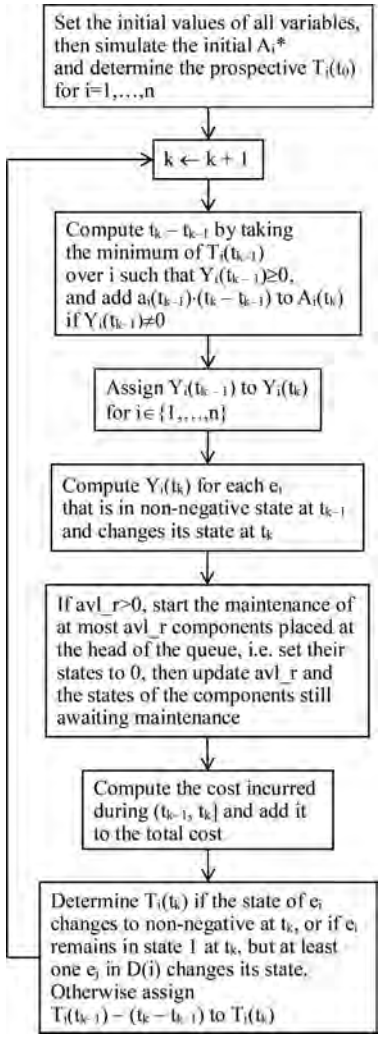

Figure 3. The simulation algorithm's block diagram.

6 THE ILLUSTRATIVE EXAMPLE

We will now present the numerical results obtained by the program based on the algorithm from the

previous section. As the complete version of the program is still under preparation, the results come from its simplified version developed according to the following assumptions:

- The components are independent, i.e. a component's aging rate does not depend on the other components' behavior and is constant during a component's lifetime ($T_i(t_k)$ needs not to be recalculated with the new aging rate when e_i remains in state 1 and another component changes its state at t_k).
- The network is built of non-repairable components; if a component fails, it is always replaced, irrespectively of its age. TTF and TTR of e_i are simulated by the functions sim(i,1) and sim(i,0) respectively. They do not variable A, because the age of a new or replaced component equals 0, and the age of an old component is irrelevant to its replacement time. In consequence, there is no age limit for e_i's repair, thus the only age limit—W[i] – is imposed on e_i's operation time.
- The failures of all components are self-revealing (dtc[i] = 1 for i = 1,…,n), thus no inspections need to be performed and the set of component states does not include state 2.

The example system has the following parameters:

Number of components: 5
Type of distribution of a component's TTF: Weibull
Scale parameter for TTF: 0.05
Shape parameter for TTF: 1.5
Type of distribution of a component's TTR: Weibull
Scale parameter for TTR: 0.5
Shape parameter for TTR: 1.5
Time unit: 1 day
Number of maintenance queues: 2
Components with priority 1: e_1, e_2, e_3
Components with priority 2: e_4, e_5
Number of maintenance teams: 1, 2, 3
C_rplc[i] – 1000
C_fail[i] – 4000
c_idl[i] – 900
c_team – 40

For the sake of this paper the following definition is adopted: a (two parameter) random variable T has Weibull distribution if the CDF of T is given by the following formula:

$$\Pr(T \le t) = 1 - \exp[-(\lambda t)^{\alpha}] \quad (1)$$

where λ and α are the scale and shape parameters respectively. It should be noted that in our example α is equal to 1.5 which is greater than 1. This is due to the fact that, as follows from the reliability theory, planned replacements are only cost-effective if the distribution of a component's TTF has the IFR property (see Barlow & Proschan (1975)). The Weibull distribution has this property only if $\alpha > 1$. Other than Weibull distributions of TTF and TTR are discussed in Barlow & Proschan (1975) and O'Connor & Kleyner (2011).

Table 1. The results of cost calculation for various W and R (* denotes the local minimum of c_A).

Our aim is to find the optimal age limit for a component's operation, i.e. the optimal age at which its preventive replacement should take place. The objective function to be minimized is the total operating cost per unit time. Let W*[i] denote the optimal age for e_i. As the components are stochastically identical, W*[i] are equal for all five components, i.e. W*[1] = … = W*[5] = W*. The obtained results of cost calculation for various values of W = W[1] = … = W[5] are given below:

The values of c_A in the first column are obtained for k_fin = 10.000, where k_fin is the number of cycles of the algorithm's main loop. Based on this accuracy (k_fin can serve as a measure of the simulation's accuracy) we conclude that c_A attains its minimum for W = 21 and R = 2. However, it is advisable to perform a more accurate simulation, because we can see that c_A fluctuates in the sampled interval $18 \le W \le 60$ and for each R it has more than one local minimum there, therefore a

more precise analysis of c_A's behavior is indicated. The computations for k_fin = 100.000 show that c_A as a function of W is not unimodal (has more than one local minimum) for each R = 1, 2, 3. The respective local minima are marked with asterisks. The optimal number of maintenance teams and the optimal value of W are equal to 2 and 25 respectively. Also, let us note that the intervals $30 \le W \le 45$ and $20 \le W \le 32$ for R = 1 and R = 3 respectively are uncertain" as regards determining the optimum value of W, but these values of R are of no practical interest, as the optimum number of maintenance teams equals 2.

7 CONCLUSION AND FURTHER RESEARCH

A newly developed algorithm simulating the maintenance process of a complex technical system, and the results of a computer program implementing this algorithm, have been presented. The author aimed at developing a software tool that would enable the system operator to assess the total cost incurred over a long operating time, and to minimize it by properly adjusting the decision variables, i.e. R, S, and V[i], W[i], i = 1,…,n, as defined in Section 2. Due to the complexity of the system model the analytical computation and optimization methods cannot definitely be used, thus Monte Carlo simulation combined with heuristic optimization is the only feasible solution.

The algorithm demonstrated in the current paper bears resemblance to the one presented in George-Williams & Patelli (2015). However, our approach focuses on the simulation of time points in which any system component changes its operational state. The time axis is divided into state-invariant intervals (no component changes its state in any such interval) thus allowing for very accurate analysis of the system operation process. It is also important that the components are mutually dependent and a component's aging rate depends on other components' states. The components states distinguished in the last-mentioned paper are different than in the present one, but the model considered herein is adjustable in this respect. Also, since failed components may await repair in a priority queue, our model makes it possible to analyze the system from the queuing theory (QT) viewpoint, enabling its operator to optimize the relevant (QT related) parameters.

The current paper defines the system operation cost as the sum of individual components' operation costs. However, the state of the whole system, expressed as an a priori defined function of the components' states (the structure function) can also be included in the overall cost calculation. Apart from the cost, other performance characteristics (e.g. the system availability) can be easily calculated, in a similar way as in step 7 in section 5.

Clearly, the main drawback of stochastic simulation is its high time complexity. The simplified version of the program, based on the assumptions from Section 6, executes in approximately 12 seconds if k_fin = 10.000, and 120 seconds if k_fin = 100.000 (on a PC machine with Intel® Core™ i5 CPU). This shows that, as expected, the execution time increases linearly with k_fin. Admittedly, the above execution times are relatively short as far as Monte Carlo simulation is concerned. However, this is due to a small number of components (5). If their number is changed to 10, the execution time increases to 22 seconds (k_fin = 10.000), which means that the algorithm's time complexity increases with n somewhat slower than at a linear pace. This is explained by the fact that steps 3 through 8 of the algorithm, except step 6, are implemented as "for" loops with n cycles, while step 6 requires avl_r (i.e. at most R) compound operations, and in a real system R is much smaller than n. Obviously, if the components are not identical (as in the provided example) and their number is high then the program may have to be run a large number of times in order to find the optimum values of the decision variables. However, the components in many systems can be divided in a number of groups such that the components in one group have identical parameters, which significantly reduces the number of decision variables, and, as a consequence, decreases the time complexity of the optimization task.

Summing up, we have endeavored to develop a possibly comprehensive algorithm that would encompass a wide range of maintenance models found in the relevant literature, and would also be applicable for practical purposes. It seems that this goal has been at least partly achieved, but there still remains considerable conceptual work to be done. The further research will be mainly concentrated on properly defining the dependence relations among the system's components, i.e. how the states of components in the set D(i) affect the aging rate of e_i. The issue of components dependence is considered in the following works: Zhang & Horigome (2001), Dukhovny & Marichal (2012), Yang et al. (2013), Nakamura et al. (2017), Zhang & Wilson (2017). Also, the algorithm should support various failure modes. Then, whether a failure is self-revealing or not may depend both on its mode and the failed component's type. Last but not least, the impact of external conditions (e.g. ambient temperature and humidity) on the components' aging rates should be taken into account in constructing future versions of the presented algorithm.

ABSTRACT: Recent field data indicates that pitch systems account for a substantial part of a wind turbines down time. Reducing downtime means increasing the total amount of energy produced during its lifetime. Both electrical and fluid power pitch systems are employed with a roughly 50/50 distribution. Fluid power pitch systems generally show higher reliability and have been favored on larger offshore wind turbines. Still general issues such as leakage, contamination and electrical faults make current systems work sub-optimal. Current field data for wind turbines present overall pitch system reliability and the reliability of component groups (valves, accumulators, pumps etc.). However, the failure modes of the components and more importantly the root causes are not evident. The root causes and failure mode probabilities are central for changing current pitch system designs and operational concepts to increase reliability. This paper presents a feasibility study of estimating pitch system reliability based on a failure rate prediction method for generic fluid power components. Special attention is given to the use of computer simulations for assessing working conditions such as flow, pressure, work cycle, fluid contamination concentration etc. The fluid power pitch system is co-simulated with the 5MW NREL wind turbine implemented in the FAST software. The estimated failure rates is compared to field data and comments are given to the correlation and discrepancies based on the uncertainties of the simulated conditions.

1 INTRODUCTION

Pitch systems are today employed on all modern multi-megawatt turbines and enable the turbine blades to rotate along their longitudinal axis in order to facilitate aerodynamic braking. This is used at wind speeds above rated and also for enabling safe emergency stopping of hub rotation. Multiple studies on turbine reliability and downtime have indicated the pitch system to be the most unreliable sub-system of the turbine (Wilkinson and Hendriks 2010, Carroll et al. 2015). Contributing to over 20% of total downtime, pitch systems not only introduce high risk, they also cause a significant loss of power production during the lifetime of turbines.

Typically modern turbines use either electrical or fluid power pitch systems, where this paper focus on reliability estimation of the latter. Currently, the most detailed publicly available field data on pitch system failures show the failure rate distribution among system components such as valves, pump, accumulators, cylinders, etc. (Carroll et al. 2015). Yet, the failure modes and root causes are not evident. Such information is crucial in order to identify critical areas of the system and to enable development of more reliable and safe concepts. Also, precise reliability estimates of system components allow for strategic maintenance planning which potentially reduces maintenance time and costs. In an attempt to reveal the highrisk areas of the pitch system, Liniger et al. conducted a systematic qualitative study on identifying critical components (Liniger et al. 2017). While the study showed promising results, the occurrence of failure modes was qualitatively determined using expert knowledge of generic fluid power systems. Thus, actual failure rates and operational dependent failure mechanisms of the pitch system in a wind turbine was not directly considered. Two quantitative studies have been conducted with the purpose of modeling fluid power pitch system reliability (Yang et al. 2011, Han et al. 2012). While these studies have aimed at creating the model basis for calculating

reliability, both the origin of failure modes and failure rates has not been fully covered. The only publicly available source of failure rate estimation for fluid power components known to the authors is the *Handbook of Reliability Prediction Procedures for Mechanical Equipment* (Jones 2011). This source presents failure rate models as functions of component dimensions, material properties and operating conditions.

The main contribution of this paper is a feasibility study of estimating pitch system reliability using the empirical failure rate models of (Jones 2011). Estimation of failure rates has the potential to close the gap in knowledge between the qualitative and quantitative studies while also incorporating turbine operating conditions into the framework. Operating conditions are generated using a simulation model of a fluid power pitch system and the 5MW National Renewable Energy Laboratory (NREL) wind turbine implemented in the Fatigue, Aerodynamics, Structures, and Turbulence (FAST) software. The estimated failure rates are compared to the most detailed and recent field failure rates available.

2 PITCH SYSTEM DESCRIPTION

The pitch system configuration used in this analysis is depicted in Figure 1 and component label description is found in Table 1. The system consists of a supply located in the nacelle of a turbine and the actuation located in the rotating hub. The supply consists of a fixed displacement fixed speed pump where pressure and flow are conditioned by dump valve V2 and relief valve V1. The supply connects to the rotating hub through rotary union R1. The actuation is a conventional fluid power cylinder drive, where cylinder position is controlled closed-loop and flow is metered by the proportional valve V6. Accumulators A1 and A2 stores energy which is used for extending the cylinder C1 in the event of an emergency shutdown.

The fluid power pitch system presented in Figure 1 is very similar to the system analyzed in the previous qualitative study (Liniger et al. 2017). The results of the previous study showed to correlate well to field failure data which indicates that the system presented here is similar to the real-life systems which are confidential. Note that conventional fluid power pitch systems also employ a locking circuit for keeping the blade pitch angle fixed when the turbine is shut down. The locking circuit and all system transducers are omitted in this analysis as their failure rates are negligibly small compared to that of the other system components (Carroll et al. 2015).

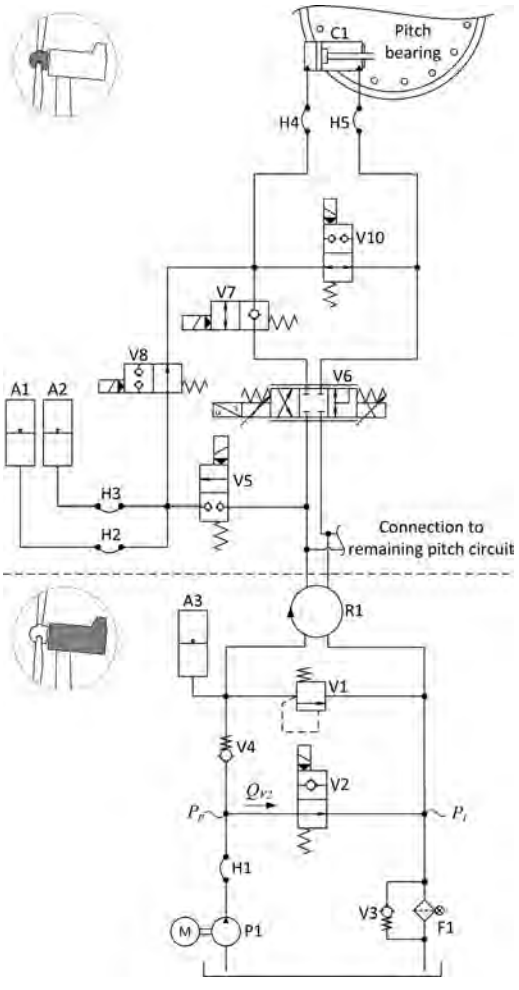

Figure 1. Fluid power pitch system diagram with indication of supply and actuation circuit locations in the wind turbine.

Table 1. Description of component labels.

Label	Description	Type
V1	Relief valve	Cartridge, poppet
V2	Solenoid dump valve	Cartridge, poppet
V3,V4	Check valves	Cartridge, poppet
V5,V7-V10	Solenoid valves	Cartridge, poppet
V6	Proportional solenoid valve	Module, spool
C1	Differential cylinder	
H1-H5	Flexible hoses	
A1, A2	Emergency accumulators	Gas charge, piston
A3	Pump accumulator	Gas charge, piston
P1	Fixed displacement pump	Internal gear

Table 2. Main data for the wind turbine and pitch system simulation model.

Turbine data	Value
Nominal power	5 [MW]
Nominal hub speed	12 [RPM]
Tower height	90 [m]
Blade length	63 [m]
Wind speed (Rated)	11.4 [m/s]
Turbulence model	Normal Turbulence Model (NTM)
Pitch system data	
Pitch cylinder (Rod/Piston/ Stroke)	Ø90/Ø140/1350 [mm]
Pump flow (Rated)	20 [l/min]
System pressure (Rated)	250 [bar]

3 WIND TURBINE SIMULATION MODEL

A simulation model of the fluid power pitch system operating in a wind turbine is utilized for generating operating conditions subsequently used for reliability estimation. The wind turbine model is based on the open-source data for a 5MW NREL turbine implemented in the FAST software (Jonkman and Buhl 2005). The main specification are given in Table 2.

It is noted that power capacity of the simulated turbine is above the 2–4MW range covered by the field data. The simulated operating loads may, therefore, be larger than those found in the real-life systems and possibly yielding higher estimated failure rates.

The dynamical model of fluid power pitch system is based on the layout described in the previous section and is developed in a previous study by the authors (Pedersen et al. 2015). The dynamical model is implemented in Matlab/Simulink and co-simulated with FAST. The model incorporates the compressibility of fluid in the cylinder chambers, proportional valve dynamics and kinematics of the cylinder-blade coupling. The pitch angle is controlled closed-loop using a gainscheduled PI-compensator. The main specification for the pitch system is given in Table 2.

4 OPERATING CONDITIONS

The operating conditions for the real-life turbines used in this feasibility study are unknown. Thus, the simulated system is operated under a wide range of conditions which are considered to fully cover the conditions of the real-life turbines. The considered range of operating conditions is mean wind speed, turbulence intensity, ambient temperature and fluid temperature. The full-field wind is generated using Turb-Sim (Jonkman 2009) and based on the IEC61400-1 wind turbine design standard Design Load Case (DLC) 1.2 (IEC 2006). This load case is used for evaluating fatigue loads of wind turbines during normal operation. While the pitch system is used for both stopping and starting the turbine, normal operation constitutes the majority of the system lifetime. Based on the availability of the real-life turbines (Carroll et al. 2015) and considering out-of-range wind speeds, the utilization percentage can be assumed to be 90%.

The mean wind speed is normally described using the Weibull probability density distribution which can be described by a shape and scale parameter (Hansen 2008). A 20-year baseline distribution shown by blue bars in Figure 2 from the Østerild location near the Danish shore is selected for the study. The black bars show the range of wind speed distributions considered by selecting shape and scale parameters ±20% from the baseline values. The wind distribution is discretized in twelve wind bins from cut-in to cut-out wind speed of the 5MW NREL turbine. To simplify the analysis, the wind direction is assumed to be ideal, that is, orthogonal to the turbine. Estimated failure rates for each wind bin is multiplied by the probability density and summarized to yield values comparable to the field data.

According to the DLC 1.2, turbulence intensity is categorized in either high (class A, 16%), medium (class B, 14%) and low (class C, 12%) for the Normal Turbulence Model (NTM). All three turbulence intensity classes are considered in the feasibility study.

The pitch systems are located in the hub and nacelle of the turbine which in most modern turbines is conditioned to be within a desirable operating temperature interval. Operating temperatures considered are T_{amb} = [0 20 60]°C.

Lastly, the fluid temperature is controlled during normal operation of the pitch system. However, it is not uncommon for the fluid temperature to be locally different than the desired value. T_{fluid} = [30 50 70]°C is selected to cover the expected range of temperatures.

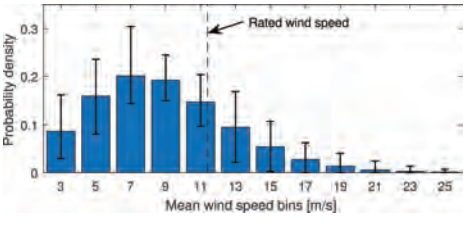

Figure 2. Mean wind speed distribution used in simulations. The black bars indicate the considered range.

5 FAILURE RATE ESTIMATION

Failure rates are estimated using the *Handbook of Reliability Prediction Procedures for Mechanical Equipment* (Jones 2011). The failure rate models are constructed such that an empirically determined base failure rate, λ_B, for a generic component is multiplied with several non-dimensional factors, C_1, C_2, C_3…, describing both material, dimensions and operating conditions for estimating the failure rate.

Some failure rates estimations are dependent on operating temperature. The operating temperature for components with direct fluid contact is set to the fluid temperature. Solenoids are if they are operated, set to the ambient temperature plus a constant offset accounting for joule heating. The offset is 100°C for valves that are continuously on during normal operation. Valve V2 is operated intermittently, thus reducing the temperature offset to 70°C. The temperature offsets are confirmed from measurements (Liniger et al. 2018).

Failure rate estimates are influenced by the amount of allowable leakage for seals and valves in the system. For pitch systems, external leakage is in most cases much more critical than internal leakage due to environmental contamination hazard of the turbine surroundings. External leakage is generally set to a very low value of $2 \cdot 10^{-7}$ l/min corresponding to a few drops a month. Allowable internal leakage is set to 10^{-4} l/min for seat valves and seals. Proportional spool type valves are normally associated with higher internal leakage, and the allowable limit for valve V6 is therefore set to 2 l/min.

Operating cycles of the valves, cylinders and accumulators are used for assessing the failure rates. Operating cycles for on/off valves are simply determined from the number of activations during normal operation. For proportional valve V6, cylinder C1 and the accumulators, the operating cycles are determined using rain-flow counting and a minimum travel threshold. The minimum threshold for C1 and the accumulators is selected to 2 mm. For valve V6, the minimum threshold is 0.2 mm. Due to the uncertainty of the threshold values, a sensitivity study is conducted in the results Section 5.2.

Contamination concentration in the fluid is also considered in the failure rate estimation. The contamination concentration at each component N_{10} is determined by the particles generated from upstream components according to the rates specified in (Jones 2011). Additionally, a particle filtration size of $C_n = 3$ μm for filter F1 is utilized in the calculations.

To simplify the description, the details for failure rate estimation of one component are given in the following section. The cartridge poppet type valve V2 is selected since valves are the most used component type in the system. Also, the failure rate estimation procedure for the parts in valve V2 is similar to most of the remaining components. All component specifications are similar to those found in actual pitch systems working in turbines with similar power capacity as for the real-life systems.

5.1 *Cartridge poppet valve V2*

Cartridge Valve V2 is shown in Figure 3. Valve V2 consists of several parts where dimensions, material and specifications are given in Table 3. All notations follow (Jones 2011) and pressures and flows are denoted according to the diagram in Figure 1. The operating time t_H is given in hours and N_{V2} denote the operating cycles of valve V2. Note that both the factors for surface finish (roughness) for the seat valves and Young's modulus for O-rings increase with time. The estimated failure rates for these parts are therefore increasing with time.

As an example, the multiplication factors for the main poppet are given in Table 4 and values are determined from a nominal operating scenario. The nominal operating scenario covers one calendar year of operation at ambient temperature T_{amb} = 20°C, fluid temperature T_{fluid} = 50°C, rated wind speed and turbulence class B. The pressure and flow rate multiplication factors depend on simulated pressure and flow time series. Multiplication factor values C_p and C_w represented in Table 4 are mean values. Due to length limitations, the time series are not shown but can be found in the work by Pedersen et al. (Pedersen et al. 2015).

The multiplication factors C_p, C_q, C_v, C_n, C_s, C_w are seen to cover operating conditions for pressure and flow. C_f, C_{dt}, C_{sw} depend on the dimensions and manufacturing of the valve. The main poppet failure rate for the nominal operating scenario is determined according to:

$$\lambda_{V2,m} = \lambda_{B,SV} C_p C_q C_f C_v C_n C_s C_{dt} C_{sw} C_w \frac{N V_2}{t_H} \qquad (1)$$

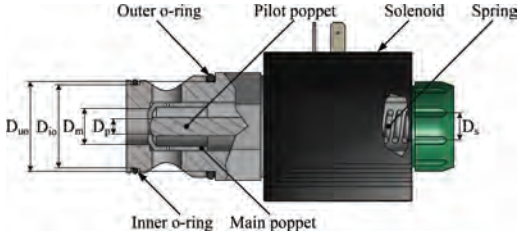

Figure 3. Cartridge poppet type valve V2 with part dimensions.

Table 3. Cartridge poppet type valve V2 data related to failure rate estimation.

Part	Dimension		Material	Specification	
Main	Seat diameter	$D_m = 15$ mm	Steel	Seat valve base failure rate	$\lambda_{B,SV} = 1.4 \cdot 10^{-6} \frac{\text{failure}}{\text{cycle}}$
Poppet	Seat width	$D_{mw} = 2$ mm		Seat pressure drop	$\Delta P_m = P_p - P_t$[bar]
				Rated flow	$FR_m = 140$ l/min
				Allowable leakage	$Q_{mf} = 10^{-4}$ l/min
				Surface finish	$F_m = \begin{cases} 15.10^{-5} \cdot N_{V2} + 0.2[\mu m] \\ \quad \text{for} \quad N_{V2} <= 4000 \text{ cycles} \\ 1.5 \mu m \\ \quad \text{for} \quad N_{V2} > 4000 \text{ cycles} \end{cases}$
Pilot Poppet	Seat diameter Seat width	$D_p = 5$ mm $D_{pw} = 0.5$ mm	Steel	Rated flow Allowable leakage	$FR_p = 1$ l/min $Q_{pf} = 10^{-4}$ l/min
Spring	Coil diameter	$D_s = 15$ mm	Steel	Spring base failure rate	$\lambda_{B,S} = 23.8 \cdot 10^{-6} \frac{\text{failure}}{\text{hour}}$
	Wire diameter	$D_{sw} = 2$ mm		Operating cycle rate	$\frac{N_{V2}}{t_H} \left[\frac{\text{cycle}}{hour} \right]$
				Active coils	$N_a = 7$
				Compression length	$C_L = 5$ mm
Outer	Inner diameter	$D_{io} = 30$ mm	NBR-70	Seal base failure rate (static)	$\lambda_{B,SS} = 2.4 \cdot 10^{-6} \frac{\text{failure}}{\text{hour}}$
O-ring	O-ring diameter	$D_{uoø} = 2.62$ mm		Allowable leakage	$Q_{uof} = 2 \cdot 10^{-7}$ l/min
				Seal pressure drop	$\Delta P_{uo} = P_p - P_{atm}$ [bar]
				Youngs modulus	$E_{NBR70} = 59 \cdot 10^{-6} \cdot t_H + 6.2$ [MPa]
				Mating surface finish	$F_{uo} = 0.8$ μm
Inner O-ring	Inner diameter O-ring diameter	$D_{uo} = 28$ mm $D_{uoø} = 1.78$ mm	NBR-70	Allowable leakage Seal pressure drop	$Q_{iof} = 10^{-4}$ l/min $\Delta P_{io} = P_p - P_t$ [bar]
Solenoid			Insulation	Solenoid base failure rate	$\lambda_{B,S} = 2.77 \cdot 10^{-6} \frac{\text{failure}}{\text{cycle}}$
			class-H	Coil temperature	$T_{coil} = T_{amb} + 70$ [°C]
				Operating cycle rate	$\frac{N_{V2}}{t_H} \left[\frac{\text{cycle}}{hour} \right]$

The main poppet and remaining part failure rates of valve V2 are given in Table 5.

Clearly, the solenoid contributes with the highest failure rate of the valve. The lowest failure rate exists for the inner o-ring. The main and pilot poppet and the spring are seen to yield similar failure rates.

5.2 *Results*

The feasibility study of the described estimation method is performed by comparing estimated failure rates to field failure rates. The field failure rates are divided into six component groups, namely accumulators, valves, pump, cylinder, rotary union, and hoses. The system presented in Figure 1 is likewise divided in the six component groups. The accumulator group consists of A1-A3. The valve group cover V1-V10 and the hose group is constructed from hoses H1-H5. Each estimation case utilize all combinations of wind speed profiles as given in Figure 2 and turbulence intensity classes A, B and C.

Figure 4 shows the comparison between the estimated and field failure rates for a range of ambient temperatures. The black error bars indicate the

Table 4. Failure rate estimation and multiplication factors for main seat valve in V2 under nominal operating conditions.

Factor name	Description	Value
Pressure	$C_p = (4.8 \cdot 10^{-3} \cdot \Delta P_m)^2$	0.44
Allowable leakage	$C_q = \begin{cases} 9.10^{-4} \cdot Q_{mf} & \text{for } Q_{mf} > 4.9 \cdot 10^{-4} \text{ l/min} \\ 4.2 - 4.8 \cdot 10^3 \cdot Q_{mf} \end{cases}$	3.72
Surface finish	$C_f = \frac{(39.4 \cdot F_m)^{1.65}}{353}$	0.46
Fluid viscosity	$C_v(T_{fluid})$ SAE 10 fluid look-up table	0.47
Fluid contamination	$C_n = \left(\frac{C_O}{10} \right)^3 F_{Rm} N_{m10} \cdot 3.79$	0.024
Contact pressure	$C_s = 0.26 \cdot \left(\frac{9000}{3 \cdot \Delta P_m \cdot 1.5 \cdot 10^{-4}} \right)^{1.5}$	0.31
Seat diameter	$C_{dt} = 1.1 \cdot D_m \cdot 0.04 + 0.32$	0.97
Land width	$C_{sw} = \begin{cases} 3.55 - 0.97 \cdot D_{mw} + 73 \cdot D_{mw}^2 - 86 \cdot D_{mw}^3 \\ 0.25 \text{ for } D_{mw} > 1.34 \cdot 10^{-2} \end{cases}$	2.0
Flow rate	$C_w = 1 + \left(\frac{Q_{V2}}{FR_m} \right)^2$	1.0
Operating cycle rate	$\frac{N_{V2}}{t_H}$	$33 \frac{\text{cycle}}{hour}$

Table 5. Part failure rate for valve V2 under nominal operating.

Part	Failure rate $\left[\frac{\text{failure}}{\text{cycle}} \right]$
Main poppet	$\lambda_{V2,m} = 2.4 \cdot 10^{-7}$
Pilot poppet	$\lambda_{V2,p} = 1.9 \cdot 10^{-7}$
Spring	$\lambda_{V2,sp} = 1.5 \cdot 10^{-7}$
Outer o-ring	$\lambda_{V2,uo} = 1.0 \cdot 10^{-8}$
Inner o-ring	$\lambda_{V2,io} = 2.7 \cdot 10^{-9}$
Solenoid	$\lambda_{V2,so} = 1.2 \cdot 10^{-6}$
Valve V2	$\lambda_{V2} = 1.8 \cdot 10^{-6}$

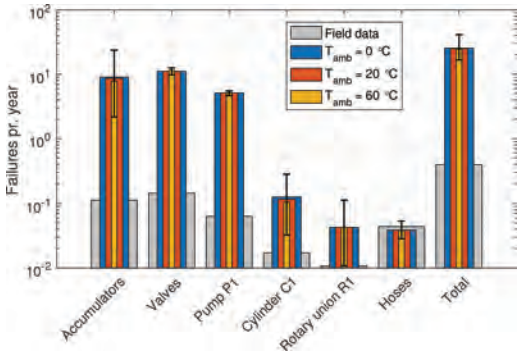

Figure 4. Component group failure rates for varying ambient temperatures. Other conditions are fluid temperature $T_{fluid} = 50°C$ and low travel threshold.

variation due to the considered wind speeds, turbulence intensities and wear models. The colored bars are mean values for each estimation case. Feasible failure rates estimation means that the field data must fall within the error bars. From Figure 4, the estimated failure rates are seen to be at least an order of magnitude larger than the field failure rates for component groups other than hoses. Increasing the ambient temperature slightly reduces the estimated failure rates. The only component group to fall within the estimated range is hoses.

The estimated failure rates for varying fluid temperatures are seen in Figure 5. Generally, the estimated failure rates increase with increasing fluid temperature. A significant change is seen for the failure rates of valves. At lowest value, the estimated failure rate of the rotary union covers the field data.

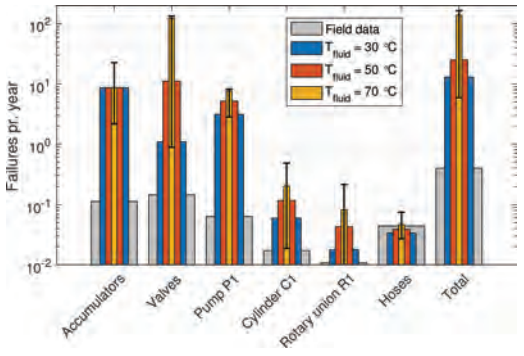

Figure 5. Component group failure rates for varying fluid temperatures. Other conditions are ambient temperature T_{amb} = 20°C and low travel threshold.

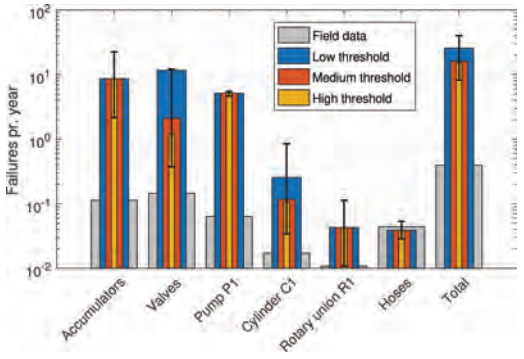

Figure 6. Component group failure rates for varying travel thresholds. Other conditions are T_{amb} = 20°C and T_{fluid} = 50°C.

The travel threshold for counting operating cycles is associated with a high degree of uncertainty. Thus, the effect of three threshold levels are analysed. The low levels are described in Section 5. Medium and high thresholds are double and triple w.r.t. the low values. Increasing the threshold lowers the operating cycles which in Figure 6 is seen to have a minor decreasing effect to the failure rates. At a low threshold value both the valves and cylinder C1 failure rates are increased significantly.

The results are generally not satisfying, and the large discrepancy between estimated and field values is either related to wrongful modeling assumptions or non-describing field data. Reasons for the estimated failure rates being larger than the field data could be a consequence of the simulated wind turbine being 5 MW rather than the 3–4 MW range of the real-life systems and non-modeled repair or replacements of components. Also, over 30% of field failures are known to be insufficiently documented and therefore not considered in this comparison (Liniger et al. 2017). On the other hand, the real-life systems are known to contain more components than presented in Figure 1 which potentially could further increase the estimated failure rates.

In spite of these facts, the large discrepancies are most likely caused by the estimation procedure being over-conservative. This is indicated by the tendency seen in Figure 6 for low threshold, where the failure rates for all component groups except hoses follow the field data with an offset. As evident from the references in the *Handbook of Reliability Prediction Procedures for Mechanical Equipment* (Jones 2011), the empirical base failure rates date back to the late 1960's. Latest developments in manufacturing processes, component design, and fluid properties are therefore not considered in the estimation procedure. A suggestion for increasing the precision of the estimation procedure could, therefore, be to adjust the base failure rates to more current data and evaluate if the multiplication factor can be used as is.

6 CONCLUSION

A feasibility study of estimating fluid power pitch system reliability has been conducted using an estimation procedure for generic fluid power components. The estimated values were determined based on operating conditions obtained from a simulation model of a pitch system in normal operation in a turbine. The estimated failure rates were compared to failure rates of real-life turbines. Large parameter variations related to wind speed, turbulence intensity, and system temperatures were performed since the operating conditions of the real-life turbines were unknown.

The estimated failure rates were over-conservative in relation to the field failure rates for accumulators, valves, pump, cylinder and rotary union. The method yielded feasible results only for failure rates of hoses.

While being over-conservative, the estimated failure rates followed the same tendency of the field data for accumulators, valves, pump, cylinder and rotary union. The similar tendency indicated that the base failure rates are incorrect for components in modern pitch systems and should be updated using more recent test data.

ABSTRACT: Norway is currently ranked as one of the top nations in regard to road safety. However, continued efforts are applied as we stretch towards a goal of zero deaths and serious injuries in road traffic accidents. In this paper we explore if Norwegian driver education could benefit from simulator training. Possible advantages are cost effectiveness, environmentally friendly training, repeatability, accessibility to different scenarios (accident scenarios and dangerous situations, darkness and snow outside of winter, difficult weather conditions and extreme road traffic density), the possibility to make errors in a safe environment, and interaction with new technology such as advanced driver assistant systems. However, there are challenges such as how to increase the number of simulators in Norway, and legal obstacles as current legislations require all mandatory parts of the Norwegian driver education to be conducted on the road. Our overall impression is that the driver education in Norway could have advantages in applying a more systematic approach to simulator training.

1 INTRODUCTION

The purpose of this paper is to investigate the use of simulator training in driver education in Norway, discuss the potential gains and challenges and look at the possibility of increasing the availability and use of driving simulators. In Norway, like in many other countries, the public authorities have established a formal theoretical and practical driver education (NPRA 2017), based on scientific and policy factors, where professional driving teachers employed by approved driving schools are the main responsible bodies to conduct the education. The driver learner program is an extensive and systematic module based program with a comprehensive syllabus. The program is to a large degree based on the Goals of Driver Education-matrix (GDE-matrix; Keskinen 1996 in Hatakka et al. 2002; Keskinen et al. 2010). In this program it is estimated that the average learning period, from novice to the issuing of the driver's license, is two years. The authorities recommend that training starts at the age of 16 in order to get the driver's license at the age of 18 – which is the lower limit for receiving a car driver's license in Norway. To reduce accident risks in novice drivers, elements of the driver training are carried out in real life situations where driver learners are accompanied by skilled driver instructors. Additionally, in Norway it is legal and recommended for experienced drivers (normally parents) to provide driver learners with extra practice. The only premise is that the driver learner has completed an introductory course and that the experienced driver must have held their driver's license for a minimum of five years without receiving any penalties or driver's license endorsements (FOR 2017). Such additional training is meant to increase the driver learners' experience behind the wheel prior to their exams and the license issuance. Our question is to whether driving simulators could be a training platform in Norway to increase driver learners' driving experience, and if they can complement or even substitute some of the more traditional learning methods used in today's education.

In many industries where human errors are likely to have critical outcomes, such as aviation, hospital medicine and commercial nuclear power, simulator training is frequently used as part of training. Simulator training can be cost efficient and can provide training in situations that are rarely seen (e.g. accident scenarios; Bye et al. 2011; McGaghie et al. 2010; Salas, Bowers & Rhodenizer 1998). Currently driving simulators are not the standard way of learning how to drive, however, in some European countries, such as in The Netherlands and the United Kingdom, simulator training has gained some acceptance as part of the driver education (Baten & Bekiaris 2003), and there are reports showing an increased use of simulators in Germany (Stiegler & Vennefrohne 2017) and France (Goepp 2017). There are several

factors explaining why simulator training is more common in other industries where human errors are likely to have critical outcomes than in driving. In medical surgery for instance, the risk of letting unskilled personnel practice on people is considered too high, so simulation has become a natural way of acquiring skills. Doing simulator training means that there is room to learn from mistakes. The same is seen in aviation. Additionally, the costs and emissions of flying a large aircraft are so substantial that doing all the training necessary to obtain a commercial pilot license is not considered economically or environmentally beneficial. Even though developing, building and handling a simulator also result in costs, it is far less expensive than training in airplanes. In aviation, as well as industries such as commercial nuclear power, simulators can be used to train personnel to avoid serious accidents and to minimize the overall consequences if unwanted events occur.

It is our impression that all of the reasons mentioned above, concerning reduced risk through extra training, prevention of fatalities and injuries, handling accident scenarios, and reduced cost and emissions, can be used as reasons to introduce car driver training in simulators. In this paper we will attempt to clarify current usage and potential gains of simulators in driving education in Norway (section 2). This is discussed in the light of the rapid technological development in today's automobile industry, and how new technology can be included in simulators. This is followed by a discussion on the structural and practical obstacles in implementing an increase in simulator training in driver education (section 3).

2 POTENTIAL GAINS IN SIMULATOR TRAINING

It has never been common to use driving simulators as part of the driver education in Norway. Currently, only 5–10 out of 1033 driving schools, offer simulator training for driving-license category B driver training (vehicle weight less than 3500 kg), and the simulators are mainly used for learning the basic introductory elements of handling and maneuvering a car. These schools seem to lack a systematic pedagogical or educational plan in their simulator use. Additionally, The Norwegian Public Road Administrations are rather strict on what is allowed to be taught in a simulator only. Any topic that is mandatory in the education will not be approved using only a simulator (NPRA 2017), despite research indicating that for instance that the mandatory dark driving demonstrations have the same learning outcome taught in real life and in a simulator (Mikkonen 2007; Robertsen et al. 2017). A different approach is taken in Finland where dark driving sessions are approved using a simulator, so these aspects are not internationally agreed upon.

There have not been many empirical studies measuring and discussing the learning outcomes from using simulators in driving education. We only found one published study on use of simulator training in driver education in Norway (Robertsen et al. 2017). This study was regarding theoretical learning outcome when comparing traditional training and simulator based training on dark driving demonstration. Dark driving is a part of first module (basic handling of the car) in the Norwegian driving education program. This study showed no significant differences in the outcome between these two groups on theoretical knowledge of dark driving. According to some of the international empirical studies concerning driving simulators, it seems like simulator training could be useful in driving education. In a study carried out in in The Netherlands by de Winter et al. (2009), they found that better driving simulator performance increased the actual driving skills on the roads and the chance for passing the final driving test. Additionally, Crundall et al. (2010) found that commentary training in a driving simulator has beneficial effects on driving behavior in the UK. For instance, it was found to improve responsiveness to hazards on the roads. Wang et al. (2010) have pointed out that road hazard performance was significantly higher for a simulator trained group of novice drivers than others. Divekar et al. (2016) also report that novice drivers' outcome in PC-based simulator training increases the awareness and driving skills in real life operations. Additionally, a German study showed that the training period could be reduced by 21 days when using a simulator instead of traditional training with a driver instructor (Reindl, Gunther, & Wottge 2016). However, in all these empirical studies there are methodological challenges in isolating and measuring the learning outcome from simulator training, and determining the transferability from improvements in the simulator to improved driving on real roads. Another common challenge in these studies is the difficulty to measure the long term effects on the drivers' skills and behavior. Nevertheless, it seems to be an agreement in these empirical studies that especially novice drivers have a significant short term positive learning outcome from training specific elements in simulators.

Based on this earlier research, a systematic offer of simulator training in the official driving education might make it easier to learn the basic skills in handling a car and making the soon-to-be drivers trained in adjusting their road traffic behavior to the circumstances on the road. Hence,

it seems likely that driving in a simulator, accompanied by other training methods, could be used to improve the various driving- and safety skills during the phase of learning to maneuver a car. Particularly, in order to reduce risks of young drivers, training with professional driving instructors combined with simulator training, seems to gradually become accepted as a useful tool in developing driving skills.

The gains of supplying adequate simulator training are also related to the possibility to train in a secure environment where the negative consequences of making mistakes are eliminated. It is also environmentally friendly, flexible, could train driver leaners in different road traffic environments any time of the year. For instance, Norway has a large road traffic density variance. This means that different mandatory training scenarios, such as urban and rural driving, are fairly easy to obtain in the cities and other densely populated areas. However, in some rural areas access to urban driving might entail a long journey. A widespread access to driving simulators could potentially reduce the number of those long journeys. Due to the long dark winter in Norway, it is particularly important to learn how to drive in the dark and handling the challenges of darkness. However due to the lack of darkness in summer, the mandatory dark driving demonstration can only be conducted from the end of October till mid-March. With a simulator of sufficient quality, dark driving demonstrations can be given all year around. Other environmental challenges are seen in other countries, such as southern France (Goepp 2017), where it is not unlikely to go through the entire driver education without facing rain. The possibility for all driver learners to experience different weather conditions and road traffic densities is a good argument for using a simulator. Additionally, simulator training has the potential to be cheaper for the driver learner, if sufficient instructions are given virtually and thereby removing the necessity of one driving instructor per driver learner.

Simulator training should also be seen in connection to the rapid technological development seen in the automobile industry. When a driver learner has finished the driving education, should he/she only be able to handle the basic technology found in every car, or should he/she have learned how to use and interact with new technology introduced in new cars to assist the driver? Staying in touch with the technological race while using a traditional training approach would entail a very frequent replacement of vehicles. Using a simulator approach might be easier as a software update could potentially provide the new technology or features to be used without replacing the simulator.

From other industries, research has shown that training for new and more automated technology is of importance in order to avoid unwanted incidents (Salas et al. 2006; Sætren and Laumann 2015). It would be beneficial to have a system for training drivers who buy new cars with new Advanced Driver Assistant Systems (ADAS) technology. Research shows that buyers have very limited knowledge of the new technology in their new cars and on how it can be used. One of the reasons could be that only 24% reported that they received instructions regarding the ADAS technology from the manufacturer when buying the car (Harms & Dekker 2017). Training in simulators could provide an important alternative for learning how to drive with ADAS technology for instance for drivers who already hold their driver license but need training for new technology.

3 CHALLENGES IN SIMULATOR TRAINING

In order to implement a broader use of simulator training in driver education there are a lot of challenges and obstacles that have to be discussed and solved. First, there are technological challenges in developing adequate hardware and software making the simulators relevant for learning to drive on the road. For instance, to what degree could and should simulators be designed to give the driver learners a "car-like" experience when training, and should the simulators be designed to make it possible to adjust for different equipped cars? A software-challenge would be to design adequate road traffic situations training the driver learners to handle and control the vehicle on the road in different road traffic settings.

One of the main challenges in simulator based training, if thought of being used for more advanced driver education, is to adjust the training to the GDE-matrix. As mentioned, the hierarchical GDE-matrix is an important base for the Norwegian driver education. The GDE-matrix originally consisted of four levels, where the first level is vehicle maneuvering, second level is mastering road traffic situation, the third level is goals and context of driving, and fourth level is goals for life and skills for living (Keskinen 1996 in Hatakka et al. 2002) and later a fifth level, social skills, was added (Keskinen et al. 2010). The skills are learned through theoretical and practical teaching in addition to individual and group work. To reach level four and five it takes time to mature, thus, the authorities recommend starting at age 16 in order to have a driver license at age 18. The main reason for this is that adequate psycho-motoric skills and physiological functions are found not to be sufficient

for good and safe driver performance. For instance, when the lowest levels of the hierarchy are learned, they are applied under guidance of higher level objectives. Hence, the training of basic skills is important but the driver learner should also be able to deal with goals higher in the hierarchy such as dealing with social pressure (Hatakka et al. 2002). There is little doubt that simulator training could be of help for the lower levels in the GDE-matrix, but in order to deal with the higher levels including self-evaluation, simulator training might not be optimal. Thus, this argues that simulator training cannot completely replace the traditional driver's education, but be a supplement.

Increasing the use of simulators in Norway has specific legal challenges. The mandatory driver's education is regulated such that it must be given by professional driver instructors while the driver learners are sitting behind the wheel of an actual car. Hence, training in simulators can only be seen as an additional part of an education program and not a part of the mandatory education. That being said, learning how to drive entails a large amount of training outside of the mandatory elements allowing driving schools to use simulators a substantial amount if they want to. The main obstacle in Norway seems to be the lack of simulators. There might be several reasons for this, but it seems that in general, the driving schools do not consider it economically beneficially to offer simulator training. In addition to the investment cost of simulator, the driving schools have to handle the cost of software updates, maintenance, and training staff in simulator handling. Without simulators, the main income of a driving school is hours spent on the road with driver learners. Introducing a simulator (particularly one that is cheaper than traditional training) the school has to change its business model for selling man-hours to include selling simulator-hours. For the driving instructors this would undermine their occupation. This is further underlined with the argument for having simulators in countries such as France, where it was emphasized that a school with 5–6 instructors, one driver instructor can be replaced with a simulator (Goepp 2017). There is no shortage of driving instructors in Norway, like for instance in Germany (Stiegler & Vennefrohne 2017), thus, the Norwegian market does not provide that need for a simulator for better efficiency.

Another challenge is simulator sickness. Simulator sickness is a subset of motion sickness, leading to many experiencing nausea after only a short while in a driving simulators, influencing the usefulness of simulator training (de Winter et al. 2012). Simulator sickness is due to the perceived discrepancies between the motion expected by the participant and the motion displayed in the simulator. This has been a problem in a wide range of simulators and virtual reality applications, but it is gradually decreased as the simulations improve in terms of both responsiveness and reduced delays. Research shows that younger individuals are less prone to simulator sickness than older (Brooks et al. 2010). This could be beneficial for driver learners, but might be a hindrance for using simulators for upholding driving skills for those who have had a driving license for some time.

4 CONCLUDING REMARKS

Our impression is that the car driving education in Norway could have advantages in using simulators more systematically than what has been done until now. There are many possible advantages from introducing simulators in driving schools such as cost effectiveness, environmentally friendly training, repeatability, accessibility to different scenarios (accident scenarios and dangerous situations, darkness and snow outside of winter, difficult weather conditions and extreme road traffic density), the possibility to make errors in a safe environment, and interaction with new technology such as advanced driver assistant systems. However, there are challenges such as how to increase the number of simulators in Norway, and legal obstacles as current legislations require all mandatory parts of the Norwegian driver education to be conducted on the road.

The experiences from other European countries and the few empirical studies that exist provide some insight into the potential for simulators to be used in driving education in Norway. However, more research should be done to find out which parts of the driving education that could be performed in a simulator, and how the simulator could set up to optimize the learning outcomes.

ABSTRACT: Natural gas supply systems are complex pipeline networks, whose features can cause severe consequences under unexpected scenarios. In this work, we present the research being performed to develop a method for efficiently measuring and locating pipelines which are critical to gas distribution. Graph theory, thermal-hydraulic simulation, optimization and network flow method are integrated to calculate the pipeline criticality with respect to the supply of gas. Graph theory is applied to model the supply-transmission-demand systems. A capacity model, superposed on the graph model, and a combination of thermal-hydraulic simulation and optimization is used to simulate the system operation under different scenarios and estimate the different supply performances of the pipelines. This allows to assess the criticality of the pipelines by the network flow method. For demonstration, the method is applied to a relatively complex gas pipeline network. The results of the application show that the method can provide analytical information useful to improve the system robustness and perform a more efficient and effective protection of the gas supply system.

1 INTRODUCTION

Reliable service of supply from natural gas pipeline networks is important for economy development and society stability. Although many efforts have been done, potential vulnerabilities still exist because of uncertain environment, system structure complexity, demand fluctuation and resource limitation. When unexpected events occur, e.g., political crisis, terrorist attacks, third-party activities, extreme weather events, etc., severe consequences may follow (Su et al., 2017; Enrico Zio, 2016).

In many application areas, the vulnerability analysis of complex transmission networks has been given increasing attention, e.g., transportation systems (Hong, Ouyang, Peeta, He, & Yan, 2015; Mattsson & Jenelius, 2015), supply chain (Thekdi & Santos, 2016), power grids (Cadini, Agliardi, & Zio, 2017; E. Zio & Golea, 2012; Enrico Zio, 2014; Enrico Zio & Sansavini, 2013), etc. However, the importance of vulnerability of natural gas transmission networks has not been given enough efforts to.

Vulnerability is a term which is applied with several different definitions in the literature (Kröger & Zio, 2011). In this paper, vulnerability is defined as inherent system defects to absorb the effects of failures or to restore the system to normal condition. Vulnerability analysis focuses on the inherent properties rather than environment and probabilities, as reliability and risk do. Applying vulnerability analysis to evaluate criticalities of components of gas pipeline network systems can help to find the "bottlenecks" of a natural gas pipeline network system, improve the ability to withstand unexpected damages and reduce potential risk of loss.

There are several common methods to quantify the element criticality with respect to vulnerability. Generally, in a transmission network system, element criticality evaluation is usually performed based on the consequences of failures or the system structure. In the consequence-based methods, criticality of element is evaluated according to the direct, and sometimes indirect, effect of the failure (Johansson & Hassel, 2010). From the system struc-

ture perspective, some identification approaches have been proposed based on different considerations, e.g. flow-based performance (Fang, Pedroni, & Zio, 2015; Nicholson, Barker, & Ramirez-Marquez, 2016a; Enrico Zio & Piccinelli, 2010), network efficiency (Deng, Li, & Lu, 2015; Han. F; E. Zio, 2014; E Zio, 2007), accessibility (Demirel, Kompil, & Nemry, 2015), etc. In this paper, we use a measure of network performance (network flow) rather than the graph-theory-based measure to evaluate the criticality. Several works have been carried out recently to compare the topological model and the flow-based model for power grids (Ouyang, Zhao, Pan, & Hong, 2014) and the results show similarities.

The flow-based element criticality analysis requires a model that is capable of capturing the system behaviours, the amount of gas requested at demand sites and the supply capacity. System dynamic methods and thermal-hydraulic methods can analyse the consequences in detail; but, they are not suitable to the element criticality evaluation because of the huge cost of computation due to rather detailed numerical simulations. Hence, it is important to develop a computation-efficient model which can reflect system behaviours and calculate the consequences of element failures.

In this paper, a method of element criticality analysis of natural gas supply service pipeline networks is developed considering the system vulnerability, based on the performance of network flow. In Section 1, a consequence analysis model is developed based on network flow theory, combined with an optimization part. The model can simulate the system responses of element failures and estimate the capacities of supply of both the demand sites and the global system, with the consideration of constraints of physical limitation. Section 2 provides three criticality measures emphasizing the transmission performance based on different considerations. Finally, in Sections 3 and 4, the method is performed based on a complex natural gas pipeline network and the results are analysed in detail.

2 NATURAL GAS PIPELINE NETWORK MODEL FOR CONSEQUENCE CALCULATION

For the development of the consequence assessment model, only the components relating to gas supply capacity in the pipeline networks are considered, i.e. pipelines, compressor stations, gas sources and consumers. This is because the objective of the assessment is supply service. The development of the model of capacity/consequence analysis has followed the steps in Figure 1.

The inputs of the model include:

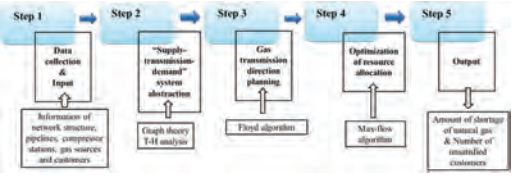

Figure 1. Process of modeling for consequence analysis.

A. Pipeline parameters: diameter, length, roughness etc.
B. Parameters of compressor stations;
C. Properties of natural gas;
D. Information of gas sources: locations, types, capacities;
E. Information of consumers: locations, demands;
F. Topology information of the pipeline network structure.

2.1 *Natural gas supply-transmission-demand system abstraction*

The pipeline network is abstracted in the form of a directed weighted network. The pipeline junctions, consumers, gas sources are represented as nodes and pipelines are represented as arcs. The weights on the arcs denote the capacities of the pipelines. The capacities are calculated by thermal-hydraulic analysis, based on the above inputs A, B and C. When the pipeline capacities change, the weights in the weighted network change accordingly.

In general, if an unexpected event occurs, operators will take actions to reduce the negative impacts on the system. Generally, the actions include adjustment of supply of gas sources and re-distribution of gas. In this model, all these actions can be swiftly performed by changing the weights on the arcs. The optimization process will be introduced in the next Sections.

2.2 *Modeling of gas transmission optimization*

In the optimization process, supply distance and economic efficiency are considered as the most relevant attributes to gas transmission planning. Firstly, a "standard cost" matrix C is developed based on network topology and the network element cost is calculated by equation 1. This so-called "standard cost", which is determined by the cost of transmission and pipeline length, represents a factor for the optimization of the transmission path, not a real cost:

$$C_{ij} = \alpha L_{ij} \cdot \beta\left(Q_{ij} \cdot c\right) \tag{1}$$

where C_{ij} represents the optimization factor combining distance and cost ($). Although the unit

of the "standard cost" is $, it is different from the actual cost. Q_{ij} represents the designed quantity of natural gas transported from i to j (MCM); L_{ij} represents the length of the pipeline from node i to node j (km); α and β, ranging from 0 to 1, represent the importance weights of distance and cost of transmission, respectively; c represents the cost of gas transportation ($/(km·MCM)).

Then, "standard cost" vectors are calculated based on matrix C. Each of the vector contains the "shortest paths" based on the "standard cost" between a gas source and all remaining nodes (except the other gas sources), found by the Floyd algorithm (Ahuja, Magnanti, & Orlin, 1993). In order to find out the sequence of the nodes that the gas flow from different sources should follow in its transmission path, the "standard cost" vectors are sorted in ascending order. For a specific gas source, priority is given to the nodes with lower "standard cost", which means lower cost and relatively higher efficiency.

The algorithm will also check whether the supply capacity of the source is exhausted: if there are still residual capacity and unsatisfied customers, the algorithm will search for the next unsatisfied demand node in the node sequence. This process continues until all demands are satisfied or the supply capacity of the source is exhausted.

2.3 *Supply capacity calculation*

On the basis of the transmission directions determined in Section 2.3, we proceed to optimize the plan of natural gas distribution in the pipeline network (volume of gas supplied by different sources and gas flow in the pipelines). This problem is converted to a max-flow problem in graph theory and solved by Ford-Fulkerson algorithm.

In this process, two constraints are to be respected:

- The sum of the flows exiting a node is equal to the sum of those entering the node (except for the sink nodes and the source).
- The flow in the arcs is within the capacity limitations.

Ford-Fulkerson algorithm is carried out by the following steps (Ahuja et al., 1993):

- Searching paths which connect the sinks and the sources with available capacities on the arcs.
- Repeating the search process until no additional flow can be added to the path.

In general, gas pipeline networks usually have more than one source or sink, however, Ford-Fulkerson algorithm is used to solve the "single source and sink" problem. To convert the "multiple sources and sinks" problem to a "single source and sink" problem, we assume a "super sink" and a "super source" connecting with all the customers and sources by arcs with unlimited capacities.

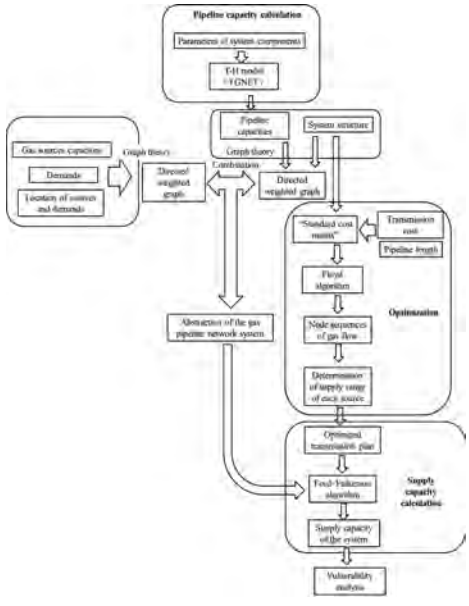

Figure 2. Flowchart of the capacity/consequence analysis model.

Finally, the model will output the supply capacities of the overall system and the customers in the gas pipeline network. By comparing with the demands requested, the amount of unsatisfied customers and the gaps between supply and demand are calculated as inputs of the element criticality analysis. The flowchart of this process is shown in Figure 2.

3 CRITICAL PIPELINE ANALYSIS OF GAS SUPPLY SERVICE

Because of its structure complexity, there may be some unknown, perhaps previously unimagined system weaknesses in a large natural gas pipeline network. Critical element analysis focuses on identifying this kind of weakness that contributes to the supply vulnerability of the gas pipeline network. A pipeline, or a combination of pipelines, is a critical component depending on how essential it is for the supply service of the pipeline network system. Compressor stations, which can also affect the supply capacity, but the impacts of their failures will eventually amount to degradation of pipeline transmission capacities.

Generally, the critical component analysis is performed by estimating the consequences of failures

of single component or multiples (Fang & Zio, 2013; Nicholson, Barker, & Ramirez-Marquez, 2016b; E. Zio & Golea, 2012). This method is performed exhaustively up to a given number (from 1 to P) of simultaneous failures. The value of P is usually from 3 to 5. In this range, every possible failure or failure combinations should be simulated, with the consequence analysis model developed in Section 1. This kind of analysis gives a comprehensive picture of the system vulnerability within the range of simultaneous failures considered.

However, in a complex natural gas network, the attack-consequence analysis method sometimes can be impossible because of the huge burden of computation. To overcome this problem, a flow-based method is applied in our research, which combines topology properties and flow properties of the gas pipeline network, to measure the criticalities of the pipelines.

Several works have explored the measure of arc criticality in a network by graph theory and network flow theory. On account that the importance of a pipeline depends on its role in the network topology and its flow capacity, an index, named weighted flow capacity rate (*WFCR*) (Nicholson et al., 2016a), is chosen to evaluate the criticalities of the pipelines. *WFCR* is the combination of flow capacity rate (*FCR*) (Nicholson et al., 2016a) and flow centrality (*FC*) (Freeman, Borgatti, & White, 1991). *FCR* is the sum of the percentages of arc flows to arc capacity for all *s-d* max flow problems: $c_{i,j}$ represents the transmission capacity of pipeline (i, j); N is the number of *s-d* pairs. *FC* represents the sum of flow in pipeline (i, j) for all possible s-d pair max-flow problems divided by the sum of all pairs max flows: $MF_{sd}(i, j)$ denotes the flow on pipeline (i, j) when the max flow MF_{sd} is from s to d (s represents gas sources and d represents demand sites).

The *FC* provides the contribution of pipeline (i, j) to the transmission capacity of the pipeline network and *FCR* accounts for its potential criticality due to constraints of capacity. Therefore, by weighting each term in equation 3 by the *FC* value, *WFCR* represents the expected impact of pipeline (i, j) to the system performance of supply:

$$FC_{i,j} = \frac{\sum_{s,d \in V} MF_{sd}(i,j)}{\sum_{s,d \in V} MF_{sd}} \tag{2}$$

$$FCR_{i,j} = \frac{1}{N} \sum_{s,d \in V} \frac{MF_{sd}(i,j)}{c_{i,j}} \tag{3}$$

$$WFCR_{i,j} = \frac{1}{N} \sum_{s,d \in V} FC_{i,j} \frac{MF_{s,d}(i,j)}{c_{i,j}} \tag{4}$$

4 CASE STUDY

We consider a complex natural gas pipeline network, assuming coherent and reasonable data and information of the pipeline network, including customer demands, pipeline parameters, compressor station parameters and gas source capacity. The pipeline network is shown in Fig. 3. Assumptions about locations, capacities and types of gas sources are reported in Table 1, whereas the demands are listed in Table 2.

5 RESULTS OF CRITICAL COMPONENT ANALYSIS

Firstly, to estimate the criticalities of pipelines, an overview of consequences of the "directly attack" method have been analysed. The exhaustive analyses were performed for *N*-1 to *N*-3 simultaneous failures. All the possible consequences are sorted from high to low and presented in Figure 4. The pipelines or the combinations with high consequences have relative high criticalities.

However, for a complex gas pipeline network with hundreds, or even thousands of pipelines, the direct attack method requires a quite large number of simulations and it is impossible to perform exhaustive analyses under high-order scenarios. Hence, in Section 2, the weighted flow capacity rate (*WFCR*) in equation 2, is proposed to measure the criticalities of pipelines. The pipelines were sorted from highest to lowest according to *WFCR* in Table 3. For a further comparison analysis, *FCR*, the measurement of the pipelines potential criticality due to capacity limitation, and *FC*, the measurement of contributions of pipelines to system transmission capacity, were also calculated. The sequences of pipeline criticalities based on *FC* and *FCR* are shown in Table 3.

In Table 3, the pipelines which are high-ranked by *FCR* are more prone to become bottlenecks because of the low margins between their capacities and loads. The pipelines with higher *FC* values have heavier burdens during the process of gas transmission in the gas pipeline network. The *WFCR* index combines the concepts of both *FCR* and *FC*, and the pipelines with higher *WFCR* values are more critical for the gas supply capacity of the gas transmission network.

The effectiveness of the proposed method was verified by a "random attack & preparedness policy" method. In the "random attack & preparedness policy" method, random attacks were firstly carried out on the pipeline network. The numbers of random attacks of *N*-1, *N*-2, *N*-3 simultaneous failures are respectively 100, 10000 and 500000. When the pipelines are sampled, their capacities will be reduced to zero. Secondly, six preparedness policies were performed. The first policy selects no pipeline to harden. The second policy randomly selects 15% of the pipelines to harden. The 3rd – 5th policies select the top 15% critical pipelines based on FC, FCR and WFCR, to harden, respectively. The 6th policy selects the top 15% critical

9	53	32	37	19	20
14	13	33	36	24	25

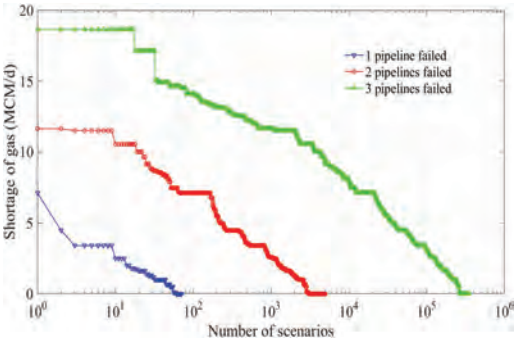

Figure 4. Distribution of shortage for N-1, N-2, N-3 simultaneous failures.

pipelines or pipeline combinations, according to the consequences of direct attacks. In the preparedness policies, the selected pipelines will maintain 70% of their normal capacities after attack. The consequences were represented by "100% × (shortage/normal demand)". The results of the "random attack & preparedness policy" simulations are shown in Figures 5–7 in the form of box plots. Supplementary statistic information is listed in Table 4.

According to the information in Table 4 and Figures 5–7, we can conclude that all the criticality-based policies can reduce the loss significantly compared with "random policy" and "do nothing". The combination index, *WFCR*, is more effective than *FCR* and *FC*, and is a little worse than the criticalities based on direct consequence calculation. However, the burden of computation of the flow-based method is far less than the direct attack method.

6 CONCLUSIONS

In this work, we develop a flow-based method to identify the critical pipelines in natural gas pipeline network from the vulnerability perspective. Comparing with the large computational cost of the direct attack method when it is used for large complex pipeline networks, the flow-based criticality measurement used in this work is much more efficient with a little loss of effectiveness. The flow-based method combines the topology and the capacity contribution of a pipeline to represent its criticality to the supply service of the gas transmission system. In the case study, both approaches have been performed and their effectiveness has been compared by the "random attack & preparedness policy" simulation. The results show that accuracy of the flow-based method is slightly lower than that of the direct "attack-consequence" method; but, the computation burden of the latter is far more higher than that of the former.

ABSTRACT: UK customers visited community pharmacies to receive NHS prescriptions 1.104 billion times in 2016. One study of dispensing errors found an error rate of 3.3%. Severe dispensing inaccuracies often receive a high level of media attention, however, lower level errors could also be causing significant inefficiencies in the delivery of primary healthcare. This paper presents a modelling approach for analysing the reliability and efficiency of community pharmacies performance using a Coloured Petri Net (CPN) methodology. The model considers how single prescriptions are processed, the use of staff resources, and the occurrence of errors. The CPN evaluates performance over a set of key performance indicators. Results are validated, where possible, against published studies of community pharmacies.

1 INTRODUCTION

1.1 *Background*

Over the past 50 years there has been a growing awareness that healthcare systems are capable of inflicting harm to patients, and this harm should be reduced (Health Foundation, 2011). Two key reports by the US Institute of Medicine (Mullan et al, 2001) and the UK Department of Health (DoH, 2000) helped to spread the message that iatrogenic patient harm within healthcare systems is an important issue. Notably, if the community pharmacy dispensing error rate of 3.3% (Franklin & O'Grady, 2007) is considered, this could mean that around 36 million UK prescriptions per year contain errors.

As well as safety concerns, studies have shown that patient satisfaction with pharmacy services is linked to waiting times (Afolabi & Erhun, 2003). Extended waiting times have been given as a reason why patients will not return to a particular pharmacy (Somani & Daniels, 1982), and content customers are increasingly likely to return to their specific healthcare provider (Dansky & Miles, 1997).

1.2 *Reliability engineering*

Reliability engineering techniques are used by many industries and it has become common for complex systems to be subjected to risk assessment processes (Andrews, 2009). These assessments have historically been carried out in conventional high risk industries, such as the aviation (Netjasov & Janic, 2008), nuclear (Hsueh & Mosleh, 1996) and space sectors (Garrik, 1988), where effects of failure can be catastrophic.

Fault trees and event trees are an example of a widely used reliability engineering techniques. They use combinatorial logic to combine events to produce both qualitative and quantitative analysis of failures (Vesely et al, 2002). Fault tree analysis requires that the occurrence of events is independent.

Markov models are memoryless processes capable of modelling more complex systems, which might typically contain repair strategies and dynamic behavior (Boyd, 1998). A key limitation to implementing a Markov model for a given system, arises from the fact that the number of system states to consider grows exponentially with the number of components in the system.

Petri Nets are an effective tool for modelling processes or systems exhibiting concurrency (Schneeweiss, 1999). Since the publication of Carl Adam Petri's thesis in 1961, a number of extensions of the basic technique have been developed. Two important examples of Petri Net extensions are timed and Coloured Petri Nets (Jensen, 1996). Timed nets use either deterministic or stochastic delay timings, to control the timing of transitions. This gives the opportunity to model temporal processes. Meanwhile, incorporating token colour sets into Petri Net modelling enables token specific information to be propagated around the net. This can then be used to

control and manipulate the nets behavior. Coloured Petri Nets have been utilized to model complex systems in a wide range of areas (Liu, 2017).

The healthcare sector, primary care especially, represents a relatively new area for reliability modelling. Previous healthcare modelling studies have been centred in secondary healthcare settings. In this field, Petri Nets have been used to model hospital departments (Dotoli et al, 2010), hospital information systems (Darabi & Galanter, 2009), and mental health care services (Dammasch & Horton, 2007). Michael R. Cohen et al utilized fault trees to conduct a risk assessment of dispensing in community pharmacies (Cohen et al, 2012), and their error probabilities are also used in this paper.

The novelty of the proposed approach in this paper is the ability to perform safety and efficiency evaluation within the framework of a single modelling technique. Therefore, a timed CPN model is developed and a wide range of performance indicators is obtained, using simulations. Model outputs can be used to support resource management and safety improvement decisions. The community pharmacy dispensing process is presented in section 2, section 3 outlines how the model is built, section 4 presents results and analysis and section 5 concludes the paper.

2 COMMUNITY PHARMACY DISPENSING PROCESS

2.1 *The main stages of dispensing*

A standard community pharmacy dispensing process is described in this section. The six key stages of the community pharmacy dispensing process are given in Figure 1 (Langley & Belcher, 2009 & NPSA, 2007 & Waterfield 2008).

To begin with, prescriptions must be received by a member of staff as and when patients bring them into the pharmacy. Prescriptions are then legally and clinically checked, to ensure that the prescription is clinically appropriate before continuing. After being received, the prescriptions' labels are generated. The labels include key information about the medicine. The next stage of the process is bringing the constituent parts of the prescription together to create the final product. First, the set of items included on the prescription is gathered together from the pharmacy stock. After this, an intermediate accuracy check is recommended, before applying the labels to medicines. After the prescription is fully assembled, it is passed onto either a pharmacist or an ACT (Accredited Checking Technician) to perform a final accuracy check on the prescription. The final accuracy check is the final opportunity for a pharmacy to intervene if a prescription has been dispensed incorrectly at some point in the process. The accuracy check involves making sure that the prescription being provided by the pharmacy exactly matches what has been written on the prescription form. This includes checking that the labels, items, doses, quantities and form of medication are all correct before handing the prescription out. Any mistakes that go unnoticed at the final accuracy check are likely to reach patients. Each stage of the process can be completed by a single member of staff, although, only pharmacists or ACTs are qualified to final accuracy check prescriptions.

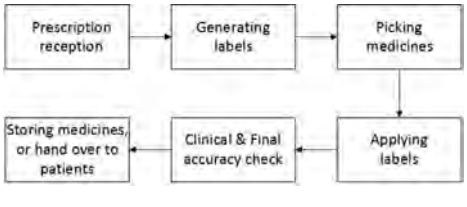

Figure 1. Dispensing process flow chart.

2.2 *Resources*

A typical community pharmacy staff team consists of a group of pharmacists, ACTs and dispensers, but the number of staff varies between pharmacies. Larger stores can have teams of up to 12 people, while the smallest independent store may be run by a single pharmacist. However, for a pharmacy to be allowed to dispense prescriptions, there must be a responsible pharmacist present during all hours of operation.

The full list of resources used in the dispensing process is as follows: prescriptions, dispensers, pharmacists, medicines, labels, labelling stations and a private room.

2.3 *Non-dispensing tasks*

As well as completing dispensing tasks, there are a number of non-dispensing tasks in pharmacies that members of staff are required to complete (Davies et al, 2014). These non-dispensing tasks include, stock management, patient counselling, advanced pharmacy services, non-prescription services, staff training, and general housekeeping. Advanced services are a set of 6 services offered in pharmacies, one example of which is the smoking cessation service.

In this study, the set of non-dispensing tasks requiring to be completed by staff is limited to stock management, advanced services and patient counselling. Although not strictly a task, lunch hours for dispensers are also included in the model.

2.4 *Failure modes*

Dispensing correct prescriptions reliably and in a time that is convenient for customers are the two main goals of community pharmacies. Therefore, the dispensing process can be considered to fail if either:

1. A prescription is incorrect when handed/delivered to a patient.
2. A prescription takes an extended amount of time to be dispensed, causing the patient to decide not to return in the future.

Prescriptions can be incorrect in a number of different ways, for example, the labels may indicate to take too much or too little of the medicine. This would be classified as a labelling error. Other examples include, items being included which are different to those prescribed. This would be classified as a contents error, and it can be due to wrong dose, wrong volume, or being a completely different medicine. Additionally, it may be the case that the labels and items were generated and picked correctly, but they are mixed up when applying the labels, this is classified as a label application error.

If one of the above errors makes it through the final accuracy check and is handed out to a patient, this is then classified as a dispensing error. If however, the error is spotted and rectified at the final accuracy check, this is classified as a near miss (Chua et al, 2003).

2.5 *Definitions: Process reliability and efficiency*

Reliability of the dispensing process, R, is defined in Equation (1) as:

$$R = \frac{p_{cc}}{p_{total}} \tag{1}$$

where p_{cc} is the number of prescriptions dispensed which are completely correct, and p_{total} is the total number of prescriptions dispensed.

Process efficiency is commonly defined as the ratio between an output gained and the level of resources needed to maintain the process. Since the cost of resources is not factored into this study, a set of efficiency indicators are used. Two examples of efficiency indicators are, the total number of prescriptions completed, and the average time to dispense walk-in prescriptions. Results for all performance indicators can be found in Table 4. The ideal outcome of the process in terms of efficiency is a high number of prescriptions completed quickly.

48	Allocate dispenser to lunch: Det(∈)	N
49	Dispenser finished lunch: Det(3600)	N

*This column designates transitions as processors.

3 MODELLING APPROACH

3.1 *Overview*

This section of the paper presents the development of a Coloured Petri Net (CPN) for modelling the dispensing process. The dispensing process being modelled in this study is that of manual dispensing pharmacy, as opposed to automated dispensing. Figure 2 shows the CPN model of a community pharmacy. Overall, the model is built according to the process flow, considering resources and errors. Model outputs are obtained after the CPN model is simulated.

3.2 *Places and transitions*

Table 1 shows the description of each place and the type of token that may occupy the places. Note that the net uses three token types: e (basic), w (staff), and p (prescriptions).

Overall, some places are used to keep track of resources, and others are used as task generators, controlling when new tasks arrive.

Table 2, shows the description and distribution of each transition. Note that Det(x) stands for a deterministic delay. Some transitions directly represent the community pharmacy dispensing tasks seen in Figure 1. Other transitions are purely used to move tokens around the net. The types of distributions and their parameter values have been assumed in this paper.

In Table 2 each transition is also designated as either a 'processor' transition, or not. A processor transition represents a task that is affected by the number of items in the prescription. For example, the transition, modelling generating labels, is a processor transition, since it will take longer to generate labels for a large prescription.

3.3 *Model assumptions*

Tasks in the model are separated into primary and secondary tasks, where primary tasks may be com-

pleted by all staff, whereas secondary tasks may only be completed by pharmacists. In addition a number of assumptions about staff behaviour and pharmacy specification are made. Below is a list of modelling assumptions about how staff behave.

- Staff complete tasks in an identical way, i.e. the same probability distributions are used to determine how long tasks take, and to generate error probabilities for different staff.
- Dispensers may only complete primary tasks, and pharmacists prioritise secondary tasks. Pharmacists are able to move to primary tasks if they are idle.
- Once primary work is begun on a prescription, the same member of staff continues working on it until the primary tasks are finished.
- Upon a customer arriving with a walk-in, the first member of staff to become available for primary tasks go to serve them.
- Dispensers have a lunch hour. It is assumed that pharmacists fit their lunch in during moments when they are not working.

Below are assumptions about the labelling stations, pharmacy opening hours, and prescriptions.

- The pharmacy is open from 9 am-5 pm.
- Walk-in prescriptions are prioritised over deliveries. Within the same type, there is a first come first served order. They arrive with increments of an Exponential distribution, as shown in Table 2.
- Delivery prescriptions arrive at the pharmacy in a single large bulk, at 10 am, 1 hour after the pharmacy opens.
- The pharmacy has 2 labelling stations capable of generating labels for prescriptions.
- Walk-ins taking longer than 15 minutes to be dispensed are classed as delayed.

3.4 *Prescription modelling*

In the CPN model, prescription tokens each have 8 colour fields which represent:

1. Delivery or walk-in
2. The number of items
3. Time taken to dispense
4. Number of iterations to compete
5. The overall outcome
6. Label error
7. Content error
8. Label application error

Table 3. Error probabilities.

Task	Error probability
Labelling	0.06
Filling	0.05
Label application	0.03
Final accuracy check	0.05

In particular the number of iterations to complete is determined by how many times a pharmacist has had to send the prescription to be corrected after a final accuracy check. The overall outcome is one of 3 outcomes: completely correct, near miss, or dispensing error. The last 3 colours, labels, contents and label application, are Boolean variables, which indicate whether an error of each type is contained within the prescription.

Upon arrival, every prescription is allocated a random number of items by sampling from a Geometric (0.35) random variable (mean = 2.86). This was chosen using two assumptions. Firstly, patients with a prescription will have at least 1 item on the prescription. Secondly, prescriptions with more items are increasingly less likely to occur than those with fewer. This number of items is then used to determine how long the processor transitions, designated in Table 2, take to fire. For example, a prescription containing 5 items will use the sum of 5 samples from the distribution that describes the duration of label generation.

3.5 *Failures*

Failures are modelled using Bernoulli random variables. At three points of the process, label generation, prescription assembly and label application, an error can occur. The error probabilities were taken from Cohen et al (Cohen et al. 2012), and are shown in Table 3.

The outcome of the final accuracy check depends on the state of the prescription being checked. It is assumed that prescriptions that are correct will always pass through the check. If there is an error present in the prescription, the pharmacist will spot it with probability 0.95, otherwise they will fail to spot it with probability 0.05.

4 PHARMACY SIMULATION SCENARIOS AND THEIR ANALYSIS

4.1 *Scenario specification*

This paper uses three pharmacy scenarios to demonstrate the ability to evaluate performance using the CPN model. These three scenarios have been chosen to demonstrate the impacts, or efficiency improvements, of adding an additional staff member.

a. Scenario 1

Staff – 1 pharmacist, 2 dispensers

Failures—Chance of failure in labelling, filling, label application and final accuracy check stages.

Advanced services—Included.

Stocking—Pharmacist must do 4 stints of stock management, each period lasting 5–15 mins.

Lunch hours – 1 hour for each dispenser, taken sequentially (only 1 dispenser may be off at the same time).

b. Scenario 2

Same as scenario 3, but with 1 pharmacist and 3 dispensers.

c. Scenario 3

Same as scenario 1, but with 2 pharmacists and 2 dispensers.

4.2 *Results and analysis*

A 9-5 day of pharmacy operation was simulated a total of 6000 times for each scenario. A test for convergence was conducted to find whether 6000 was a large enough number to reach convergence. A further 1000 simulations were carried out for each scenario, then the indicator values for the set of 7000 simulations were compared to the values calculated for 6000 simulations. Every field was the same between the two sets of data to 2 significant figures.

Results of key performance indicators for each scenario are shown in Table 4.

Since walk-in (WI) prescriptions are given priority over delivery prescriptions, walk-in prescriptions get completed first, but a smaller pharmacy which takes longer to dispense prescriptions is unable to complete all their deliveries. This can be seen in scenario 1, where 39 of the 150 delivery prescriptions are unfinished. In both scenarios 2 and 3, having an additional staff member of either type (pharmacist or dispenser) improved the efficiency of the pharmacy sufficiently so that on average almost all the deliveries were being completed. This suggests that the pharmacy may be able to complete a larger number of delivery prescriptions when employing 4 staff. The average time to dispense was also improved by more staff in scenarios 2 and 3. A large decrease (of 217s) in the average time to dispense walk-ins was seen when introducing an extra pharmacist in scenario 3. A smaller decrease (of only 75s) was gained by introducing an extra dispenser to the pharmacy team in scenario 2.

Previous studies have reported near miss rates of between 0.024% (Knudsen et al, 2007) and 1.84% (Sanchez, 2013), and dispensing error rates of between 0.014% (Knudsen et al, 2007) and 3.3% (Franklin & O'Grady, 2007). There are many more near misses occurring during the simulations than have been seen in previous studies of errors, i.e. all 3 scenarios had near misses occurring in over 10% of all prescriptions being dispensed. This may be due to underreporting of near-misses in self report based studies, or the final accuracy check failure probability is set too low in the model. The dispensing error rate produced by simulations fell within the reported range.

These simulations suggest that the simulated dispensing process has good reliability. The reliability for scenarios 1, 2 and 3 were as follows, $R_1 = 0.992$, $R_2 = 0.992$, $R_3 = 0.992$. The same reliability for tall three scenarios is due to the fact that the error rates do not depend on the type of staff and pharmacy set-up.

4.2.1 *Distribution of time to dispense*

Figure 3 shows how the distribution of the time to dispense walk-ins depends on the scenario. The duration of 600,000 walk-in prescriptions were used for comparison, i.e. around 100 walk-in prescriptions from each of the 6,000 simulations. It can be seen in Figure 3 that all scenarios have a similar underlying distribution. However the skewness decreases with each additional member of staff. A larger decrease in skew is seen when an additional pharmacist is added. Note that the dashed vertical line represents 15 min dispensing time limit.

4.2.2 *Causes of delays*

A prescription could be delayed due to one of many reasons, such as, prescriptions containing more items taking longer to dispense, delays due to a large amounts of walk-ins already being processed or waiting in the queue when a patient arrives, members of staff being busy with non-dispensing activities, or due to a near miss that has been picked up at the final accuracy check.

Table 5 shows how looking at single scenarios, for more increasingly delayed prescriptions, the average size, and number of iterations required to complete prescriptions increases. This appears to confirm the prospect that prescriptions which contain more items, or need to be dispensed multiple times are more likely to be delayed.

Table 4. Simulation results.

	Efficiency					Reliability		
Scenario	Deliveries completed	Total completed	Advanced services completed	Delayed	WI dispense time mean sec	R	Near misses	Dispensing errors
1	111.1	211	1.8	25.0	711	0.992	29.7	1.6
2	149.4	250	1.8	19.3	636	0.992	32.8	1.9
3	149.5	250	1.8	8.3	494	0.992	32.9	1.9

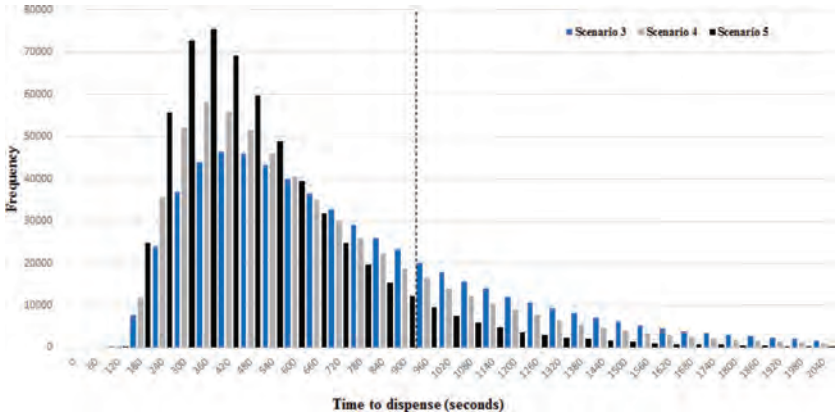

Figure 3. Distributions of the time taken to dispense walk-in prescriptions.

Table 5. Causes of delays.

Scenario		t < 15 mins	15 ≤ t < 20 mins	20 ≤ t < 25 mins	25 ≤ t < 30 mins	30 ≤ t < 35 mins	35 ≤ t < 40 mins	40 ≤ t mins
1	% of total	75.08	12.64	6.15	3.01	1.49	0.754	0.884
	Avg items	2.37	3.83	4.20	4.49	4.76	5.02	5.79
	Avg itts	0.074	0.226	0.349	0.498	0.673	0.838	1.24
2	% of total	80.66	10.40	4.72	2.17	1.03	0.495	0.533
	Avg items	2.40	4.10	4.52	4.88	5.25	5.70	6.70
	Avg itts	0.0803	0.276	0.425	0.606	0.796	0.997	1.33
3	% of total	91.74	5.27	1.77	0.66	0.295	0.141	0.122
	Avg items	2.50	5.70	6.46	6.57	7.33	8.21	9.51
	Avg itts	0.104	0.485	0.765	1.027	1.232	1.37	1.73

Comparing scenarios, it can be seen that scenarios 2 and 3 offer an improvement in the number of walk-in prescriptions being completed on time. Scenario 3 increased the percentage of prescriptions being completed on time by 16%, while scenario 2 managed an increase of only 5.5%.

5 CONCLUSION

In conclusion, this paper has demonstrated the use of CPNs as an effective tool for modelling the community pharmacy dispensing process. CPN is a suitable tool to evaluate efficiency and safety in one model. Pharmacy dispensing complexity is captured through: the inclusion of all major dispensing stages, their duration, and a variety of staff roles, errors and remedial action. Adding a pharmacist improved the pharmacy efficiency more than adding a dispenser. Dispensing errors are within the range reported in the literature, whereas near misses are overestimated.

Process reliability remained constant in all scenarios. By assigning staff wage costs to scenarios, this model could support decisions related to the cost-benefit of employing extra staff member.

Future work will focus on optimizing a pharmacy dispensing process. This would involve finding the optimal choice of how many staff should work in the pharmacy, given the working conditions and cost of staff wages. Metaheuristics such as, genetic or ant colony optimisation algorithms, are promising methodologies for this purpose. In addition, in-field data collection would be carried out, and ethical approval has been granted by the University of Nottingham. Other routes for future research could include constructing an alternative model capable of comparing the performance of automated and manual dispensing pharmacies. Future iterations of the model could be designed to include the dependency between the overall state of the pharmacy, and staff error rates. For example, if a pharmacy is busy, with many patients waiting for walk-ins to be dispensed, this could put pressure onto staff, who may be then more likely

to make errors. Another possible improvement to the model could be to consider how errors of each type, labelling, contents or label application, can actually occur in each item in a prescription.

ACKOWLEDGEMENTS

The authors would like to acknowledge and thank the ESPRC for their support and funding, without which, this research would not be possible (Grant ref EP/M50810X/1).

ABSTRACT: Advances in Information and Communication Technologies (ICT), pervasive computing and Artificial Intelligence (AI) are affecting all daily human life domains in multiple ways. Safety-critical transport systems are being massively affected by this technological shift. The Autonomous Vehicles (AV) are being considered the most promising new element in this future transport paradigm. It is expected that the AVs bring relevant benefits to the society, mainly reducing accidents and increasing accessibility. Given that any new safety-critical system, concept or technology is placed in operations only if its benefits outweigh the safety risks, assuring these future transport systems will be safe during their operation is a mandatory duty. This paper proposes a safety analysis Framework to be applied to the future intelligent Roadway Transport Systems (RTS) paradigm. Based on a combined fast and real time simulation approaches, the Framework allows analyzing, in a broad sense, the impacts of concepts, technologies and procedures on RTS safety and efficiency. A Proof-of-Concept (PoC) is provided, where representative RTS scenarios are modeled, simulated and analyzed using OpenDS, Matlab and Sumo+Veins+OMNet++. The RTS scenario elements (environment, vehicles, roadways, and driver) interact with each other. Autonomous and 'non-autonomous' vehicles share the RTS infrastructure, and AV is modeled combining a pair of RTS elements "driver+vehicle", with the control algorithms embedded in the autonomous driver element to manage AV movement. In this PoC, both the autonomous vehicle behavior and the impact of its embedded autonomous control algorithms over the RTS safety and efficiency are analyzed. Concluding, the Framework is capable to deal with the representative future RTS scenarios, mainly regarding to AV, analyzing the impact of concepts in component level (e.g. AI-based algorithms) over system level properties (e.g. safety) and the relationship among properties at various levels of RTS.

1 INTRODUCTION

Advances in Information and Communication Technologies (ICT) and pervasive use of computing and Artificial Intelligence (AI) are affecting all domains of daily human life, including those ones that could lead to deaths and health, environmental and patrimonial injuries. One of these safety-critical domains, the Transport systems, is being directly and massively affected by this new technological changing wave. Autonomous Vehicles (AV) - also called as self-driven or robot cars—could be considered the most notably new element in this future paradigm of Intelligent Transport System—ITS (PARLIAMENT & UNION 2010). Regarding to the Road Transport Systems (RTS), it is expected that the AVs will bring significant improvements in traffic safety and efficiency for all modes of transport. For example, it is expected to reduce significantly the number of traffic accidents when the need for a human driver is eliminated, or even reduced, given that the causes to more than 90% of accidents are attributed to human error (Singh 2015). Besides, AVs would increase accessibility to the individual transport by people with disabilities, elderly people, children and even vehicles without people on board (e.g. delivery or rental fleet reallocation).

As like any new safety-critical system, concept or technology, the AV will be incorporated into daily human life only if its benefits outweigh the safety risks. Therefore, it is mandatory assuring that the future safety-critical AVs, as well as the whole transport systems, are going to be safe enough during their operations on public roads in the real world environment. Given that information, communications systems and networks (i.e.

ICT) and Machine Intelligence (MI) are key enablers to the future ITS—mainly to the autonomous vehicles—it is necessary to evaluate how ICT, MI and other technologies and concepts will impact on (and contribute to) the autonomous transport safety risks and, consequently, how to apply them in an innovative, cost-effective and safe way.

U.S. National Highway Transportation Safety Administration (NHTSA) released a guidance to orient developers of Automated Driving Systems (ADS) – AV included—to "*analyze, identify, and resolve safety considerations prior to deployment using their own, industry, and other best practices*" (NHTSA 2017). It recommends the combination of simulations, test track, and on-road testing to validate the ADS safety performance. However, it is observed that the current AV safety evaluation and validation are being supported by track and on-road testing. Virtual testing approaches are a recent, in-development field interesting to manufacturers (Kim et al. 2017).

Tests are useful to improve the confidence on the system. However, it is impossible to cover all the possible system's conditions (behaviors) using tests. Kalra and Paddock (2016) show that '*fully autonomous vehicles would have to be driven hundreds of millions of miles and sometimes hundreds of billions of miles to demonstrate their reliability in terms of fatalities and injuries*', which is unfeasible in terms of costs and other available resources. In this way, they recommended that innovative, alternative methods of demonstrating safety and reliability need to be developed, as the "*virtual testing and simulation*", to supplement real-world testing in order to assess autonomous vehicle safety.

Thus, there is a need to develop new virtual testing and simulation approaches, mainly using accelerated time scales, in order to analyze the safety levels of AVs on a Roadway Transport System (RTS), as well as the safety levels of the RTS as a whole. This paper proposes a simulation-based safety analysis Framework to be applied to the RTS in this future ITS paradigm. Based on a combined fast-time and real-time computer simulation approaches, this Framework allows analyzing the impacts of concepts, technologies and procedures on the future RTS safety and efficiency, in a broad sense.

In this proposed Framework, specific RTS in predefined traffic scenarios (or 'Use Case') are modeled, simulated and analyzed. A Use Case represents a complete road traffic scenario under analysis, including the RTS architecture and specification, traffic configuration (vehicles trajectories and other traffic elements behavior) and the procedures to be applied during the analysis (simulations). By means of a Use Case, it is possible to analyze the influences of any RTS element inserted in a specific traffic configuration over the system safety metrics (e.g. collision rates) and over the way the hazardous situations evolve (system behavior). Mostly, it is possible to analyze how the AVs impact the safety and efficiency of the whole transport system they belong to, and identifying hazardous situations that emerge from the behavior of the AV on transport systems.

In addition to proposing and presenting the safety analysis Framework, this paper provides a Proof-of-Concept (PoC), where a representative Use Case is modeled, simulated and analyzed. The RTS elements interact with each other, and autonomous and 'non-autonomous' vehicles are sharing the same RTS infrastructure and running in the predefined traffic scenarios. Further, the validation of the Framework is presented using an AI-based autonomous control approach (Naufal et al. 2017) that manages risks related to the operations of AVs in a simulated RTS scenario.

This paper is structured in 5 sections. Section 2 presents details about the development of the proposed simulation-based safety analysis Framework. Section 3 provides a Framework PoC, in which a representative RTS scenario (Use Case) is implemented (modeled) and simulated by real-time and fast-time Open Source Simulation Tools. Section 4 presents the results obtained from the PoC and used to validate the proposed Framework. Finally, Section 5 presents conclusions about this work and some future directions.

2 THE SAFETY ANALYSIS FRAMEWORK FOR THE ROADWAY TRANSPORT SYSTEMS

Our proposed simulation-based safety analysis Framework is intended to be applied to the future, intelligent RTS paradigm. It is based on an Automotive (road and vehicle) Cyber Physical Systems (CPS) safety and resilience theoretical conceptual bases in the RTS domain. The Automotive CPS (ACPS) concept is a fusion among RTS, CPS and ITS concepts, as detailed in section II and III of Naufal et al (2017). These theoretical conceptual bases were used to understand the future, intelligent road transport system context in which AV are going to be inserted. Consequently, they were used to identify the elements and characteristics demanded to execute a simulation-based safety analysis of a RTS.

The developed Framework is composed of 5-modules as illustrated in Figure 1:

1. the "ACPS Elements module", a repository (class library) containing the classes of ACPS-based elements used to model an ACPS-based Roadway Transport System (RTS);
2. Framework users design a specific Use Case in the "Use Case elaboration" module using classes and attributes available in ACPS Elements module. ACPS-based RTS architecture, specification

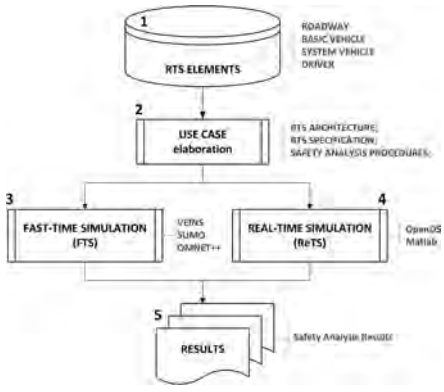

Figure 1. The simulation-based safety analysis framework.

and safety analysis procedures (safety metrics and parameters) are then submitted to the simulation-based safety analysis approach;

3. "Fast-Time Simulation (FTS) module", where the Use Case is instantiated and simulated—following the safety analysis procedures—using the open source fast-time computer-based simulation tools available in this Framework;
4. "Real-Time Simulation (ReTS) module", where the Use Case is instantiated and simulated—following the safety analysis procedures—using the open source real-time computer-based simulation tools available in this Framework;
5. The simulation reports with the simulation results are analyzed in "RESULTS module".

2.1 *ACPS elements*

Based on these ACPS conceptual bases, four classes of elements were identified: Roadway (physical place where vehicles run), Vehicle (the central traffic element, moving people and goods), Driver (manages the Vehicle movement according to the traffic rules and vehicle model) and Environment (weather conditions—e.g. rain, fog, snow—and obstacles—e.g. pedestrian, animals, roadway blockages) other than Vehicles). Table 1 presents these ACPS elements (classes) and their characteristics (attributes). These elements are both transport system safety-related (physical) elements and represent a real RTS in the ITS context (US-DoT 2017).

Regarding to the ACPS Elements, the 'DRIVER' class has no defined characteristic (attributes) because the DRIVER, in this Framework, only execute actions (methods). ROADWAY and Environment were included in the same class of elements (ROADWAY). Figure 2 illustrates the interactions among ACPS elements used to model the Use Cases in the proposed Framework. Different from a typical RTS in which Drivers get information directly from Environment and Roadway (observing them), DRIVERs monitor the Environment and Roadway using the sensors and other technologies embedded in the VEHICLE that they are driving. This enables modeling the future highly automated and fully-autonomous vehicles, given that they will take driving decisions using data obtained by themselves from the Environment.

In the proposed Framework, these ACPS elements embody a repository (a class library) containing classes of ACPS-based elements (elements, attributes, methods and interfaces). These elements represent an ACPS-based RTS and, consequently, this repository is used by Framework users to model any specific ACPS-based road traffic scenario (Use Case) and to develop a simulation-based safety analysis.

Table 1. RTS main elements and characteristics.

ACPS Elements (*Classes*)	Characteristics (*Attributes*)
ROADWAY (Environment included)	Interdicted area
	Direction of the road
	Obstacles on the road
	Physical characteristics of the road
	Signs
	Weather conditions
VEHICLE	Turn right command
	Turn left command
	Brake command
	Speed up command
	Distance from detected Vehicles/ Obstacles on the Road (DVOTR)
	Vehicle size
	Maximum braking rate
	Maximum vehicle speed
	Maximum acceleration rate
	Mechanical vehicle system status
	Steering wheel status
	Accelerator pedal status Brake pedal status
	Vehicle Speed status

DRIVER	

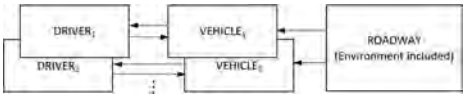

Figure 2. Relationship among ACPS elements.

2.2 *Use case elaboration*

During the Use Case elaboration, the RTS architecture, specification and safety analysis procedures

(safety metrics and parameters) are specified and modeled. The Use Case (ACPS-based RTS model and the analysis procedures) is instantiated and simulated using real-time and fast-time approaches by specific, open source simulation tools. Results (Reports) are obtained from these tools (safety analysis) and used to analyze the impacts of concepts, technologies and procedures on RTS safety and efficiency.

The Use Case shall contain the ACPS-based RTS architecture and specification (i.e. configuration of the ACPS elements characteristics—Roadway, Vehicle and Driver—which represent the specific use case scenario), as well as the safety analysis procedures—the safety metrics and parameters that will be analyzed in this scenario. For the safety analysis efficiency purposes, the Use Case should represent a road traffic scenario that maximizes the occurrence of conflicts points, hazardous situations and accidents. Besides, it is possible to analyze the influences of ACPS elements and their characteristics (Use Case Specification) over system safety metrics (e.g. collision rates) and hazardous situations evolution (behavior).

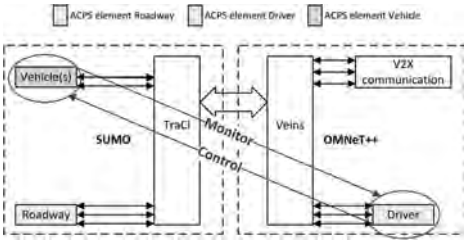

Figure 3. FTS high-level architecture.

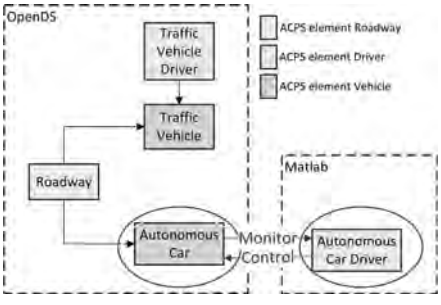

Figure 4. ReTS high-level architecture.

2.3 *Fast-Time and Real-Time simulation modules*

The Use Case is implemented (instantiated), simulated and analyzed using Fast-Time and Real-Time computer-based Simulations approaches in Framework modules 3 (FTS) and 4 (ReTS) using two different sets of open source tools. In the FTS (Framework module 3), *Veins* is used. It is an event-based network simulator that allows simulating vehicular communication, and integrates with *SUMO* (*Simulation of Urban MObility*) – a road traffic simulator—and *OMNeT++* (*Objective Modular Network Testbed in C++*). In the ReTS (Framework module 4), it is used the OpenDS(TM) – a driving simulator primarily intended for research and driving training, and Matlab(TM).

Molina et al. (2017) assessed these two open-source simulation tools sets suitability with the modeling and simulation capabilities demanded by the analysis Framework, and evaluated if they are capable to model and simulate, using fast-time and real-time simulation approaches, the Road Transport Systems (indeed, ACPS) elements characteristics required by the Framework. Besides, the tool's best features were highlighted and the process of adapting these tools for the safety analysis purposes was presented.

Figure 3 and Figure 4 illustrate the high-level architecture of FTS and ReTS modules, respectively. Roadway, Vehicles and Driver are represented in both FTS and ReTS. A functional Vehicle (AV) is modeled combining a pair "Driver + Vehicle" elements, the vehicle control algorithms are embedded in the Driver element, which manages the Vehicle's movement. In ReTS, Vehicles are represented by 'Traffic Vehicles' and 'Autonomous Cars'.

Using FTS approach, it is possible running several simulations over a Use Case scenario, allowing the estimation (statistical) of risk metrics, as well as identifying worst cases scenarios. On the other hand, using ReTS approach, system behavior during specific scenario conditions (including failure modes), especially to the worst cases scenarios can be analyzed in details, as identified by the fast-time simulation.

2.4 *Results*

Finally, '*RESULTS*' (module 5) represents the safety analysis reports generated by the simulation tools. These reports contain the safety and efficiency metrics, as well as any other relevant information, obtained by simulating the Use Case scenarios according to the Safety Analysis Procedures. These reports may contain the status of the system elements when a collision (or any safety-related event) occurs, as well as safety risk metrics and other parameters specified by the analyst in the Use Case. Therefore, using information provided in these reports, it is possible to systematically identify the potential causes of hazards or failure modes and identify how failures or defects in the system elements might contribute to hazards or accidents (e.g. collisions) – i.e. performing a Safety Analysis (MoD 2017).

3 PROOF-OF-CONCEPT (PoC) FRAMEWORK IMPLEMENTATION

This section presents a Proof-of-Concept (PoC) to the proposed Framework. The PoC is oriented by a Use Case composed by a representative number of ACPS Elements to effectively test, and validate the Framework. Besides, the Use Case presents a road traffic scenario that maximizes the occurrence of hazardous situations and accidents ('Vehicle to Anything Else' – V2X collisions). Thus, it is possible to analyze both the influences of ACPS elements (autonomous vehicles included) over RTS safety and efficiency metrics (e.g. collision rates and traffic flow and capacity) and the hazardous situations evolution (system behavior).

3.1 *AI-based Autonomous Vehicle (AV)*

The proposed Framework is used to analyze the capabilities of an AI-based autonomous vehicle (AV) control approach in managing safety risks related to the operation of an autonomous vehicle (AV) in a simulated ACPS-based RTS scenario. The analyzed AI-based AV control approach was proposed by Naufal et al (2017) and named as "A^{2}CPS Engine". It is a run-time, software-based, vehicle-centric risk management approach, which its algorithm was developed using Fuzzy Logic (an AI technique). A^{2}CPS Engine algorithms monitor the environment and the AV behavior and control AV actions, mitigating hazards and reducing accidents severity related to the AV operation. Table 2 presents the risk management rules performed by the analyzed AV Control algorithms. Depending on the calculated Risk Level and its Risk Criteria, a specific Treatment (action to be executed by the AV) is performed.

The AV Control algorithms were embedded in the autonomous vehicle DRIVER, monitoring and controlling the autonomous VEHICLE. Figure 5 illustrates the AI-based AV Control algorithms (based on A^{2}CPS Engine proposal) embedded in the autonomous DRIVER and the I/O interface with Autonomous VEHICLE. In this implementation, the AV Control algorithms receive its Speed from

Table 2. Risk management rules performed by the AV control.

Risk level	Risk criteria	Risk treatment	Action (brake intensity)
No risk	Negligible	Do noting	No brake
Low	Undesirable	Speed reduction	Small
Moderate			Medium
High	Intolerable	Stop vehicle	High
Very high			Very high

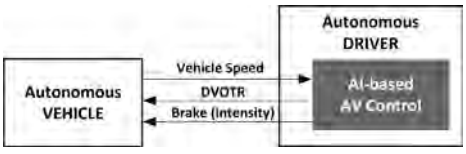

Figure 5. AI-based AV control inputs/output interface.

Autonomous Vehicle and the Distance from detected Vehicles and Obstacles on the Road (DVOTR), and it controls the brake intensity application.

The proposed safety analysis Framework is used for analyzing both (i). the autonomous vehicle behavior in the road traffic scenarios and (ii). the impact of AI-based autonomous control algorithms (autonomous vehicle behavior) over the RTS safety and efficiency levels. It is worth noting that this analysis has considered both *safety* and *efficiency*, because they are competing system characteristics in transportation systems. Traffic efficiency (e.g. traffic flow and capacity) is often impaired when system safety is prioritized. So, a tradeoff between safety and efficiency (availability included) is required. Consequently, a Use Case is designed to analyze:

1. Both *safety metrics* (#collisions) and *traffic efficiency metrics* (average speed and standard-deviation (E[v]; VAR[v]); average total distance traveled). These metrics were obtained in function of *maximum vehicle speed* (V_{MAX}) and *Incident Zone Warning* (IZW) configuration—a main characteristic of the AI-based AV Control approach (A^{2}CPS Engine), representing a dynamic zone of protection around the vehicle (Naufal et al. 2017). By these metrics, it could be possible to analyze the influence of AV Control over the autonomous vehicle behavior and how it affects the global, transport system safety versus efficiency relationship (i.e., the analysis objective 'ii.'). Given the statistical characteristic of metrics, they were obtained by the Fast-Time Simulation (FTS) approach (Framework module 3);
2. The autonomous vehicle Stopping Distance (SD) – distance the autonomous vehicle stops from a static obstacle. SD was obtained in function of the maximum vehicle speed (V_{MAX}) and the IZW configuration. By this metric, it could be possible to analyze how the AV Control algorithms affects the autonomous vehicle braking behavior (i.e., the analysis objective 'i.'). This analysis was performed by the Real-Time Simulation (ReTS) approach (Framework module 4).

3.2 *Use case details*

The ACPS-based RTS high-level architecture considered in the Use Case is illustrated in Figure 6.

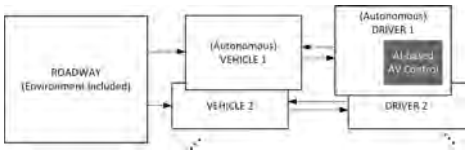

Figure 6. RTS high-level architecture USE CASE.

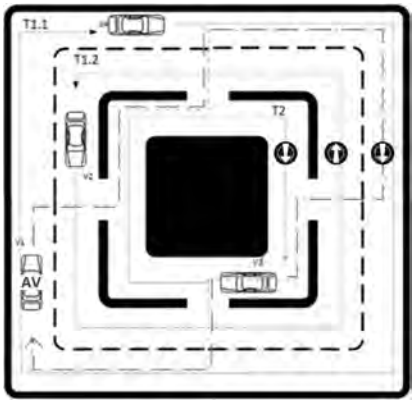

Figure 7. Use case road traffic scenario (FTS).

The AI-based AV Control (A^2CPS Engine) algorithms are embedded in the Autonomous Driver, managing the Autonomous Vehicle. The pair "Driver + Vehicle" models the Autonomous Vehicle (VEHICLE 1), which runs along the Roadway together with other Vehicles (2, 3, …).

The RTS traffic scenario considered in the FTS approach (Framework module 3) is illustrated in Figure 7. Four (4) Vehicles (V1 to V4) are travelling, in a closed traffic circuit, with pre-defined trajectories and speed profiles through a Roadway composed of 2 roads (T1 and T2) – a two-way road (T1.1 and T1.2) and a one-way road (T2). One of the four vehicles (V1) is an autonomous vehicle, and its (autonomous) Driver has the embedded AI-based AV control approach under analysis. The Roadway architecture, including each road direction, is represented by arrows. V1 to V4 trajectories are shown, where V1 (the AV) runs through all the roads (T1.1, T1.2 and T2) following the signed trajectory; V2 runs only on T1.2; V3 runs only on T2; and V4 runs only on T1.1. In this road traffic scenario, V1 trajectory exposes itself and the other vehicles (V2-V4) to the occurrence of harmful events (collisions), most of than on the crossing points. Consequently, the occurrence of hazardous situations and accidents are maximized, improving the safety analysis efficiency.

The RTS traffic scenario considered in the ReTS approach (Framework module 4) is illustrated in Figure 8. The autonomous vehicle running in a straight trajectory and with its maximum speed

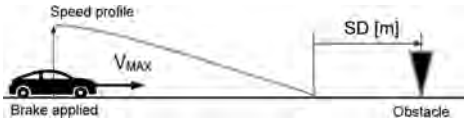

Figure 8. Use case road traffic scenario (ReTS).

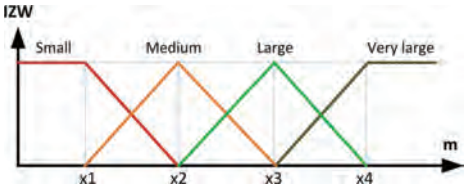

Figure 9. IZW fuzzy logic variable (x1–x4 parameters).

(V_{MAX}). In the end of this trajectory is placed a static obstacle. During the simulation it is measured the time to stop, speed and the distance from autonomous vehicle to the obstacle when vehicle stops (the stopping distance—SD) to different IZW's configurations and V_{MAX}. Using these values, it is possible to analyze if the autonomous vehicle keeps a safe and efficient distance from other vehicles.

3.3 *RTS and FTS Modules*

The Use Case traffic scenarios, including the RTS architecture and specification, and the AI-base AV control algorithms are modeled (instantiated), simulated and analyzed in the FTS and ReTS modules of Framework using its open-source tools sets (Figure 3 and Figure 4, respectively). The Use Case attributes configured to the RTS elements were: VEHICLEs = {max. acceleration = 3,3 m/s^2; maximum braking rate = 7,6 m/s^2; maximum speed = 120 km/h}; ROADWAY = {track geometry = uniform—without spines}. Drivers managed both longitudinal and lateral movement of their vehicles. Vehicles 2, 3 and 4 (non-autonomous vehicles) were driven by the native control embedded in the FTS simulation tool. In FTS, the total simulation time was 10.000 s.

In the FTS approach, it was considered 3 maximum speed (V_{MAX}) to the autonomous vehicle (V1): V_{MAX} = {15; 20; 30} m/s = {54; 72; 108} km/h; Vehicles 2, 3 and 4 run in constant speed of 5 m/s (18km/h). In the ReTS approach, it was considered 3 maximum speed (V_{MAX}) to the autonomous vehicle (V1): V_{MAX} = {30; 60; 120} km/h. Both simulation approaches (FTS and ReTS) considered the same 4 configurations to the IZW fuzzy logic variable parameters (Figure 9): {{20; 60; 95; 180}; {10; 30; 47,5; 90}; {5; 15; 23,75; 45}; {20; 60; 150; 180}}.). IZW_1 version ({20; 60; 95; 180}) was defined during the model calibration and it was the configuration-base to the other tests. IZW_2 version ({20; 60;

150; 180}) has changed only one of the parameters and used to analyze the impact of IZW shape on safety and efficiency. IZW_3 ({10; 30; 47.5; 90}) and IZW_4 versions ({5; 15; 23.75; 45}) configurations were based on the IZW_1, which was divided by 2 and 4, respectively. Parameter 'x4' physically represents the size of protection zone (45 m, 90 m and 180 m).

4 RESULTS AND DISCUSSION

The results obtained by the FTS approach are presented in Table 3. For all four IZW configurations (IZW_1 to IZW_4), three (3) autonomous vehicle maximum speeds (V_{MAX}) were considered. The number of collisions, average speed, standard-deviation and total distance travelled by AV (during the simulation length of 10,000 s) were obtained by fast-time simulation.

The results obtained by the ReTS approach are presented in Table 4. Just as it was adopted for the FTS approach, three (3) autonomous vehicle maximum speeds (V_{MAX}) were considered to each one of the 4 IZW configurations. The Stopping Distance (SD) was obtained by real-time simulation.

Table 3. FTS results (Metrics × V_{MAX} × IZW).

	V_{MAX} (AV) [m/s]		
Metrics	15	20	30
IZW_1 = {20; 60; 95; 180}			
#collisions	28	28	28
Average speed [m/s]	5.0	5.0	5.0
Standard deviation	3.1	3.1	3.1
Total distance [m]	50,050	50,049	50,049
IZW_2 = {20; 60; 150; 180}			
#collisions	30	30	30
Average speed [m/s]	5.0	5.0	5.0
Standard deviation	2.5	2.5	2.5
Total distance [m]	50,072	50,072	50,072
IZW_3 = {10; 30; 47,5; 90}			
#collisions	24	24	24
Average speed [m/s]	5.0	5.0	5.0
Standard deviation	2.3	2.3	2.3
Total distance [m]	50,115	50,115	50,115
IZW_4 = {5; 15; 23,75; 45}			
#collisions	184	195	315
Average speed [m/s]	10.0	11.5	15.9
Standard deviation	4.4	6.1	8.4
Total distance [m]	99,855	114,398	142,327

Table 4. ReTS results (SD × V_{MAX} × IZW).

V_{MAX} (AV) [km/h]	Stopping Distance (SD, in [m])			
	IZW_1	IZW_2	IZW_3	IZW_4
30	10.00	10.10	1,9	collide
60	7.47	9.92	collide	collide
120	6.67	8.80	collide	collide

Safety is measured by the number of collisions observed during 10.000 seconds (about 3h) of traffic execution. Efficiency is measured by means of average speed and standard-deviation, and total distance traveled during the simulation. The autonomous vehicle braking behavior is analyzed by means of the Stopping Distance (SD) metric (Figure 8). It is observed how these metrics change when V_{MAX} and IZW configuration are modified.

Considering the ReTS results (Table 4), it is possible to analyze the capability of four AI-based AV Control (A^2CPS Engine) algorithms versions (IZW_1 to IZW_4) in identifying a potential collision condition, assessing the related level of risk during runtime execution and stopping the autonomous vehicle *safely* (before a collision) and *efficiently* (as close as possible to the obstacle). The IZW_4 version could not stop the AV safely in any speed. Consequently, the AV has not a safe behavior using this A^2CPS Engine version. This is confirmed by the FTS results (Table 3), which IZW_4 has the largest number of collisions obtained among all IZW versions. Therefore, it is possible concluding that a smallest tested IZW (zone protection shorter than 45 m) cannot protect the AV against collision.

IZW_3 version produces an AV zone protection twice larger than IZW_4. But, IZW_3 version protects the AV against collisions only at low speeds (30km/h) with a high efficiency (AI-based AV Control algorithms stop the vehicle near to the obstacle—about 2 m). Now, considering IZW_1 and IZW_2 – with a zone protection twice larger than IZW_3 and four times larger than IZW_4 – they can protect the AV against collisions at any tested speed (from 30km/h to 120 km/h). This observation is confirmed by the FTS results (Table 3), which the speed has no influence in the traffic safety (the same number of collisions was observed in IZW_1 and IZW_2 at any speeds). The difference between these IZW_1 and IZW_2 versions is observed in the braking efficiency, where SD was between 6,67 m and 10 m (five times less efficient than the last analyzed version at 30 km/h which), and the worst braking efficiency is observed in the IZW_2 version.

The internal shape of linguistic variable IZW (Figure 9) has influence on SD (braking) efficiency, but it has neither influence on traffic safety (the number of collisions is the same in both versions) nor on traffic efficiency (same average speed and total distance).

Finally, it is possible to observe that best AI-based AV Control (A^2CPS Engine) algorithms version in terms of traffic safety (lower number of collisions) and efficiency is the IZW_3. However, regarding to the ReTS results (Table 4), this

version protects the AV against collisions only at low speeds (30 km/h). Observing the average speed and standard deviation, AV has travelled in this scenario only at low speeds. Therefore, this version is safe and efficient in terms of traffic flow/productivity.

5 CONCLUDING REMARKS

This paper proposed a simulation-based safety analysis Framework to be applied to the future, intelligent Roadway Transport Systems (RTS) paradigm. Based on a combined Fast-Time Simulation (FTS) and real-time simulation (ReTS) approaches—implemented by the open-source tools OpenDS, Matlab, Sumo, Veins and OMNet++, this Framework allows analyzing the impacts of concepts, technologies and procedures on RTS safety and efficiency. For demonstration and validation purposes a Framework Proof-of-Concept (PoC) was provided. It was applied to analyze the capabilities of a AI-based autonomous vehicle control approach—the A^{3}CPS Engine proposed by Naufal et al (2017) – in managing safety risks related to the operation of an autonomous vehicle in a simulated RTS scenario.

PoC was useful to demonstrate the Framework capability of modeling and simulating real-world, representative ACPS-based Road Transport System scenarios, in which Vehicles, Roadway (environment included) and Driver elements are interacting with each other. It enables modeling roadway traffic scenarios where both autonomous (unmanned) and manned vehicles share the same roadway infrastructure. The autonomous vehicles are modeled combining a 2-tuple of ACPS elements "Driver + Vehicle". The autonomous vehicle control algorithms, even those algorithms developed by a third-party (not by Framework user), are embedded in the autonomous Driver element and they manage the (autonomous) Vehicle movement. Using these approaches, it is possible to analyze the behavior of the autonomous vehicle's behavior in traffic scenarios and evaluate the impact of autonomous vehicles on the of RTS safety properties.

Representing an Autonomous Vehicle by the combination of a 'off-the-shelf', general purpose Vehicle element whose behavior is managed by an autonomous control algorithm embedded in the Driver element is adherent to the state-of-the-art adopted by the autonomous vehicles developers. Today, AV developers are using current manned vehicles from the consolidated automotive industry worldwide and embedding in them systems, software and machine intelligence. Therefore, this Framework can be used efficiently to evaluate the Autonomous 'Driver', the part that makes a vehicle be 'autonomous', as well as its impacts on system safety when operating in a simulated, but complete, RTS scenario.

Using the proposed Framework, it is possible observe the impact of a new concept/technology (component level) over several system parameters (in this case, traffic safety and efficiency) and, at the same time, understand and analyze the relationship among several system properties (some of them intrinsic to systems elements, others intrinsic to the system). 'Safety' and efficiency are competing metrics in transport systems, where the traffic efficiency (e.g., traffic capacity or flow rate) is often impaired when system safety is prioritized. Therefore, a trade off between safety and efficiency (availability included) is required to these safety-critical systems.

Concluding, this work has advanced on addressing the question '*how to assure that the future safety-critical autonomous transport systems are going to be safe enough during their operation?*'. Relevant ACPS-based RTS elements and characteristics to be considered in a safety analysis were identified. As the following works, authors are evolving this Framework, implementing both environment/system changes during runtime simulation and collaborative communication among system elements (V2X) capabilities. This Framework evolution will allow resilience analysis over the ACPS-based Road Transport Systems, evolving on the development of new approaches to safety assurance.

Robust management of distributed energy resources for frequency control in microgrids with unreliable communication

H.D. Mo & G. Sansavini
Reliability and Risk Engineering Laboratory, Department of Mechanical and Process Engineering, Institute of Energy Technology, ETH Zurich, Switzerland

ABSTRACT: Effective coordination of Distributed Energy Resources (DERs) in power systems via control strategies mitigates the frequency fluctuations stemming from stochastic renewables and uncertain demand. Recently, open communication networks are used to deploy Load Frequency Control (LFC) strategies to overcome the lack of dedicated communication infrastructures and the ubiquity of DERs system. However, open networks are exposed to communication degradation and can reduce the LFC performance. This work investigates the real-time performance and reliability of the integrated DER system and open communication networks, i.e. the cyber-physical microgrid system, with reference to LFC against communication degradation. In particular, LFC is provided by a discrete PID controller tuned via particle swarm optimization. The cyber-physical microgrid system is implemented on a real-time platform simulating various MAC protocols and open-communication-network architectures, developed in the Truetime simulator. The impact of communication degradation on LFC performance is assessed. Simulation results demonstrate that transmission delays and packet dropouts jeopardize the ability of cyber-physical microgrid systems to maintain system frequency deviations within tolerance bounds. In particular, the use of Ethernet ensures higher reliability as compared to 802.11 b/g. Moreover, the impact of interfering traffic and of the percentage of used bandwidth on the LFC performance reduction is evaluated. The optimized PID controller is able to compensate for communication degradation and uncertainty of the microgrid, and ensures robust LFC against unknown network configurations.

1 INTRODUCTION

The power sector is experiencing a structural trend towards decentralization stemming from the integration of large shares of Renewable Energy Resources (RERs) (Driesen and Katiraei, 2015). This is fostered by Distributed Energy Resources (DERs), which require the integration of power generation means located at or near the end-user side (Kumar et al., 2017). However, the stochastic nature of RERs and of the load demand induces system frequency fluctuations (Shotorbani et al., 2012). An effective control strategy is needed to keep the system frequency to its nominal value by balancing power generation and demand in real time. To this aim, Automatic Generation Control (AGC) schemes are developed for damping frequency oscillations in Distributed Generation Systems (DGS) (Shotorbani et al., 2012; Lee and Wang, 2008).

Recently, the AGC has been integrated with the open communication network, due to low cost, high speed, simple structure and flexible access. Data exchanges among PMUs, generators and control center are provided by the open communication network in the form of time stamped data packets (Kuzlu et al., 2014). Stable AGC depends heavily on the performance of the open communication network (Ahmadi and Aldeen, 2017).

However, open communication networks are exposed to various types of degradation processes, i.e. network-induced time delays (Lee and Wang, 2008) and packet dropouts (Mo et al., 2016). As a result, the measurement signals (control signals) received by the control center (ESSs or generators) degrade, effective AGC cannot be carried out and the system frequency response worsens (Pan and Das, 2016). Studying the performance of open communication networks is critical for understanding the occurrence of time delays and packet dropouts.

Time delays are variable, challenging to predict, deteriorate the AGC performance and reduce the stability region (Pan and Das, 2016). Packet dropouts refer to lost messages, which occupy network bandwidth but cannot reach destination. They affect the operations of DERs and the reduction of frequency fluctuations, particularly in uncertain network environments. Optimal feedback AGC regulators for DERs are investigated in numerous

works for perfect communication networks and the impact of transmission delays and packet dropouts on the controller cannot be captured (Ghoshal, 2004). Robust PID controllers against constant or uniformly distributed time delays are designed to cope with perturbations of the control parameters (Pan and Das, 2016). However, constant or uniformly distributed time delays cannot be generally assumed in realistic communication networks.

In this work, we investigate (a) the operations of the integrated DER system and open communication network, and (b) the design of optimal AGC strategies in the face of communication degradation. The ability of the integrated system to maintain system frequency within tolerance margins quantifies system reliability, and is evaluated by Monte Carlo simulation (MCS). Stochastic time delays are modelled by generating random congestion based on MAC protocols. Congestion of network channels depends on the activity level of the interfering traffic, which is the root cause of network-induced delays and packet dropouts (Peng and Han, 2016). The open communication network model is implemented via Truetime simulator testing different MAC protocols (Grenier and Navet, 2004; Cervin et al., 2010). Multiple activity levels of the interfering traffic are simulated via the disturbance node, which sends random interfering packets over the network. Packet dropout is described by Bernoulli-distributed variables (Minero et al., 2009). To stabilize system frequency against RER, demand variability and communication degradation, a discrete PID controller is used (Pan and Das, 2016). Particle Swarm Optimization (PSO) is adopted to minimize the stochastic objective function and achieve the optimal PID controller for various architectures and conditions of the open communication network (Ghoshal, 2004; Pan and Das, 2016). Finally, the robustness of the optimum-PID-controlled AGC against communication degradation is assessed.

The rest of the work is organized as follows. Section 2 describes the DGS model. The open network and the communication degradation models are described in Section 3. Section 4 defines the reliability of the integrated system, and introduces the PSO-based PID controller. Section 5 presents the simulation results. Section 6 concludes the work.

2 MODEL OF DGS WITH DERS

The schematic of the integrated system, which is made of a cyber layer and a physical layer, is illustrated by Fig. 1. The structure of physical layer is general, representative of DGS, and widely adopted in the literature (Pan and Das, 2016). It models a hybrid microgrid, which consists of conventional

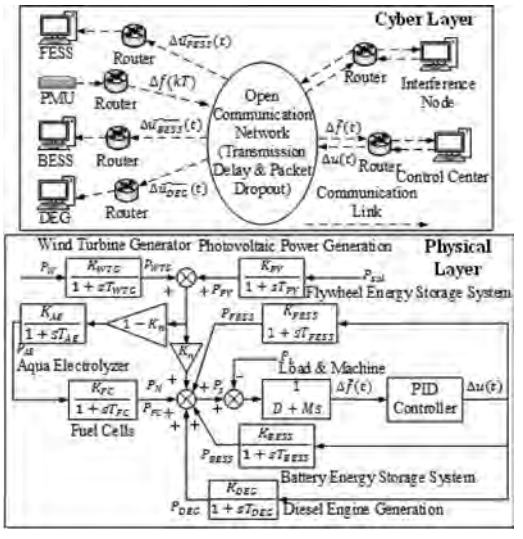

Figure 1. Schematic of the integrated system.

generators (Diesel Engine Generator, DEG), RERs (wind turbine generator, WTG, and photovoltaic generator, PV), ESSs (battery and flywheel energy storage system, BESS and FESS) and power-to-gas technology (aqua electrolyzer, AE, and fuel cell, FC). The cyber layer, i.e. the open communication network, provides data exchange between the control center and the controllable components, i.e. the ESSs and DEG, in the physical layer. PMU measurements and control signals are transmitted via the shared and open communication network. The cyber layer is detailed in Section 3. Power imbalance is the root cause of system frequency fluctuations. The control center remotely monitors the ESS and the diesel generator to reduce the imbalance and to ensure good AGC performance.

The small signal stability analysis of the hybrid microgrid in Figure 1, is based on time-domain simulations, i.e. transfer function models. In the AGC, the WTG, PV, AE, FC, DEG, FESS and BESS are described by first order transfer functions with specified gain and time constant. A centralized controller is used by Pan and Das (2016), as opposed to multiple decentralized controllers for each controllable component (Ray et al., 2011). It enables easier maintenance and reduces wiring cost, and makes the AGC design problem traceable by reducing the number of controller parameters. On the other hand, the centralized controller impacts the AGC performance, because a unique control signal is used by all the components. Nevertheless, current studies show that the centralized controller can ensure acceptable real-time AGC performance (Pan and Das, 2016). The transfer

functions $G_{WTG}(s), G_{PV}(s), G_{FC}(s)$ and $G_{DEG}(s)$ of the WTG, PV, AE and DEG, respectively, are expressed as

$$G_{WTG}(s)=\frac{K_{WTG}}{1+sT_{WTG}}=\frac{P_{WTG}}{P_W} \tag{1}$$

$$G_{PV}(s)=\frac{K_{PV}}{1+sT_{PV}}=\frac{P_{PV}}{P_{sol}} \tag{2}$$

$$G_{FC}(s)=\frac{K_{FC}}{1+sT_{FC}}=\frac{P_{FC}}{P_{AE}} \tag{3}$$

$$G_{DEG}(s)=\frac{K_{DEG}}{1+sT_{DEG}}=\frac{P_{DEG}}{\widetilde{u_{DEG}}(t)} \tag{4}$$

where K_{WTG}, K_{PV}, K_{FC} and K_{DEG} are the gain, and T_{WTG}, T_{PV}, T_{FC} and T_{DEG} are the time constant of the WTG, PV, AE and DEG. P_{WTG} and P_{PV} are the electrical power produced from the RERs, i.e. wind power P_W and solar power P_{sol}. P_{AE} and P_{FC} are the output of the AE and the power produced of the FC. The DEG is controlled by the control signal $\widetilde{u_{DEG}}(t)$ sent by the remote control center and it generates power only when the RERs cannot meet the demand.

In the DGS, the AE is used to absorb the rapidly fluctuating output power from the WTG and PV by producing hydrogen (Das et al., 2012). The hydrogen is stored and used as fuel in the FC to feed power to the grid. The dynamic property of AE is described by the transfer function $G_{AE}(s)$

$$G_{AE}(s)=\frac{K_{AE}}{1+sT_{AE}}=\frac{P_{AE}}{(P_{WTG}+P_{PV})(1-K_n)} \tag{5}$$

where K_{AE} and T_{AE} are the gain and time constant of the AE. $1-K_n$ denotes the fraction of power generated by the WTG and PV to produce hydrogen in the AE. K_n is equal to $P_N/(P_{WTG}+P_{PV})$ and is set to 0.6 (Pan and Das, 2016).

The ESSs are critical in eliminating frequency fluctuations due to their fast response to the control signal. Based on Lee and Wang (2008), the transfer functions $G_{FESS}(s)$ and $G_{BESS}(s)$ of the FESS and BESS are given as

$$G_{FESS}(s)=\frac{K_{FESS}}{1+sT_{FESS}}=\frac{P_{FESS}}{\widetilde{u_{FESS}}(t)} \tag{6}$$

$$G_{BESS}(s)=\frac{K_{BESS}}{1+sT_{BESS}}=\frac{P_{BESS}}{\widetilde{u_{BESS}}(t)} \tag{7}$$

where K_{FESS} and K_{BESS} are the gain, T_{FESS} and T_{BESS} are the time constant, P_{FESS} and P_{BESS} are the output power, $\widetilde{u_{FESS}}(t)$ and $\widetilde{u_{BESS}}(t)$ are the control signal of the FESS and BESS.

Remark 1: The DEG, FESS and BESS have rate constraint, i.e. $|P_{DEG}|<\overline{P}_{DEG}$, $|P_{FESS}|<\overline{P}_{FESS}$ and $|P_{BESS}|<\overline{P}_{BESS}$, where $\overline{P}_{DEG}$, $\overline{P}_{FESS}$ and $\overline{P}_{BESS}$ are the maximum rated output power of the DEG, FESS and BESS, respectively.

The transfer function $G_{HPS}(s)$ of the hybrid power system (HPS) models the relationship between the power imbalance, i.e. $\Delta P_S-\Delta P_L$, and the system frequency $\Delta f(t)$

$$G_{HPS}(s)=\frac{1}{D+Ms}=\frac{\Delta f(t)}{\Delta P_S-\Delta P_L} \tag{8}$$

where M and D are the inertia constant and dampi constant of the HPS (Pan and Das, 2016), P_S is the total power generated, denoted by $K_n\cdot(P_{WTG}+P_{PV})+P_{FC}+P_{DEG}+P_{FESS}+P_{BESS}$, and P_L is the power demand. The models for P_{WTG}, P_{PV} and P_L are detailed in (Lee and Wang, 2008).

3 THE OPEN COMMUNICATION NETWORK

The model of the data transmission across the open communication network accounts for the composition of network-induced delays and for the stochastic packet dropout. We assess two general architectures for the communication network used in power systems, i.e. the Ethernet (Grenier and Navet, 2004) and a mix of Ethernet and WLAN (henceforth called hybrid network) (Pan and Das, 2016), and implement them via Truetime simulator (Cervin et al., 2010).

3.1 *Model of time delay and packet dropout*

The time delay in the communication channel consists of four components, i.e. the preprocessing time T_{pre}, the waiting time T_{wait}, the time for traveling across the channel T_{tx} and the post-processing time T_{post}. (Ghoshal, 2004). Therefore, the total time delay T_d can be expressed as

$$T_d=T_{pre}+T_{wait}+T_{tx}+T_{post} \tag{9}$$

where T_{pre} and T_{post} depend on the processing speed of the device firmware. T_{tx} depends on the physical bandwidth, propagation spend and transmission distance. T_{wait} is the major source of the te delay and it is influenced by the MAC protocol.

The time delays τ_{sc} at forward channel and τ_{ca} afeedback channel are determined by (9), and their impact on the transfer function from the control signal $U(s)$ to the system output $Y(s)$ is described as

$$\frac{Y(s)}{U(s)} = G(s)\, e^{-(\tau_{sc}+\tau_{ca})s} \tag{10}$$

where $G(s)$ denotes the transfer functions of the DERs.

A second source of disturbance in the source-destination communication is packet dropout, which occurs for three major reasons, i.e. the network disconnection, time-out transmission and time-out re-transmission (Cervin et al., 2010). Binary switching sequences are usually applied, which specify the expected packet dropout probability. The stochastic parameter γ_k of the binary switching sequence is Bernoulli distributed (Liang et al., 2010), taking value of 0 or 1 with

$$\mathrm{P}\{\gamma_k = 0\} = L_d \tag{11}$$

where $0 < L_d < 1$ is the packet loss probability.

3.2 *Network architecture and implementation*

The architecture for the AGC of DERs via Ethernet and hybrid network, is illustrated by the cyber layer in Figure 1. The data exchange among the control center, DERs, interference node and PMU is wired in the Ethernet architecture. In the hybrid architecture, the data exchange between the routers and the RTU (BESS, FESS, DEG and PMU) is wireless and provided by the WLAN. The data exchange among routers is wired and provide by the Ethernet. Low product prices make WLAN more convenient and cost-effective compared to the traditional LAN. As such, WLAN has become an efficient approach to provide flexible data communication between routers and RTU, and is employed for monitoring and controlling DERs, offshore wind farms and smart home energy managemensystems (Pan and Das, 2016).

The interference node simulates the interference user in the open network, who sends disturbing traffic over the channels and cause congestion. Generally, the length of data traffic is constant (i.e. 80 bytes in this work), and the interference node sends it to the network at every time period T_i if

$$\mathrm{UN}_i < \mathrm{BWShare} \tag{12}$$

where UN_i is a uniformly distributed random number sampled at time period T_i in the interval $[0,1]$, and BWShare is the expected ratio of the network bandwidth used by the interference node.

The architectures of the real-time AGC of DERs via the Ethernet and hybrid network all consists of:

- PMU node (time-driven): the PMU takes measurements of the system frequency at every sampling interval T_s = 0.01s and sends $\Delta f(kT_s)$ to the control center over the network. The size of data packets is 80 bytes and the phase delay caused by the filter of the PMU is 0.006 s (Martin et al., 1998).
- Control center node (event-driven): when a data packet from the PMU reaches the control center, the controller takes 0.002 s to compute the control signal $u(t_n)$ and sends it to the DERs. The length of control signal is 500 bytes.
- DERs nodes (event-driven): the DEG, BESS and FESS adjust their operations based on the control signal received.
- Interference node (time-driven): it sends disturbing traffic over the network with period T_i and causes congestion, to generate different scenarios of time delay and packet dropout.

4 THE PSO-TUNED PID CONTROLLER

4.1 *Discrete-time PID controller*

Due to periodic PMU measurements and packet dropouts, the AGC process is discrete. Therefore, a discrete-time PID controller is adopted to compute the control signal

$$\begin{aligned} u(t_n) = -(&K_P \Delta\tilde{f}(t_n) \\ &+ K_I \sum_{k=0}^{n} \Delta\tilde{f}(t_k) * T_s + K_D \frac{\psi}{T_s}) \end{aligned} \tag{13}$$

where K_P, K_I and K_D are the proportional, integral and derivative gain of the controller, and $\psi = \Delta\tilde{f}(t_n) - \Delta\tilde{f}(t_{n-1})$.

For the implementation of the discrete-time PID controller, the role of a first-order pole filter on the derivative action should be considered [36]. Therefore, the transfer function of the discrete-time PID controller in Eq. (18) is

$$C(z) = -\left(K_P + K_I a(z) + K_D \frac{N_L}{1 + N_L b(z)} \right) \tag{14}$$

where N_L is the filter's coefficient indicating the location of the pole in the derivative filter and $a(z) = b(z) = T_s/(z-1)$.

4.2 *Reliability of the integrated system*

Frequency values outside the tolerance band compromise the components in the physical layer, reduce their useful lifetime and deteriorate the AGC performance. In this work, the reliability is defined as the ability of the integrated system to

maintain system frequency within a predefined tolerance band, in the face of stochastic RERs, uncertain load demand, variable time delays and random packet dropouts. The value of the reliability R measures the ability of the integrated system to provide adequate AGC performance, and is computed as

$$R = T_I / T \tag{15}$$

where T_I is the total time in which the system frequency remains within the predefined tolerance band and T is the total operating time of the AGC.

Due to the uncertainties in the DGS and the random communication degradation effects, the AGC performance evolves through stochastic trajectories. Thus, the reliability in Equation 15 and objective function in Equation 16 are stochastic and generally evaluated as the expected values of a stochastic process (Cervin et al., 2010). Thus, the reliability and t objective function are estimated via the MCS method (Pan and Das, 2016). In order to achieve a statistically acceptable estimate, the reliability is computed via 200 MCS-based samples, i.e. the integrated system is evaluated for 200 trials to compute the expected reliability (each sample simulates a time frame of 100 s and requires around 4 s on a 64 b Wdows desktop with 32 GB memory and an Iel(R) Xeon(R) E5-1650 v3 @ 3.50GHz CPU).

4.3 *Performance of the PID-controlled AGC*

The AGC performance of the integrated system depends on the discrete-time PID controller. Therefore, the PID controller is optimized to mitigate the communication network disturbances, and offer optimum AGC performance by reducing system frequency fluctuations. As a result, system reliability is also optimized. The objective function for the optimization of the PID controller is an integral performance index over the total operating time T, which quantifies frequency and control signal deviations (Pan and Das, 2016):

$$J = \int_0^T \left[\eta_1 (\Delta f)^2 + (1 - \eta_1) * \eta_2 (\Delta u)^2 \right] dt \tag{15}$$

where η_1 indicates the relative importance of the two terms and η_2 is the normalizing constant to scale both terms in a uniform range and is set to 0.002. The first term is directly related to the reliability of the integrated system and the second term measures the disturbance rejection ability of the controller, which is the total control effort to be minimized. The total process time T is set to 100 s.

Many heuristics algorithms, e.g. the genetic algorithm (Das et al., 2016) and the PSO (Pan and Das, 2016), are appropriate in such case to find the near-optimum solutions, taking into account the stochastic nature of the objective function. The fitness value of the stochastic population-based algorithms is the expectation of the stochastic objective function obtained from MCS

$$E[J] = \sum_{i=1}^{N} J_i \tag{16}$$

where J_i is defined in Equation 16 and $N = 200$ samples. We use PSO to solve the optimization problem for $\vec{x} \in \mathcal{R}^3$

$$\text{minimize } \mathrm{E}\left[J(\vec{x}) \right] \tag{17}$$

where $J(\vec{x}) : \mathcal{R}^3 \to \mathcal{R}$ is defined in Equation 16. The variable $\vec{x}$ are the controller parameters, i.e. K_P, T_I and T_D, and the 3-dimensional search space $\mathrm{G} \in \mathcal{R}^3$ is pre-specified as $\mathrm{G} = [0, 100]^3$ to widely span the optimization range of the controller design.

5 RESULTS AND DISCUSSION

This Section investigates the reliability of the integrated energy-communication system equipped with optimum PID controller to enhance the AGC performance and reduce system frequency fluctuations. We assess the impact of the two architectures, i.e. Ethernet and hybrid, and of various configurations of the open communication network on the system reliability and on the AGC performance.

5.1 *Specifications for the integrated system*

The physical system operates in nominal conditions, i.e. the stochastic wind speed, the variable sun irradiance and uncertain load, affecting, respectively, P_{WTG}, P_{PV} and P_L, given by Das et al. (2016). The coupled algebraic and ordinary differential equations for the DGS and the open communication network in Fig. 1, are numerically integrated using the Dormand-Prince method implemented in Matlab ode45 function with a fixed step size of 0.005 s. The parameters of the transfer functions for the DERs in Figure 1 are provided in Das et al. (2016). Additionally, the physical layer has the following specifications:

- The base value for the apparent power is 150 kW.
- The rated apparent power of the WTG is 150 kW, the rated electrical frequency is 60 HZ and the rated voltage for the induction machine is 440 V.

- The structure of a 150 kW PV power generation has 93 parallel strings and consists of 7 series-connected modules (SunPower SPR-230E-WHT-D).
- Based on ***Remark 1***, $0 \le \Delta P_{DEG} \le 0.7$ pu, $|\Delta P_{FESS}| \le 0.3$ pu and $|\Delta P_{BESS}| \le 0.3$pu, provide the largest rated output of the DEG, FESS and BESS (Pan and Das, 2016).

The open communication network is implemented in Truetime simulator (Cervin et al., 2010). The data rate of the communication architectures is 800 Kbits/s, and the WLAN is characterized by transmission power 20 dbm, receiver signal threshold –48 dbm, ACK timeout 0.04 ms and the retry limit 5.

5.2 *Reliability of the integrated system*

For illustrating purpose, the frequency tolerance band is set to ± 0.05. The parameters of the PID controller are tuned as $K_P = 37.78$, $K_I = 17.24$ and $K_D = 0.16$ (Pan and Das, 2016). Five combinations of BWShare, T_i and L_d are taken into account to investigate multiple communication scenarios in the Ethernet and in the hybrid network. For comparison purpose, the reliability of the integrated system with perfect communication, i.e. no time delays and no packet dropouts, is $R = 98.36\%$ and the value of objective function is $J = 16.36$.

Figure 2 illustrates the relationship between the reliability of the integrated system with Ethernet, and the communication parameters. Figure 2 shows that the AGC becomes unstable and the system reliability degrades if $L_d \ge 40\%$, the controller does not have sufficient observations of the system frequency measurement, and is unable to derive correct control signals. The case (BWShare = 0.1 & $T_i = 0.01$) has the largest reliability due to light congestion. In this case, data collisions between the PMU and the interference node are fewer than for other cases with smaller T_i. In the case (BWShare = 0.2 & $T_i = 0.005$), the interference node sends out disturbing traffic every 0.005 s and consumes 20% of network bandwidth, therefore data collisions between the PMU and the interference node increase. As a result, increased time delays degrade system reliability as compared to the other two cases. Increasing the activity level of the interference user and the used bandwidth leads to increasing data collisions, and therefore network congestion, which causes longer time delays. Thus, system reliability decreases, i.e. comparing case (BWShare = 0.1 & $L_d = 0.1$) and case (BWShare = 0.2 & $L_d = 0.1$), and comparing case ($T_i = 0.01$ & $L_d = 0.1$) and case ($T_i = 0.002$ & $L_d = 0.1$), respectively. Additionally, if $T_i \ge 0.01$, the competition for sending data packet between the interference node and the PMU reduces, network conditions improve and thus the system reliability increases.

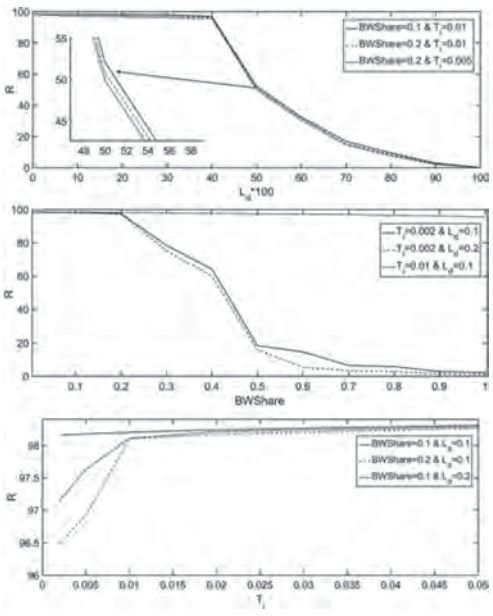

Figure 2. System reliability as a function of BWShare, T_i and L_d.

Table 1 provides the estimated reliability of the integrated system with Ethernet and with hybrid network. Such values of communication parameters are selected because they generate 10 ms to 2 s time delays, and losses of 1% to 10% of the overall packet stream, which are representative of real communication networks (Cervin et al., 2010). A negative correlation between system reliability and $E\left[J(\vec{x}) \right]$ can be inferred from Table 1. This is expected because when the system reliability is high, most of the system frequency measurements are within the tolerance band, which thereby leads

Table 1. Reliability of the integrated system for different network configurations [BWShare T_i L_d] of the two architectures.

Configurations	R_1	$\mathrm{E}\left[J_1(\vec{x}) \right]$	R_2	$\mathrm{E}\left[J_2(\vec{x}) \right]$

[0.3 0.005 5%]	97.33	18.41	88.55	45.44
[0.1 0.005 5%]	98.24	17.25	97.14	18.73
[0.2 0.0025 5%]	96.72	19.30	91.65	42.75
[0.2 0.01 5%]	98.21	17.67	97.74	18.19
[0.2 0.005 10%]	96.92	19.17	96.27	20.03
[0.2 0.005 1%]	98.23	17.34	97.84	18.12

*R_1 and $\mathrm{E}\left[J_1(\vec{x}) \right]$ are the reliability and objective value of the integrated system with Ethernet.
*R_2 and $\mathrm{E}\left[J_2(\vec{x}) \right]$ are the reliability and objective value of the integrated system with hybrid network.

to a small value of the objective function. Table 1 shows that the Ethernet architecture ensures higher reliable to the integrated system as compared to the hybrid architecture. This is expected because the data exchange between the AP and the RTU in the hybrid architecture is provided by WLAN, which introduces additional time delays and packet dropouts, and results in lower system reliability.

5.3 *Optimal PID controller for the AGC of DERs*

PSO is employed to design the optimal PID controller. In the PSO, the number of particles and the number of iterations are set to 30 and 50. For each particle, the stochastic objective function $\mathrm{E}\left[J(\vec{x}) \right]$ is estimated from 200 MC samples. The performance of the adopted PSO is discussed by Pan and Das (2016) with respect to the convergence rate. The PSO can achieve the local optimal PID controller after 50 iterations (Pan and Das, 2016).

Table 2 lists the optimal control parameters $[K_P\ K_I\ K_D]$ for the integrated system with two network architectures, which minimize $\mathrm{E}\left[J(\vec{x}) \right]$ under various configurations of [[BWShare T_i L_d]. Different combinations of BWShare, T_i and L_d generate different levels of network traffic in different scenarios of a day, i.e. light, medium and heavy [27]. Large BWShare, small T_i and large L_d simulate intense communication flows in the open communication network. For the perfect communication, the optimal control parameters are $K_P = 36.06$, $K_I = 16.06$ and $K_D = 0.23$, the reliability is $R = 99.37$ and $\mathrm{E}\left[J(\vec{x}) \right] = 9.99$. Table 2 quantifies the amount of system reliability and control effectiveness that is lost due to the effects of communication degradation with respect to the perfect communication case. As an example, $\mathrm{E}\left[J(\vec{x}) \right] = 17.47$ is the minimum expected value of the objective function for the Ethernet work configuration [0.2 0.005 5%], which implies that the PID controller can provide the best AGC performance and highest system reliability. The increase in the BWshare and L_d, and decrease in T_i cause the reduction of R and the increase of $\mathrm{E}\left[J(\vec{x}) \right]$, which is in line with common intuition. Such changes definitely deteriorate the performance of communication network, and lead to inaccurate control of the DERs and large system frequency fluctuations.

Table 2. Optimal PID controllers $[K_P\ K_I\ K_D]$ for different network configurations [BWShare T_i L_d] of the two architectures.

	R	98.26	98.21
	$\mathrm{E}\left[J(\vec{x}) \right]$	17.04	17.64

5.4 *Impact of communication degradation on optimum AGC operations*

The degradation of the communication network performance can affect the AGC operations even for optimally-controlled DER components. We quantify the extent of this impact for three architectures, i.e. perfect communication, Ethernet, and hybrid network, and the same WTG output, PV output and load demand. The three integrated systems are equipped with optimum PID controllers for the communication configuration [0.2 0.005 5%], given in Table 2 Line 1. Figure 3 shows the power curves of FESS, BESS and DEG, the power imbalance $\Delta P_S - \Delta P_L$, and the system frequency Δf, in the three integrated systems for $t \in [49.5\,s, 60\,s]$ of one MC simulation. The DER system experiences a sudden load increase at $t = 50$ s, and ΔP_L rises from 0.8 pu to 0.95 pu. In the perfect communication case, at $t = 52$ s, the output of the FESS, BESS and DEG rises, respectively, from 0.026 pu to 0.124 pu, from 0.008 pu to 0.038 pu, and from 0.009 pu to 0.029 pu. As a

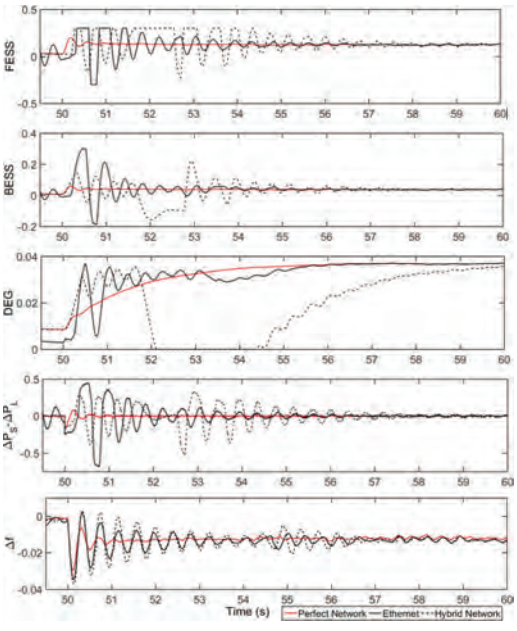

Figure 3. Evolution of FESS, BESS and DEG output, power imbalance $\Delta P_S - \Delta P_L$ and system frequency for a sudden load increase (0.15 pu) at $t = 50\ s$. Positive values of FESS and BESS power result in net injection into the grid.

result, $\Delta P_S - \Delta P_L$ is negative and very small, and, therefore, a negative and small frequency deviation $\Delta f = -0.013$ occurs.

For the integrated system with Ethernet and hybrid network, the FESS, BESS and DEG output, $\Delta P_S - \Delta P_L$ and Δf converge to the same values as the AGC with perfect communication with small convergence rates due to time delays and packet dropouts. The strong effects of communication degradation introduced by the WLAN in the hybrid network yield the smallest convergence rate in Figure 3. Additionally, Figure 4 highlights delays in the response of the controllable components to the control signal for the integrated systems with imperfect communication. For example, the output of FESS in the hybrid architecture and the output of BESS in the Ethernet architecture do not change in the time interval [50s, 50.2s], as compared to the perfect communication case. FESS and BESS keep absorbing (releasing) the same power from (to) grid even in unbalanced conditions because the data packets containing the control signals do not reach the destination. The control center lacks enough frequency measurements from the PMU, and issues inaccurate commands. Delays in component response and missing control signals ultimately cause the FESS, BESS

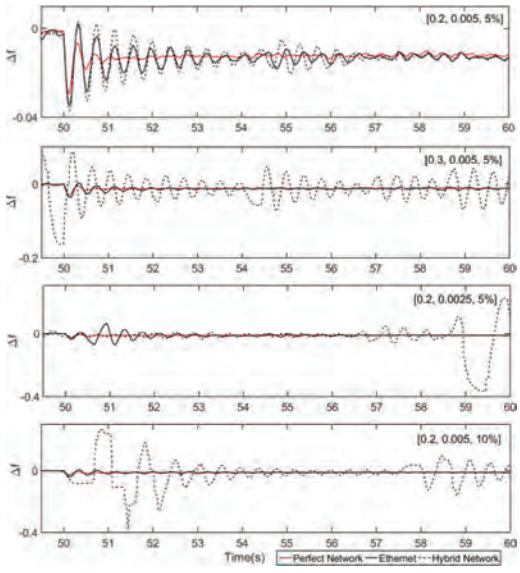

Figure 4. Evolution of system frequency for a sudden load increase (0.15 pu) at $t = 50\ s$ under increasing communication degradation.

and DEG to perform untimely and inaccurately, leading to large frequency oscillations.

Finally, we investigate the robustness of the PID-controlled AGC operations optimized for the configuration [0.2 0.005 5%] in Table 2, Line 1, subjected to increasing communication degradation. Figure 4 plots the system frequency Δf in the three integrated systems for $t \in [\,49.5\ s, 60\ s\,]$ of one MC simulation. Four configurations are shown, respectively, the optimization conditions, BWShare. increased from 0.2 to 0.3, T_i decreased from 0.005 to 0.0025, and L_d increased from 5% to 10%. Similar to Figure 4, ΔP_L rises from 0.8 pu to 0.95 pu at $t = 50$ s. Fig. 5 unveils the abilities of various controllers in providing satisfied AGC performance for unknown communication configurations. The optimized controller for Ethernet is still robust to degraded communication but small frequency fluctuations occur. The reliability in the four configurations is, respectively, 98.22%, 96.17%, 95.84% and 95.63%. Conversely, the optimized controller for hybrid network cannot provide robust AGC operations under degraded communication, and the system frequency becomes unstable. The reliability in the four WLAN network configurations is, respectively, 98.15%, 71.58%, 85.9% and 73.85%. The analysis of the PID tuning indicates that the PSO produces different optimal PID controllers for different runs of the optimization algorithm [10]. Nonetheless, even if PID controllers tuned using heuristics have different values

of R and $\mathrm{E}\left[J(\vec{x}) \right]$, they are capable of stabilizing the system frequency quickly in the analyzed network configurations.

6 CONCLUSION

This work proposes a system-of-systems framework for investigating the operations of integrated DER systems and open communication networks, and the design of optimal AGC strategies in the face of communication degradation. The results show that the activity level of interference traffic and the expected percentage of bandwidth used by the interference user have a significant impact on system reliability. Low system reliability is observed for large BWShare and small T_i. The AGC based on a discrete-time PID controller is developed to suppressed the frequency oscillations in the integrated system and enhance reliability. Optimization results show that the PSO-based PID controller is capable of reducing system frequency fluctuations and improve AGC performance. The communication degradation delays the component response to the control signal and cause their output to remain unchanged even in the presence of power imbalance until an updated packet is received. Finally, the AGC with Ethernet shows the largest reliability and robustness against unknown communication configurations, and results in small frequency oscillations.

Future work will focus on the time-delay compensation by designing a real-time Smith predictor based on the estimated communication delay. Additionally, the effect of packet dropout can be mitigated by reconstructing missing the data set to form a complete one.

Bayesian information fusion for non-competing relationship degradation process

Junyu Guo, Hong-Zhong Huang, Yan-Feng Li, Jie Zhou & Xiang-Yu Li
Center for System Reliability and Safety, University of Electronic Science and Technology of China, Chengdu, Sichuan, P.R. China

ABSTRACT: The degradation analysis method is widely used to the reliability analysis of the products with long life and high reliability. There is a non-competing multi-degenerate situation widely exist in some mechanical products, non-competing relationship multiple degradation model is proposed in this paper to describe it. The degradation process of products which proposed in this paper have two degradation indicators, the gamma process is used to characterize the degradation process. A Bayesian fusion framework of degradation analysis is presented to deal with the small sample size problem of the products and the MCMC method is used to simulate the samples of model parameters. A case-study of the spool valve is discussed to demonstrate the model and method we proposed.

1 INTRODUCTION

Nowadays, with the progress of the times and the development of science and technology, the complex systems such as industrial, transportation and military, are generally required to performance with a high reliability level (Ye et al., 2014). Methods such as degradation analysis have been developed to enhance the reliability analysis of these systems (Chen and Tsui, 2013, Nelson, 1981). Degradation analysis methods have been widely used in academic research and industrial productions. In general, the complex products with long life and high reliability may have multiple performance processes. The multiple degradation processes based on the competing relationship have been widely studied (Peng et al., 2016, Pan et al., 2011). In the competing relationship multiple degradation models, the products confront a failure when anyone of the performance indicator reaches a predefined threshold. However, there is a non-competing multi-degenerate situation widely exist in mechanical products (Yang et al., 2016), the competing relationship multiple degradation models may not be suitable for this situation. To address the problem, a modified multiple degradation processes model is proposed. A classic example, i.e., spool valve, is investigated in this paper to demonstrate the proposed method. The wear rate of spools and sleeves are two non-competing performance indicators of spool valve.

Earlier spool valve reliability models did not consider the small sample size problem in reliability analysis, but in some cases, small sample size problem is inevitable. A modified model that considers the small sample problem is introduced in this paper. In order to obtain more accurate analysis result under limited degradation observations, it is imperative to take full advantage of the degradation information from Original Equipment Manufacturers (OEMs) and user plant's. Degradation information from different sources have the mathematically common, so they can be fused during the reliability analysis (Feng and Zhou, 2008).

The objective of this paper is to present a hierarchical Bayesian method of gamma process model for degradation process modeling and analysis. The hierarchical Bayesian method could fusion degradation information from different sources. The Markov chain Monte Carlo (MCMC) method is used to estimate the model parameters.

The remainder of this paper are organized as follows. Section 2 introduces the gamma process model for the non-competing relationship multiple degradation model. In Section 3, a Bayesian information fusion method is presented. Section 4 presents the degradation analysis of spool valve to illustrate the proposed method. Section 5 summarizes the whole work and prospects of the future work.

2 THE DEGRADATION MODELS

2.1 *Gamma process model*

The performance degradation process of a product is usually an evolutionary process. The stochastic process model can describe this process well.

The gamma process is a stochastic process generally used to describe the performance degradation of mechanical products. Because the increment of the gamma process is non-negative, it is consistent with the performance evolvement of the mechanical products.

The gamma process is a stochastic process $\{X(t), t>0\}$ with the shape parameter α(t) and scale parameter λ is denoted as $X(t) \sim Ga(\alpha(t), \lambda)$. The gamma process has the following properties: $X(t)$ is independent incremental process with $X(0)=0$, and the degradation increments $\Delta X(t) = X(t+\Delta t) - X(t)$ follow gamma distributions as $\Delta X(t) \sim Ga(\Delta\alpha(t), \lambda)$ with $\Delta\alpha(t) = \alpha(t+\Delta t) - \alpha(t)$. The mean and variance of $X(t)$ are $\alpha(t)/\lambda$ and $\alpha(t)/\lambda^2$, respectively, where $\alpha(t)$ is a right-continuous non-decreasing function in $[0,\infty)$, with $\alpha(0)=0$ (Abdel-Hameed, 1975).

The probability density function (PDF) $g(x)$ of the gamma process is defined by

$$g_{X(t)}(x|\alpha(t),\lambda) = \frac{\lambda^{\alpha(t)}}{\Gamma(\alpha(\mathrm{t}))} x^{\alpha(t)-1}\exp(-\lambda x) I_{\mathrm{X}(0,\infty)}(x) \tag{1}$$

where

$$I_{(0,\infty)}(x) = \begin{cases} 1 & x \in (0,\infty) \\ 0 & x \notin (0,\infty) \end{cases} \tag{2}$$

and $\Gamma(\alpha) = \int_0^\infty x^{a-1}e^{-x}dx$ is gamma function (Noortwijk, 2009).

Suppose that a product's degradation process is characterized by $\{X(t), t>0\}$, it fails when the performance indicator reaches a predefined threshold C. Thus, the lifetime of the product is defined as $T = \inf\{t | X(t) \geq C\}$. The reliability $R(t)$ of product or system at time t can be expressed as:

$$R(t) = \Pr\{\sup_{s\leq t}(X(s)) \leq C\} \tag{3}$$

$$\begin{aligned} R(t) &= P_r\{T \geq t\} = P_r\{X(t) < C\} \\ &= \int_0^C g_{X(t)}(x|\alpha(t),\lambda)dx \\ &= \frac{1}{\Gamma(\alpha(\mathrm{t}))}\int_0^{C\lambda} u^{\alpha(t)-1}e^{-\lambda}du \end{aligned} \tag{4}$$

2.2 *The non-competing relationship multiple degradation model*

Suppose that the m performance indicators of the product are mutually independent, $D_p(t)$ is the degradation data of the Lth degradation processes at the time t. All degradation processes lead to one failure mode, the reliability $R(t)$ at time t can be defined as: $R(t) = \Pr\{D_1(t) + D_2(t) + ... + D_p(t) < C\}, p = 1,...,L$. If $D_p(t)$ follows a gamma process with shape parameter α_p(t) and scale parameter λ with $p = 1,2,...,L$, when the shape parameter function α_p(t)=$\alpha_p t$, then the degradation increment ΔD_p follows the gamma distribution as follows:

$$\Delta D_p \sim Gamma(\alpha_p \Delta t, \lambda) \tag{5}$$

Based on the additivity of the gamma distribution, the following relationship can be obtained as:

$$\sum_{p=1}^{L} \Delta D_p(t) \sim Gamma\left(\sum_{p=1}^{L}\alpha_p \Delta t, \lambda\right) \tag{6}$$

According to the properties of gamma process, $(D_1(t) + D_2(t) + ... + D_p(t))$ follows a Gamma process with shape parameter function α(t) = $\sum_{p=1}^{L}\alpha_p t$ and scale parameter λ. The reliability $R(t)$ at time t can be defined as:

$$R(t) = \frac{\int_0^{C\lambda} u^{\sum_{p=1}^{L}\alpha_p t - 1} e^{-\lambda}du}{\Gamma\left(\sum_{p=1}^{L}\alpha_p t\right)} \tag{7}$$

3 RELIABILITY ANALYSIS BASED ON DEGRADATION MODEL

3.1 *Basic Bayesian framework of degradation process*

Bayesian method has two advantages for degradation analysis: (1) The capability of Bayesian method for data and information fusion, making the OEMs and user plant's performance degradation data fusion analysis possible (Peng et al., 2016). (2) The handling capacity of Bayesian approach to the uncertainty, making the performance degradation analysis and reliability analysis results are guaranteed (Efron, 2013). These two points are the basic principles to construct the basic framework of Bayesian performance degradation analysis and reliability analysis.

This framework is based on Bayesian method to take the degradation data of the OEMs and the user plant as the essentials, including the acquisition of the prior distribution and the solution of the posterior distribution.

According to the different sources of degradation data, the framework divides the acquisition of the prior distribution into two methods. The method of subjective information quantization is used to obtain the prior distribution. The prior

distribution of the degradation analysis of the user plant is directly transformed by the posterior distribution of the degradation analysis of the OEMs.

In order to estimate the posterior distribution, this paper construct the posterior distribution of parameters in degradation process model based on Bayesian method, and sampling of posterior distribution from the degradation data through MCMC method.

3.2 *Degradation process analysis method*

In this paper, we analyze the non-competing relationship multiple degradation model of two degradation indicators. Suppose that the degradation data of $D_1(t)$ and $D_2(t)$ are observed for N units. Let $D_1(t_{ij})$ and $D_2(t_{ij})$ denote the jth observation for unit i at time point t_{ij} with $j=1,...,M$ and $i=1,...,N$. Let $\Delta d_{ij}=D_1(t_{ij})-D_1(t_{i,j-1})$ and $\Delta d'_{ij}=D_2(t_{ij})-D_2(t_{i,j-1})$ be the degradation increment. According to the gamma process model, the Δd_{ij}^{p} follow the gamma distribution $\Delta d_{ij}^{p}\sim Gamma(\alpha_p\Delta t_{ij},\lambda)$.

The performance degradation data of the non-competing relationship multiple degradation model includes the OEMs data D_p^O and user plant's data D_p^U. When the performance degradation data D_p^O and D_p^U are unified as D_p with $\nu=(\alpha_1,\alpha_2,\lambda)$, the likelihood function can be presented as:

$$\begin{aligned}
&L(D_1,D_2,v\mid\alpha_1,\alpha_2,\lambda)\\
&=\prod_{i=1}^{N}\prod_{j=2}^{M}g(\Delta d_{ij}\mid\alpha_1,\lambda)g(\Delta d'_{ij}\mid\alpha_2,\lambda)\\
&=\prod_{i=1}^{N}\prod_{j=2}^{M}\frac{\lambda^{\alpha_1\Delta n_{ij}}}{\Gamma(\alpha_1\Delta n_{ij})}\Delta d^{\alpha_1\Delta n_{ij}-1}\exp(-\lambda\Delta d_{ij})\\
&\quad\frac{\lambda^{\alpha_2\Delta n_{ij}}}{\Gamma(\alpha_2\Delta n_{ij})}\Delta d'^{\alpha_2\Delta n_{ij}-1}_{ij}\exp(-\lambda\Delta d'_{ij})
\end{aligned}\tag{8}$$

where $\Delta d_{ij}=D(t_{ij})-D(t_{i,j-1})$, $\Delta d'_{ij}=D_2(t_{ij})-D_2(t_{i,j-1})$ and $g(\bullet)$ is the PDF of a gamma distribution.

Suppose that the prior information about the samples is quantified and obtained as joint prior distribution for the parameters of degradation process model as $\pi(\theta)=\pi(\alpha_1,\alpha_2,\lambda)$. Following the Bayesian method, the joint posterior distribution of the parameters can be obtained as:

$$\begin{aligned}
&p(\alpha_1,\alpha_2,\lambda,\nu\mid D_1,D_2)\propto\pi(\theta)L(D_1,D_2,\nu\mid\theta)\\
&=\pi(\alpha_1,\alpha_2,\lambda)L(D_1,D_2,v\mid\alpha_1,\alpha_2,\lambda)\\
&=\pi(\alpha_1,\alpha_2,\lambda)\prod_{i=1}^{N}\prod_{j=2}^{M}\frac{\lambda^{\alpha_1\Delta n_{ij}}}{\Gamma(\alpha_1\Delta n_{ij})}\Delta d_{ij}^{\alpha_1\Delta n_{ij}-1}\\
&\exp(-\lambda\Delta d_{ij})\frac{\lambda^{\alpha_2\Delta n_{ij}}}{\Gamma(\alpha_2\Delta n_{ij})}\Delta d'^{\alpha_2\Delta n_{ij}-1}_{ij}\exp(-\lambda\Delta d'_{ij})
\end{aligned}\tag{9}$$

From the Equation (9), it is a comprehensive description of the a prior information and degradation process.

3.3 *Bayesian information fusion method*

According to the degradation process modeling and Bayesian method, the degradation data of the OEMs and the user plant are analyzed to obtain the joint posterior distribution of the model parameters. The realization process is as follows:

$$\begin{aligned}
&p_I(\alpha_1,\alpha_2,\lambda,\nu\mid D_1^O,D_2^O)=\pi(\alpha_1,\alpha_2,\lambda)\\
&\prod_{i=1}^{N}\prod_{j=2}^{M}\frac{\lambda^{\alpha_1\Delta n_{ij}}}{\Gamma(\alpha_1\Delta n_{ij})}\Delta d_{ij}^{O\,\alpha_1\Delta n_{ij}-1}\exp(-\lambda\Delta d_{ij}^{O})\\
&\frac{\lambda^{\alpha_2\Delta n_{ij}}}{\Gamma(\alpha_2\Delta n_{ij})}\Delta d_{ij}^{O'\,\alpha_2\Delta n_{ij}-1}\exp(-\lambda\Delta d_{ij}^{O'})
\end{aligned}\tag{10}$$

$$\begin{aligned}
&p_{II}(\alpha_1,\alpha_2,\lambda,\nu\mid D_1^U,D_2^U,D_1^O,D_2^O)\\
&=p_I(\alpha_1,\alpha_2,\lambda,\nu\mid D_1^O,D_2^O)\\
&\prod_{i=1}^{N}\prod_{j=2}^{M}\frac{\lambda^{\alpha_1\Delta n_{ij}}}{\Gamma(\alpha_1\Delta n_{ij})}\Delta d_{ij}^{U\,\alpha_1\Delta n_{ij}-1}\exp(-\lambda\Delta d_{ij}^{U})\\
&\frac{\lambda^{\alpha_2\Delta n_{ij}}}{\Gamma(\alpha_2\Delta n_{ij})}\Delta d_{ij}^{U'\,\alpha_2\Delta n_{ij}-1}\exp(-\lambda\Delta d_{ij}^{U'})
\end{aligned}\tag{11}$$

where D_1^O and D_2^O are the degradation data from the OEMs, $\pi(\alpha_1,\alpha_2,\lambda)$ is prior distribution quantified by the prior information for products, $p_I(\eta,\delta,\gamma,\nu\mid D^O)$ is the posterior distribution of the model parameters obtained by combination of prior information and the information contained in the degradation data of the OEMs. D_1^U and D_2^U are the degradation data from the user plants, $p_{II}(\eta,\delta,\gamma,\nu\mid D^U,D^O)$ is a model parameters posterior distribution, it is a description of the combination of prior information and information contained in the degradation data from OEMs and user plants.

From the Equations (10) and (11), the MCMC method is used to estimate the model parameters because of their computational complication. In most actual applications with Bayesian methods, it is difficult to obtain the posterior distribution. The MCMC method is used to construct a Markov chain, the invariant distributionis of the Markov chain is the posterior distribution that is needed to be accurately estimated. In this paper, we assume that the prior distributions of the model parameters are non-informative, and the OpenBUGS is used to perform the Gibbs sampling after the model parameters is estimated.

4 ILLUSTRATIVE EXAMPLE

The reliability of hydraulic systems is determined by various subsystems, and the spool valves is one

of the most important subsystems. The reliability of the spool valves directly affects the reliability of the hydraulic system. The main failure mode of the spool valves is the wear degradation of spools and sleeves. When the total wear degradation of spool and sleeve reach predetermined threshold, the spool valves is considered as failure. The Bayesian information fusion.

To obtain information about degradation of spool valves in the hydraulic system, the wear degradation of spools and sleeves of six spool valves are monitored. The wear degradation paths of OEMs are presented in Figure 1, and the wear degradation paths of user plants are shown in Figure 2.

As discussed in Section 3, the wear degradation increment of sleeves is $\Delta d_{ij} = D_{SL}(t_{ij}) - D_{SL}(t_{i,j-1})$ which is modeled as $Ga(\alpha_{SL}\Delta t_{ij}, \lambda)$ and the wear degradation increment of spools is

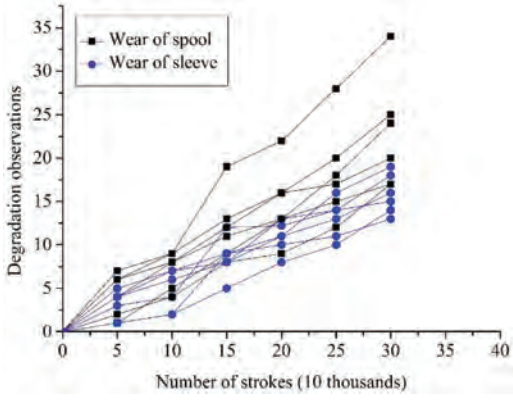

Figure 1. The wear degradation paths of OEMs.

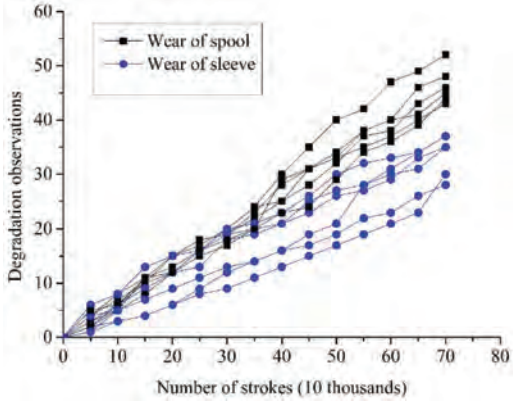

Figure 2. The wear degradation paths of user plants.

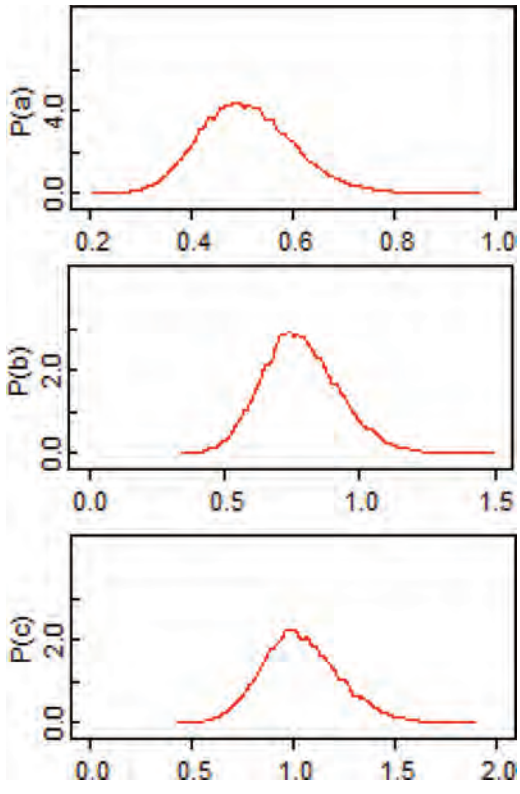

Figure 3. The posterior pdf of model parameters: (a) $\alpha_{SL}^{(OEMs)}$, (b) $\alpha_{SP}^{(OEMs)}$, (c) $\lambda^{(OEMs)}$.

$\Delta d'_{ij} = D_{SP}(t_{ij}) - D_{SP}(t_{i,j-1})$ that is modeled as $Ga(\alpha_{SP}\Delta t_{ij}, \lambda)$. Owing to the limitation on the available prior information, the non-informative prior distribution, which is the prior distributions for parameters of the degradation process model of OEMs, quantized from the subjective information. It could be given as:

$$\alpha_{SL} \sim U(0,100), \alpha_{SP} \sim U(0,100), \lambda \sim U(0,100)$$

The $U(a,b)$ is a uniform distribution.

The MCMC method is used to simulate the samples of model parameters, and then we use the OpenBUGS to generate 20000 samples.

The posterior pdf of model parameters for degradation process of the OEMs are presented in Figure 3. Based on the framework discussed in Section 3, these posterior distributions transformed into the prior distribution of degradation process model parameters of user plants.

The results for parameter estimation given in Table 1 are obtained from the generated posterior samples. The predefined degradation threshold is

Table 1. The results for parameter estimation.

	Mean	Standard deviation	Confidence interval	
			2.5%	97.5%
α_{SL}	0.6542	0.06317	0.5374	0.7827
α_{SP}	0.9189	0.0886	0.7538	1.102
λ	1.348	0.1308	1.104	1.62

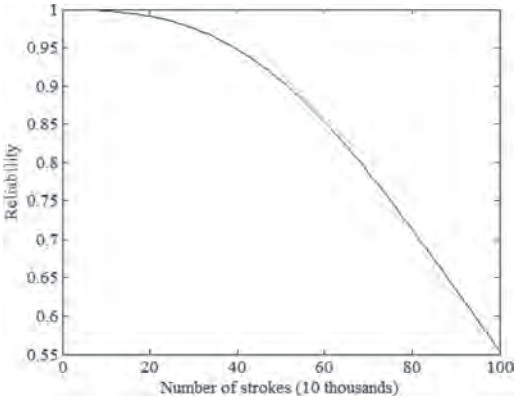

Figure 4. Reliability of the spool valves.

$C = 120$, the reliability of the spool valves can be obtained from the posterior distribution of model parameters as presented in Figure 4.

5 CONCLUSIONS

In this paper, a reliability analysis model for the non-competing relationship multiple degradation process of products with two performance indicators is presented. The characteristics of these degradation process are modeled by gamma process. Then, a hierarchical Bayesian method is presented to fusion the degradation information from different sources. Therefore, the Bayesian method is used to estimate the model parameters and the MCMC method is used to simulate the samples of model parameters. A case-study of a spool valve is provided to demonstrate the proposed model and method.

It should be noted that there are some open questions for future work. According to the individual heterogeneity of the products, the random effect could be introduced to the non-competing relationship multiple degradation process. The different working environment of the products in the OEMs and the user plant could be considered into the modeling of the degradation process.

L. Gil
University of Economy and Innovation, Lublin, Poland

ABSTRACT: Polymer composites used in engineering structures are exposed to various types of mechanical stress. The most commonly used methods of assessing their strength are the ones based on static or dynamic testing. Rare attempts are made to assess reliability of composites under a given load. The influence of the manufacturing technique on the mechanical strength of composites is also a well-known fact. The production of fibre reinforced composites using an autoclave allows for the production of high strength composites and a very small number of structural defects. However, this method is expensive and available with restriction. Much more often composites are produced by cheaper methods like hand lay-up, infusion or vacuum bag. The aim of this study is to determine the influence of the technique of making selected polymeric composites on the probability of failure before achieving a certain tensile strength threshold. Composite materials reinforced with carbon and glass fabrics have been prepared as the most commonly used composites in aviation. Composites were made by such methods as hand-lay-up, vacuum bag and pressing. Static stretching was performed, followed by a statistical analysis and a reliability analysis. The reliability analysis was performed using the Weibull model. It was found that, in terms of tensile strength, the differences between the composites made by the compression method and the manual method are negligible. Vacuum bag composites exhibit the lowest tensile strength compared to other composites. On the other hand, the analysis of reliability indicates that the highest probability of maintenance of structure continuity under load is exerted by composites with fiberglass made by the pressing technique.

1 INTRODUCTION

Reliability, which is understood quite well intuitively, is a synonym for self-assurance in operation. Since the very beginning of constructing broadly understood technical objects, this terms has been comprehended in this sense. The intention was always to maximize suitability for use, generally described by the Q quality. It needs to be stressed that the R reliability is one of the constituent elements of quality, along with e.g. efficiency, usefulness or accuracy. As a narrower concept, it describes the ability of an object to perform a specific task under certain conditions and at a given time (Godziszewski 1983, Bentley 1999).

The theory of reliability has got two main objectives (Szopa 2009):

- the formulation of theoretical grounds for the description of the laws underlying the occurrence of damage and malfunction in technical systems,
- seeking methods of design and rules of systems operation so as to minimize the possibility of damage at certain expenditures.

The reliability practice, however, is geared towards (Smalko 1972):

- exploring physical processes of the occurrence of damage,
- removing damage,
- the ability to predict the occurrence of damage and counteract them.

Thus, the science of reliability is of multidisciplinary nature. The stimulus for its development was the necessity to meet increasingly higher demands for modern technical objects. At the beginning of its existence, it served to project the expected behaviour of complex objects during their operation (e.g. aircraft, computers). Additionally, taking into account modern trends, research is conducted on the methodology of designing objects whose operation is reliable in a defined time (Słowinski 2002).

The assessment of the reliability of composite materials is based on the analysis of physical changes which affect them. The factors which influence the behaviour of the laminate can be divided into three main categories:

- mechanical load,
- material factors,
- environmental factors

One of the greatest threats in maintaining reliability of the composite strength is the separation of the matrix and the reinforcement. On the boundary of the phases there occur forces of adhesion and adsorption, which account for their overall strength (Hart-Smith 1990, Godzimirski 2008).

The foreseeable duration of composite utility will be specified by means of the likelihood of damage occurrence, which is determined on the basis of static and dynamic investigations. The most trustworthy results are those of tensile strength and bending (Krzyzak 2015, Esfandiari 2008, Wu, Cheng & Kang 2000).

Damage is defined as a transition from a fully-operational state to the state of deficiency or failure to comply with at least one major parameter (Godziszewski 1983).

2 METHODOLOGY

The main objective of this study is to examine the influence of a manufacture technique of selected polymer composites upon the probability of damage prior to reaching a specified threshold tensile strength. In aviation, the autoclave method is used for the manufacture of advanced aircraft parts. However, the hand lay-up and vacuum bag are the most common methods used for repair. In the research, the authors proposed an alternative pressing method.

The object of research was composites which are most commonly used in aviation, with a particular focus on polymer-matrix laminates. The authors examined four-layer composites reinforced with commonly available woven fabrics of glass fibre (G) and carbon fibre (C). The matrix was epoxy resin C.E.S. R70 on the basis of bisphenol A/F of density $\rho_R = 1.16$ g/cm^3 combined with C.E.S. H72 hardener whose density equalled $\rho_H = 1.02$ g/cm^3 in the ratio of 100:54.

The polymer composites were produced with three methods: hand lay-up (hand), pressing method (press) and vacuum bag (bag). During the hand lay-up lamination, particular attention was drawn to the total saturation of the reinforcement fabric with resin, as well as the reinforcement setup in such a way that the fibers ran parallel. The subsequent layers measuring 0.6×1 m were pressed together by a roller. In order to ensure complete curing of the resin, the composites were left for 72 hours.

Another batch of samples was made by means of the hydraulic press Mecamaq PDM 50S. The initial production process was identical as in the case of the hand lay-up method. Having laid and saturated the reinforcement layers with resin, the sheets were placed in a press and subjected to a compressive force of 5,000 kg or 49,033 N for 2 hours. Subsequently, they were removed and left for another 48 hours. During the pressing process, the composite was subjected to the pressure of 0.082 MPa.

The third series of the pieces was produced by the vacuum bag method. The reinforcement layers were saturated manually with resin and placed in a tape-sealed working area. Next, the delamination fabric was placed for an uninterrupted separation of the manufactured laminate from the auxiliary materials. Another layer of the perforated film was to allow removing excess resin. Next, lignin, which was responsible for the resin absorption, was laid. Finally, everything was tightly covered with a polymer film. The negative pressure was achieved by the TW-1A 1/6 HP pump.

The pump generated a negative pressure of approximately 1 bar, thus it equalled 0.1 MPa when calculated for the laminate surface which pressed the reinforcement layers.

Similarly to pressing, after 24 hours, the laminate was extracted and left for 48 hours. Due to practical limitations associated with the availability of a proper carbon fabric, it was merely possible to manufacture glass-reinforced samples by means of the vacuum bag method.

The obtained boards served for cutting test pieces of 10×100 mm. Special attention was drawn to the cutting direction. It was important to ensure the assumed direction of the reinforcement. The cutting was performed with a stream of water and garnet (for abrasive cutting) under high pressure. It was possible to obtain smooth and equal edges and high dimensional accuracy.

3 RESULTS

3.1 *Tensile strength*

The static tensile tests were performed on a fatigue testing Zwick/Roell machine, equipped with pneumatic grips, in accordance with the research norm DIN EN ISO 527-1 at a constant speed of the traverse movement equal to 2 mm/min. The measurement length equalled 50 mm and the length of the gripping hands was 25 mm. The samples were fitted in the grips, paying particular attention to

Table 1. Basic statistics results of composite tensile strength.

Composite material	Number of sizes	R_m	Standard deviation of the mean	Coefficient of variation
C (hand)	20	457.38	54.70	11.96%
C (press)	20	452.31	66.47	14.69%
G (hand)	20	275.64	14.93	5.42%
G (press)	20	291.33	22.38	7.68%
G (bag)	18	240.89	21.62	8.97%

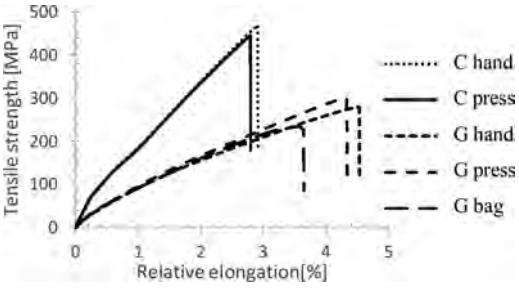

Figure 1. Tensile strength in function of relative elongation for composites made by diffirent methods (examples).

their vertical orientation. Even minor deviations in this respect would negatively affect the reliability of the results obtained.

The highest average tensile strength of materials reinforced with a carbon fabric was exercised by the laminate made with the hand method C (hand) – 457 MPa, which only slightly exceeded the pressed product C (press) – 452 MPa. In the case of the glass composites, the situation is quite different. The highest tensile strength was exercised by the composite G (press) – 291 MPa, a slightly lower by G (hand) – 276 MPa. The laminate manufactured with the vacuum bag method G (bag) reaches the minimum tensile strength at 241 MPa. Both the standard deviation, the standard error of the mean and the coefficient of variation indicate that the repeatability of research results is far greater in the case of carbon-reinforced composites, irrespective of the manufacture method, than for glass laminates.

In the case of composites, due to their two-phase structure and the occurrence of tiny matrix cracks affecting the emergence of permanent deformations, it is difficult to determine a typical elasticity boundary (Mallick 2007, Zhang, Li, Is & Yu 2013). While analysing an increase in force with respect to elongation in the process of stretching, however, it may be concluded that the test pieces underwent purely tensile deformation, only in the initial phase of the test. In the following part, until the breaking, they behaved like fragile bodies (Figure 1). Given the characteristics of composite materials and their two-phase structure, it can be deduced that the emerging matrix microcracks were to blame.

Relative extension of carbon composites during stretching was on average equal to 2.8%. The differences between C (hand), and C (press) were negligible. The situation concerning various types of samples made by hand and by pressing was similar. Both types showed similar relative deformation of 4.35% and 4.22%, respectively. Taking into account the standard deviation of results, this small discrepancy may be accidental. It was noted, however, that there is a significant maximum decline in relative elongation of the samples produced by the bag vacuum method, with regard to the samples obtained by other methods. The average value of the considered parameter was, in this case, 3.57%.

3.2 *Permissible value of mechanical strength*

The results obtained and the descriptive statistical analysis may give rise to determining permissible tensile strength to stretching of the examined composites. The safety coefficient is determined on the basis of, among others, numerous studies and a statistical analysis, however in the case of composite materials there are no rigid guidelines for its adoption. This is explained by a variety of factors determining the strength and structural characteristics of composites and, in the selection of an index, the computations as well as the constructor's experience play a large role.

Thus, the authors adopted the permissible strength value n_m as an average strength of the composites made by hand decreased by the safety coefficient on the level of 5%. In the case of composites made by the manual lamination method, with carbon reinforcement, the permissible value of the tensile strength equalled 435.51 MPa, whereas for composites with glass reinforcement it was 261.86 MPa. It was assumed that the largest structural defects occur in composites made by manual lamination, therefore the above-mentioned permissible strength will also be adequate for composites produced with methods of more advanced technology.

3.3 *Analysis of reliability*

The Weibull reliability analysis was conducted. Thus, the authors initially determined the regression functions of reliability likelihood and coefficients of determination R^2.

The formula of the function determined through approximation, using the method of least squares

errors, in a simple form $y = ax + b$, was obtained from the following formulas:

$$a = \frac{\sum (xy) - N\bar{x}\,\bar{y}}{\sum x^2 - N\bar{x}^2}$$

$$b = \bar{y} - a\bar{x}$$

where:
x – predictor value,
y – dependent variable value,
$\bar{x}, \bar{y}$ – mean values,
N – number of observations.

The coefficient of determination informs how much the accepted model explains the collected measurement data. The better model adjustment, the closer is its value to one. It is calculated using the formula:

$$R^2 = \frac{\sum_{i=1}^{n} \left(\hat{y}_i - \bar{y}\right)^2}{\sum_{i=1}^{n} \left(y_i - \bar{y}\right)^2}$$

where: $\hat{y}_i$ – prediction on the basis of the regression model of the variable value.

The figures (Figure 2, Figure 3) show the approximation of the probability distribution of maintaining strength with regard to the type of reinforcement and the methods of manufacturing the composite.

The approximated functions of probability distribution indicate slight differences between the examined carbon composites. The situation is slightly different in relation to laminates reinforced with glass. In this case, the obtained functions clearly indicate that the biggest damage in the slightest stretching stresses occur in materials manufactured by means of the vacuum bag method. On the other hand, pressed composites exercised the biggest strength, demonstrating a significant advantage over laminates produced manually.

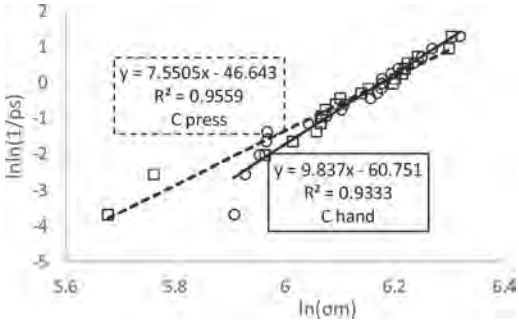

Figure 2. Approximation of the probability distribution of failure when stretching carbon-reinforced composites.

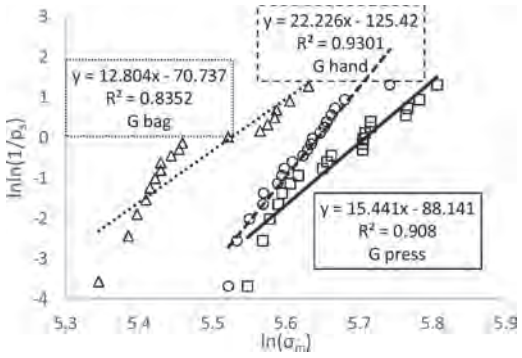

Figure 3. Approximation of the probability distribution of failure when stretching glass-reinforced composites.

The obtained values of the coefficient of determination prove that the regression function and experimental results are quite coherent. It also means that results modelling are based on proper assumptions as for the testing and adoption of distribution. It can be concluded that the obtained function can be used for the interpolation of the results within the value of variable research factors exploited in the conducted experimental studies.

When the investigated parts become damaged, mainly due to sudden wear (cracks, fractures, etc.), it is recommended to use the Weibull distribution (Saghafi, Mirhabibi & Yari 2009). It is characterized by a variable intensity of damage, which is monotone (non-decreasing) in its nature. The distribution applies to the description of fatigue service life of different materials and machinery. The reliability function, i.e. the dual parametre model has got the form:

$$R(t) = \exp\left(-\frac{t^m}{\sigma_0}\right)$$

where: t – expected operating time of objects, in strength investigations predefined as permissible strength of materials,
σ_0 – scale parametre of the Weibull model [MPa],
M – shape parametre of the Weibull model [–].

The Weibull model m is equal to the directional coefficient a of the determined approximating straight line. In other words, it corresponds to the angle of inclination of the regression line to the X-axis (Maksymiuk 2003, Yadav, Singh & Goel 2006). Alongside the increase in the Weibull module, there is a decrease in load spreading, where the critical damage is likely to occur.

The scale parameter σ_0 is a tension determined for the accumulated likelihood of failure at (Warszyński 1988):

$$p = 1 - \frac{1}{e} \approx 0.632$$

The designated parameters of the Weibull model have been listed in Table 2.

The graphs (Figure 4, Figure 5) show the functions of failure, or probability distribution functions of damage occurrence. They depict predetermined permissible tensile strength values $\sigma_m = n_m$ which constitute the adopted safe operation border (vertical dotted line). The likelihood read out at the intersection of the graph with this line indicates the percentage of the population in which there was decohesion with tension below the permissible one. The continuous horizontal line also marked probability $p_f = 0.632$ at the level. Above this value, there is accumulated occurrence of catastrophic damage for the whole population. The second quarter of the plane determined by the two restrictions is the area which excludes material out of operation. Obtaining the likelihood of damage above $p_f = 0.632$ under the influence of tension less than $\sigma_m = n_m$ is tantamount to the exclusion of the composite from use.

Table 2. Parametres of the Weibull method.

Fibre	Method	m [–]	σ_0 [MPa]
Carbon	hand	9.84	480.89
	press	7.55	484.53
Glass	hand	22.23	280.12
	press	15.44	300.23
	bag	12.80	241.18

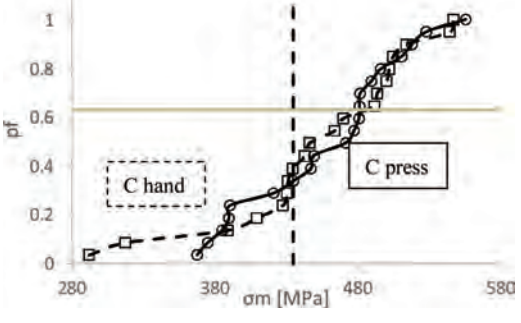

Figure 4. Empirical function of failure of carbon composites due to tensile strength.

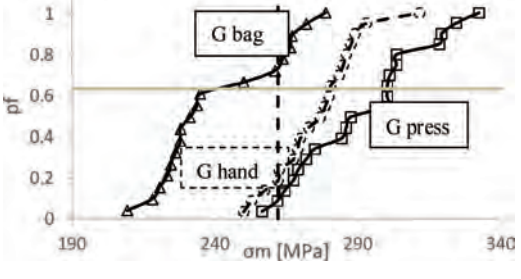

Figure 5. Empirical function of failure of glass composites due to tensile strength.

By analysing the above diagrams, it can be concluded that polymer composites manufactured by means of pressing and the manual method, both carbon and glass ones, are highly reliable and can be safely used with the adopted values of tensile stress. Laminates manufactured using the bag vacuum do not satisfy the conditions of operation at a certain level of load with assumed reliability.

It is assumed that fulfilling the condition $n_m > \sigma_m$ indicates a high probability of uninterrupted service life of a part manufactured with a given technique.

The following table (Table 3) shows the likelihood $p_f(n_m)$ of reducing the strength of the material below a predetermined permissible value. The authors adopted the following criteria of risk gradation of substantial debilitation:

$p_f(n_m) \leq 0.02$ – very low,

$0.02 < p_f(n_m) \leq 0.2$ – low,

$0.2 < p_f(n_m) \leq 0.5$ – average,

$0.5 < p_f(n_m) \leq 0.8$ – high,

$p_f(n_m) > 0.8$ – very high.

In accordance with the earlier observations, only materials produced by the vacuum method indicate a high probability of a decline in strength below the permissible safety value. The composites produced by hand and pressed are characterized by average and high reliability.

Table 3. Characteristic strength n_m and lack of reliability $p_f(n_m)$ of polymer composites manufactured with various techniques.

Fibre	n_m [MPa]	Method	σ_0 [MPa]	$p_f(n_m)$
Carbon	434.51	hand	480.89	0.34
		press	484.53	0.40
Glass	261.86	hand	280.12	0.19
		press	300.23	0.09
		bag	241.18	0.74

4 CONCLUSIONS

The technique of making polymer composites exerts an influence the likelihood of damage before achieving a certain threshold tensile strength, which can be clearly proved by analysing the results of glass laminates. The smallest probability of the emergence of such damage can be seen in the pressed samples, the reason for which might probably be more compact and free from air bubbles composite structure as compared to the samples made manually, obtained by the pressure exerted on the material in the production process. Improved matrix continuity allows an even distribution of stresses on the reinforcement in the whole volume of the element.

It was also found that the composite materials produced by the vacuum bag method (bag) showed by far the biggest likelihood of the occurrence of destructive damage prior to reaching the set threshold strength. This is surprising since the pressure exerted on the laminate in the production process should theoretically lead to a decrease in such a likelihood, similarly to the pressing method. However, these two techniques varied. Due to the pressure exerted on the laminate, the matrix may have been squeezed out of the reinforcement layers and its excess was absorbed by the lignin. This may have led to an insufficient volume share of resin in the final product. The consequence might be the failure to distribute tensions over the whole of the reinforcement, which could explain a reduction in strength. In the pressing method, resin could not find its way out of the manufactured composite. Taking into account the peculiarity of the vacuum bag technique, it can therefore be assumed that the reduction in the negative pressure generated by the pump or not using lignine could result in the reduction of the probability of the sample decohesion by reducing the outflow of the matrix from the laminate at the production stage.

Due to the fact that the approximated functions of probability distribution indicate slight differences between the examined carbon composites, and due to a relatively small number of tests performed, it was found that any conclusions so as to improve or deteriorate the properties of laminates, depending on the technique of making them, would be a too far-reaching presumption. The pressure exerted by the press appeared to be insufficient to obtain similar effects to those in glass composites, due to more compact structure of the carbon fabric used as reinforcement. The results obtained do not therefore deny the previously formulated conclusions, however they are incapable of confirming them. Presumably, it is necessary to make composites by the pressing method again, this time with more compressive load.

ABSTRACT: Lock mechanism is one of the important and problematic components on aircraft, whose performance and reliability directly affect the mission or even safety of the aircraft. However, lock mechanism always have characteristics of complex forms, few samples and high reliability, traditional reliability assessment methods and reliability test method based on statistics is not appropriate for its reliability assessment. In addition, damage of the lock components increase with work time, the damage will make the performance of lock mechanism degradation or even cause failure. Therefore, reliability of the lock mechanism is not only function of random variables but also function of work time. In this paper, a time-variant reliability analysis method based on physics of failure was put forward, in the method, both time-invariant factors and time-variant factors are considered, and the degradation model of the components can be obtained from both practicality experiment or damage mechanism model. Taking a lock as the study object, failure modes and failure mechanism of the lock mechanism were analyzed combined with dynamical responses. Then, Response Surface Method (RSM) was used to obtain relationship between design variables and dynamic responses. Component damage was regard as a random process, after damage degradation law was obtained, considering randomicity of all the parameters, lock mechanism reliability with work time was obtained and the reliable life was predicted.

1 INTRODUCTION

Numerous mechanical systems on aircraft have lock mechanisms, such as landing gear system, cargo door system, et al. The reliability of the lock mechanisms has a great influence to the mission accomplishment and the safety of the aircraft. If the lock of landing gear door won't open in the landing time, the landing gear door cannot put down; If the cargo door lock mechanism cannot open, the airborne or airdrop mission will fail.

Several studies have been focused on the reliability of the lock mechanism. (Ouyang 1994) analyzed wear depth of the lock hook surface based on Archard's wear model, gained the changing trend of the wear reliability with the opening and closing times. (Gu, et al. 1995) used the fault tree method, from the startup and running two aspects, assessed reliability of the landing gear door's lock. (Ouyang, 1994) only focused on the partial wear of the lock mechanism, without considering the impact on the overall performance. Although lock reliability is analyzed with overall performance in consideration (Gu, et al. 1995), the degradation process and the physical processes that cause the degradation were ignored. Reliability problems of other mechanisms like lock mechanism have received extensive attention. These studies mainly focused on kinematical accuracy (Tsai et al. 2008, Wang et al. 2011), joint clearance effect (Rhee & Akay 1996, Erkaya & Yzmay 2012) and motion seizure (Ballu 2008) and other aspects. To the performance degradation caused failure problems, (Wang & Chen 2011) analyzed the time variant reliability for gear with multi-failure mode, presented the relation between reliability and work time. (Jin et al. 2013) accord to performance degradation data come from actual physics of failure test, based on failure-physics method established a model to describe MW's failure process and finally predict the work lift-time. To the component damage caused component failure or function failure, there's no too much literatures. To sum up, the present literatures don't give out an intensive study towards mechanism time-variant reliability.

The lock mechanism reliability was affected by many factors, such as the manufacturing and assembling errors, material properties, external load and other non-time-variant factors. Therefore, the lock mechanism has the possibility of

failure in the early service period, and in general, the design safety margin can make sure that the mechanism has a higher reliability in early service. However, there is a kind of factors, whose parameters varies with serving time, such as joint wear, material stress relaxation, gasket aging and corrosion. In the early service period, their influence on the lock mechanism is not significant, but with the increase of service time, these factors will degrades performance of mechanism, for example, joint wear will cause the hinge gap increases, the contact condition will become worse, causing friction increases; the stress relaxation and creep will cause the motion accuracy decreases; the sealing parts corrosion and aging may cause the performance of hydraulic system degradation, cause the driving ability decrease. Therefore, the failure probability is not only function of the variable, but also function of service time. With the service time growth, the reliability of mechanism will continue deteriorates until the failure occurs.

In this paper, failure modes and failure mechanism are analyzed, and a lock is used as an object of study. This paper is organized as follows: failure modes and failure mechanism were analyzed based on the dynamical simulation results, use failure physics method to establish damage model of the lock part, use response surface method (RSM) to obtain the deterministic function of the system, which reveals the relationship between system performances and the design variables. Then, part damage results are used to update the simulation model. Finally, considering the randomicity of variables, and using the knowledge of statistics, obtained the reliability degradation law and predicted the lifespan of mechanism.

2 RELIABILITY ESTIMATION METHOD BASED ON PHYSICS OF FAILURE

2.1 *Reliability estimation framework based on physics of failure*

Different from electronic system, mechanisms in aircraft always have properties of form complex, small sample size, and long life, high reliability requirements, so the traditional reliability assessment method based on statistics is not suitable for aircraft mechanism, and the reliability assessment

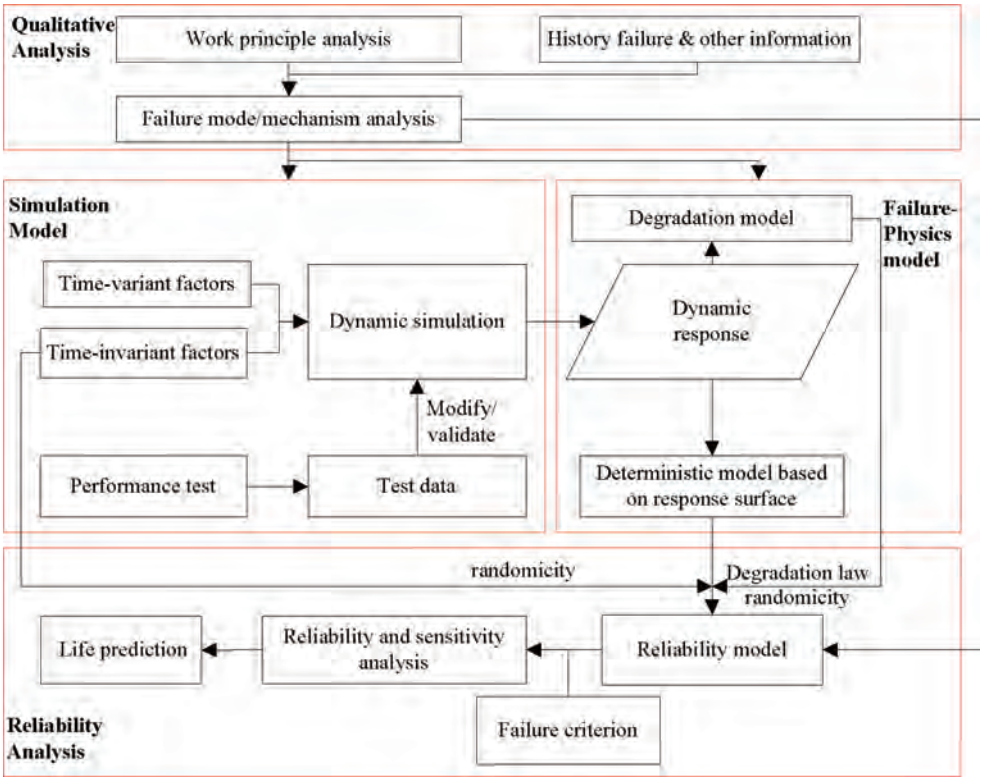

Figure 1. Time-variant reliability estimation framework based on physics of failure.

based on test method needs to spend too much time and cost. In order to solve these problems, time-variant reliability assessment framework based on failure physics was presented, as shown in Figure 1:

The main work of the time-variant reliability assessment based on failure-physics method consists of following aspects:

1. Failure modes and mechanism analysis

In this stage, failure modes and failure mechanism were obtained based on work principle analysis, history failure and other test information. Failure modes analysis is the foundation of reliability analysis, the common methods are Failure Modes Effect Analysis (FMEA) and Failure Tree Analysis (FTA). Where FMEA is a bottom-up method, which begins from components failure and follows certain logic to find out the effect to the system and then find out the crucial components and main failure modes. Its effect is very accurate at the level components but becomes progressively weaker as the fault effect propagates further away from the component and into the subsystem and system-level effects. While FTA is an up-down method, start form high level failure to find out the reasons which cause the fault.

2. Simulation model establishment

Mechanism is a mechanical system consists of several components and related joints. For some complex mechanisms, establishing and solving the dynamic models are very difficult. But the existing commercial software such as MSC ADAMS and LMS Virtural.Lab, present an easy way to model mechanism, and the dynamic results can be accurate if only the simulation model is reasonable. Therefore, this paper established the dynamics simulation model of mechanism in LMS Virtual. Lab, the model was modified and validated by the performance test, and then the model can provide accuracy results compared to real mechanism. Thus we can obtain the physical models which reflect the relationship between inputs and outputs of mechanism system.

3. Physics of failure model

Physics of failure model of mechanism contains performance function which reflects the relationship between inputs and outputs of mechanism system and the damage model which reflects the geometry and physical parameters change law with the work time. In the former step, the performance function is implicit, if use simulation model to analysis the reliability, every sample should be simulated in the model, which make it quite time consuming, for example, a single simulation cost 20 seconds, that is to say 10000 samples need 200000 seconds (about 56 hours). In order to obtain an explicit performance function, response surface method was used, this time, only a few samples need to be run in the simulation model, if bucher's sampling method is applied, the number of samples is $2n+1$, here, n is the number of random variables.

Damage in the mechanism of behaves as joint wear, plastic deformation, seal parts corrupt and aging, spring stress relaxation and so on. These damage models can be obtained by fitting the degradation data or by the damage model. Presently, many scholars have done a lot of research work in such domains (Wen Tsinghua University press, Su, Tianjin University press). In the reliability analysis process, we can directly choose the appropriate model to application.

4. Reliability assessment and lift prediction

For a certain mechanism, it is likely that two or more failure modes exists at the same time, and different failure modes may be in series, parallels or mix relations. To analysis reliability, proper reliability model needs to be established. Then bring failure criterion and variables' distribute parameters into the response surface, the reliability and sensitivity can be obtained, at last, based on the reliability result give a lift prediction of the mechanism. The operation time at which the reliability of the mechanism is lower than the required reliability is the lifespan of the mechanism.

2.2 *Time-variant reliability analysis method for mechanism*

Unlike structure's static response, dynamic responses of the mechanism changes with its configuration, so the mechanism performance can be described by a set of performance curves, namely $\boldsymbol{F} = \boldsymbol{F}(t)$. These curves can describe position, velocity, acceleration, load et al. In addition, time-variant factors makes the response quantity of different motion cycle not the same, namely $\boldsymbol{F} = \boldsymbol{F}(t,n)$, wherein t represents a runtime mechanism in single cycle, n represent the cycle number of the mechanism. In the reliability assessment process, it's not necessary to focus on the response of whole cycle time, but care about the response of the maximum value, the minimum value or a certain time value of each cycle, namely $\boldsymbol{F}(n) = \max(\boldsymbol{F}(t,n))$, $\boldsymbol{F}(n) = \min(\boldsymbol{F}(t,n))$ or $\boldsymbol{F}(n) = \boldsymbol{F}(t_c,n)|_{t = tx}$. When any $\boldsymbol{F}(n)$ exceed its allowed domain, the mechanism will failed.

In a generally way, mechanism performance can be represented by a set of response expressions, namely $F_i(\mathrm{n}) = \max(F_i(t,n))$, $i = 1,2,\ldots,s$. And the performance is mainly influenced by the m factors of x_j, $j = 1,2,\ldots,m$. Among which p factors are time-invariant and q factors are time-variant.

In this paper, linear response surface function was used to describe the relationship between the inputs and outputs of system, the form is

$$F(\bar{x}) = b_0 + \sum_{i=1}^{m} b_i x_i = B[1 \quad x], i = 1,2,...s \tag{1}$$

Assuming that time-invariant variables obey normal distribution, time-variant obey normal process and the distribution parameters of both time-invariant and time-variant factors are obtained, i.e.

$$x_j \sim N(u_j, \sigma_j^2), j = 1,2,...,p$$
$$x_j \sim N(u_j(n), \sigma_j^2(n)), j = 1,2,...,q$$
$$p + q = \boldsymbol{m}$$

Generally, $F_i(n)$ is a monotonic function, here assume it is a monotonic increasing function, namely, $F_i(n)$ increase with the mechanism performance degradation. Then the failure probability, reliability and lifespan of each failure mode can be represented as

$$P_{f_i}(n) = P\{F_i(n) > L_i\}$$

$$R_i(n) = P_r\{F_i(n) < L_i\} = \int_o^{N_i} f[F_i(n)]d[F_i(n)] \tag{2}$$

$$N_i = inf\{N | F_i(n) > L_i, \mathrm{n} \geq 0\}$$

where, L_i represents the failure threshold of each dynamic response and the inf{·} is the infimum function.

All the failure modes of the mechanism can be regard as in series, failure probability of the system can be written as

$$P_{sf} = \sum_{i=1}^{s} P_i - \sum_{1 \leq i < j}^{s} P_{i,j} + \sum_{1 \leq i < j < k}^{s} P_{ijk} - \cdots + (-1)^{s-1} P_{12\cdots s} \tag{3}$$

Previously, performances of mechanism system are treated independently, the correlations between different failure modes are been ignored (Leira et al. 2005, Franchin et al. 2003), namely, assume reg $\rho_{ij} = 0$. So the probability of the mechanism can be described as

$$P_f(n) = \sum_{i=1}^{s} P\{F_i(n) > F_{iC}\} = \sum_{i=1}^{s} P_i \tag{4}$$

However, all components in mechanism suffer a common load environment. Effects of Multi-factors coupling and multi-body coupling made failure modes in a mechanism dependent with each other, it means different failure modes have relations with each other. So the previous method which ignoring the correlations between different failure modes will lead to an overestimation of the system probability of failure and underestimate of the system reliability (Wang et al. 2007, Levitin 2001).

If correlations between different failure modes are been considered, for a mechanism have two or three failure modes, equation (4) can be written as:

For $s = 2$, $P_{2f} = P_1 + P_2 - P_{12}$ (5)

For $s = 3$, $P_{3f} = P_1 + P_2 + P_3 - P_{12} - P_{13} - P_{23} + P_{123}$ (6)

For functions of Equ. (1), the correlation coefficient ρ and covariance matrix C between different failure modes can be described as

$$\rho_{i,j} = \frac{Cov(F_i, F_j)}{\sqrt{DF_i} \cdot \sqrt{DF_i}} \tag{7}$$

$$C = \begin{bmatrix} \sigma_{F_1}^2 & \rho_{12}\sigma_{F_1}\sigma_{F_2} & \rho_{12}\sigma_{F_1}\sigma_{F_3} & \cdots \\ \rho_{12}\sigma_{F_1}\sigma_{F_2} & \sigma_{F_2}^2 & \rho_{12}\sigma_{F_2}\sigma_{F_3} & \cdots \\ \rho_{12}\sigma_{F_1}\sigma_{F_3} & \rho_{12}\sigma_{F_2}\sigma_{F_3} & \sigma_{F_3}^2 & \cdots \\ \vdots & \vdots & \vdots & \ddots \end{bmatrix} \tag{8}$$

According to knowledge of probability theory, failure probability of k failure modes occur in the same time can be obtained through integrate joint density function of the multi-dimension random valuables in the failure domain,

For $k = 2$,

$$P_{ij} = \iint_G f(F_i, F_j) \mathrm{d}F_i \mathrm{d}F_j \tag{9}$$

For $k = 3$,

$$P_{ijk} = \iiint_G f(F_i, F_j, F_k) \mathrm{d}F_i \mathrm{d}F_j \mathrm{d}F_k \tag{10}$$

And we can also use multivariate normal cumulative distribution function in MATLAB to calculate the failure probability, the form is

$$P_{ij\ldots} = \mathrm{mvncdf}\ (\boldsymbol{L}, \boldsymbol{u}_F, \boldsymbol{C}) \tag{11}$$

Because distribute random parameters of time-variant valuable is variant with operation time, the failure probability calculated form equation (6) is the function of operation cycle. Assume that the reliability of the system is required to be high than Rc, then the lifespan N can be calculated as

$$N = inf\{T | R(n) > Rc, n \geq 0\} \tag{12}$$

3 FAILURE MECHANISM OF A LOCK MECHANISM

3.1 *Working principle of the lock mechanism*

The lock mechanism consists of eleven parts named 1 to 11, the closed state is shown in Figure 3. The opening process can be divided into three phases: (1) the hydraulic system work to push part 2, which makes part 3 rotate clockwise. At the same time, wheels assembled on part 3 shove part 4, make part 4 rotate clockwise until part 4 and part 5 apart; (2) When part 4 is open, wheels roll along the up surface of part 4 and shove part 5, at the same time, force transfer though part 6 to part 7 and part 7 rotate anticlockwise, until points A, B and C get in a line; (3) after that, with the effect of compress spring 11, part 8 open automatically, and with the spring force of 10, part 4 rotate anticlockwise and keep the lock in the open state. The closing process is in opposite to the opening process.

3.2 *Failure modes and mechanism analysis of lock mechanism*

There are too many potential failure modes in lock mechanism, in order to find out the most probable failure modes, dynamic simulation was implemented, dynamic responses of main structure are show in Figure 2.

Obviously, max value of contact force occurs in the first period and the max value of link and driving force occur in the second period.

Force analysis for the first period is shown in Figure 3, part 4 bear five forces of F_{n1}, F_{f1}, F_{n2}, F_{f2}, F_s, among which, only F_{n1} help to open the lock and all others prevent it from opening. Here F_{n2} is determined by lock hook force F_p, F_{1n} is supplied by F_L, and F_{f1} is determined by F_{n1} and friction

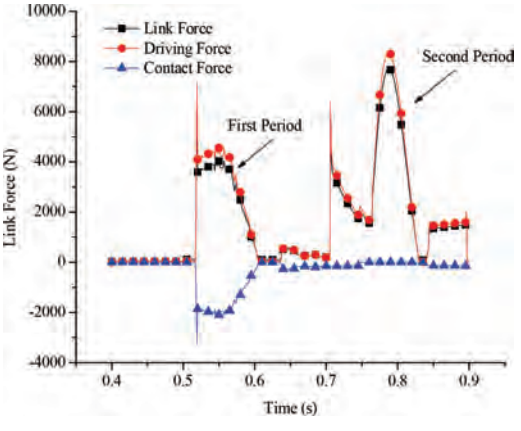

Figure 2. Dynamic simulation results.

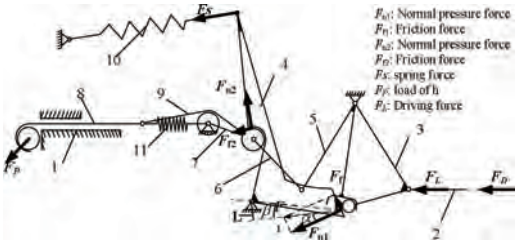

Figure 3. Force analytical of first period during opening phase.

coefficient f_1. From the direction of F_1, which is the composition force of F_{n1}, F_{f1}, it can be seen that with the increase of f_1, the arm of F_1 to the rotation axis decreased when the friction coefficient f_1 increased. And the force arm decrease to very small value or even zero if f_1 increases to a certain extent. At the same time, the wear and impact lead to slope surface of the key roughness and unevenness, which will directly affect the magnitude of the positive pressure and friction force, and affect the direction of the composition force as well.

In the performance test, we record the pressure of the hydraulic pressure in the cylinder actuator and the force in the link, after several operation cycles we found that the driving force and the link force increased compared to the beginning trial. Then the lock mechanism is carefully examined and found that there are wear and extrusion marks in the slope surface of the part 4, other parts without obvious change. Damage modality of part 4 is shown in Figure 5.

In the second period of lock opening process, part 7 contrarotate and make point C move from underside to upside of the line made of point A and point B, during this process, part 7 suffer F_1 and F_2, force analytical model is shown in Figure 4. Here F_1 supplied by hydraulic system act as the driving force and F_2 determined by Fp act as the drag force. As point C gradually close to the line form underside, distance between point A and point C increased, this result in Fp increased because much large force needed to conquer the deformation of the port. And the radius of the part 8 also influences F_P, if F_p is too large, the hydraulic pressure will not large enough to open the lock, this time the lock mechanism will get seizure.

According to what have been said, the lock mechanism have two main potential failure modes: 1) in the first period, the roller load is become larger and larger, when the maximum load exceed the terminal load, which is the maximum load the structure can bear, the structural damaged, manifested as roller plastic bending or link buckling; 2) in the second period, link buckling or lock mechanism

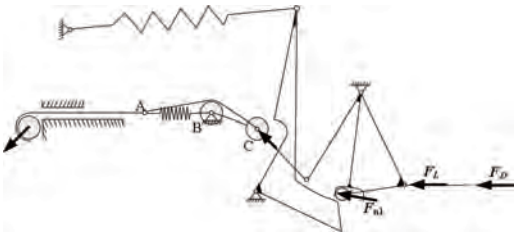

Figure 4. Force analytical of second period during opening.

Figure 5. Damage modality.

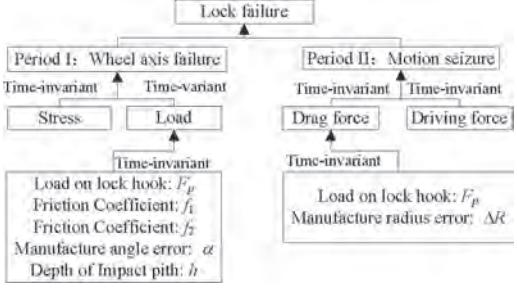

Figure 6. Failure mechanism of the lock mechanism.

get seizure. The failure mechanism is shown in Figure 6.

To sum up, the failure modes of lock mechanism is roller plastic bending in the first period and mechanism seizure in the second period.

Further, as Figure 7 shows, with the effect of degradation factors, characteristic parameters of the lock mechanism will increase with the work time, and make the reliability degradation.

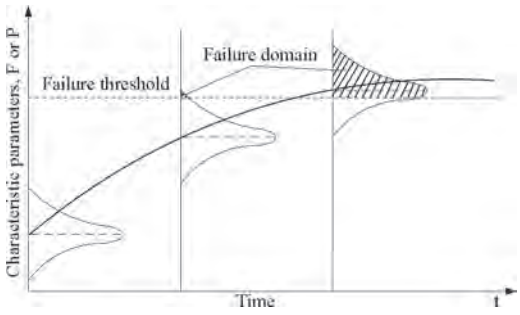

Figure 7. Sketch map for performance degradation.

4 TIME-VARIANT RELIABILITY ANALYSIS OF THE LOCK MECHANISM

4.1 *Parameter characterization of local damage*

When the lock begins to open, wheel move along X direction quickly in the hydraulic action, and then wheel assembled on the axis will impact part 4, since hardness of axis is greater than part 4, after repeated impact, surface of part 4 will generate an impact pit. The curvature of pit is approximate to radius of wheel R, the sketch map of damage modality is shown in Figure 8. Here h represents the depth of impact pit, and the dimension is equal to difference of R and D.

4.2 *Reliability model of lock mechanism and distribution parameters of variables*

4.2.1 *Reliability model of lock mechanism*

Section 3.2 shows that potential failure modes of lock mechanism is roller failure, manifested as roller plastic bending in the first period and mechanism seizure in the second period. Analysis result shows the critical force F_c lead to roller plastic bending is 8346 N and the maximum driving force is 10000 N. In order to simply the analysis process, the dispersion of the value has been ignored. Then failure criterion of the failure mode can be described as

$$g_1(\vec{x},n) = F_{C1} - F_1(\vec{x},n) < 0 \tag{13}$$

$$g_2(\vec{x},n) = F_{C2} - F_2(\vec{x},n) < 0 \tag{14}$$

According to Equ. 4, the failure probability of the lock mechanism can be written as

$$p_f(n) = P\{g_1 < 0\} + P\{g_2 < 0\} - P\{g_1 < 0 \cap g_2 < 0\} \tag{15}$$

In the above equation, $F_1(\vec{x},n)$ is the max contact force in the nth cycle and $F_2(\vec{x},n)$ is the force needed to open lock in the nth cycle.

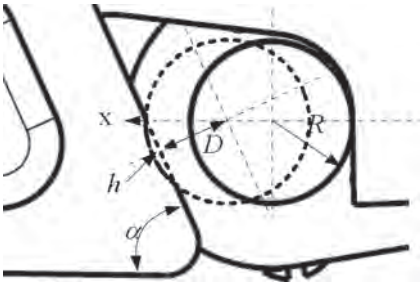

Figure 8. Depiction for the damage modality.

4.2.2 *Distribution parameters of variables*

Failure analysis of the lock in section 3 shows four factors affect the maximum roller force in the open process, they are load of hook F_p, friction coefficient between key and roller, slope of key f_1, friction coefficient between key and rocker f_2. And the key's slope α. Assuming all variables obey normal distribution.

Load of hook is a random variable affected by the flight state of the aircraft, which has no relation with the lock operation times.

The performance test shows there's almost no wear between key and rocker, so the friction coefficient between key and rocker can be regarded as a time-invariant variable.

4.3 *Performance function modeling based on response surface method*

For complex mechanism, it is unpractical to establish and solve the dynamic equations and the through test to obtain the dynamic responses and their relationships between design parameters because of the limitation of time and costs. However dynamic simulation is a good choice to solve these difficulties.

Establish the lock simulation model in LMS Virtual.Lab platform, then use test data to modify and the simulation model until the results are precise enough, and then effective simulation model is obtained.

According to the distribute parameters of valuables, adopt Bucher sampling method to get the samples, then simulation all the samples in the simulation model and obtain correlative results.

From equation (1), we get the performance functions of max contact force in the first period and the max driving force in the second period like

$$F_1(\mathbf{x},n) = B_1[1 \quad f_1 \quad f_2 \quad \alpha \quad F_p \quad h]^T \tag{16}$$

$$F_2(\mathbf{x},n) = B_2[1 \quad \Delta R \quad F_p]^T \tag{17}$$

Thereinto,

$$B_1' = \begin{bmatrix} -6295.1208 \\ 4418.1333 \\ 8495.65 \\ 78.8655 \\ 363.0785 \\ 191.5783 \end{bmatrix} \quad B_2' = \begin{bmatrix} 8291.466 \\ 132.1717 \\ 34.691 \end{bmatrix}$$

From B_1, it can be seen that all the coefficients are positive except the constant term. It means contact force increases with the increase of each parameter. B_2 shares the same conclusion. The conclusion is accord with our intuitive feelings.

Comparison is made for measured values and fitted values in Figure 9, it can be seen that the two kinds of values almost superposition, that is to say, the linear response surface is precision enough to replace the simulation model.

4.4 *Reliability analysis and life-span prediction*

Substitute the distribute parameters into limit state equations, the mean value and standard deviation can be obtained.

$$u_{F1}(n) = 2128.1 + 0.4418n + 0.0192n^{1/3}$$

$$\sigma_{F1}(n) = \sqrt{2.0189 \cdot 10^6 + 13.9868n + 0.1748n^2 + 0.00367n^{2/3}}$$

$$u_{F2}(n) = 8464.921$$

$$\sigma_{F2}(n) = 881.2249$$

The driving force and contact force distribution in different work cycles are show in Figure 10. From which it can be seen that driving force distribution is constant during lifetime, while contact force distribution changes constantly during lifetime, the mean value increase obviously with the increase of the work cycles and the deviation also increase tardily.

According to the reliability analysis method represented above, reliability of lock mechanism was obtained, as Figure 11 shows, reliability of failure mode II (motion seizure in the second period) is a constant value of 0.9592 during lifetime, while reliability of failure mode I (wheel axis damaged) decreased with the increase of the work cycles, the change is much obviously after 1000 work cycles.

Another conclusion is that in the beginning of service time, failure mode II plays as the main failure mode and after 1000 work cycles, failure mode I plays as the main failure mode.

Table 1. Summary statistics of the basic variables in the modal.

Variables	Mean, u	Standard deviation, σ	Max	Min	Average
f_1	0.04+0.0001*n	0.1*u	0.1	0.04	0.07
f_2	0.2	0.0166	0.15	0.25	0.2
α/deg	60	0.3333	61	59	60
ΔR/mm	0	0.00667	0.02	–0.02	0
F_p/kN	5	0.3333	6	4	5
h/mm	0.0001*$n^{1/3}$	0.1*u	0.3	0	0.15

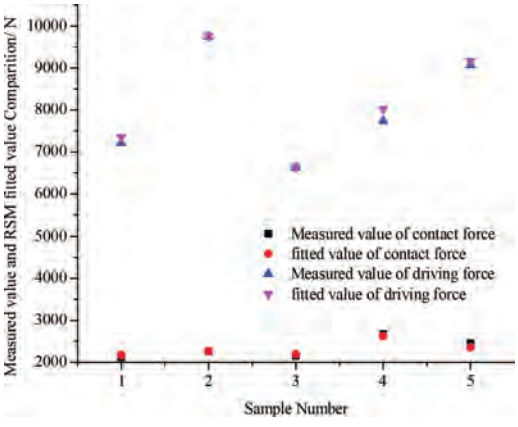

Figure 9. Comparison of measured values and fitted values.

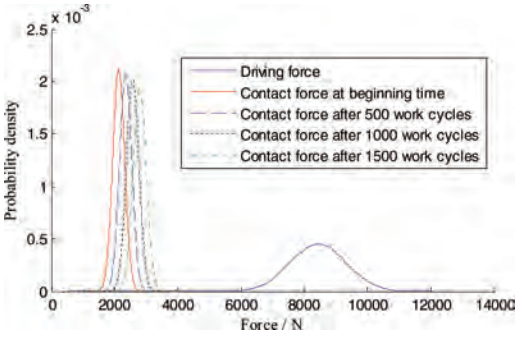

Figure 10. Diving force and contact force distribution.

From system reliability curve in Figure 11, it can be seen that lock reliability is 0.9592 at the beginning time, and decreased slowly in the following 1000 work cycles. Then, the lock reliability decreased quickly. According to the requirement that reliability much higher than 0.9, the reliable life is 5027 work cycles.

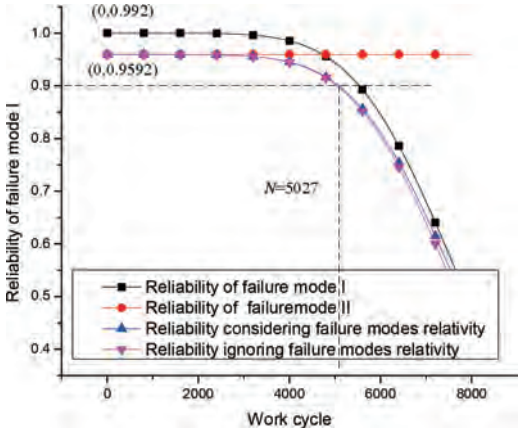

Figure 11. Degradation law of lock reliability.

5 CONCLUSIONS

1. In order to solve problems exists in the traditional statistic method and test method for lock mechanism reliability analysis, a time-variant reliability analysis method was presented, which is based on virtual simulation and with component damage into consideration.
2. Based on dynamic simulation results, failure modes and failure mechanism was analyzed, obtained that two main potential failure modes of lock mechanism are wheel axis failure and motion seizure, then analyzed the failure mode influence factors.
3. Performance functions were found through RSM, time-variant reliability of lock mechanism was evaluated with lock key damage and randomicity of variables into consideration. The results show lock reliability is 0.9592 in the early days. After 1000 operation times, its reliability decreases to 0.9451. As the reliability is required to be higher than 0.9, the reliable operation time is 5027 times.

A metal-oxide-semiconductor devices reliability assessing method based on physics of failure

Hantian Gu, Ming Zhu, Wei Zhang, Lei Zhang, Hengjing Zhu & Min Tang
China Aerospace Components Engineering Center, CASC, Beijing, P.R. China

ABSTRACT: With the development of Metal-Oxide-Semiconductor (MOS) devices, reliability is becoming a key differentiator in a competitive market. Considering the different stress types and levels during application, an algorithm is proposed to evaluate the reliability of MOS devices under complicated operation conditions. This algorithm is based on the theories of Physics of Failure (PoF). Failure modes, mechanisms and effects analysis is conducted to achieve the potential failure mechanisms and physics models. Then through modeling and simulation, thermal, mechanical and electrical parameters of MOS devices under different conditions are obtained. Using the physics models, cumulative damage theory and random sampling algorithm, the matrix of time to failure of each unit is taken. At last, competing failure model is applied to acquire the time to failure of MOS devices in working condition. The algorithm provides a new approach based on PoF for evaluating the reliability of MOS devices under complex environments.

1 INTRODUCTION

Reliability is an important requirement for almost all users of integrated circuits (ICs). Scaling for enhanced performance and cost reduction has pushed existing MOS devices materials much closer to their intrinsic physical and reliability limits. Besides, A newly developed semiconductor technology node cannot be released to user without going through a rigorous work of reliability evaluation (Saeidi et al., 2013, Hava et al., 2013). All of these demonstrate that the reliability evaluation for MOS device is necessary and it is facing a huge challenge.

For reliability evaluation, a common and realistic practice is to perform accelerating tests under conditions that are much more severe than those under operation conditions. The severe conditions in accelerating tests generally mean a much higher stressing temperature or stressing current or both than the operation conditions. After obtaining the time-to-failure and failure distribution on severe conditions, the evaluation of reliability under normal operation is realized through accelerating models by extrapolation. However, there are two disadvantages in this approach. The first one is only one failure mechanisms are considered during accelerating tests, so the time-to-failure under normal operation by extrapolation is only associated with that mechanism. The second one is that the devices are always operating in a constant stress level. It is not match with operating conditions in actual. In other words, the results are qualitative and they cannot be used to evaluate the lifetime of devices under actual environment.

Therefore, a new algorithm is put forward to evaluate the reliability of MOS devices in this paper, which consider different failure mechanisms and stressing conditions in the entire life of devices.

In the next second of the paper basic theories associated with the algorithm are introduced. In the third part the procedure of reliability evaluation for MOS devices will be given and the detailed algorithms will be told. The fourth part of this paper is a case study. In this section we will describe each step in details combined with a simple MOS device and make a discussion with the results of simulation. At last, conclude this paper and look into the future of this methodology.

2 BASIC THEORIES

This methodology that put forward in this paper is based on Physics-of-Failure (PoF). The concept of PoF, also known as Reliability Physics, involved the use of degradation algorithms that describe how physical, chemical, mechanical, thermal, or electrical mechanisms evolve over time and eventually induce failure (Borgarino et al., 2001, Pecht and Gu, 2009). In this paper, PoF is used to establishment the relationship between the operation environment and the degradation of performance

parameters of MOS devices. The used failure modes include three groups according to their origin: (i) failure modes associated with chip; (ii) failure modes resulting from leads; (iii) failure modes due to overstress. In this paper, we analyze the failure modes and mechanisms which have higher probability of occurrence and greater impact on the performance of MOS device at first. Then we calculate the stress of device under operation conditions to find the reasons that possibly lead to failure through simulation analysis. At last, *TTF* is predicted by PoF models. Hence, all of the work in this paper is about PoF.

3 ALGORITHM

3.1 *General algorithm*

As Figure 1, the input of this algorithm consists of three parts: parameters of structure, material properties, potential failure mechanisms and local stress under operation conditions.

1. Parameters of structure include dimensions of packaging and die;
2. Material properties describe the deformation of material under load;
3. Failure Mode, Mechanism and Effects analysis (FMMEA) helps to understand the potential failure mode, mechanisms and models of MOS devices during under operation conditions.
4. Local stress under operation conditions will be obtained from simulation analysis, including thermal analysis, random vibration analysis and electronic parameters analysis.

According to inputs, the main part of algorithm is developed with the work of random sampling, cumulative damage and data processing. Considering the uncertainty of size, properties of materials and operation conditions in practice, we treats the uncertain parameters as random variables described by some appropriate statistical distribution, which may be sampled using Monte Carlo methods. After sampling we get the matrix of the uncertain parameters for failure mechanisms. In practice, the MOS devices experience variable amplitude loading. And cumulative damage theory allows us to calculate the damage for each cyclic loading. Here we obtain the matrix of *TTF* of simulation unit for each critical failure mechanisms under operation conditions. At last, we need to calculate the *TTF* of MOS device according to the matrix of *TTF* of simulation unit by data processing.

In the following section, we will discuss this methodology in detail and give the algorisms in each phase.

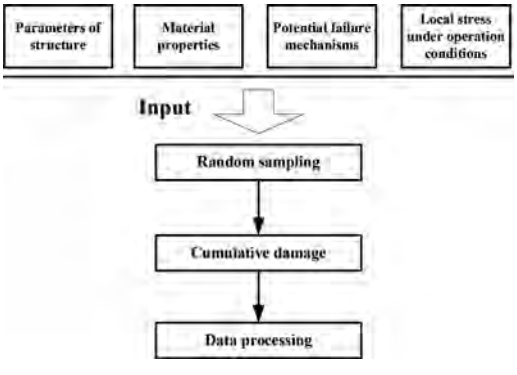

Figure 1. The workflow of reliability evaluation by simulation.

3.2 *Input information*

The input information is divided into three classes:

1. Parameters of structure include dimensions of packaging and die;
2. Material properties describe the deformation of material under load;
3. Failure Mode, Mechanism and Effects analysis (FMMEA) helps to understand the potential failure mode, mechanisms and models of MOS devices during under operation conditions.
4. Local stress under operation conditions will be obtained from simulation analysis, including thermal analysis, random vibration analysis and electronic parameters analysis.
5. Parameters of structure

For structure parameters, different approaches are selected to obtain. The following table shows the approaches to extract them:

3.3 *Material properties*

Material properties include the density, elastic modulus, poisson's ration, conductivity, coefficient of thermal expansion and so on. They are easy to get from handbook.

Table 1. Approaches of parameters extraction.

Parameters	Sources
Parameters of packaging	Datasheets Measurement
Parameters of die	Design files of layout of chip Measurement

3.4 *Potential failure mechanisms*

Considering the interaction among performance, physical characteristics of products, materials and environment stress, failure mode, mechanism and effects analysis (FMMEA) can be used to determine the potential failure mechanisms and models. Besides, the priority of failure mechanisms can be determined based on the severity and probability of occurrence.

After FMMEA, the critical failure mechanisms, which mean higher probability of occurrence and greater impact on the performance of the specific MOS device, and models are determined. They are the focus of analysis and calculation in the following phases.

3.4.1 *Local stress under operation conditions*

Since the parameters of operation conditions are the environment which the system working in and it is different from the MOS devices' working environment, the simulation modeling and analysis are necessary. Local stress of MOS devices will be given by simulation modeling and analysis. In this phase, there are three simulation are indispensable: thermal analysis, random vibration analysis and electrical parameters analysis.

- Thermal analysis

Thermal analysis is used to obtain the local temperature distribution under specific operation conditions. The solution procedures in this paper are based on computational fluid dynamics (CFD) techniques, which are concerned with the numerical simulation of fluid flow, heat transfer and related processes.

- Random vibration analysis

Random vibration analysis is used to obtain the equivalent stress, equivalent strain and model under specific operation conditions. The solution procedures in this paper are based on finite element analysis (FEA) techniques, which are concerned with the force-balance equation, deformation compatibility equation and material properties.

- Electrical parameters analysis

Electrical parameters analysis is used to obtain the related electrical parameters of MOS structure under specific bias voltage, such as the current density for electromigration and oxide field for TDDB.

3.5 *Algorithm of random sampling*

Considering the uncertainty of size, properties of materials and operation conditions in practice, we treats the uncertain parameters as random variables described by some appropriate statistical distribution, which may be sampled using Monte Carlo methods. Here, the parameters of PoF models are subject to various kinds of uncertainty, which may include: uncertainty of material properties, the effect of variations in manufacturing process and the uncertainty associated with stochastic fluctuations of operational stresses. In order to generate the samples fitting the given distribution, the algorism for random sampling is,

1. Calculate the inverse function of cumulative distribution function (CFD), $F^{-1}(x)$;
2. Generate samples of uniform distribution in the interval (0,1), $\vec{a} = (a_1, a_2, \ldots, a_n)$;
3. Calculate $\vec{x} = F^{-1}(\vec{a})$, so vector $\vec{x}$ is the samples that we wanted.

The matrix of the uncertain parameters for specific failure mechanism is,

$$\alpha = \begin{vmatrix} \alpha_{11}, \alpha_{12} \cdots \alpha_{1n} \\ \alpha_{21}, \alpha_{22} \cdots \alpha_{2n} \\ \cdots \\ \alpha_{1m}, \alpha_{m2} \cdots \alpha_{mn} \end{vmatrix} \tag{1}$$

Here, α_{mn} means the nth sample of uncertain parameter, α_m.

3.6 *Algorithm of cumulative damage*

In practice, MOS devices experience not a few of different stress levels during lifetime, but a life profile which the different stress levels are arranged in a certain order. Calculating the *TTF* under different stress levels respectively cannot descript the actual situation in application. So it is necessary to develop cumulative damage analysis. In this paper, we introduce two approaches: acceleration factor method and cumulative damage rule method.

- Acceleration Factor Algorithm (AFA)

Acceleration Factor is a multiplier that relates a product's life at an accelerated stress level to the life at the use stress level. AFA is suitable for failure mechanisms of electromigration, hot carrier injection, gate-oxide time dependent dielectric breakdown and so on. Here, in order to think about the influence of life profile with several stress levels, we convert it to a new profile with only one stress level, which we call it reference stress level using acceleration factor at first. In terms of temperature, the algorithm is as following,

1. Start;
2. Input the profile of temperature with two vectors $\vec{t} = [t_1, t_2, t_3, \cdots, t_n]$ and $\vec{T} = [T_1, T_2, T_3, \cdots, T_n]$, reference temperature T_0, $t\_trans = 0$;
3. Set $i = 1$;
4. If $T_{i+1} = T_i$, $t' = (t_{i+1}) \times \mathrm{AF}(T_i)$, otherwise, $t' \int_{t_i}^{t_{i+1}} AF(T(t)d(t))$. In the formula, $AF(T)$ is

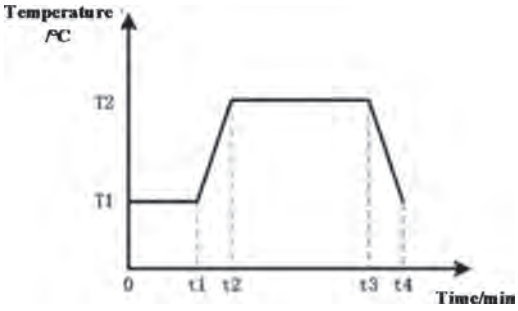

Figure 2. A profile of temperature used to help describe AFM.

the is the acceleration factor of temperature T which has been transferred to T_0;

5. Calculate $t\_trans = t\_trans + t'$;
6. $i = i + 1$;
7. Repeat the step 4) to 6) until $i = n - 1$.

Then calculate the *TTF* under operation condition of new profile and it is easy to transfer it to the *TTF* under original profile.

For example, a profile is as following,

In this profile, there are two different stress levels, *T1* and *T2*, and the dwell is *t1* and (*t3* – *t2*), respectively. The two stages with temperature change are (*t2* – *t1*) and (*t4* – *t3*). Here, assuming that we transfer them to the stress level of *T0*, the formula is,

$$t\_trans = t1 \times AF(T1) + \int_{t1}^{t2} AF(T(t))d(t) \\ (t3 - t2) \times AF(T2) + \int_{t3}^{t4} AF(T'(t))d(t) \quad (2)$$

Here, *t_trans* is the equivalent time of original profile under stress level of *T0*, *AF(Ti)* is the acceleration factor of temperature *Ti* which has been transferred to *T0*, *T(t)* and *T'(t)* are the function of *T* vs. *t*.

Calculate the *TTF* under temperature *T0*, than *TTF* under original profile is,

$$TTF_o = \left[\frac{TTF}{t\_trans}\right] \times t4 \quad (3)$$

Here, [*] mean the number that is nor more than *; *TTF* is time-to-failure of specific MOS structure under *T0* in terms of certain mechanism; TTF_o is time-to-failure of specific MOS structure under original profile.

- Cumulative Damage Rule Algorithm (CDRA)

In terms of mechanisms such as random vibration fatigue, CDRA is more appropriate to solve the problem of the cumulative damage. Here, considering the order and interaction effects of variable amplitude loading, the Corten-Dolan approach is determined to calculate the *TTF* of failure mechanisms. The formula is,

$$N_g = \frac{N_1}{\sum_{i=1}^{m} \alpha_i \left(\frac{\sigma_i}{\sigma 1}\right)^d} \quad (4)$$

Here, N_g is the cycles to failure for variable amplitude loading; N_1 is the cycles to failure for the maximum amplitude loading; σ_i is the equivalent stress of leads for the i^{th} amplitude loading, which has obtained from the random vibration analysis of phase 4; σ_1 is the equivalent stress of leads for the maximum amplitude loading; d is a constant that is decided by materials, m is the number of stress level, α_i is a percentage that can given from,

$$\alpha_i = \frac{\sigma_i}{\sigma_1 + \sigma_2 + \cdots + \sigma_m}, i = 1, 2, \cdots, m \quad (5)$$

According to the life profile of random vibration, N_g is easy to transfer to *TTF*.

Then we can calculate the *TTF* using the algorism of PoF models and cumulative damage theory (Hall and Strutt, 2003, Haggag et al., 2000).

Assuming a specific PoF model can be expressed as,

$$TTF = f(S, M, E) \quad (6)$$

Here, *TTF* is the short for the time-to-failure, S, M and E means parameters of structure, properties of materials and operation conditions, respectively. So the vector of *TTF* of simulation unit for specific failure mechanism under certain stress level is,

$$\vec{TTF} = f(\vec{S}, \vec{M}, \vec{E}) \quad (7)$$

Calculate the *TTFs* for each critical failure mechanisms obtained from phase 2, the matrix is,

$$TTF = \begin{bmatrix} TTF_{11}, TTF_{12}, \cdots, TTF_{1n} \\ TTF_{21}, TTF_{22}, \cdots, TTF_{2n} \\ \cdots \\ TTF_{k1}, TTF_{k2}, \cdots, TTF_{kn} \end{bmatrix} \quad (8)$$

Here, k is the k^{th} critical failure mechanism of MOS device, n is the number of samples.

According to matrix (8), choose different cumulative damage approaches for different failure mechanisms to calculate and the matrix of the

TTF of simulation unit for each critical failure mechanisms under life profile is,

$$TTF_o = \begin{bmatrix} TTF_{o11}, TTF_{o12}, \cdots, TTF_{o1n} \\ TTF_{o21}, TTF_{o22}, \cdots, TTF_{o2n} \\ \cdots \\ TTF_{ok1}, TTF_{ok2}, \cdots, TTF_{okn} \end{bmatrix} \quad (9)$$

3.7 *Algorithm of data processing*

Now the analysis objects are simulation units, which are parts of MOS devices, such as MOS structure. In order to evaluate the *TTF* of MOS devices, the following work is necessary.

- *TTFs* for single mechanism to *TTFs* for multiple mechanisms

At first, we need to transfer the *TTF* vectors for single mechanisms of certain simulation unit to vector for multiple mechanisms of certain simulation unit.

The algorithm for distribution fitting and testing is as follows:

1. Start;
2. Set $i = 1$;
3. Extract the vector $TTF_o(i,:) = [TTF_{oi1}, TTF_{oi2}, \ldots, TTF_{oin}]$ from matrix (9);
4. Assume that data of vector obey certain distribution;
5. Calculate distribution parameters $\theta i = [\theta i_1, \theta i_2, \theta i_3]$;
6. Hypothesis testing and repeat step 4) and 5) until the null hypothesis is accepted.
7. $i = i + 1$;
8. Repeat step 3) to 7) until $i > k$;
9. Then we get the matrix of distribution parameters of simulation unit,

$$\theta = \begin{bmatrix} \theta_{11}, \theta_{12}, \theta_{13}, \\ \theta_{21}, \theta_{22}, \theta_{23}, \\ \cdots \\ \theta_{k1}, \theta_{k2}, \theta_{k3}, \end{bmatrix} \quad (10)$$

   here if the number of distribution parameters of some failure mechanisms is p and $p < 3$, the parameters $\theta_a = 0 (q = p + 1, \cdots 3)$;
10. Set $j = 1$;
11. Random sampling according to distribution parameters $\theta(i,:) = [\theta_{i1}, \theta_{i2}, \theta_{i3},]$ and we get vector $t_{mj} = [t_{mj1}, t_{mj2}, \cdots t_{mjk}]$;
12. Competing failure model help to get the minimum value, $t'_m = [t_{mj1}, t_{mj2}, \cdots t_{mjk}]$;
13. $j = j + 1$;
14. Repeat step 11) and 12) until $j > n$;
15. Now we get the *TTF* vector for multiple mechanisms of certain simulation unit, $t_m = [t_{m1}, t_{m2}, \cdots t_{mn}]$.
16. End.

- *TTFs* for each simulation unit to *TTFs* for MOS device

In order to obtain the TTFs for MOS devices, repeat algorithm listed above. At last, we achieve the vector of *TTF* for MOS device,

$$TTF_d = (TTF_{d1}, TTF_{d2}, \cdots, TTF_{dh},) \quad (11)$$

The last work is to distribution fitting and testing for vector TTF_d. The vector is sorted into ascending order and fitted to a suitable distribution to obtain the TTF of MOS device. Assuming that the vector is fitted a distribution of f(t), the *TTF* of MOS device is,

$$TTF = \int_0^{+\infty} tf(t)dt \quad (12)$$

4 CASE STUDY

In this paper, we select a MOS device with plastic dual inline-pin (DIP) package which provide the system designer with direct implementation of the NOR function with the weight of 1.1 g and power dissipation of 200 mW. In the following, we will depict the process of reliability evaluation by simulation in detail with this device.

4.1 *Input information*

4.1.1 *Parameters of structure*

At first, it's necessary to extract the parameters of structure. According to datasheet, design files and, they are listed as Table 2.

1. Structural parameters

4.1.2 *Material properties*

This part include the parameters about weight, power dissipate and material properties and so on.

According to the results of FMMEA, the potential failure mechanisms which have a greater impact on the performance of the specific MOS device include: solder joint thermal fatigue,

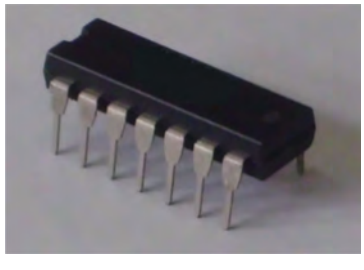

Figure 3. The MOS device which is applied in case study.

random vibration fatigue, corrosion, gate-oxide time dependent dielectric breakdown (TDDB), electromigration, hot carrier injection (HCI) and shock. So in the following steps, we focus on these seven failure mechanisms and evaluate the reliability with them. In Table 4, the failure mechanisms and PoF models are listed.

4.1.3 *Local stress under operation conditions*

At first, we need to introduce the operation conditions.

The MOS device is located in the middle of printed circuit board (PCB) with the dimensions of 120 mm × 80 mm × 2 mm. The operation conditions consist of three types of stresses, ambient environment, power spectral density of random vibration and relative humidity. The profile of

Table 3. Material properties of MOS device.

Plastic of Packaging	Density	1206 kg/m^3
	Elastic Modulus in X direction	15900 MPa

Activation Energy (HCI)		0.05 eV

MOS device during lifetime is as Figure 5, Table 5 and Table 6.

The relative humidity is always 20%.

According to the parameters of structure and operation conditions, the CAD, CFD and FEA models are as Figure 6.

We develop researches on thermal analysis, random vibration analysis and electrical parameters analysis and results are as Table 7.

4.2 *Random sampling*

Considering the uncertainty of parameters, monte carlo approach is widely used. Now we give the distribution types of the different parameters as Table 8.

In following section, we will introduce how to develop the monte carlo simulation to obtain the vector of *TTF* for electromigration.

At first, get the 10000 samples of uncertain parameters (W, d, T and j) by monte carlo approach as following,

$$\alpha \begin{bmatrix} 0.790114832, 0798267848, 0.79834634, 0.800647454, \ldots, 0.799123104 \\ 0.981133085, 1.007929821, 1.008361467, 1.000597051, \ldots, 1.015567806 \\ 55.84119123, 56.5393662, 55.23497947, 56.09943779, \ldots, 55.60634757 \\ 0.298663927, 0.302170728, 0.301507547, 0.299965692, \ldots, 0.299706913 \end{bmatrix}$$

4.3 *Cumulative damage*

In terms of the seven potential failure mechanisms, we divide them into depletion-type and overstress-type. It is only need to confirm whether it is strong enough to stand the specific stress under

Table 8. The distribution type of each uncertain parameters.

Failure mechanism	Parameter	Distribution
Solder Joint Thermal Fatigue	L_D: *LENGTH*	Triangular Distribution
	h: Solder Height	Triangular Distribution
	ΔT: Cyclic Temperature Swing	Weibull Distribution
	Tsj: Mean Cyclic Temperature of the Solder in Degrees C	Normal Distribution
	α_c and α_s: Coefficients of Linear Thermal Expansion for Component and Substrate	Triangular Distribution
Random Vibration Fatigue	*B*: Length of the PCB Edge Parallel to the Component Located at the Center of the Board	Normal Distribution
	L: LENGTH	Triangular Distribution
	t: Thickness of PCB	Normal Distribution
	f_n: Minimum Natural Frequency	Normal Distribution
Electro-migration	*W*: Width of Interconnects	Normal Distribution
	d: Thickness of Interconnects	Normal Distribution
	T: Temperature	Normal Distribution
	j: Current Density	Triangular Distribution
TDDB	Eox: Oxide Field	Triangular Distribution
	T: Temperature	Normal Distribution
HCI	T: Temperature	Normal Distribution
Corrosion	RH: Relative Humility	Normal Distribution
	T: Temperature	Normal Distribution

operation conditions for overstress-type while it is necessary to consider the cumulative damage for depletion-type.

According to the result of FMMEA, potential failure mechanism of shock is the only overstress-type and the stress is not enough to make device failure. Besides, the change of temperature is already be considered by solder joint thermal fatigue itself, there is no need to calculate the cumulative damage. So for the other five potential failure mechanisms, the methods of cumulative damage analysis and relative formula are as Table 9.

Table 9. The algorithms of cumulative damage analysis and relative formula.

Failure mechanism	Methods of cumulative damage analysis	Formula
Electromi-gration	AFA	$AF_i = \frac{MTTF_0}{MTTF_i} = \left(\frac{T_0}{T_i}\right)^m \exp\left[\frac{Ea}{k}\left(\frac{1}{T_0}, -\frac{1}{T_i}\right)\right]$
TDDB	AFA	$AF_i = \frac{MTTF_0}{MTTF_i} = \exp\left[\frac{Ea}{k}\left(\frac{1}{T_0}, -\frac{1}{T_i}\right)\right]$
HCI	AFA	$AF_i = \frac{MTTF_0}{MTTF_i} = \exp\left[\frac{Ea}{k}\left(\frac{1}{T_0}, -\frac{1}{T_i}\right)\right]$
Corrosion	AFA	$AF_i = \frac{MTTF_0}{MTTF_i} = \exp\left[\frac{Ea}{k}\left(\frac{1}{T_0}, -\frac{1}{T_i}\right)\right]$
Random vibration fatigue	CDRA	$N_g = \frac{N_1}{\sum_{i=1}^{m} \alpha_i \left(\frac{\sigma_i}{\sigma_1}\right)^d}$

For electromigration, according to PoF model and matrix α, the vector of *TTF* is,

$$TTF = [11297.991, 11113.816, 12055.017, 11445.712, \ldots, 11954.772]$$

For each element of vector of *TTF*, calculate the time-to-failure considering the cumulative damage theory under the profile given in section 4.1.The result is,

$$t = [6312.42, 6209.51, 6735.38, 6394.95, \ldots, 6679.37]$$

Then calculate the *TTFs* of other potential failure mechanisms and form the matrix of *TTF* for one MOS structure,

$$t = \begin{bmatrix} 6312.42,\ 6209.51,\ 6735.38,\ 6394.95, \ldots,\ 6679.37 \\ 8944.57,\ 8418.34,\ 9010.22,\ 8262.84, \ldots,\ 9900.97 \\ 11396.04, 11361.27, 11360.94, 11351.17, \ldots, 11357.64 \\ 9344.20,\ 10396.72,\ 9835.80,\ 9241.89, \ldots,\ 9546.54 \end{bmatrix}$$

Since potential failure mechanisms of solder joint thermal fatigue and random vibration fatigue will never happen in MOS device, the matrix of *TTF* only includes four failure mechanisms.

4.4 *Data processing*

Calculate the matrix of *TTF* for different simulation unit and develop the data fitting and hypothesis testing. At last we transfer them to a vector of *TTF* for MOS device,

$$T = [6435.21, 5547.34, 6859.25, 6378.53, \cdots, 6678.67]$$

The data is well fitted as a weibull distribution and the *TTF* of MOS device is 6415.9h under the operation conditions given in section 4.1.

5 CONCLUSION

With the development of semiconductor technology, it is more and more obvious that the field of reliability engineering is facing the problem of reliability evaluation under complex operation conditions. So a methodology is put forward to evaluate the reliability of MOS devices in this paper. At first we need to extract large amounts of parameters of MOS device as input of following steps. Then FMMEA used to determine potential failure mechanisms and they are the focus that we will consider. The third step is simulation modeling and analysis to obtain the stress parameters under operation conditions. Then considering the cumulative damage and uncertainty of parameters, we can obtain the *TTF* of each potential failure mechanism for every simulation unit by MCS. At last, we evaluate the *TTF* of MOS device according to the data obtained before. In the end of this paper, we select a typical MOS device and it is evaluated as the case study of this methodology. The *TTF* of MOS device under certain operation conditions is 6415.9h.

Case study of the effects of hurricanes on the coupled electricity and water systems of St Kitts

C.A. Johnson & R. Flage
University of Stavanger, Stavanger, Norway

S.D. Guikema
University of Michigan, Michigan, USA

ABSTRACT: When modelling critical infrastructure, it is important to account for the effects of interdependencies. Although there is much literature on how to account for interdependencies, there is a shortage of real-world examples. In an effort to increase the number of real-world examples, a model of the interdependent power and water systems of the Caribbean island of St Kitts has been developed. System dependencies arise due to electrically powered water pumps within the water system. Given the location of the island, it is not uncommon for it to encounter tropical storms, which may result in disruptions to the island's power system. Depending on the severity of the disruption to the power system, the effects may be able to propagate, through the dependencies, into the water system. The developed model uses the track and wind speed of past and simulated hurricanes, or up to date weather predictions, to simulate possible disruptions to the island's power system. Any propagation of these disruptions to the water system through the interdependencies are also simulated. The recent occurrence of hurricane Maria provides a useful case study to compare the output of the coupled system model with the actual effects that resulted due to the hurricane. The models are run with the known track and wind speeds of hurricane Maria. The predicted disruptions to the power system, as well as the cascading effects throughout the water system are then compared to the actual disruptions exhibited in the interdependent systems. The results can be used to validate the model and give an indication if improvements to the current model can be made.

1 INTRODUCTION

When modelling disruptions to critical infrastructure, it is agreed that any interdependencies present need to be taken into account (Buldyrev et al. 2010). There is much literature available on the various methods to model infrastructure interdependencies, however there is a lack of examples which model real interdependent infrastructure systems (Ouyang 2014). Some examples which look at real interdependent systems include Johansson and Hassel (2010) and Dueñas-Osorio et al. (2007).

To provide another real example of interdependent infrastructure modelling, a model of the coupled water and electrical power system on the Caribbean island of St Kitts has been developed by the Guikema Research Group. The model was developed with the intension to see how tropical storms affect the island's coupled power and water systems. The coupled water and power system of St Kitts provides a good opportunity to model a coupled infrastructure system given that they are relatively simple and self-contained as they service only the island of St Kitts.

In the next section, a brief overview of the island of St Kitts and the natural hazards, such as Hurricane Maria, that affect the island will be given. Section 3 will provide more detail about the model of the island's power system, water system and the dependency that exists between the two systems. The results of the model when simulating the effects of Hurricane Maria will be presented in Section 4. This will be followed by a discussion in Section 5 about the challenges associated with developing and validating this model, and more general any interdependent infrastructure model that aims to simulate real systems. The final section, Section 6 will then draw the conclusions of the paper.

2 THE ISLAND OF ST KITTS

St Kitts is the larger of the two islands of the Federation of St Christopher (St Kitts) and Nevis, which are part of the Leeward Island group in the Eastern Caribbean (The Commonwealth, The Offical Website of St Kitts and Nevis). The total

population of St Kitts and Nevis is estimated to be just over 50,000. St Kitts is of volcanic origin and thus the centre of the island is mountainous with a highest peak at Mount Liamuiga. Therefore the majority of the population live along the coastline of the island (The Offical Website of St Kitts and Nevis).

The total area of St Kitts is 69 square miles or roughly 180 square kilometers and thus is a relatively small island. The small size of St Kitts means that modelling infrastructure systems of the island is feasible, without having to overly simplify the system. These systems are also self-contained due to the geographic constraints that they service only the island of St Kitts.

Due to the location of St Kitts, the natural hazard of tropical storms is an annual threat to the island. The most notable storm to hit St Kitts in recent years was Hurricane George in September 1998, for which the estimated damage costs to St Kitts and Nevis was 445 million United States Dollars (USD) (Relief Web 2002). Other storms that have had great impacts recently on St Kitts include Hurricane Lenny in 1999 with estimated damage costs of around 41 million USD, Hurricane Hugo which hit the island in 1989 and caused damage to roughly 20 percent of the poles in the electricity power system, and Hurricane Luis in 1995 which caused great damage to the power and water systems of the island (Relief Web 1995, Relief Web 1999, US Aid 1990).

2.1 *St Kitts and Hurricane Maria*

The National Oceanic and Atmospheric Administration (NOAA) first issued a tropical storm watch on 16th September 2017, with the first advisory report being issued at 11:00 Atlantic Standard Time (AST). By 17:00 AST, NOAA were recording tropical storm force surface winds of what was then Tropical Strom Maria. At this time a hurricane watch was in effect for St Kitts and Nevis along with Antigua, Barbuda and Montserrat. At the time of Advisory 6 of Maria 17:00 AST, hurricane force winds had been recorded and the storm had been upgraded to a hurricane. The St Kitts hurricane watch had been upgraded to a hurricane warning. As of 19th September 05:00 AST, St Kitts was experiencing tropical storm force winds as Hurricane Maria passed by the south west coast of the island (NOAA). The eye of Hurricane Maria was reported as passing within 90 miles of the island (St Kitts & Nevis Observer 2017). Advisory 15, issued on 19th September at 17:00 AST was the last advisory to issue a hurricane warning to the island of St Kitts (NOAA).

Figure 1 shows the path of the centre of Hurricane Maria as it passed by St Kitts, as well as the wind speed severity category bands (The New York Times 2017). From Figure 1 it can be seen that St Kitts experienced tropical storm severity wind speeds as Hurricane Maria passed by the south-west of the island.

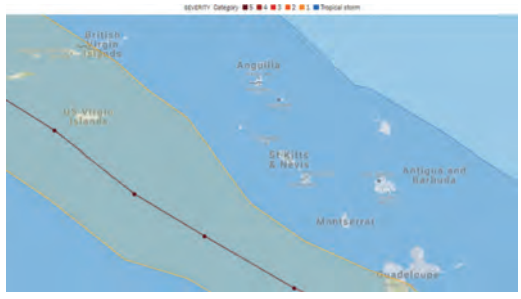

Figure 1. Track of Hurricane Maria—The New York Times, 2017.

3 COUPLED POWER AND WATER SYSTEM OF ST KITTS

The island of St Kitts is a relatively small island with an area of 69 square miles. The power and water systems which provide electricity and clean water to the island are self-contained as they do not provide utilities to other islands and can be modelled without having to be over simplified. The water system of St Kitts contains 30 wells which rely on the electricity system to pump the water from the wells into the water system. This dependence can be modelled along with the power and water systems to develop a model of the coupled power and water system for St Kitts.

The water system model was developed using information provided by St Kitts Water Department. The model encompasses the entire clean water distribution system, including the supply sources and demand nodes. Figure 2 shows the modelled water system of St Kitts, including the pipelines, reservoirs and wells. The blue lines in Figure 2 represent the water pipes, the red dots are the water nodes (wells and junctions) and the black nodes are the reservoirs and tanks within the water system.

The water system was modelled using EPANET 2.0, a program that can "perform extended period simulation of hydraulic and water quality behaviour within pressurised pipe networks" EPANET (2000).

The power system was modelled using the limited information available on St Kitts Electricity Company Limited (SKELEC) website. The main lines of the power system were modelled, however

Figure 2. Model of St Kitts water system.

Figure 3. St Kitts electricity power system model.

due to lack of available information the smaller distribution lines of the power system could not be included in the model. As stated in Section 2, most of the island's population resides on the coastal areas of St Kitts. Therefore the 3 main power lines that surround the island are modelled. The model contains 157 nodes, representing 157 wooden electricity poles that the power cables are attached to. The three main power lines can be seen in Figure 3. The northern line is represented by red squares and contains 70 poles, the southern line is shown as blue dots and contains 39 poles and the western line is shown as purple triangles and contains 48 of the 157 poles.

For each pole, a fragility curve giving the probability of failure given the on-island wind speed has been determined based on historical damage reports of hurricanes that were readily available to the public. If one pole fails in a power line, then all the poles downstream of the failed pole will also be modelled as inoperable.

The water system depends on the power system at each of the 30 wells within the system to get the water from the well into the water distribution system. To model the water system's dependency on the power system, each well is dependent on the closest electricity node, or pole, to provide power to the well. During the simulation, if a node becomes inoperable that a well depends on, the well that depends on it is then removed from the water system model. Figure 4 shows the modelled electricity lines, as black triangles, and the water wells as red squares and other water nodes as blue dots. Sixteen wells depend on nodes within the northern power line, 7 wells depend on electricity from the western line and 8 wells depend on the southern line.

The track as well as the maximum wind speed recorded every 6 hours for the centre of Hurricane Maria from 17th to 28th September 2017 was used to estimate the maximum speed of the hurricane over St Kitts using a model previously developed by Guikema et al. (2014). This provided the probability of failure for each of the 157 poles within the electricity power system. These probabilities were then used in the MATLAB model developed within the Guikema Research. To look at the effects of Hurricane Maria on St Kitts coupled power and water systems, the MATLAB model was run for 60000 iterations, where first it was modelled which poles would fail or break due to the hurricane before modelling the cascading effects of these poles down each power line and through to the water system.

Figure 4. Coupled power and water system of St Kitts.

4 RESULTS

4.1 *Electricity power system*

For each of the 60000 iterations that the model completes, each pole is recorded as failing due to the wind or not. Therefore, the model gives the frequency of initial pole failure, which can be seen in Figure 5. The frequency, given as a percentage, of each pole failing due to Hurricane Maria is shown using the colour scale as shown in Figure 5.

There are a few poles with relatively low frequency of failing in the southern line, closest to the centre of the island. However, the southern line is mostly unaffected by Hurricane Maria. On the northern power line there is one pole, around a third of the way along the line that has a high frequency of failure. Failure of this pole would cause disruptions to the rest of the line up to the north-east of the island, and thus any wells that depend on any nodes on this section of the northern line to also be disrupted. On the western power line there are more poles within the line that have initial failures due to the hurricane. This is expected as Hurricane Maria passed by the south-west of the island. The most frequent initial failure in the western line is a pole that lies around halfway along the western coast. This would cause disruptions along the rest of the line, all along the western coastline, and these disruptions would cascade to any wells that depend on this section of the western power line.

4.2 *Actual power outages*

When looking for data of what affects Hurricane Maria had on the electricity system of St Kitts, the only information found came from SKELEC website. This information was a restoration update that named residential areas that were experiencing power outages due to Hurricane Maria. The press release stated "Most of our feeders remained intact and online during the passage of the storm. Some like the Canada feeder which services Conaree, Halfmoon and Canada Estates came offline, also Basseterre North Buckley's to Trinity also is fully offline" SKELEC (2017).

Figure 6 shows the areas that SKELEC reported to have experienced outages due to Hurricane Maria. The three areas to the north of the island are Canada, Halfmoon and Conaree. Canada has been filled red rather than just outlined as the Canada feeder was the feeder identified as causing these outages to the north of the island. These three outlines were not specified by SKELEC but are the outline of the three areas named by SKELEC in the press release. Due to no further information being found in relation to power outages due to the hurricane this is best representation of possible affected areas that can be given. The larger section on the south-west of the island represents the area from Basseterre North Buckley's to Trinity. The outline encases all residential areas between, and including, Basseterre North Buckley's to Trinity. Again, the press release from SKELEC is the only information on which to base the actual areas affected and thus the areas cannot be more specific.

Figure 7 shows the results of the model for frequency of initial pole failure compared to the areas that SKELEC reported to experience power outages due to Hurricane Maria. When looking at the predictions and actual areas to exhibit outages on the northern power line, the high frequency of a

Figure 5. Frequency of initial pole failure.

Figure 6. Areas of St Kitts that experienced power outages due to Hurricane Maria.

Figure 7. Frequency of initial pole failure compared to areas to experience power outages.

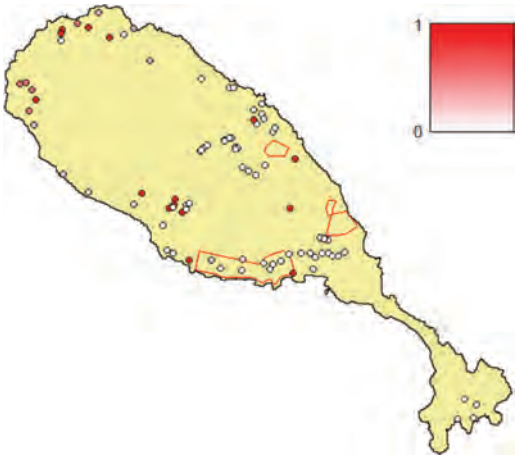

Figure 8. Frequency of water nodes with pressure lower than 20 psi.

pole break on the northern side of the island given by the model coincides with the press release that the northern side was affected such that a feeder came offline. When looking at the south-west area that experienced outages, if the main line was affected by the hurricane, it would understandable to see more outages along the line. However, these outages could have been caused to failures or disruptions within the smaller distribution lines that are not included in the model.

4.3 *Water system*

When looking at disruptions to the water system, the frequency that nodes exhibit pressure below 20 psi as well as 0 psi are both considered. The pressure of the nodes within the water system is important to measure as if the pressure becomes negative this can cause the water to flow in the wrong direction, or cause pipes to break. These both can cause the water to become contaminated. Pressures lower than 20 psi are investigated as in the USA this is the minimum pressure required to use a water system for firefighting purposes (EPA 1992).

Figure 8 shows the frequency that water nodes exhibited pressures lower than 20 psi. Comparing Figure 8 to Figure 5 the low pressures towards the lower end of the island coincide to the areas in which the initial pole failures occurred. The low pressures exhibited towards the north-western part of the island are due to the initial failures in both the northern and western power lines cascading to the north of the island.

Figure 9 shows the frequency that the water nodes exhibited pressures less than 0 psi. There are

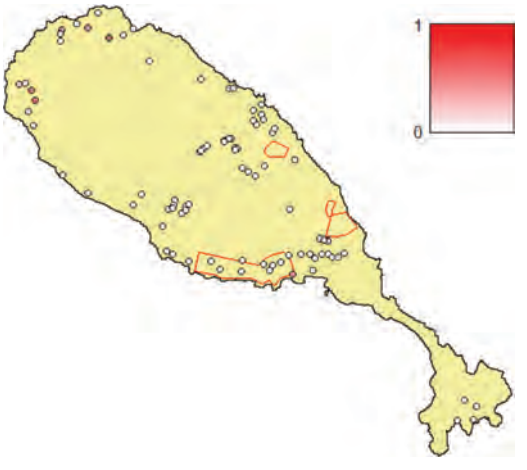

Figure 9. Frequency of water nodes with pressure lower than 0 psi.

few instances of nodes exhibiting pressure lower than 0 psi, with a few occurring on towards the north-west end of the island. Although the initial aim was to compare the results of the model to how Hurricane Maria affected the coupled infrastructure power and water system of the island, it was challenging to find any data related to disruptions to the water system.

The location of wells compared to the actual outage data was also considered to see if any wells would have been without power during the outages.

When looking at Figure 10, there are three wells that are situated in the south-west area of

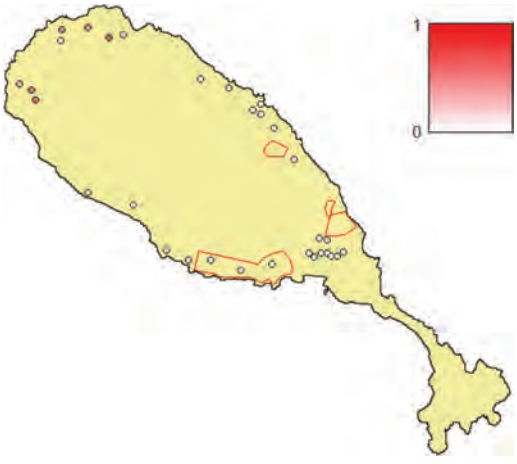

Figure 10. Frequency of water wells with pressure lower than 0 psi and reported power outages.

St Kitts that experienced power outages. To further test the water system model, these three wells were removed from the model, as is they had lost power. However, all other nodes in the water system model maintained a pressure above 0 psi, thus even if these three wells were without power, the water system would not have any disruptions.

Although no information directly related to disruptions to the water system was found, the Prime Minister of St Kitts and Nevis stated that the island's infrastructure such as the electricity and water systems "sustained extensive damage" (Relief Web 2017).

5 CHALLENGES WHEN MODELLING AND VALIDATING REAL INFRASTRUCTURE MODELS

When modelling the coupled power and water infrastructure system of St Kitts, information regarding the water system was provided by St Kitts Water Department. This, along with ongoing communication with the water department while developing the model, allowed an extensive model of the system to be developed. However, when developing the electricity model, the only information available was that in the public domain, primarily on SKELEC website. This meant that the model was an oversimplified representation of the main power lines in the island's electricity system.

Accessing and collecting data to form the basis of infrastructure models is a well-documented issue with constructing models of independent infrastructures as well as interdependent infrastructures (Ouyang 2014, Johansson and Hassel 2010, Rinaldi et al. 2001). Another problem highlighted by Ouyang (2014) is that infrastructure are large, complex systems that are constantly changing and thus the data used to produce the model may not be relevant for very long after the model has been developed. Any major changes to the infrastructure would have to be updated within the model.

When trying to validate the model, information on the disruptions to both the water and power systems due to Hurricane Maria were also hard acquire. The electricity company did have some information available, however, this is aimed at the customers of the infrastructure and is there to reassure them that the company is aware of the problems and are fixing the issues. The information relates only to general areas, and not specific parts of the system that would be useful when validating the model.

Within the USA, publicly available outage data of power companies is becoming increasingly more available. Most power utility companies are now showing daily outage data on their websites, see the website Power Outage for more information on which utilities provide outage data. However, other utilities in the USA, such as those who manage water infrastructure are still less willing to share outage data.

6 CONCLUSION

The aim of the paper was to compare the results of the coupled power and water system of St Kitts to the disruptions the systems exhibited during Hurricane Maria. Although the electricity model is a simplified representation of only the island's main power lines, the areas that experienced power outages did coincide with poles that had a high frequency of initial failure. This showed that the model is quite accurate on estimating the maximum wind speed for the different areas of the island. However, as the smaller distribution lines could not be included in the model and limited outage information is available, it is difficult to access the accuracy of the model. Improvements could be made by increasing the complexity of the model, if the necessary information can be obtained from St Kitts Electricity Company.

Although the water system model is a good representation if the island's water system, the lack of data available relating to disruptions due to Hurricane Maria again means it is difficult to validate the model. The lack of available information relating to infrastructure systems is a well-recognised challenge when developing models of infrastructure systems.

Availability simulation model of global navigation satellite system based on operation

A.G. Zhao, X. Sun & Y. Sun
School of Reliability and Systems Engineering, Beihang University, Beijing, China

B.D. Li
China South Industry Institute, Beijing, China

ABSTRACT: Availability is a core attribute of Global Navigation Satellite System (GNSS) and many topics are studied in this area. However most of them are about a part of GNSS, which is single satellite availability, navigation constellation availability or the availability of ground stations. Very few studies are concerned with the availability of the whole system. In view of this, the availability simulation modeling of the whole GNSS including space segment and ground segment were studied in this paper. The influence of satellite failure, interruption, coverage and ground station fault, repair etc. on system operation was considered to establish the model. Then the simulation logic was developed to simulate the operation of navigation system. Based on the STK/MATLAB hybrid simulation, the service availability of the GPS for Beijing was analyzed finally. The simulation results verify the applicability of the model and the simulation algorithm.

1 INTRODUCTION

Global Navigation Satellite System (GNSS) is used in various fields and bring great conveniences to people's lives. It has become an indispensable necessity in people's life. Availability is a core parameter of GNSS and reflects the degree to which the needs of users are met. Therefore, the level of availability of GNSS is directly related to the quality of the service it provides. At present, many scholars at home and abroad have carried out relevant research on it and achieved some results.

In the aspects of availability of ground stations, Joo built a series model of availability considering early stage and stabilization stage and obtained the availability of the ground control sections by the actually used data (Joo et al. 2007). Li took the coverage performance of the ground station as its available basis and put forward a availability model of the monitoring station (Li et al. 2010). In the aspects of availability of navigation constellation, Xiang established the constellation system reliability model and analyzed the impacts of the reliability of the satellite, the constellation configuration and the number of backup satellites on the reliability of the constellation system (Xiang et al.2007). Zhou analyzed the impacts of the single-satellite reliability change on the constellation availability aiming at the network supplement mode of terrestrial backup satellite (Zhou et al. 2014). Zhao proposed a Markov model for calculating per-slot availability considering the influence of standby satellite on slot availability (Zhao et al. 2013). Hou calculated the availability of the navigation constellation based on the failure of the subsystem component and built service availability calculation model based on constellation state probabilities (Hou et al. 2014). In the aspects of availability of navigation system, Zhao established a multidimensional parameter system of the availability of satellite navigation system (Zhao et al. 2014). Liang modeled and simulated the system structure of the ground system of the remote sensing satellite based on DoDAF (Liang et al. 2017). Yang proposed a system efficiency modeling and analysis method that comprehensively considers various kinds of factors, such as various types of interrupting randomness and lossy failure performance, and used Markov chain to build the availability model of navigation satellite (Yang et al. 2017).

In summary, the availability classification and model of GNSS present the diverse features such as the accuracy availability and integrity availability, single-point availability and service area availability, single-satellite availability and navigation constellation availability. At present, the researches on the availability of GNSS are more focused on local issues. For example, some scholars consider the availability of single satellite while others study the

availability of navigation constellations in terms of reliability and maintainability, or only consider the availability of ground stations, all of which are difficult to support the comprehensive analysis and evaluation of the overall availability of GNSS. In view of this, based on the composition, mission requirements, usage patterns and user requirements of GNSS, a systematic and comprehensive availability simulation model was built considering the operation, interruption, maintenance and guarantee of GNSS and the overall simulation logic flow was developed in order to realize the simulation of GNSS operation, networking, network supplement, interruption and other process, and analysis of its availability level. At the same time, backup satellite program can also be provide with a basis to shorten the satellite supplement waiting time and improve the navigation system availability.

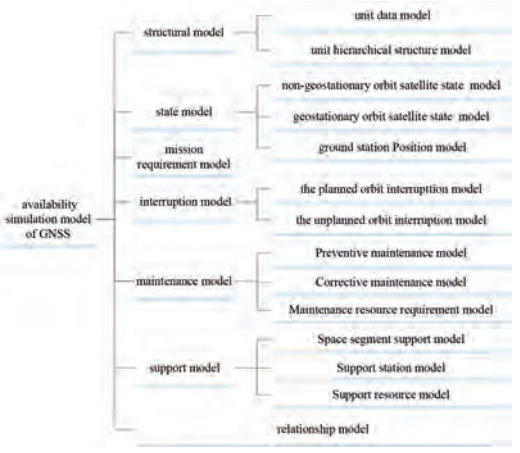

Figure 1. Framework of GNSS availability simulation model.

2 FRAMEWORK OF AVAILABILITY SIMULATION MODEL OF GNSS

Availability is the description of the working state of a system. According to the different mission requirements of GNSS, its availability can be divided into instantaneous availability, single point availability, service area availability and moving target availability. As GNSS is affected by the internal failures and refurbishment and external weather and environment, it cannot be available at all time. The availability of GNSS is mainly affected by the following factors: (1) the reliability of equipment (2) equipment maintenance (3) system structure (4) backup strategy. The above four factors were considered comprehensively and the availability simulation model of GNSS was established in this paper.

According to the overall structure and operation characteristics of the navigation system, in order to describe the whole process of composition, operation, maintenance and support of GNSS completely, the framework of the overall availability simulation model was established, as shown in Figure 1.

The model consists of seven parts, which respectively are the structural model, the state model, the mission requirement model, the interruption model, the maintenance model, the support model and the relationship model among them. The structural model is mainly used to describe the constituent elements, the hierarchical structure and the reliability characteristics of the constituent elements of the system. The state model is used to describe the state of each satellite to calculate its coverage area. The mission requirement model is used to describe different types of missions for different user groups. The orbit interruption model is used to describe the repair process of the space segment of GNSS, including the type of outage, repair time and the station information. The maintenance model is used to describe the information including the purpose of maintenance, the type of maintenance, the time required for maintenance and the resources required for maintenance. The support model is used to describe the relationship among the maintenance support factors and operational support factors including the storage and supply of satellites, the support equipment and the support facilities and personnel etc. The relationship model is used to describe the relationship among the system structure, state, missions, interruption, maintenance and support. With the above seven models, all the elements describing the operation, interruption and maintenance of GNSS are realized.

3 DISCRIPTION OF AVAILABILITY SIMULATION MODEL

3.1 *Structural model*

The structural model mainly describes the organizational relationship of the constituent units of the system at the functional structure level, and provides reference and support for the system composition and reliability data of the simulation modeling.

GNSS is a typical complex system, which has a variety of equipment types such as space segment equipment, ground segment equipment and user segment equipment, and each equipment has its own composition and characteristics. Therefore, it was divided the functional structure of GNSS by

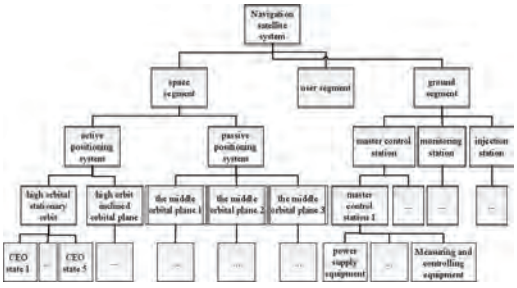

Figure 2. GNSS structural model.

layers from top to bottom in this paper, which is divided into large system layer, system layer, subsystem layer, module layer and equipment layer. Taking into account the acquisition of equipment fault information, it was intended to decompose the space segment to the satellite level, and the ground segment to the power supply equipment level, as shown in Figure 2. Data structures are shown in Table 1–2 below. Table 1 describes the unit fault mode and basic reliability data, and Table 2 describes the main relationship between units, including the relationship of structure and quantity.

3.2 *State model*

The state model is used to describe the initial state of each unit. The longitude, latitude and coverage of dynamic satellite of each satellite that change with time are calculated by the satellite operation rules, so as to complete the calculation of the coverage of the mission area. The satellite navigation system includes space satellite and ground station equipment. The space satellite can be subdivided into non-geostationary orbit satellite and geostationary orbit satellite. The operating rules and status of each unit are different. According to the different operating states, this paper divides the state model into non-geostationary orbit satellite model, geostationary orbit satellite state model and ground station state model. The data structures are shown in Table 3.

From the below three groups of state models, it can be seen that the operational state model of satellite determines the under-satellite point and coverage area at each moment of time, and the state of the ground station determines its geographical position so as to determine whether the coverage of satellite to the ground meets the mission conditions.

3.3 *Mission requirement model*

Mission requirement model is mainly used to describe the mission requirements and the logical relationship between different submissions. The main function of GNSS is to use satellite to provide users with the quick navigation and positioning, short digital message communication and timing services. According to the different functions, its main missions can be divided into the following three aspects: (1) high-precision navigation (2) high-precision positioning (3) high-precision timing. For different types of missions, and targeting different user groups, the geographical location information, movement information, and time information of the stationary users, mobile

Table 1. Unit data.

Data item	Definitions
Unit name	The unit containing the system
Fault mode	Different types of fault of the unit
Parameter name	Fault parameters, such as failure rate, MTBF, etc.
Distribution type	Parameter distribution type, including the exponential distribution and normal distribution
Parameter 1	Parameter corresponding to the distribution type
Parameter 2	Parameter corresponding to the distribution type
Initial working time of unit	The start of service of each satellite or equipment

Table 2. Unit hierarchical structure.

Data item	Definitions
Unit name	Subunit identification
Parent unit name	Parent unit identification
Unit matching number	Matching quantity of the unit that the current parent unit is affiliated with
Unit type	Determine whether the unit is a system, subsystem, module, or unit

Table 3. State model.

Non-geostationary orbit satellite state	Geostationary orbit satellite state	Position of ground station
Unit ID	Unit ID	Unit ID
Orbit semi-long axis	Longitude	Longitude
Eccentricity	Orbit height	Latitude
Orbital inclination	Field angle	Ground height
Right lifting node longitude		
Perigee argument		
True near corner point		
Field angle		

users and regional users shall be provided. In view of this, the data structure of mission requirement model was established as shown in Table 4, to describe the requirements of different missions.

The three typical missions of GNSS shall be completed in the space segment, user segment and ground segment together. It is assumed that the user segment is intact in this paper. Therefore, the navigation system is represented as a series logical relationship between the space segment and the ground segment. Reliability Block Diagram is used to express the success criterion of the mission, as shown in Figure 3, when the functions of different devices comply with the following logic condition of reliability, the navigation system mission is succeeded.

Table 4. Mission requirement model.

Data item	Definitions
Mission type	Divided into navigation, positioning and timing
Coordinate 1 Coordinate 2 Coordinate 3 Coordinate 4	For positioning and timing, the coordinates refer to the longitude and latitude of the spatial location of the mission initiation point or the latitude and longitude coordinates of the mission initiation region. For the navigation, the coordinates can express a point, which refer to the spatial location of the mission initiation point; or express a distance, which refer to that from the mission initiation point coordinate to the mission end point coordinate.
Height	The level of the ground surface where the user is
Speed	For the navigation mission, the client speed affects the satellite service area switching, so the speed parameter needs to be given
Accelerated speed	For navigation users, in addition to the user speed, the user status, acceleration, deceleration or uniform speed shall be described
Time to start work	Time to start work
Time to end work	Time to end work

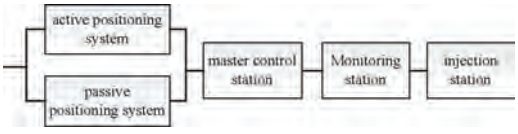

Figure 3. RBD for success criterion of the mission.

3.4 *Orbit interruption model*

The orbit interruption model is used to describe the repair process of the space segment orbit interruption of the satellite navigation system, including the type of outage, the time of interruption and the information of the orbit which it is located. Depending on different causes of the orbit interrupt, the interrupt time and repair measures are also different. Therefore, two types of space orbit interruption models are established in this paper: the planned orbit interrupt model and the unplanned orbit interrupt model. The former is used to describe the conditions that the satellite orbit is stopped and the satellite cannot provide service caused as operation and maintenance activities of satellite and the replacement of satellites, and the specific data structure is shown in Table 5. The latter is to describe the interruption repair measures and interruption repair time after the orbit is stopped caused as short-term hard fault and long-term hard fault caused as the accidental fault, and the specific data structure is shown in Table 6.

Table 5. Planned orbit interruption.

Data item	Definitions
Outage unit	The name of the unit that is the planned interruption is in, given by the structural model, as defined in Table 1
Planned outage type	The types of outages corresponding to planned interruption include operation and maintenance and end of life
Calendar time interval	Calendar time intervals of preventive maintenance
Repair time	The time consumed for the planned interrupt operation
Name of orbit	Orbit plane that the satellite is in

Table 6. Unplanned orbit interruption.

Data item	Definitions
Outage unit	The name of the unit that is the unplanned interruption is in, given by the structural model
Non-planned outage type	The types of outages corresponding to unplanned interruption include short-term hard faults and long-term hard faults
MTTI distribution type	The distribution function type of the average interrupt time of the unit
MTTI parameter1	Shape parameter 1 of interruption time distribution function
MTTI parameter2	Shape parameter 2 of interruption time distribution function
Name of orbit plane	Orbit plane that the satellite is in

3.5 *Maintenance model*

The maintenance model is primarily used to describe maintenance activities on equipment that fails on ground segments, including preventive maintenance activities and corrective maintenance activities. In order to fully describe the maintenance activities, the data structure of the preventive maintenance, the corrective maintenance and the maintenance resource requirement were established in this paper details can be seen in Tables 7–9.

Table 7. Preventive maintenance.

Data item	Definitions
Maintenance unit name	The name of the unit that the preventive maintenance operation is in, as defined in Table 1
Preventive maintenance type	Refer to the type of preventive maintenance operations, including operations and maintenance
Calendar time interval	Calendar time interval of preventive maintenance
Duration	Time consumed for this preventive maintenance operation
Maintenance station name	Maintenance site where the unit is in

Table 8. Corrective maintenance.

Data item	Definitions
Maintenance unit name	The name of the unit performing the corrective maintenance
MTTR distribution type	The distribution function type of the unit repair time
MTTR parameter 1	Shape parameter 1 of repair time distribution function
MTTR parameter 2	Shape parameter 2 of repair time distribution function
Maintenance station name	Maintenance site where the unit is in

Table 9. Maintenance resource requirement.

Data item	Definitions
Maintenance unit name	The name of the unit performing the corrective maintenance
Maintenance method	Describe the type of maintenance of the maintenance unit
Resource name	Maintenance resource for the unit to perform the corresponding level of maintenance work
Resource quantity	Maintenance resource quantity for the unit to perform the corresponding level of maintenance work

3.6 *Support model*

The support process is a complex process that contains various dynamic factors. The support model is a model that describes the support system of the navigation system, including the storage and supply of spare parts, support equipment and facilities. According to the different composite objects, the space segment support model and the ground segment support model were respectively established. The former is used to describe the information about the backup satellite configuration at all levels and the ground network supplement time, as shown in Table 10. The latter mainly describes the information about the ground support station and the support resources, as shown in Tables 11–12.

3.7 *Relationship model*

Based on the above models, if we want to establish a complete satellite navigation system availability model, we must establish the relationship between the models to lay the foundation for the subsequent establishment of simulation logic. The relationship model mainly describes the relationship of system structure, status, mission and interrupt maintenance station, as shown in Figure 4.

1. Status and missions

The operating status of the satellite determines its subastral point and coverage area and the status of the ground station determines its coverage. During the mission process, the coverage of satellite and

Table 10. Space segment support.

Data item	Definitions
Orbit plane name	The orbit plane that the repair orbit is in
Level	Describe the support level of station, usually refer to the orbit plane level
Storage quantity in orbit	Quantity of backup satellites in the orbit
Network supplement time in orbit	Refer to the time interval from that the back-up satellite in the orbit reaches the assigned orbit and debugged completely to the start of work.
Superior name	Describe the support organization relationship between the orbit plane and the ground
Ground storage quantity	Refer to the quantity of backup satellite in the ground launching base
Ground network supplement time	Describe the time required for network supplement, launch, and commissioning between the ground and the orbit plane

Table 11. Support station.

Data item	Definitions
Station name	The station used to maintain the equipment
Station level	Describe the support level of the station, including the orbit plane level, station level and launch base level
Superior station level	Represent the superior station of this station, and describe the support organization relationship between stations
Support time between stations	Describe the transit time from the superior station

Table 12. Support resource.

Data item	Definitions
Station name	The station used to maintain the equipment
Resource name	Resources required in the maintenance process, including manpower and equipment
Resource quantity	Resource quantity provided in this station

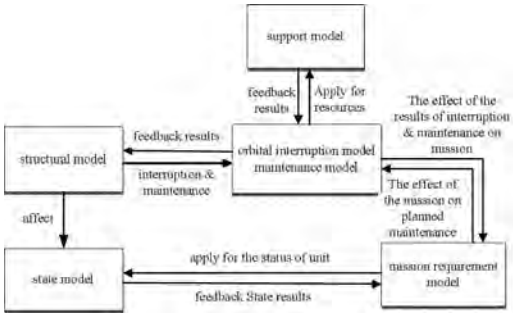

Figure 4. Relationship model.

ground station in the mission area is calculated, and then whether the mission is complete is judged by success criterion of the mission.

2. Structure and status

When the unit breaks down in the course of carrying out the mission, it is fed back to the state model. When the satellite needs to be supplemented during the repair process, it also needs to be fed back to the state model after updating the unit.

3. Maintenance interruption and mission

During the mission, the mission may be affected when the unit is interrupted or repaired. The mission process can also have some impact on the planned maintenance.

4. Interruption and support

During the repair process, whether the satellite is needed or not shall be determined. When the orbit plane does not comply with the required satellite, the interruption repair event is standby, when the quantity of the back-up satellites in the orbit plane is less than the setting value, an application is made to the ground station for satellite supplement.

5. Maintenance and support

In the maintenance process, the spare parts and other support resources are needed. When the number of resources in the maintenance station is insufficient, the maintenance event is standby. After the maintenance is completed, release the resources, and wait for the maintenance of other fault parts. After the standby maintenance event complies with the maintenance conditions, judge whether it can be maintained and determine to maintain or continue to wait.

4 AVAILABILITY SIMULATION LOGIC

4.1 *The main simulation logic*

Taking the components of the navigation system as the subject of the simulation and mission events as the traction to trigger failure events and all events in repairing model, interrupt model and support model, in the thought of discrete event simulation technology, the main process of the overall availability simulation for GNSS was established, which is shown in Figure 5. With the advancement of simulation events, determine whether the failure and maintenance events affect the implementation of the mission one by one, and carry out the corresponding maintenance activities, until the end of the mission, and then perform the availability statistics.

Based on the main simulation logic, each event has a detailed process. Eight events and their simulation algorithms were developed in this paper. The list of simulation events are shown as Table 13.

4.2 *The simulation process of typical events*

In view of the limitation of pages, only several simulation processes of typical events are presented in this paper.

4.2.1 *Simulation process of mission event*

Mission event is the key for implementation of satellite navigation system availability simulations. Driven by the mission, the equipment failure and maintenance process are simulated, and the impact on the mission is determined. In this paper, the satellite visibility is used as the evaluation criteria for

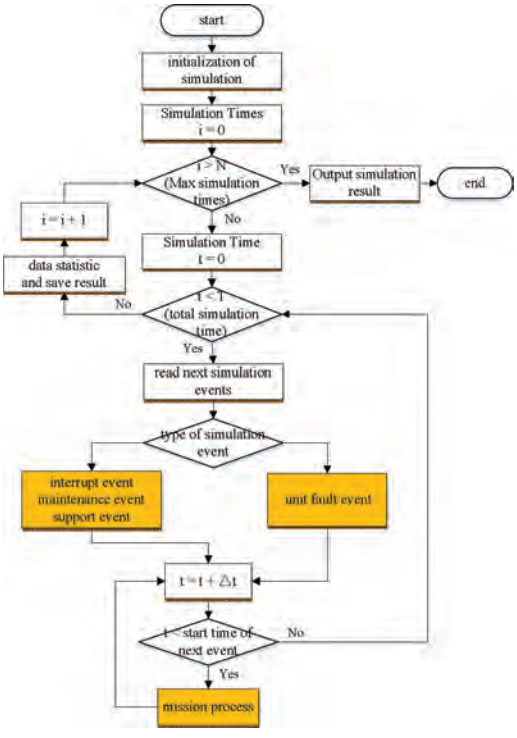

Figure 5. Main simulation logic.

8	Ground support resource

the availability of the navigation system. The mission simulation process is shown in Figure 6.

First determine the mission type, where the navigation, positioning and timing missions are subject to different success criteria of missions, and then determine the mission implementation under each simulation step. According to the mission requirements of the navigation system, the state of each unit in the state model is read to determine whether the covered multiplicity complies with the coverage of the user in the area, that is, whether the coverage of the mission point by the space unit is met. For a given mission, the satellite has defined the location information of the mission point. So read the dynamic position information in the structural unit and determine the covered multiplicity. Since the minimum number of units required for each mission type is constant, the phase mission is judged to be successful when the number of units that can be covered can reach the minimum value specified by the mission. The phase mission fails if the number of available systems is not enough.

4.2.2 *Simulation process of unplanned interrupt repair event*

Maintenance event is also an important part of the availability simulation and is the necessary event in the simulation of the real operation of the navigation system. the simulation process of unplanned interrupt repair event for the space segment is shown in Figure 7.

If the satellite is interrupted, first determine whether the satellite can receive the ground signal. If it cannot, it is judged as a long-term hard fault, belonging to the unplanned long-term interrupt type, where the satellite needs to be replaced. It is necessary to determine whether there are backup satellites for the replacement satellites.

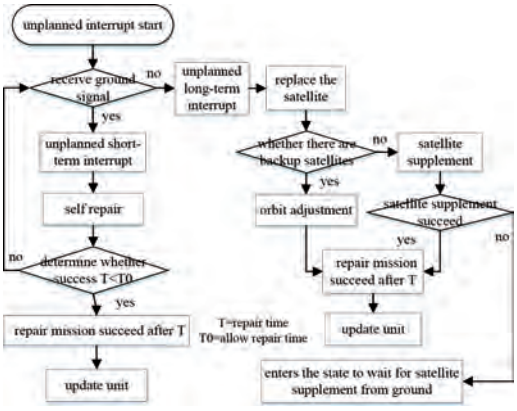

Figure 7. Simulation process of unplanned interrupt repair.

If it does not met, make a request to ground for satellite supplement. If the satellite supplement fails, it enters the state to wait for satellite supplement from ground. If the satellite supplement succeeds, the event of satellite supplement complete will be sent out after the time T, and the state unit will be updated at the same time. If there are backup satellites for the replacement satellites, then the satellites in the orbit will be subject to orbital position adjustment, and a request to ground for satellite supplement is made, and then it enters the state to wait for satellite supplement from ground. If it can receive the ground signal, the fault type is short-term interruption, belonging to short-term unplanned interruption caused by short-term hard faults. At this point, the satellite will be subject to self-repair, if the repair fails, the satellite will be redetected whether it can receive terrestrial signals. If the repair is successful, the event of repair complete will be sent out after the time T, and the state unit will be updated at the same time.

5 CASE ANALYSIS

Taking GPS as the target, Beijing area was selected to perform the single-point positioning mission and STK/MATLAB hybrid simulation method was used to simulate and analyze the service availability of GPS in Beijing. The latitude and longitude coordinates of Beijing is (40, 116), and the ground elevation is 20 m.

The data of GPS was derived from (U.S. Department of Defense. 2008). Failure data and maintenance data were gave based on experience. It is assumed that one backup satellite in B, D and F orbit and two backup satellites in ground launch base. The availability simulation model of GPS was built according the method mentioned in this paper. Setting the frequency of the simulation as 10 times, the simulation time as July 01 2007 to June 30 2015 and the simulation step as 1 minute, STK/MATLAB hybrid simulation was conducted. The trajectory of each unit is shown as below:

1 Jul 2007 12:19:00.000	8

Figure 9. Quantity of visible GPS satellite in Beijing.

During the simulation, the available time section of each satellite to the ground mission area can be obtained. The satellite coverage multiplicity in each time section in Beijing is obtained by statistics, shown in Figure 9. Finally, we got the coverage multiplicity data list for each event. The single point service availability of the statistical system in each state is obtained by Matlab simulation.

The availability statistics model is as below:

$$\Phi_i=\begin{cases} 0, & \text{F-N} < 0 \\ 1, & \text{F-N} \geq 0 \end{cases} \tag{1}$$

$$A_o = \frac{\sum_{i=1}^{n} \Phi_i \cdot \Delta t}{T} \tag{2}$$

where F is the actual coverage multiplicity, N is the minimum coverage multiplicity required for the success of the mission, and is the available state function of the unit.

The GPS satellite navigation system availability was obtained to be 99.95% by statistics.

6 CONCLUSION

Based on the characteristics of satellite navigation system and considering the operation, interruption, maintenance and support of navigation system, the framework of availability simulation model of GNSS was established and the detailed model including space ground state, interruption, maintenance, support model and the relationship model were described. The availability simulation logic flow based on operational process were also developed, which supports the availability simulation of GNSS. Combined with the simulation analysis data, it can provide basis for improvement of operational program, and development of system dynamic interrupt plan and in-orbit backup scheme, in order to increase the system availability.

A safe flow-management method for air traffic considering the UAS presence into the non-segregated airspace

Euclides Carlos Pinto Neto, Derick M. Baum, Marco A. Brinati, Jorge R. Almeida Jr., Paulo S. Cugnasca & João B. Camargo Jr.
School of Engineering, University of São Paulo (Poli - USP), São Paulo, Brazil

ABSTRACT: Air transportation is essential for society and it is increasing gradually. Furthermore, new technologies that improve the airspace operation in terms of safety are under development, such as the Unmanned Aircraft Systems (UAS). In the past few years, there has been a growth in UAS numbers into the segregated airspace. However, there are many challenges to be faced in order to integrate these autonomous aircraft into the non-segregated airspace. In this context, the relationship between UAS and Air Traffic Controller (ATCo) is a important aspect due to the fact that the presence of UAS into the non-segregated airspace may represent an increase in ATCo workload and, ultimately, a reduction in safety levels. This increase results from the lack of familiarity of the ATCo with the UAS, which leads these professionals to perform additional activities (e.g. cognitive activities) in order to conduct the air traffic safely. In fact, the Technology Maturity Level (TML), which is a measurement system that models the level of familiarity of ATCo with a particular aircraft, shows the impacts on workload levels of different aircraft. The main goal of this research is to propose a flow-management method for balancing the workload of sectors in order to reduce the impact on safety levels of the UAS presence in the non-segregated airspace. This workload balancing method considers the TML of Manned Aircraft (MA) and UAS, which may increase (in case of UAS) or decrease (in case of MA) the ATCo workload. The results show that this method can be employed for balancing workload effectively, even considering the UAS presence, and that integrating a small number of UAS into non-segregated airspace may present acceptable safety levels from the ATCo workload perspective.

1 INTRODUCTION

The increasing importance of air transportation for society (Marquart, Ponater, Mager, & Sausen 2003) has been considered an enabler for the development of technologies that improve the airspace operation, such as Unmanned Aircraft Systems (UAS) and Decision Support Tools (DST) for Air Traffic Controllers (ATCos) (e.g. Arrival and Departure managers) (Noskievič & Kraus 2017). These new technologies are proposed for improving airspace operation from many perspectives, such as efficiency and capacity. The DSTs, for instance, ensure the Air Traffic Controller (ATCo) the decisions made are effective, which lead to a reduction on his/her workload (i.e. the time spent on controlling aircraft) and, ultimately, on airspace complexity from ATCo perspective (Majumdar & Ochieng 2002). Although these technologies are used in many cases, they may bring uncertainties due to the fact that the personnel (e.g. ATCos) are not familiar to deal with them.

Furthermore, in the past few years, there has been a growth in UAS numbers into segregated airspace (Guerin 2015). These aircraft are composed of subsystems such as Unmanned Aircraft Vehicle (UAV), payload, control station and communication subsystems (Fasano, Accado, Moccia, & Moroney 2016) (Austin 2011) and have several militaries and civil applications (e.g. firefighting). However, the integration of these aircraft into the non-segregated airspace may lead to the creation of new ways of reaching the wellknown unsafe states. For instance, human mistakes in paloting can be made by bug in software. As the acceptance of this new technology is increasing due to its advantages compared to manned aircraft (e.g. efficiency), it stands out as a challenge for ATCos due to the lack of familiarity.

Moreover, the workload of ATCo is a result of the interaction of several factors, including the Air Traffic Control (ATC) complexity (Mogford, Guttman, Morrow, & Kopardekar 1995), and challenging situations for ATCos are related to a higher workload (Meckiff, Chone, & Nicolaon 1998), i.e., ATCo workload is related to safety (Neto, Baum, Hernandez-Simes, Almeida, Camargo, & Cugnasca 2017) as well as complexity, which is one of

the main factors that impact on ATCo workload (Majumdar & Ochieng 2002).

In this sense, the Air Traffic Flow Management (ATFM) enables the Air Traffic Management (ATM) to be effective in terms of safety, efficiency, cost-effectiveness, environmental sustainability and interoperability of ATM systems (ICAO 2014). The ATFM is conducted by a ATC cell. For instance, in European airspace, ATFM activities are carried out by Eurocontrols Network Manager Operations (Alam, Chaimatanan, Delahaye, & Féron 2017). However, there are many challenges in terms of flow management, such as the unpredictability of weather conditions and unexpected delays. Furthermore, the interaction between the UAS and the ATCo may present impacts, in terms of safety, in the airspace. Considering a high air traffic density and that a higher workload level leads to a lower airspace capacity (Majumdar & Polak 2001), the lack of adaptation of the sectors' capacity due to the presence of the UAS during the ATFM process may compromise the safety levels.

The main goal of this research is to propose a flow-management method for balancing the workload of sectors in order to reduce the impact on safety levels of the UAS integration in the non-segregated airspace. This workload balancing method considers the level of familiarity of ATCos with Manned Aircraft (MA) and UAS, which presents a lower (in case of UAS) or higher (in case of MA) impact on the ATCo workload.

This paper is organized as follows: Firstly, Section 2 presents the related works. Secondly, Section 3 presents the aspects of flow management into the airspace. Thirdly, the ATCo workload considering the relationship between ATCo and UAS is presented in Section 5. After that, Sections 4, 6 and 7 present, respectively, the aspects of UAS, the method and the case studies adopted in this research. Then, Section 8 presents a discussion on the results achieved in the experiments. Finally, Section 9 shows the conclusions of this research.

2 RELATED WORKS

In (Alam, Chaimatanan, Delahaye, & Féron 2017), the authors present a distributed air traffic flow management model for addressing the four-dimensional trajectory planning over the European Functional Airspace Blocks (FAB), which is a concept adopted in European airspace for allowing cooperation for improving the air traffic flow in an efficient and safe manner. Thus, this distributed approach of ATFM enables the information sharing between airspace blocks in strategic planning minimizing interaction between trajectories. Furthermore, this method is implemented and tested with a real air traffic data over the European airspace and interaction-free 4D trajectories are produced in short computational time (according to the time constraints of this operation). The results showed that this distributed method is viable and the interaction is reduced. In addition to this contribution, we propose a ATFM method for balancing the ATCo workload over the ATC system. Furthermore, we consider the presence of UAS into the non-segregated airspace.

In (Ivanov, Netjasov, Jovanovi, Starita, & Strauss 2017), the authors propose a two-level mixed-integer optimization model for solving the en-route demand-capacity imbalance problem in order to explore the possibility of controlling the ATFM delay distribution. Thus, the minimization of the delay propagated to subsequent flights can be achieved. Considering that this research comes from a practical background and that the model proposed is compatible with the models that are being used in the real-world, tests are conducted in realistic experiments. In order to mitigate the effects of delays in flights, aircraft operators usually embed a buffer time in their schedules. The current practice for allocating ATFM delays does not consider, though, if flights are able to absorb ATFM delay and still reduce delay propagation to subsequent flights, i.e., if the flights have any remaining schedule buffer. The results show that the proposed method reduces the delay propagated to subsequent flights and improves airport slot adherence. However, although this is an interesting contribution in terms of ATFM and delay reduction, this research does not consider the UAS presence.

The authors in (Neto, Baum, Almeida, Camargo, & Cugnasca 2017) present a simulation tool that aims evaluate safety (from workload perspective) and efficiency in aircraft sequencing in final sector considering the UAS presence. In this paper, a novel approach for measuring the impacts of the integration of UAS into the non-segregated airspace is proposed. This approach, called the Technology Maturity Level (TML), models the level of familiarity of ATCo with these aircraft. The realistic results achieved in the experiments showed that, depending on the familiarity of ATCo with the UAS, these aircraft may present a considerable impact in the workload levels and, ultimately, in the airspace capacity. However, although the authors present an approach for integrating the UAS into the non-segregated airspace, aspects of Air Traffic Flow Management (ATFM) are not taken into account.

The authors in (Clothier, Denney, & Pai 2017) propose a manner to create a Risk Informed Safety Case (RISC) applied to the context of safety assurance of UAS operation. This approach aims to

facilitate safe and cost-effective operations of sUAS by presenting the comprehensive measures considered in order to eliminate, reduce, or control the safety risk. The RISC proposed is composed by barrier models of safety, which support the development of safety measures, and structured arguments, which provide assurance of safety in operations (through, for instance, appropriate evidence). The authors also propose a model for UAS operational risk, which considers, for instance, specific hazards (e.g. collision) and operational risks (depending on the UAS). Ultimately, this paper shows key safety-related assurance concerns to be addressed and the development of a layered framework for reasoning about those concerns, which can be useful for regulators and various stakeholders in justifying confidence in operational safety in the context of the absence of the relevant aviation regulations for UAS.

3 AIR TRAFFIC FLOW MANAGEMENT (ATFM)

According to (ICAO 2014), the ATFM is "an enabler of Air Traffic Management (ATM) efficiency and effectiveness. It contributes to the safety, efficiency, cost-effectiveness, and environmental sustainability of an ATM system". ATFM enables the airspace to operate smoothly and resiliently, considering the possible difficulties that may be faced (e.g. bad weather conditions). The planning of the traffics movements (e.g. scheduling) helps the ATC units to, collaboratively, adapt the airspace for current needs in a global view.

Among the objectives of the ATFM, we can highlight (ICAO 2014): (1) improvement of the safety of the ATM system; (2) Optimization of flow in all phases of flights; (3) Simplification of collaboration between stakeholders (e.g. ATC units and airlines); (4) A better understanding of the ATM system resource constraints in terms economic and environmental priorities.

The approach of involving more stakeholders in the planning is a strategic manner of predicting future problems (e.g. unexpected delays and conflicts), mitigating risks (e.g. by using a delay buffer in each flight, regions with bad weather conditions can be avoided by the aircraft) and avoiding unsafe states. Thus, the traffic planning enables balanced definitions on the trade-off between safety and efficiency. As efficiency is, naturally, a metric to be maximized (due to, for instance, profit increase), the flow in planned in this sense. On the other hand, the impacts on the safety levels of the airspace must be taken into account in the decision-making process. Finally, safety represents the most important restriction in this context, i.e., the efficiency is desired to be maximized but the safety must remain at an acceptable level.

4 UNMANNED AIRCRAFT SYSTEM (UAS) INTEGRATION INTO THE NON-SEGREGATED AIRSPACE

UAS, in which the interest of engineering community has increased in the past few years (Fasano, Accado, Moccia, & Moroney 2016), is an autonomous system composed of subsystems (e.g. communication system and control station) (Fasano, Accado, Moccia, & Moroney 2016) (Austin 2011). There are many advantages provided by the UAS in large scale (e.g. airspace efficiency improvement) and in small-scale (e.g. reduction of risks associated with pilots in applications, such as firefighting).

Nowadays, the UAS that are being built vary in terms of size and can be classified into three categories in terms of weight (Romero & Gomez 2017): (1) Small UAS; (2) Medium UAS; (3) Large UAS. The class One (small UAS) represents the UAS that has many applications in smaller scenarios, with weight less or equal to 149 kg. Class Two (medium UAS) weights up to 600 kg. Finally, large UAS weights more than 600 kg. In this research, as we consider a futuristic scenario and the impacts of UAS are measured from the workload perspective instead of performance perspective (e.g. speed difference between large aircraft and small UAS), large UAS with size and performance similar to the commercial aircraft are adopted.

In order to control the aircraft, UAS and Manned Aircraft (MA), throughout the airspace, a set of activities must be performed by the ATCo (Neto, Baum, Hernandez-Simes, Almeida, Camargo, & Cugnasca 2017). In this research, activities are proposed by specialists of Safety Analysis Group (GAS), of the University of São Paulo. These specialists are actual Air Traffic Controllers and have more than 10 years of hands-on experience. The activities performed by the ATCo in each sector and their duration (in seconds) are: (1) First Contact (10s); (2) Instruction (15s); (3) Surveillance (10% of the mean time spent by the aircraft within the sector); (4) Communication with adjacent ATC unit (10s);

In this context, the Technology Maturity Level (TML), which is a measurement system that measures the familiarity between the ATCo and the aircraft, is employed (Neto, Baum, Almeida, Camargo, & Cugnasca 2017). Aircraft with higher TMLs are related to operations with lower workload levels, whereas aircraft with lower TMLs are related to operations with higher workload levels. For instance, nowadays, it is reasonable to consider that the UAS have a lower TML, whereas

the Manned Aircraft have a higher TML. In terms of workload, it is reasonable to consider that the familiarity of the ATCo with MA is higher than the familiarity of the ATCo with UAS. This is due to the fact that the ATCos, nowadays, are used to deal with MA but are not used to deal with UAS (which do not operate in the non-segregated airspace) (Złotowski, Yogeeswaran, & Bartneck 2017). In this context, it is reasonable to consider that the UAS has a Technology maturity Level (TML) equals to 0 and MA equals to 10. Thus, the time spent in the activities performed by the ATCo in the MA operation is multiplied by 1, whereas the time spent in the activities performed by the ATCo in UAS operation is multiplied by 2 (Neto, Baum, Almeida, Camargo, & Cugnasca 2017).

5 WORKLOAD BALANCING MODEL (WBM)

This section presents the main contribution of this research, the ATCo Workload Balancing Model (AWBM) for safe Air Traffic Flow Management (ATFM), from the workload perspective, considering the UAS presence. Firstly, the flow network employed in the AWBM is presented. Then, aspects of the allocation process are highlighted. Finally, the final considerations are shown.

5.1 *Flow network*

The airspace is composed by (but not limited to) sectors and tracks. The aircraft that operate into the non-segregated airspace use these track in order to fly to different regions. Naturally, these flights lead the aircraft to cross a set of sectors, which are controlled by ATC units. Each ATC unit is responsible for one sector, i.e., although a collaborative work is conducted, metrics of each ATC unit are independent (e.g. ATCo workload) and, in order to maintain the safety levels, the ATCo workload of a given sector must not exceed the maximum acceptable workload established. Finally, a reasonable maximum acceptable workload, i.e., a reasonable workload threshold, represents 80% of an hour (Majumdar & Polak 2001) (Majumdar, Ochieng, Bentham, & Richards 2005). The safety levels may be, then, compromised if the the current workload exceeds the workload threshold.

Figure 1 illustrates a region of the airspace and its respective set of sectors. Each sector has its own ATC unit and, consequently, its own workload threshold. Note that there are points (b_1, b_2, b_3, …, b_8) that connect the sectors according to the tracks that represent the sectors boundaries, which are logical elements that identify the region in which the aircraft changes from one sector to another. In order to abstract this scenario, a flow network is

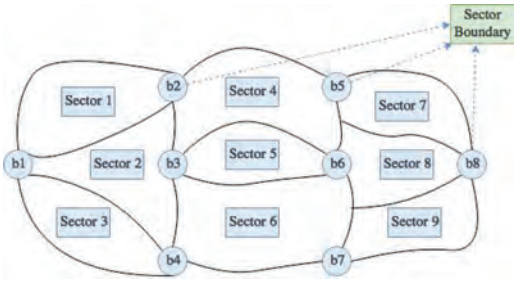

Figure 1. Region of the airspace and its respective set of sectors.

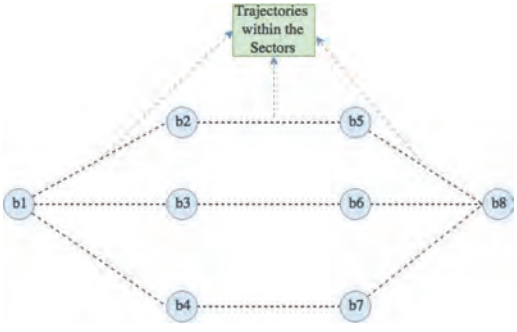

Figure 2. Flow network used for representing the scenario presented in Figure 1.

appropriate due to its suitability for dealing with problems in which goods (in this case, aircraft) must be sent from one point to another, considering specific constraints (in this case, workload and safety). In order to model the problem considered in this research, the flow network can be faced as a graph that considers a flow, a capacity, source and sink nodes, goods (i.e. aircraft) to be delivered and specific constraints (Ford & Fulkerson 1962).

Suppose a undirected graph G with nodes b_1, b_2, …, b_n and edges e_1, e_2, …, e_m. The nodes represent the sector boundaries, i.e., each node is a logical element that illustrates the point in which the aircraft changes from one sector to another. One should note that this point refers to the change of ATC unit that controls the aircraft due to the fact that each ATC unit is responsible for one sector. Furthermore, the edges represent the direct trajectory from one sector to another. Each trajectory has a particular length. Finally, a fleet composed by a set of aircraft (MA and UAS), a_1, a_2, …, a_n, must be allocated to paths that connect the source and the target of the network, i.e., origin and destination of each aircraft.

Figure 2 illustrates the flow network used by the AWBM for representing the scenario presented in

Figure 1. In this scenario, each trajectory has a specific length. One should note that as a trajectory is within a sector and a sector has a limited workload threshold[1], there is a limited number of aircraft that can operate simultaneously in each trajectory.

5.2 *Allocation process*

The scheduling problem faced in this research is constituted by allocating the set of aircraft to selected paths. This allocation process is aimed to balance the ATCo workload levels in the airspace in order to maintain a proper safety level in all sectors. For instance, if all aircraft are delivered to a single path, that path is expected to have a high ATCo workload level whereas other possible paths have a low ATCo workload level, i.e., the workload is unbalanced and some sectors may present critical scenarios in terms of safety. Firstly, in order to select a path for a given aircraft going from node b_k to the node $b_{k'}$, all possible paths are found in the graph. Secondly, an evaluation of the ATCo workload of the sectors that composed each path is conducted in order to identify which path presents the lowest workload level. Finally, the path with the lowest sum of ATCo workload is selected and the aircraft is allocated to that path.

Once the aircraft is allocated, the attributes of the path are updated. For each sector, the ATCo workload is updated with the ATCo workload related to controlling that aircraft, which depends on its Technology Maturity Level (TML). This research is focused on the planning of flights, i.e., the flights assigned to paths are expected to generate a certain level of ATCo workload and, thus, controlling the amount of traffic that fly in each path is an effective manner of balancing the workload.

Thus, this challenge can be faced as a optimization problem: Equation 1 shows the function that must be minimized in order to balance the workload in the airspace. In fact, this equation measures how different the workload of the different sectors are from each other, i.e., scenarios with higher variations of workload present a higher value in this equation. Note that the minimum value achieved is 0, which is achieved in the case in which the ATCo workloads of all sectors are the same. The W function measures the workload for a given sector, which is represented by an edge e_m. Finally, this equation sums the absolute value of the subtraction of the workload of all sectors. However, the restrictions of this problem must be respected. Equation 2 illustrates a restriction that highlights that the actual workload of a given sector, represented by the edge e_i, must be less or equals to the workload limit of its workload threshold (Wt). This restriction aims to ensure that the safety levels, from the workload perspective, are maintained at an acceptable level. Furthermore, the Equation 3 shows that each aircraft must be assigned to one path as a restriction. Solutions of this optimization problem, considering specific scenarios, represent solutions of the ATFM considering the UAS presence.

$$\min \quad f = \sum_{i=1}^{m-1} \sum_{j=i+1}^{m} \left| W(e_i) - W(e_j) \right| \tag{1}$$

$$W(e_i) \leq Wt(e_i) \quad i = 1,2,3,\ldots,m \tag{2}$$

$$Paths(a_k) = 1 \quad k = 1,2,3,\ldots,n \tag{3}$$

5.3 *Final considerations*

Finally the ATCo Workload Balancing Model (AWBM) has some considerations on the scenarios modeled. Firstly, the distance between the paths is expected to be similar. Secondly, the performance of the aircraft is expected to be similar and bad weather conditions are not present in the scenarios. Finally, unsafe states are not expected, i.e., the aircraft minimum separation is respected during all flights.

6 METHOD

This section presents the steps that guide the application of our proposal in different problems. Note that this approach can be applied in scenarios of different sizes (e.g. the number of sectors) and type of aircraft (e.g. MA and UAS). This process is illustrated in Figure 3.

Firstly, the input data is provided. This input data is composed of the list of aircraft with the same source and target nodes. Furthermore, the type of each aircraft must be provided, i.e., each aircraft must be identified as Manned Aircraft (MA) or Unmanned Aircraft System (UAS). This information is used in the workload evaluation. Secondly, the scenario is described. This description is based on the transformation of a scenario into a flow network, which contains sectors (represented by edges) and sectors boundaries

Figure 3. Method adopted in this research.

1. The workload threshold is the maximum workload supported by a given sector in order to maintain the safety levels.

(represented by nodes). In fact, this phase identifies the characteristics of the situation that is used in the model.

Thirdly, The adjustment process is conducted, which is conducted in order to make sure that the description represents a viable scenario, i.e., if the flow network considered connects the source to the sink. After that, the scenario building is conducted. This process aims to build a flow network pragmatically based on the description provided. This scenario is, then, validated by checking if all aspects of the model are properly defined. If the validate is conducted successfully, the experiments can be conducted, otherwise, the adjust is conducted again. The experiments constitute the process of allocating the aircraft to the available tracks in a suitable manner. In this phase, the data the workload levels of each sector are estimated. Finally, the evaluation aims to identify the insights on the results in order to show the impact of our proposal in the workload balancing.

7 CASE STUDIES

This section presents the case studies considered in this research. Firstly, a simpler and abstract scenario is presented. After that, a more complex scenario is shown. Finally, a scenario based on a realistic scenario is presented.

7.1 *Case study I*

The main goal of this case study is to show the applicability of our proposal in a simpler scenario, in which the fleet is reduced. We consider a fleet of 5 aircraft, in which 2 are UAS (UAS_1 and UAS_2) and 3 are MA (MA_1, MA_2 and MA_3). In this scenario, illustrated in Figure 4, the aircraft must be sent from the node b_1 to the node b_8.

The characteristics of the tracks of this scenario are illustrated in Table 1. In this Table, the distances, in Nautical Miles, the mean time of the aircraft in that track (or sector) T and the ATCo workload threshold, both in seconds. The workload threshold represents the maximum ATCo workload supported by each sector, are presented for each track.

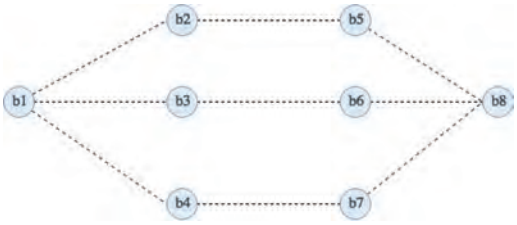

Figure 4. Scenario adopted in case study I.

Table 1. Characteristics of tracks in case study I.

Track	Distance (nm)	T (s)	Threshold (s)
b_1 - b_2	52	624	681,8
b_1 - b_3	45	540	623
b_1 - b_4	51	612	673.4
b_2 - b_5	60	720	749
b_3 - b_6	58	696	732.2
b_4 - b_7	57	684	723.8
b_5 - b_8	48	576	648.2
b_6 - b_8	43	516	606.2
b_7 - b_8	51	612	673.4

Table 2. Solution proposed in case study I.

Aircraft	Path
MA_1	b_1 - b_2 - b_5 - b_8
MA_2	b_1 - b_3 - b_6 - b_8
MA_3	b_1 - b_2 - b_5 - b_8
UAS_1	b_1 - b_4 - b_7 - b_8
UAS_2	b_1 - b_3 - b_6 - b_8

During the allocation process, the solution achieved is illustrated in Table 2. In this solution, the aircraft are allocated in a balanced manner throughout the network in order to share the ATCo workload.

7.2 *Case study II*

The main goal of this case study is to show the applicability of our proposal in a more complex scenario, in which the fleet is larger than the fleet considered in the case study I. We consider a fleet of 10 aircraft, of which 5 are UAS (UAS_1, UAS_2, …, UAS_5) and 5 are MA (MA_1, MA_2, …, MA_5). In this scenario, illustrated in Figure 5, the aircraft must be sent from the node b_1 to the node b_{10}.

Furthermore, the characteristics of the tracks of this scenario are illustrated in Table 3. Similarly as presented in the case study I, the distances, in Nautical Miles, the mean time of the aircraft in that track (or sector) T and the ATCo workload threshold (s), both in seconds. The workload threshold represents the maximum ATCo workload supported by each sector, are presented for each track.

The results achieved in the allocation process, illustrated in Table 4, showed that the aircraft are sent from the node b_1 to the node b_{10} in a balanced manner, i.e., many paths composed by different tracks are explored.

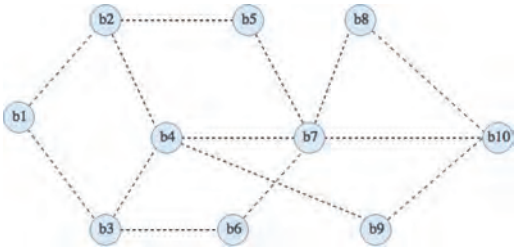

Figure 5. Scenario adopted in case study II.

Table 3. Characteristics of tracks in case study II.

Track	Distance (nm)	T (s)	Threshold (s)
b_1 - b_2	52	624	1353,8
b_1 - b_3	45	540	623
b_2 - b_4	57	684	723.8
b_2 - b_5	55	660	597.8
b_3 - b_4	42	504	707
b_3 - b_6	49	588	656.6
b_4 - b_7	49	588	656.6
b_4 - b_9	80	960	917
b_5 - b_7	57	684	723.8
b_6 - b_7	57	684	723.8
b_7 - b_8	57	684	723.8
b_7 - b_{10}	65	780	791
b_8 - b_{10}	62	744	765.8
b_9 - b_{10}	58	696	732.2

Table 4. Solution proposed in case study II.

Aircraft	Path
MA_1	b_1 - b_2 - b_4 - b_7 - b_8 - b_{10}
MA_2	b_1 - b_2 - b_5 - b_7 - b_{10}
MA_3	b_1 - b_2 - b_4 - b_7 - b_8 - b_{10}
MA_4	b_1 - b_3 - b_4 - b_9 - b_{10}
MA_5	b_1 - b_2 - b_4 - b_9 - b_{10}
UAS_1	b_1 - b_3 - b_4 - b_9 - b_{10}
UAS_2	b_1 - b_3 - b_6 - b_7 - b_{10}
UAS_3	b_1 - b_2 - b_5 - b_7 - b_{10}
UAS_4	b_1 - b_3 - b_6 - b_7 - b_8 - b_{10}
UAS_5	b_1 - b_3 - b_4 - b_7 - b_{10}

7.3 *Case study III*

The third case study presents a realistic scenario present in the Brazilian airspace. We consider a fleet of 20 aircraft, in which 10 are UAS (UAS_1, UAS_2, …, UAS_{10}) and 10 are MA (MA_1, MA_2, …, MA_{10}). In this scenario, illustrated in Figure 6, the aircraft must be sent from the node *belém* (*bl*) to the node *santarém* (*sr*). In this realistic scenario, there are 11 tracks and their characteristics are

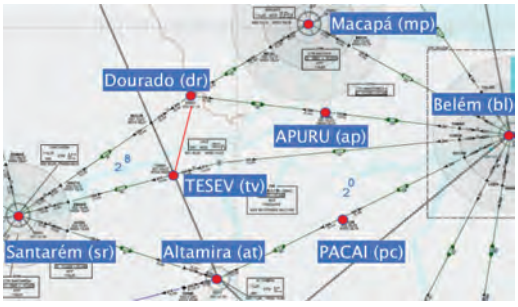

Figure 6. Scenario adopted in case study III adapted from (DECEA 2017).

UAS_9	*bl - mp - dr - sr*
UAS_{10}	*bl - tv - sr*

illustrated in Table 5 (the distance and the mean time of the aircraft in the track).

The results of the allocation, presented in Table 6, shows that all available tracks are used, i.e., the ATCo workload is shared among the 11 sectors.

8 DISCUSSION

In the first case study, the ATCo workload level in each track is illustrated in Figure 7. Note that the workload levels of all tracks are much lower than their respective workload threshold, i.e., they support more traffics (Figure 7 and Table 1). However, this balanced manner of aircraft distribution maintains the different sectors with similar workload levels. Finally, the result of the unbalancing measure (Equation 1) is 3094.8s. Note that, for instance, if the only the path use is $b_1 - b_2 - b_5 - b_8$ and the ATCo workload threshold is respected, the unbalancing measure is 21390.6s, which is considerably higher than the value achieved by the proposed solution and, consequently, indicates a possibility of safety issues in those sectors.

The second case study presents a higher number of tracks and the workload of each track is illustrated in Figure 8. Although the path $b_7 - b_{10}$ presented a workload (756s) similar to its workload threshold (791s), the method proposed in this research ensures that the threshold is respected. Finally, the result of the unbalancing measure (Equation 1) is 30614.1s. One should note that this value may be considerably higher depending on the paths the aircraft are allocated to, i.e., if the workload levels of the tracks are very different, this measure increases.

Finally, the third case study also presented balanced results, which are illustrated in Figure 9.

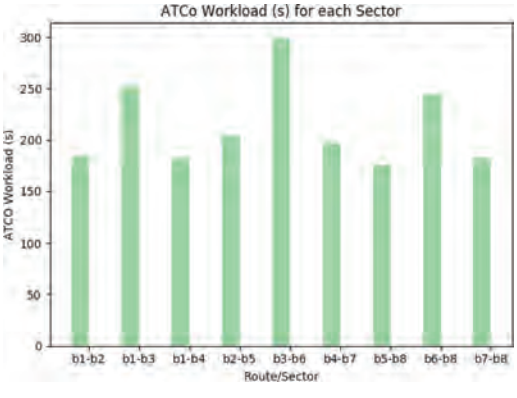

Figure 7. ATCo workload level of each track (case study I).

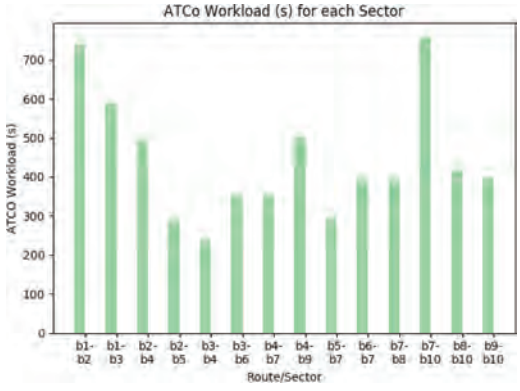

Figure 8. ATCo workload level of each track (case study II).

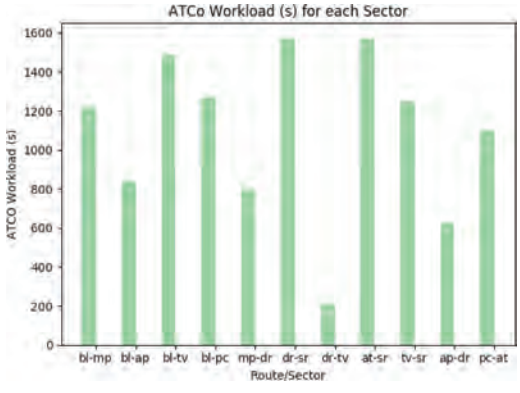

Figure 9. ATCo workload level of each track (case study III).

Note that the values vary considerably. However, this solution presents a balanced solution compared to solutions that use few of these paths. Furthermore, all sectors present a workload level below its respective workload threshold (presented in Table 5). Finally, the unbalancing measure of this case study achieved 51096s. Note that other solutions may present a considerably higher unbalancing measure, for instance, if all aircraft are sent through the path $bl - tv - sr$ respecting the ATCo workload threshold, which represents 72018.8s of unbalancing measure and may indicate problems, from the safety perspective, in those sectors.

9 CONCLUSION

In this paper, a safe flow-management method for integrating the UAS safely into the non-segregated airspace was presented. The method aims

to distributes the workload among the sectors in order to maintain the safety levels. The results achieved in the proposed experiments showed that our method distributes the workload among the sectors effectively, even considering the UAS presence. As future intentions, the authors aim to consider aspects such as delays buffer and resilience in case of failures in the UAS operation (e.g. failures in the command and control link).

ACKNOWLEDGEMENT

The authors would like to thank Boeing Research & Technology Brazil (BR&T-Brazil) for the support for this research and for its institutional support to the Safety Analysis Group (GAS) of the School of Engineering of the University of São Paulo (Poli-USP).

Active power dispatch strategy of wind farms under generator faults

K. Ma & J. Zhu & M. Soltani & A. Hajizadeh

P. Hou & Z. Chen
Department of Energy Technology, Aalborg University, Aalborg, Denmark

ABSTRACT: Generator is a critical component of the wind turbine. It transforms the mechanical energy to the electric energy and transmits electricity to the grid. Based on the previous experience, the fault rate of the generator is fairly high which increases the downtime of the turbine. It has a significant effect on the performance and the economic benefit of the wind farm. The traditional wind farm controller adopts the proportional dispatch strategy and does not consider the fault severity. In this paper, a power dispatch strategy of wind farm focusing on the fault condition of the generator is proposed. The main faults are divided into three levels according to their severities. The wind farm controller dispatches power references to wind turbines onthe basis of fault level, wind condition and power demand from the grid. When the fault level is high, the strategy gives priority to protect the generator. If the fault level is not high, the wind farm should follow the power demand. In addition, the wake effect is also an important factor that must be taken into account in the wind farm control. Because it can affect the power production directly. To verify the advantage of this strategy, it is compared with the proportional dispatch strategy in the simulation. The result shows that the proposed strategy can make a good trade-off between component protection and power production.

1 INTRODUCTION

Wind energy is one of the most widely used renewable energies. With the rapid development of technology and industry application, it plays an important role in the energy market of the world. By 2016, wind energy overtook coal and became the second largest form of power generation capacity in Europe (Europe 2016). Wind Farm (WF) is seen as a mature and effective form to utilize wind energy for commercial operation. The large-scale offshore WF is the development trend of wind energy. This also implies that the wind energy penetration in the grid is larger and larger. However, wind energy has its congenital defects. One of them is the high failure rate of the Wind Turbine (WT) due to the harsh operating environment and the highly turbulent wind speed. Therefore, the stability and reliability of WF are more and more important to the grid. The fault of WT should not be neglect in the operation of WF as well.

In recent years, wind farm control draws more and more attention of the researchers. Previous Wind Turbine Control (WTC) can no longer guarantee the good performance of WF during operation, no matter from the aspects of power production, fatigue loads, etc. For the coordination, control and management of all WTs in the entire WF, it is apparent that Wind Farm Control (WFC) is more direct and effective. The research on WFC can be divided into two categories depending on whether participating in the individual turbine control. One is to achieve the control objectives of WF through adjusting WTC from the WF level (Ebrahimi et al. 2016, Tian et al. 2017, Gonzalez et al. 2013). While the other is opposite, it only coordinates and distributes the variables that are not involved in WTC such as start/stop and power reference (Soleimanzadeh and Wisniewski 2011, Soleimanzadeh et al. 2012, Zhang et al. 2015). The former method seems to be able to get better results due to more controllable variables. However, the latter method does not need to change the original controller from the manufacturer, it is easier to apply in the practice. Normally, the objectives of WFC includes power maximization, fatigue and wake reduction, frequency response, voltage control, following some specific requirements from TSO, etc.

The generator faults will influence the power output of WT directly and even result in the emergency stop. Although the failure rate of the generator is not the highest in all components, the average fault-removal time is quite long and the maintenance cost is high as well. Most research on generator faults focuses on Fault Detection and Diagnosis (FDD). The common methods need to detect some physical quantities such as voltage, current, power and then analyze the signals based on the model or signal-processing (Balasubramanian and Muthu 2017, Qiao and Lu 2015). However,

there are few articles considered generator faults in WFC. Some similar research on the fault of blade and drive-train can be found in (Badihi et al. 2015, Odgaard et al. 2009).

The analysis of generator faults shows that some faults can be mitigated by reducing load, such as turn-to-turn short circuit (Lešić et al. 2013). The down-regulation of WT can not only prevent the faulty generator from further damage but also reduce the downtime.

The contribution of this paper is to distribute power demand to the individual WTs reasonably when the generator fault occurs. According to the severity and mechanism, we divided the faults of Doubly-Fed Induction Generator (DFIG) into three levels. The proposed power dispatch strategy will take different distribution type depending on the fault level and try to fulfil the power demand under the premise of ensuring WT's safety, assuming that all faults can be detected.

This paper is organized as follows. Section 2 describes DFIG faults briefly and the fault classification. The WF model with wake effect is presented in section 3. Section 4 gives the active power dispatch strategy of WF. Section 5 provides the simulation results of different cases.

2 FAULT CLASSIFICATION

DFIG is a widely used generator in WT because of its low capital cost and good energy yield (Hansen and Hansen 2007). The components with high fault rate include slip ring/brush, bearing, cooling system, winding insulation, encoder, etc (Shipurkar 2015). Although DFIG has many different types of fault modes, the only control variable in this paper is the power reference which can adjust the electrical load of WT. So we focus more on the fault modes that can be mitigated by reducing the load. The characteristic of the fault according to Fault Tree Analysis (FTA) and Failure Modes Effect Analysis (FMEA) is used for reference. In addition, the safety of WT is always the most important. Fault severity is another factor need to be considered. The fault classification is as follows:

Fault level 1 (FL1): this fault level includes the faults that are not serious or cannot be mitigated by down-regulation. For example, some fault of the redundant sensor, minor rotor misalignment and bearing vibration.

Fault level 2 (FL2): this fault level includes the early inter-turn short-circuit faults of the stator and rotor, as well as the initial fault of the cooling system. The characteristic of this level is that the overheating caused by fault can have a more serious effect on the generator. However, down-regulation operation can reduce generator heating by decreasing the current. For protecting generator, there is a limit value of power $P_{limit,f}$. This value depends on the specific fault mode and means that the load of WT should not exceed it. The specific value of $P_{limit,f}$ can be estimated according to the fault mechanism and lifetime estimation.

Fault level 3 (FL3): this level has the highest severity, such as the phase to phase short-circuit of stator and rotor. It will result in the generator failure directly. Therefore, WT must be shut down when the fault of this level is detected for protecting WT.

3 WIND FARM MODEL

WF consists of several WTs. However, simply taking the ambient wind speed as the wind speed of all the WTs, then adding all power output of WTs as the power output of WF is not accurate due to the aerodynamic interaction. To show the results of power dispatch strategy, a WF model that taking wake effect into account is used. WF model includes three parts: WT model, wake model and WF layout.

3.1 *Wind turbine model*

A 5MW DFIG WT model is adopted here. According to the Betz theory, the mechanical power extracted by the turbine from wind energy can be calculated by the following equations:

$$P_m = \frac{1}{2}\rho\pi R^2 v^3 C_p(\lambda,\beta) \tag{1}$$

$$\lambda = \frac{\omega_r R}{v} \tag{2}$$

$$F_t = \frac{1}{2}\rho\pi R^2 v^2 C_t(\lambda,\beta) \tag{3}$$

where, P_m is the mechanical power extracted by turbine; ρ is the air density; R is the radius of rotor; v is the wind speed; C_p is the power coefficient, which depends on λ and β; λ is the tip speed radio; β is the pitch angle; ω_r is the rotor speed; F_t is the thrust force; C_t is the thrust coefficient, which depends on λ and β as well. The surfaces of C_p and C_t are shown in in Figure 1.

Pitch system adjusts the aerodynamic characteristic of blades by controlling the pitch angle. It can change the efficiency of energy capture and offer aerodynamic brake. Gearbox supports the necessary speed conversion for DFIG. Generation system includes a DFIG and a partial scale power electronic converter.

These subsystems are the major parts of DFIG WT and will be simplified as an inertial system.

The control strategies of normal operation are Maximum Power Point Tracking (MPPT) and Constant Power in low and high wind speed region respectively. The down-regulation strategy should be emphasized here because it can affect the wake.

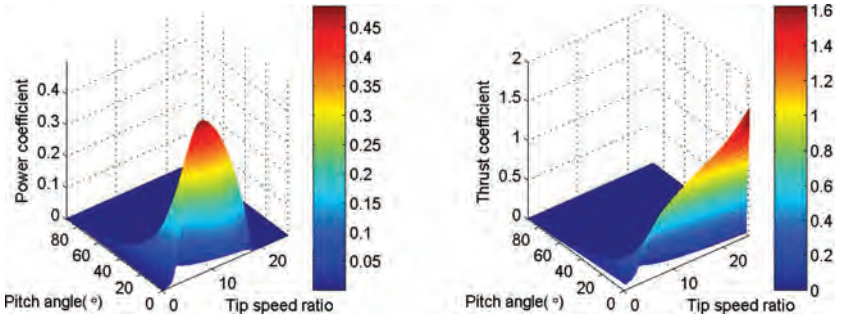

Figure 1. Surfaces of C_p and C_t.

The strategy adopted here is Max ω, which is the most widely used in the industry (Mirzaei et al. 2014).

3.2 *Wake model*

Wake effect can decrease the power production of WF and increase the fatigue load of downwind WT. Therefore, it should be considered in WFC. There are several research focus on how to describe wake effect accurately (Göçmen et al. 2016). Among engineering applications, Jensen wake model is widely used because its practicality and simplicity. In this paper, we adopt Jensen wake model for the single wake and quadratic summation method for the multiple wakes (Katic, Højstrup, & Jensen 1986). The velocity deficit can be expressed as:

$$1-\frac{v}{u}=\frac{1-\sqrt{1-C_t(\lambda,\beta)}}{(1-2\alpha X/D)^2} \tag{4}$$

where, v is the downwind wind speed at position X; u is the ambient free wind speed; X is the distance between upwind and downwind WT; D is the diameter of rotor; α is decay constant, choosing 0.05 for offshore WF.

To calculate the velocity deficit of the j^{th} WT in multiple wakes, the following equation can be used.

$$\left(1-\frac{v_j}{u}\right)=\sum_{i=1}^{n}(1-\frac{v_{ij}}{u})^2 \tag{5}$$

where, v_j is the wind speed of the j^{th} WT; n is the number of wakes that the j^{th} WT is in; v_{ij} is the wind speed of the j^{th} WT under the influence of the wake of the i^{th} WT.

3.3 *Wind farm layout*

In order to reflect the wake effect to WF and to simplify the calculation, five WTs are arranged in a straight line. The selected wind direction makes the downwind WTs are in the full wake of the upwind WTs. This layout allows the study of the worst-casewake effect. The distance between two WTs is 6.5 times the diameter of the rotor. The layout is shown in Figure 2.

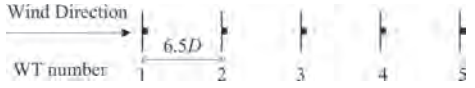

Figure 2. Wind farm layout.

4 ACTIVE POWER DISPATCH STRATEGY WITH FAULT ACCOMMODATION

The traditional active power dispatch strategy is proportional dispatch strategy (Grunnet, Soltani, Knudsen, Kragelund, & Bak 2010). Power demand is distributed to WTs proportionally to the available power of each WT by the WF controller as follows:

$$P_{a,i}=\frac{1}{2}\rho\pi R^2 v^3 C_{p,max} \tag{6}$$

$$P_{r,i}=\frac{P_{a,i}}{\sum P_{a,i}}P_{dem} \tag{7}$$

where, $P_{a,i}$ is the available power of the i^{th} WT; $C_{p,max}$ is the maximum coefficient of power of WT; $P_{r,i}$ is the power reference of the i^{th} WT; P_{dem} is the power demand of WF from TSO.

The traditional proportional strategy neither considers the impact of the wake effect on power production, nor does it consider the fault of WT. The proposed strategy is also based on the proportional dispatch strategy. But it takes generator fault classification and wake effect into consideration, and tries to follow the power demand ensuring WT's safety as the precondition.

The whole strategy according to the fault level is also divided into three parts:

1. Strategy for FL1: The fault in FL1 is not severe and cannot be remitted by down-regulating

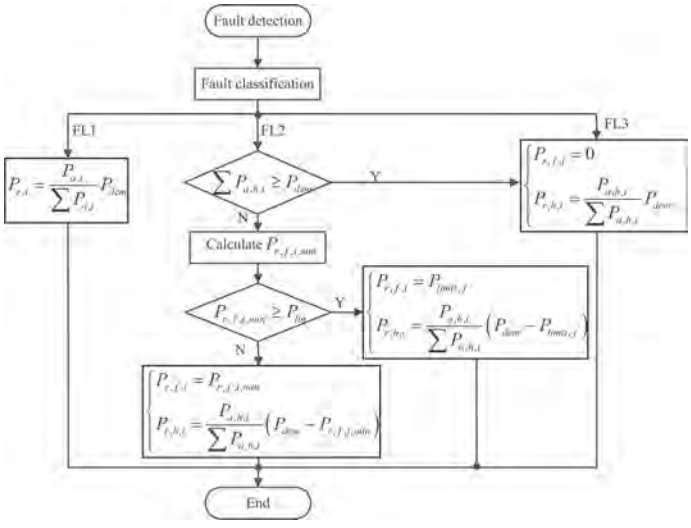

Figure 3. Flowchart of the proposed active power dispatch strategy.

WT. Therefore, the active power dispatch will maintain the original proportional strategy for both healthy WT and faulty WT.

2. Strategy for FL2: This strategy is the focus of this paper as it relates to the trade-offs between fault protection and following power demand. The general idea includes three steps.

Step 1. If the sum of the power of healthy WTs can follow the Power demand enough, it is allowed to shut down the faulty turbine. Then the power demand will be distributed as follows:

$$\begin{cases} P_{r,f,i} &= 0; \\ P_{r,h,i} &= \dfrac{P_{a,h,i}}{\sum P_{a,h,i}} P_{dem}. \end{cases} \tag{8}$$

where, $P_{r,f,i}$ is the power reference of the i^{th} faulty WT; $P_{r,h,i}$ is the power reference of the i^{th} healthy WT; $P_{a,h,i}$ is the available power of the i^{th} healthy WT.

Step 2. If the sum of the power of healthy WTs cannot follow the Power demand. The minimum power reference of the faulty WT that can fulfil the power demand should be found by the exhaustive method. There are two possible reasons why the power demand can still be followed by reducing the power of a particular WT. One is that the available power of WF is higher than power demand. The other reason is that, due to the wake effect, the down-regulation of upwind WT will increase the wind speed of the downwind WTs, and the power loss because of down-regulation will be compensated by the downwind WTs. The wind speeds of WTs are highly coupled due to wake effect and are related to the power references of all the WTs. Therefore, the exhaustive method is the simplest and quickest way.

Step 3. If $P_{r,f,i,min}$ is higher than $P_{limit,f}$, the power reference of faulty WT will be set as $P_{limit,f}$. So the power output of WF must be less than the power demand. This power deviation is ineluctable for protecting WT. The power distribution will be as follows:

$$\begin{cases} P_{r,f,i} &= P_{limit,f}; \\ P_{r,h,i} &= \dfrac{P_{a,h,i}}{\sum P_{a,h,i}} \left(P_{dem} - P_{limit,f} \right). \end{cases} \tag{9}$$

If $P_{r,f,i,min}$ is smaller than $P_{limit,f}$, the power reference of faulty WT will be set as $P_{r,f,i,min}$. In this way, the strategy can follow power demand and reduce the load of faulty WT as much as possible. The power distribution will be as follows:

$$\begin{cases} P_{r,f,i} &= P_{r,f,i,min}; \\ P_{r,h,i} &= \dfrac{P_{a,h,i}}{\sum P_{a,h,i}} \left(P_{dem} - P_{r,f,i,min} \right). \end{cases} \tag{10}$$

3. Strategy for FL3: The generator fault with high severity is a serious threat to WT's safety. Therefore, the WT with FL3 must be shut down as soon as possible. The power distribution is the same with equation 8. The whole strategy is shown in the flowchart in Figure 3.

5 SIMULATION

To verify the advantage of the proposed active power dispatch strategy, the WF model mentioned in Section 3 is used. The parameters of a 5MW DFIG WT are shown in Table 1. Figure 2 shows the

distribution of wind speed under wake effect in this WF. The ambient wind speed of WT1 is 10 m/s. All power references are set to 5MW as MPPT strategy. The distribution shows that the wind speed of the downwind WT drops due to the wake effect. The following simulation will also use this WF model.

The strategies for FL1 and FL3 will not be simulated here. Because these two parts can be understood easily and there is no difference with the existing protection measure. To illustrate the fault protection, the phase current of faulty WT, $I_{N,f}$ is used in the comparison. Because all of these faults has the relationship with the current. With respect to the simulation of strategy for FL2, $P_{limit,f}$ is set to 2 MW. Three cases will be studied here to show the simulation results in different situations.

In Case 1, wind speed is 12 m/s, and power demand is 15MW. An FL2 fault occurs on WT3. The sum of power of healthy WTs can follow the Power demand enough, so the faulty WT can be shut down. It will not affect the power demand tracking. The power output of each WT is shown in Fig. 4. The red and blue bars represent the power output in Traditional Proportional Strategy (TPS) and Proposed Proportional Strategy (PPS) respectively. The power references, Power output of WF and the phase current of faulty WT are shown in Table 2. The result shows that the faulty WT is shut down, but WF can still produce enough power to follow the power demand. The faulty WT is also protected from further deterioration.

In Case 2, wind speed is 12 m/s, and power demand is 17.5MW. An FL2 fault occurs on WT5. The healthy WTs cannot supply enough power. Through the exhaustive method, the value of $P_{r,f,i,min}$ is 2.28MW in this case. It is higher than $P_{limit,f}$. According to the proposed strategy, although WF power cannot follow the power demand, in the consideration of protecting generator, the faulty WT has to be limited to 2MW. The result is shown in Table 3. The phase current of faulty WT has been decreased from 2.70kA to 1.71kA.

In Case 3, wind speed is 10 m/s, and power demand is 10MW. An FL2 fault occurs on WT3. The healthy WTs cannot fulfill the power demand either. The value of $P_{r,f,i,min}$ in this case is 0.73MW and much lower than $P_{limit,f}$. Therefore, the faulty WT can be down-regulated to 0.73MW. Meanwhile, the power demand can also be followed. The result

P_{WF}(MW)	10.04	10.00
$I_{N,3}$(kA)	1.55	0.62

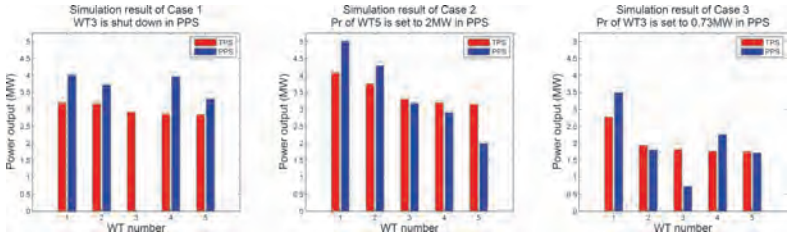

Figure 5. Comparison of power output of WTs in two strategies.

can be found in Table 4. The phase current of faulty WT can be decreased from 1.55kA to 0.62kA.

Figure 5 shows the power output of WTs in these three cases. From the simulation results, it can be seen that the proposed active power dispatch strategy can effectively ensure the safety of WT in the event of a generator fault, and follow the power demand as much as possible.

6 CONCLUSIONS

In this paper, an active power dispatch strategy of WF under generator fault is proposed. It gives the idea of implementing power distribution based on fault level. With the comparison of traditional proportional strategy, the simulation results show that the proposed strategy can make a good balance between generator protection and power production. It not only reduce the downtime caused by non-severe fault, but also follow the power demand as much as possible under the premise of ensuring WT's safety. The general idea can also be extended to some other faults in WT.

However, the shortcoming is lack of detailed research on the specific fault mode and the reliability evaluation. The fault model, lifetime estimation of generator and reliability model should be studied to combine the failure, condition, power production and reliability together in the further research.

Probabilistic assessment of the impact of connecting a new distributed generation unit to a potentially congested power system

J. Sun & P.E. Labeau
Université Libre de Bruxelles, Brussels, Belgium

A. Vergnol
Elia System Operator, Brussels, Belgium

ABSTRACT: The large-scale use of distributed electricity generation is possibly associated with increasing grid congestion; hence, Distributed Generation (DG) curtailment is envisioned to solve those congestions in affected power systems. By resorting to curtailment as part of an Active Network Management (ANM) scheme under real-time supervision/control of the DG units, more distributed generation can be accommodated in a distribution grid, while keeping the power system secure. In this paper, a method, based on an importance sampling scheme systematically targeting electrically challenging scenarios, is given to assess the curtailment risk associated to DG unit connections to the grid. It simultaneously resorts to correlated sampling in order to estimate the risk evolution due to "perturbed" situations, i.e. due to a newly connected DG unit. This significantly reduces the computation time of the risk indicators. The effectiveness of the proposed method is demonstrated on a test power grid.

1 INTRODUCTION

The European Union (EU) has set very aggressive emission reduction targets, establishing a 20% reduction in greenhouse gases with respect to 1990 levels by 2020, and a 80% reduction and 100% clean electricity by 2050 (European Climate Foundation Roadmap 2050, 2010). In this context, a lot of distributed electricity generation is expected to be part of the future power systems. This requires additional investments in the network, including expensive and time-consuming reinforcements and modernization of the power system infrastructure. In addition, the variations in power generation and the interconnection may constitute barriers to achieving an optimal system for connecting distributed sources to the grid. Therefore, the adaptation of current grid planning to the new situation in order to facilitate the integration of Distributed Generation (DG) units is more affordable (Do, M.T., Francois, B. 2017).

However, the connection of large amounts of DG units to the power system introduces many technical and economic challenges. Reverse power flows, leading to line congestions and voltage problems, are likely to take place when the non-locally consumed power is injected to the high-voltage (HV) grid (Faghihi, F., Labeau, P.E. et al. 2014). As a consequence,Transmission System Operators (TSOs) will need to operate the grid by means of an Active Network Management (ANM) scheme in (almost) real-time control (Järventaustac, P. et al. 2009), by possibly curtailing their production in case of grid congestion in order to maintain grid security and reliability.

In general, power system reliability assessment focuses on the evaluation of some indicators (such as system average interruption duration index, interruption frequency index and expected energy not supplied) to reflect the ability to supply adequate electric service on the long term, while Probabilistic Risk Assessment (PRA) aims to estimate the probability or frequency of disturbances to system operation and their consequences, both of these two elements being the constituents of the risk (Rocchetta, R. et al. 2015). In this study, indicators related to the expected curtailment are envisioned, by propagating on a grid model the uncertainties on the loads and productions. As a direct Monte Carlo Sampling (MCS) turns out to be extremely time-consuming, an alternative approach was proposed, consisting in decoupling the probabilistic assessment of possibly challenging situations from the corresponding curtailment assessment using an Optimal Power Flow (OPF) (Labeau, P.E., Faghihi, F. et al. 2014).

This methodology rests on the concept of net balance (algebraic sum of all productions minus total load in a substation). The net balance state space associated to the grid under study is discre-

tized and the cases corresponding to this mesh are first systematically analyzed in order to identify unsafe cells with respect to possible grid congestion. Then, this database of unsafe cells is updated based on possible congestion in the MV/HV transformers. The curtailment of DG units is calculated, based on a targeted (systematic) importance sampling of only those detailed variants (all individual productions and loads) likely to lead to congestion, i.e. those corresponding to net balances belonging to unsafe cells. Risk indices can therefore be calculated efficiently. However, this approach only allows calculating the risk indices of interest for a global set of q DG units already connected to the grid. The present work aims to develop an accurate way of estimating the impact of a (q + 1)th DG unit to be connected to a node of the grid, on the previous value of the risk indices for the grid with q DG units. Resorting to correlated sampling, one computation will simultaneously bring the risk estimation for a reference case (with q + 1 DG units) and for both a first perturbed case (the previous situation with q DG units) and for a second perturbed case (corresponding to a different installed capacity of the (q + 1)th unit), for each season (associated to a given rating of the elements) and each grid topology considered (N and N-1 conditions).

The paper is organized as follows. Section 2 defines the risk indices and the mathematical theory supporting their estimation. Section 3 presents the application of this methodology to the grid. A test case with realistic power grid data is used to illustrate the approach. Results and analyses are given in Section 4 and conclusion is in Section 5.

2 RISK INDEX CACULATION

The classical definition of risk is adopted as the product of the probability of occurrence of the undesired event (i.e. contingency) and the related consequence (i.e. severity). To take into account all undesired events, the definition is extended by summing all contributions as:

$$RI = \sum_i P(E_i) \times f(E_i) \tag{1}$$

where $P(E_i)$ is the probability of occurrence of the undesired event E_i and $f(E_i)$ is the severity of the related consequence. In probabilistic risk assessment, contingency frequencies are used as probabilities and severity functions as consequences.

2.1 *Risk index in a grid with DG units*

In the context of power systems, a contingency is defined as the unexpected loss of one/more electric elements (e.g. line, cable, or transformer) that the power system is made of. Overloads, influenced by seasons, related with the feeders' thermal limits, and bus voltage magnitude, related with frequency and system balance, are both indicators of power system stress and correspond to the consequences for the risk calculation (P.A. Gooding et al. 2014). Thus, the risk index associated with one contingency can be expressed as follows for the whole power network:

$$RI(C_k/\chi) = \sum_{l=1}^{n_s} q_l \times P_l(C_k/\chi) \times f_l(C_k,\chi) \tag{2}$$

where χ is the set of all seasonal conditions (e.g. summer, inter-season, winter). C_k is the kth contingency (e.g. N/N-1 configuration). q_l is the probability of the lth season. $f_l(C_k,\chi)$ is the performance function under congestion for electric element i in the conditions of the lth season. $P_l(C_k/\chi)$ is the probability of occurrence of congestion k. n_s is the total number of seasonal conditions, n_c is the total number of configurations. Let p_k be the probability of configuration k. The risk index due to all contingencies is, then, obtained as:

$$RI = \sum_{k=1}^{n_c} \sum_{l=1}^{n_s} p_k \times q_l \times P_{kl}(C_k/\chi) \times f_{kl}(C_k,\chi) \tag{3}$$

Suppose that the power grid under study comprises n substations, to which wind farms (WFs) and/or combined heat and power (CHP) units are connected. The total load in substation i is denoted L_i while the total production of DG units connected to node i is denoted by P_i. The total risk under all contingencies in a grid can be expressed as:

$$RI = \sum_{k=1}^{n_c} \sum_{l=1}^{n_s} p_k q_l \iint f_{kl}(\bar{L},\bar{P}) \varphi_{kl}(\bar{L},\bar{P}) d\bar{L} d\bar{P} \tag{4}$$

where $\bar{P}$ and $\bar{L}$ are the vectors of DG units generation and load, respectively. $\varphi_{kl}(\bar{P},\bar{L})$ is the joint probability density function(pdf) of the variants in configuration k and season l. $f_{kl}(\bar{P},\bar{L})$ represents the severity function associated to the curtailment solving a possible congestion. For a given situation kl, eq. (4) can be simplified as:

$$RI_{kl} = \iint f_{kl}(\bar{L},\bar{P}) \varphi_{kl}(\bar{L},\bar{P}) d\bar{L} d\bar{P} \tag{5}$$

In order to identify more easily possible congestions, the concept of net balance NB is used again (see section 1). Suppose that n_i is the total number of DG units connected to node i. The production of DG unit j connected to node i is denoted P_{ij}. The risk index formula now writes:

$$NB_i = \sum_{j=1}^{n_i} P_{ij} - L_i \tag{6}$$

$$RI = \iint f(\overline{L}(\overline{NB},\overline{P}),\overline{P})\theta(\overline{NB})\varphi(\overline{L}(\overline{NB},\overline{P}),\overline{P})d\overline{NB}d\overline{P} \tag{7}$$

where $\theta(\overline{NB})$ is an indicator function: if $\overline{NB}$ causes agrid congestion, it is equal to 1; otherwise it is 0. This will divide the net balance space into two regions, a safe region where there is no congestion and an Unsafe Region (UR) where congestion can occur. The UR is delimited based on a discretization of the accessible region in the net balance space. Hence the UR is bounded by n_{cel} unsafe cells (UC). Therefore, Eq. (7) can be written as:

$$\int ...d\overline{NB} = \sum_{c=1}^{n_{cel}} \int ...d\overline{NB} \tag{8}$$

$$RI = \int_{UR} d\overline{NB} \int f(\overline{L}(\overline{NB},\overline{P}),\overline{P})\varphi(\overline{L}(\overline{NB},\overline{P}),\overline{P})d\overline{P} \tag{9}$$

$$NB_{i,\min}^{UC} \le P_{w,i} + P_{CHP,i} - L_i \le NB_{i,\max}^{UC} \tag{10}$$

$$RI = \sum_{UC} \int d\overline{NB} \int f(\overline{L}(\overline{NB},\overline{P}),\overline{P})\varphi(\overline{L}(\overline{NB},\overline{P}),\overline{P})d\overline{P} \tag{11}$$

where $P_{w,i}$ is the total production of WFs connected to substation i; $P_{CHP,i}$ is the total generation of CHP units at node i; L_i is the total load at substation i. $NB_{i,min}^{UC}$ and $NB_{i,max}^{UC}$ are the extreme values of net balance for unsafe cell UC in the dimension corresponding to node i. The loads at the different nodes are correlated, and so are the wind productions, but correlations between wind productions and loads are negligible. CHP productions are independent of the other variables. Therefore, our risk index is calculated as follows:

$$\varphi(\overline{P}_w,\overline{P}_{CHP},\overline{L}) = \varphi_w(\overline{P}_w)\cdot\varphi_L(\overline{L})\cdot\prod_{i=1}^{n}\varphi(\overline{P}_{CHP,i}) \tag{12}$$

$$RI = \sum_{UC} \iiint f(\overline{P}_W,\overline{P}_{CHP},\overline{\mathrm{L}})\cdot\varphi(\overline{P}_W,\overline{P}_{CHP},\overline{\mathrm{L}})d\overline{P}_W d\overline{P}_{CHP}d\overline{\mathrm{L}} \tag{13}$$

where $\varphi(\overline{P}_w,\overline{P}_{CHP},\overline{L})$ is the total joint pdf of all variants, consisting of the product of the joint pdf $\varphi(\overline{P}_w)$ of all wind productions, the individual pdf's $\varphi(\overline{P}_{CHP,i})$ of all CHP generationsand the joint pdf $\varphi(\overline{L})$ of the loads. The detailed variant sampling procedure will be illustrated in section 3.3.

2.2 *Risk index under perturbed cases*

Considering that a new DG unit of a specific type and installed capacity is likely to be connected to a substation, its impact on the previously assessed risk indices should be estimated. As already mentioned, the risk indices presented above correspond to a global set of q DG units connected to the grid. The UR related to (q + 1) DG units is an extension of that obtained with q units, in the dimension corresponding to the node where this new unit could be connected. Additionally, a different installed capacity for this new DG unit means changing this extension range, see Eq. (14) and Eq. (15). It is thus possible to resort to correlated sampling to assess more accurately the difference in the risk indices between the three situations, considering the case with (q + 1) units under a certain capacity as the reference situation (*ref*), and the case with q units as perturbed situation no. 1 (*per1*), and the case with a newly connected DG unit with a smaller installed capacity as perturbed situation no. 2 (*per2*).

$$NB_{\min_i}{}^{(ref)} = NB_{\min_i}{}^{(per1)} + \sum_{j=1}^{n_i} P_{add}\min_{ij} \tag{14}$$

$$NB_{\max_i}{}^{(ref)} = NB_{\max_i}{}^{(per1)} + \sum_{j=1}^{n_i} P_{add}\max_{ij} \tag{15}$$

Of course, the joint pdf's of the uncertain loads and generations are affected by the addition of the new DG unit. The risk indices will thus be estimated according to the previous procedure for the reference case, and those associated to the perturbed cases are derived from a correlated sampling procedure. We can then write for the risk index definitions and Monte Carlo estimates on N sampled variants:

$$RI^{(reference)} = \iiint_{UC} f(\overline{P}_W,\overline{P}_{CHP},\overline{\mathrm{L}})\cdot\varphi^{ref}(\overline{P}_w,\overline{P}_{CHP},\overline{L}) \cdot d\overline{P}_w d\overline{P}_{CHP}d\overline{L} \tag{16}$$

$$RI^{(perturbed)} = \iiint_{UC} f(\overline{P}_W,\overline{P}_{CHP},\overline{\mathrm{L}})\cdot\frac{\varphi^{per}(\overline{P}_w,\overline{P}_{CHP},\overline{L})}{\varphi^{ref}(\overline{P}_w,\overline{P}_{CHP},\overline{L})} \cdot\varphi^{ref}(\overline{P}_w,\overline{P}_{CHP},\overline{L})d\overline{P}_w d\overline{P}_{CHP}d\overline{L} \tag{17}$$

$$\tilde{RI}^{(reference)} = \frac{1}{N}\sum_{j=1}^{N}[\sum_{UC} f^{ref}(\overline{P}_{W,i},\overline{P}_{CHP,i},\overline{\mathrm{L}}_i)\cdot\prod_{i=1}^{n}\varphi^{ref}(\overline{P}_{CHP,i})] \tag{18}$$

$$\tilde{RI}^{(perturbed)} = \frac{1}{N}\sum_{j=1}^{N}[\frac{\varphi_w^{per}(\overline{P}_w)}{\varphi_w^{ref}(\overline{P}_w)}\cdot\frac{\varphi_L^{per}(\overline{L})}{\varphi_L^{ref}(\overline{L})}\cdot\frac{\prod_{i=1}^{n}\varphi^{per}(\overline{P}_{CHP,i})}{\prod_{i=1}^{n}\varphi^{ref}(\overline{P}_{CHP,i})}\cdot \sum_{UC} f^{ref}(\overline{P}_{W,i},\overline{P}_{CHP,i},\overline{\mathrm{L}}_i)\cdot\prod_{i=1}^{n}\varphi^{ref}(\overline{P}_{CHP,i})] \tag{19}$$

Therefore, $\frac{\varphi^{per}(\bar{P}_w,\bar{P}_{CHP},\bar{L})}{\varphi^{ref}(\bar{P}_w,\bar{P}_{CHP},\bar{L})}$ is the correction factor ('statistical weight') of the various contributions tothe risk indices of the reference situation,allowing obtaining in the same simulation an estimate of the risk indices inthe perturbed situations. In fact, the correction factor calculation is specially defined for two scenarios:

a. the added DG unit is WF and the joint pdf of WFs, $\varphi_w(\bar{P}_w)$, has been changed, the correction factor is simplified by $\frac{\varphi^{per}(\bar{P}_w)}{\varphi^{ref}(\bar{P}_w)}$;
b. the added DG unit is CHP and the corresponding correction factor will be represented by $\frac{\varphi^{per}(\bar{P}_{CHP})}{\varphi^{ref}(\bar{P}_{CHP})}$.

3 ASSESSMENT METHODOLOGY

According to Eq. (13), the risk index is computed by the probability of the load-generation patterns leading to a specific congestion in the grid, curtailment power of each DG unit and the correction factor of reference variables. Therefore, the main structure of this practical methodology consists of three parts: curtailment evaluation, probabilistic assessment and correction factor estimation, shown in Figure 1. The details of the risk calculation process is introduced in the following paragraphs.

3.1 *Preprocess*

The preprocess stage, structuring the variants sampling, aims to partition the net balance space into safe and unsafe cells. SCADA system performs the network monitoring, which collects every 15 minutes multiple low-frequency signals including the existing generations and the loads. Based on this data collection, the net balance domain can be determined. Variants within the net balance domain can either lead to an acceptable solution of the load flow calculations, applied to both the N situation and all the N-1 ones, or not. The net balance variants can be grouped based on their similarity in making congestion on the grid. As shown in Figure 2, a security boundary divides the net balance space into the corresponding safe and unsafe regions. Adding a DG unit capacity to node 1 corresponds to extending the net balance domain by the yellow area, without affecting the security boundary.

In order to obtain an approximation of this security boundary between the safe and unsafe regions of state space, a mesh is defined on the NB domain, creating cells. If all the corners of a cell are

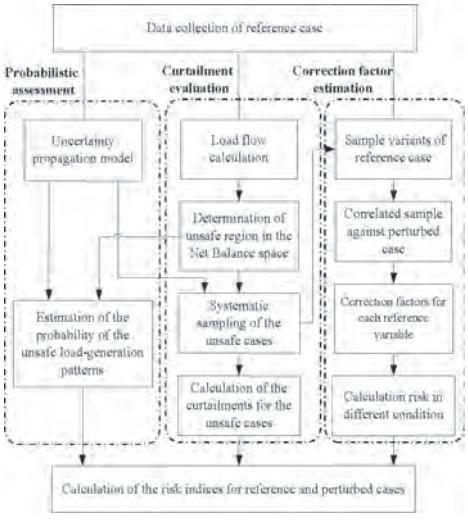

Figure 1. Framework flowchart of the proposed methodology.

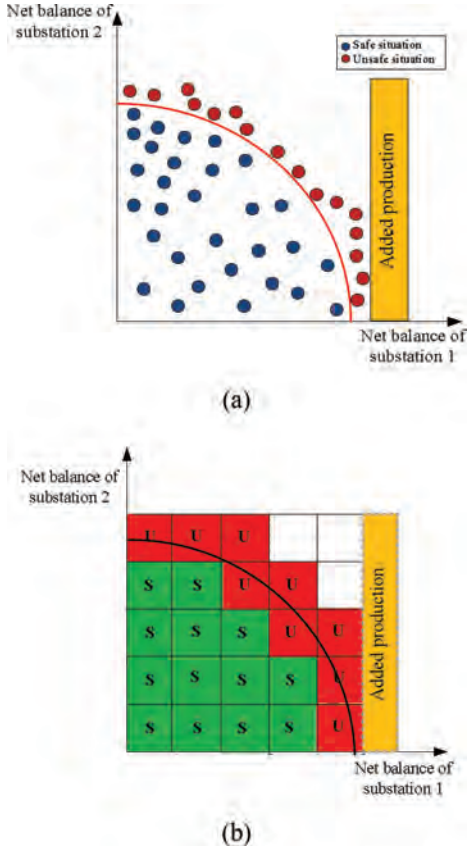

Figure 2. Preprocess:(a) safe and unsafe regions in the net balance space; (b) discretization of the net balance space in safe and unsafe cells.

safe (i.e. if they cause no congestion on the grid), then this cell is considered as a safe cell; otherwise it is considered as an unsafe cell, see Figure 2.

3.2 *The framework of curtailment*

Assessing the curtailment of the different DG units is not an easy task. For such a problem, Monte Carlo algorithm is an appropriate solution. Through Monte Carlo Sampling inside the unsafe cells, the input sample will be produced and the probabilistic modeling will be built.

At this stage, the curtailment calculation of each DG unit considers the curtailment cost of each specific DG type as well as its type of access. The Principles of Access (PoA) correspond generally to considering that the last connected producer is the first one to be curtailed. An OPF tool is applied to the sampled variants, both in N and N-1 situations, in order to calculate the (possible) curtailments of all DG units via the objective function. In this research, the objective function is the minimization of the total cost of curtailment.

In parallel with the curtailment analysis, the Capacity Factors (CF) and utilization factors (UF) are computed for each DG unit. The UF is defined as the ratio of the actual energy (after the curtailment) that can be produced in one year over the corresponding theoretical maximum at peak value, while CF is the ratio with no curtailment. Both of them are obvious indicators of the economic performance under reference and perturbed cases that a producer expect.

3.3 *Probabilistic assessment*

The risk analysis of congestion/curtailment is only associated to these unsafe cells, and the variants corresponding to the safe cells have no contribution to the risk indices. Thus, the systematic MCS based on a probabilistic modeling using historical data is performed by focusing on the unsafe cells. The stochastic input variables, i.e. distributed generation and loads, are modeled by their joint pdf's.

For WFs, the pdf that has been most used to represent the wind speed distribution is the Weibull law, which is mathematically described as:

$$f(v)=\frac{k}{c}\left(\frac{v}{c}\right)^{k-1}\times\exp\left[-\left(\frac{v}{c}\right)^{k}\right] \tag{20}$$

where v is the wind speed; k and c are the shape and scale parameters, respectively. An example is illustrated in Figure 3. Based on these marginal distributions, their joint pdf is constructed thanks to a Gaussian Copula. Sampled wind speeds are converted to electric power using the power curve.

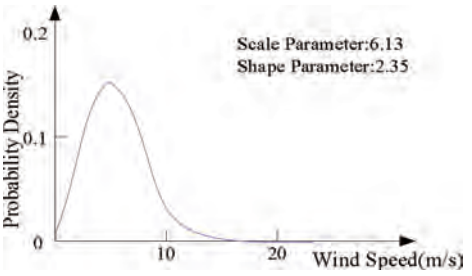

Figure 3. Wind speed marginal distribution.

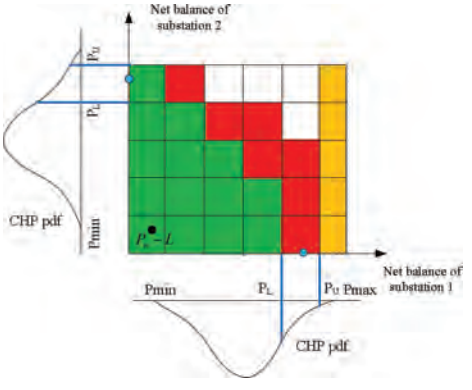

Figure 4. CHP sampling from the truncated pdf.

The load modelis obtained bynormalizing the historical load data of each year to the maximum consumption of the corresponding substation in that year. These normalized data implicitly containsa more informative consumption pattern in the different substations. A copula is used as well to define the joint pdf.

For the CHP units, their productions are independent and historical data are fit to obtain generation profiles. In the sampling procedure, after sampling wind and load from the corresponding joint pdf's, significant values of CHP productions correspond to values likely to make the net balance fall in an unsafe cell. In Figure 4, the net balance limited to wind and load, i.e. $\left(\Sigma P_{w,i}-L_i\right)$, is presented. For each unsafe cell UC, a compatible value of the CHP production at each node i is sampled from the corresponding truncated pdf in this UC, if possible, which is then given by:

$$\tilde{\varphi}_i^{UC}(P_{CHP,i})=\varphi_i(P_{CHP,i})/P_{CU,i} \tag{21}$$

where $\tilde{\varphi}_i^{UC}\left(P_{CHP,i}\right)$ is the truncated pdf of the CHP generation inside an unsafe cell UCat the ith substation,while $\varphi_i\left(P_{CHP,i}\right)$ represents the joint pdf of the CHP generation at node$i$. $P_{CU,i}$ is probability

of having the CHP production at node *i*in the right range.

The expression of the risk index for the perturbed case is then expressed as:

$$\tilde{RI} = \frac{1}{N}\sum_{j=1}^{N}\left[\frac{\varphi_w^q(\bar{P}_w)}{\varphi_w^{q+1}(\bar{P}_w)}\cdot\frac{\varphi_L^q(\bar{L})}{\varphi_L^{q+1}(\bar{L})}\cdot\frac{\prod_{i=1}^{n}\varphi^q(\bar{P}_{CHP,i})}{\prod_{i=1}^{n}\varphi^{q+1}(\bar{P}_{CHP,i})}\right. \quad (22)$$
$$\left.\sum_{UC} f(\bar{P}_{W,i},\bar{P}_{CHP,i}^{UC1},\bar{L}_i)\cdot\prod_{i=1}^{n}P_{CU,i}^{UC}(P_{wj,i},L_{ji})\right]$$

3.4 *Correction factor calculation*

In correlated sampling, the correction factor is the ratio between the probability of the perturbed variant and that of the reference case in the corresponding unsafe cells. The calculation of this factor uses the variants from the reference probabilistic assessment, see Figure 5. In the meantime, a correlated sampling, expressed in these 3 steps, is adopted so as to decrease the curtailment computation time for the perturbed cases.

a. Identify the perturbed pdf's and the type of the added DG unit (WF or CHP);
b. Sample variant from the joint pdf of the reference case;
c. Calculate the corresponding correction factors for each reference variable.

As shown in Figure 5, calculate the correction factor from the reference situation to the case of a new WF with different installed capacity connected to a grid. It will be necessary to evaluate the Weibull parameters of this perturbed case's new WF and filter the reference data which are more than this perturbed case's newly WF installed capacity. While for the case of a new CHP unit accepted to the grid, since CHP sample is to a large extent relied on the joint pdf's of wind-load pattern data and itself historical data, it is unavoidable to firstly execute reference wind-load correlated sampling so as to get perturbed CHP correlated sampling.

However, to apply efficiently the correlated sampling, the correlated sample size must be large enough.

3.5 *Risk estimation*

Finally, the risk indices for reference and perturbed cases can be estimated by averaging the product of the curtailment magnitude and the corresponding correction factor which is linked to the probability of the corresponding unsafe cells.

The weighting factor in each unsafe cell actually means the corresponding probability and is the ratio of the number of CHP samples taken from its truncated pdf inside the cell divided by the total number of random samples coming from the CHP pdf. Inevitably, the weighting factor calculation in each situation (e.g. season condition, N/N-1 contingency) needs to be taken into account.

A case study on a test power grid using this methodology will be treated in the following section.

4 TEST RESULTS AND DISCUSSION

In this section, the effectiveness of this practical methodology is illustrated on a test power grid. As

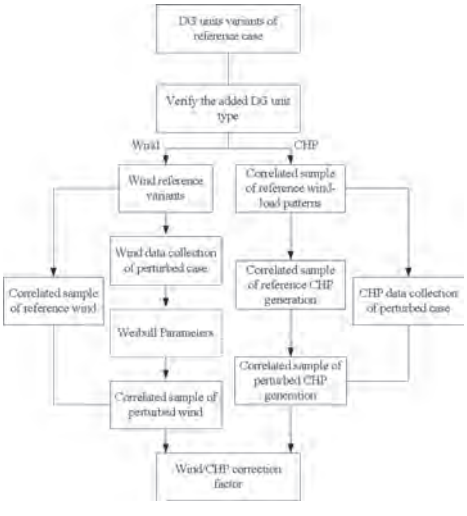

Figure 5. Flowchart of correction factor calculation.

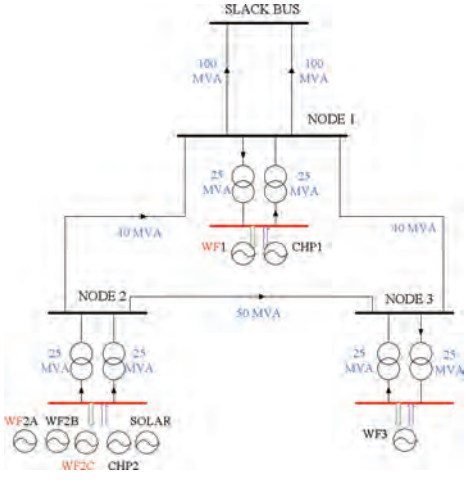

Figure 6. Test grid.

shown in Figure 6, the reference case corresponds to connecting a new WF to NODE 2. The grid ad is composed of 4 wind farms (57 MW), 2 CHP units (15 MW), 1 PV unit (1 MW) and a new connected wind farm (20 MW). The transmission network is operated at two voltage levels and comprises 4 high-voltage substations and 11 transmission lines (including transformers) connected to the MV side. The collection data has been conducted for this power grid during January 1,2015 to December 31,2015 every 15 min.

As for the perturbed case no.1, there are 7 DG units (without accounting for the added WF) connected to the substations in the power grid, while perturbed case no.2 corresponds to a new 10MW installed capacity WF accepted at NODE2. Assume that all DG units are connected to the MV side, the risk indices are estimated for the N and N-1 configurations (i.e. out of the HV/MV transformer at node 2), and for the different seasons leading to different line/transformer ratings. Due to the correlated sampling method used, the risk index for both the reference and perturbed cases are simultaneously obtained in one computation.

Figure 7 shows the Wind2A conditional risk under different cases. The probability of the seasons

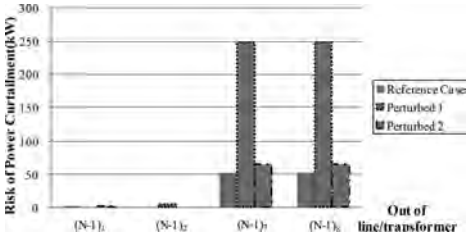

Figure 7. Wind2 A conditional risk in Summer.

and N/N-1 configurations are not considered. The solid rectangle represents the conditional risk in the reference situation, while the point rectangle and dotted line rectangle corresponds to the per1 and per2 cases, respectively. The detailed values are provided in Table 1. It obviously shows that the conditional risk of Wind2 A power curtailment in the reference case is smaller due to the addition of a new WF to node2. However, if the system lacks the transformers connected to NODE2, it will need more curtailment than for the other N-1 cases. The power curtailment of the newly connected WF in NODE2 will increase with a more adding installed capacity. And owing to the seasons' influence of wind energy, curtailment will decrease in winter.

In order to integrate the different energy curtailments under different N-0/N-1 rules, multiply the electrical elements rating and get the total risk of energy curtailment, see Figure 8. It clearly describesthe influence of different installed capacity of adding a new DG unit. The larger capacity case will produce more curtailment for this new DG unit but for the others DG units in the NODE2 will decrease. Therefore, it seems that the reference case will need more total energy curtailment.

As shown in Table 2, the utilization factors validates, there is a decrease of first and second curtailed producer under both the reference and perturbed 2 cases. Especially for the reference case, the impact is very visible, both capacity and utilization factors of Wind2A fall down from the perturbed 1 case where there is no new DG unit connected. However, the perturbed case 2 is able to have a higher value of capacity and utilization factors than reference case since the new added WF installed capacity is more suitable to NODE2.

Table 1. Conditional risk of different cases (in kW).

5 CONCLUSION

The large-scale use of distributed electricity generation is possibly associated with increasing grid congestion; hence, Distributed Generation (DG) curtailment is envisioned to solve those congestions in affected power systems. By resorting to curtailment as part of an Active Network Management (ANM) scheme under real-time supervision/control of the DG units, more distributed generation can be accommodated in a distribution grid For the purpose of retaining the power system secure and adapting the grid code, any possible new connection is able to accept a certain risk level in long-term planning.

In the work presented in this paper, an efficient methodology for probabilistic assessment of the risk of connecting a new DG unit to an existing grid, using an ANM scheme for a defined season and a configuration of the grid (N and N-1 conditions), is proposed. Furthermore, the use of correlated sampling allows significantly reducing the computation time so that one computation is able to simultaneously provide the risk estimation for both reference case and perturbed cases in order to choose a more suitable installed capacity DG unit. The concept of net balance in the preprocess stage is on one side to account for the dimensions of the problem (i.e. number of DG units and substations), and on the other side, it allows for a rather quick identification of the unsafe region by performing a set of load flow calculations on the corners of the cells in the constructed mesh. A probabilistic wind model has been implemented, resorting to a Gaussian Copula to build the joint pdf of all WFs at the different nodes of the grid; in the meantime, the compatible CHP variants inside each unsafe cell were produced. Thus, the variants belonging to an unsafe cell acted as input variables of the optimal power flow (severity function), based on the curtailment cost, for congestion/curtailment calculations.

Last but not least, the advantages of this practical methodology lie on fast estimating the impact of the possible acceptance of new DG units with different installed capacities into an existing grid, what provides foundation for the future grid planning and its reinforcements.

ABSTRACT: In recent years, there has been a growing interest in nuclear fusion as energy source due to its several principle advantages over fission, which include reduced radioactivity in operation and in waste, large fuel supplies, and increased safety. The most promising configuration of a nuclear fusion system is currently the tokamak, the largest of which, called the largest of which (ITER), is under construction in Cadarache, France. The safety of nuclear fusion systems has to be proved and verified by a systematic analysis of the system behavior under normal transient and accidental conditions. One challenge to the analysis is that the operation of tokamaks presents complex dynamic features as it is based on the transformer principle: in particular, they employ superconducting magnets, a subset of which operates with variable current to generate one of the components of the magnetic field needed to confine the plasma in the chamber where nuclear fusion reactions occur. In the present paper, we apply techniques of Integrated Deterministic and Probabilistic Safety Assessment (IDPSA), which combine phenomenological models of system dynamics with stochastic process models, taking for the first time as reference system the cooling circuit of a superconducting magnet for fusion applications, subject to a Loss-Of-Flow-Accident (LOFA).

1 INTRODUCTION

The need of satisfying a growing demand of energy, while protecting the environment and reducing the dependence on fossil fuels, has recently increased the interest in the use of nuclear fusion as energy source. Nuclear fusion presents several advantages over fission, which include reduced radioactivity in operation and in waste, large fuel supplies, and increased safety (EC, 2004).

The most promising configuration for electrical energy production from fusion is the tokamak, the largest of which (ITER) is now under construction at Cadarache (France), under an international collaboration between seven member entities (i.e., China, the European Union, India, Japan, Korea, Russia and the United States) (ITER, 2014).

Nuclear fusion reactors will use superconducting (SC) magnets to generate a powerful magnetic field needed to confine the plasma in the shape of a torus, where D-T fusion reactions occur at a temperature of the order of 10^8 K. On the other hand, all the SC coils need to be cooled at cryogenic temperatures in order to avoid the quench of the magnets (i.e., the loss of their superconducting state) during operation: for example, the ITER SC coils are cooled by supercritical helium (SHe) at a pressure of 0.5–0.6 MPa and temperature of about 4.5K (ITER, 2014). Dedicated cryogenic cooling loops remove the heat load from the magnets, releasing it to saturated liquid helium (LHe) pools, acting as thermal buffers in the transfer of the load to the refrigerator (Hoa et al., 2012; Zanino et al., 2013).

The safety of nuclear fusion systems has to be proved and verified by a systematic analysis of the system behavior under normal transient and accidental conditions (Taylor and Cortes, 2014; Rivas et al., 2015; Perrault, 2016; Wu et al., 2016), for two main reasons. First, the presence of radioactive sources (e.g., tritium and materials activated by the neutrons produced by the fusion reactions)

imposes a careful study to avoid the contamination of the workers, the public and the environment (Taylor, 2015; Taylor et al., 2017). Second, in view of the cost of the SC magnet system (Mitchell et al., 2008 and 2012), its protection and integrity should be guaranteed (ITER, 2014; Savoldi Richard et al., 2014; Savoldi et al., 2017 and 2018).

One challenge to the related safety analyses is that the operation of tokamaks presents *complex dynamic features*, as it is based on the transformer principle. In particular, they employ SC magnets, a subset of which operates with *variable* current to generate one of the components of the magnetic field needed to confine the plasma in the chamber where nuclear fusion reactions occur (Zohm, 2014). The *order* and *timing* of failure events occurring along an accident scenario, the *magnitude* of failures and the *values* of the process variables at the time of event occurrence are critical in determining the evolution of the system response (Aldemir, 2013; Kirschenbaum et al., 2009; Zio and Di Maio, 2009, 2010; Zio et al., 2010; Zio, 2014; Turati et al., 2017 and 2018).

To perform the safety assessments we resort to the Integrated Deterministic and Probabilistic Safety Assessment (IDPSA) framework (Di Maio et al., 2016) to combine (deterministic) phenomenological models of system dynamics with (probabilistic) stochastic process models. The IDPSA methodology is here used for the first time to analyze the response—to abnormal transient conditions—of the cooling system of a SC magnet, namely a *single* ITER Central Solenoid Module (CSM) in a reference (cold) *test facility* (Spitzer et al., 2015). In particular, a Loss-Of-Flow Accident (LOFA) is considered as reference abnormal scenario. The 4C code (Savoldi Richard et al., 2010) is employed for the (deterministic) simulation of the system behavior. Multiple Value Logic (MVL) is adopted for the description of the components failures (Garibba et al., 1985). The MVL allows describing that the components can fail at any time along the scenario, with *different* (discrete) *magnitudes* (Di Maio et al., 2015; Zio, 2013).

The paper is organized as follows. In Section 2, the single ITER CSM in the cold test facility is presented together with the corresponding simulator. In Section 3, the different regimes of system operation are described. The components failures causing the deviations from the nominal CSM conditions in the test facility are described in detail in Section 4, together with the use of MVL for generating accident scenarios. In Section 5, the results obtained are illustrated and analyzed. Finally, conclusions are drawn and summarized in Section 6.

2 DESCRIPTION OF THE SYSTEM AND PRESENTATION OF THE SIMULATOR

The ITER CS allows inducing the current in the plasma and maintaining it during long plasma pulses. It is composed by 6 CS modules (CSM) stacked in the vertical direction; each of them is being manufactured and will be independently tested. Each module is composed by 7 pancake-wound conductors, namely 6 hexa-pancakes and 1 quad-pancake. Each pancake is cooled in parallel, resulting in 40 parallel cooling channels per module, each featuring 14 turns. The He inlets are located at the coil bore, while the outlets are at the outer side of the magnet. All the pancakes of each module are electrically connected in series through suitable joints (Libeyre et al. 2015).

The main components of a reference facility for the CSMs *cold tests* (which is the subject of the present analysis) are the He refrigerator, producing the supercritical He (SHe) at 4.5 K, which is used to cool the magnets during the tests, and the test chamber where the module will be put into a cryostat. Besides these two main components, several manifolds, pipelines, heat exchangers (HXs) control valves (CV) of the cryoplant and a liquid He (LHe) thermal buffer will connect the refrigerator to the coil, and a dedicated power supply system will provide a current up to ~50 kA.

From the hydraulic point of view, the analysis reported here is focused on the loop cooling a single CSM. This closed loop, much simpler than that foreseen in ITER for the cooling of the CS, provides SHe at ~4.5 K to the inlets of the 40 hydraulic paths, collects the (warmer) SHe at their outlets and by means of a cold circulator drives it to two HXs, where the heat removed from the coil is transferred to a LHe buffer. The LHe evaporated in the buffer is, then, extracted and cooled down by the refrigerator.

The 4C thermal hydraulic code (Savoldi Richard et al. 2010) is used here to model both the coil and its SHe cooling loop. Figure 1 shows a scheme of the loop model. The SHe at the outlet of the cold circulator is cooled in HX1 to remove the heat generated by the compression process. Then, it is driven to the coil inlets through CV1 (fully open in normal operation) and a supply cryoline (cryoline 1). At the coil outlet, the SHe reaches HX2 through a return cryoline (cryoline 2) and CV2 (fully open in normal operation). The main input parameters of each component model are reported in Table 1. For the details of the model of each component, please refer to (Bonifetto et al. 2012) and (Zanino et al. 2013). A realistic characteristic of the cold circulator has been implemented in the circuit model, as described in detail in (Zanino et al. 2013) for another system.

With reference to a Loss-Of-Flow Accident (LOFA) (scenario of interest in the present paper, see the Introduction), the strategy adopted by the control system is assumed here to be similar to that adopted in ITER and described in (Savoldi et al., 2018) for the Toroidal Field (TF) coils. In particular, in order to protect the CS, a *controlled discharge* of the CS circuits is carried out in ITER, consisting of a *current ramp down* of about 30s (ITER_D_K7G8GN v2.1, 2014), driven by the plasma control system. Obviously, the current variation causes AC losses, which induce a (possibly significant) *heat deposition* in the conductor. In the reference system at hand, a similar fast controller discharge is assumed to be taken by the control system in case of LOFA. As far as the cryoplant is concerned, the basic circuit control in case of a LOFA includes the isolation of the circulator from the coil by means of the full closure of both CVs and the opening of the by-pass valve (BV) to equalize the pressure at the circulator suction and discharge (preventing any damage to the pump itself as fail-safe condition). In the present work, this action is taken (by controller C1 in Figure 1), when a SHe mass flow rate below 10% of the nominal value is measured both at the inlet and at the outlet of the CSM, after a validation time of 1s (Savoldi et al., 2018). Notice that the "nominal value" of the mass flow rate here considered corresponds to the nominal CSM conditions *during a test* in the reference facility, *not* to the "future" normal operating conditions in ITER. In case of excessive pressurization at the coil boundaries, two Safety Valves (SV) at the CSM inlet and outlet open, driven by the PID controller C2 (gain = 1 $e^{-7}Pa^{-1}$, integration time = 0.2 s, derivation time = 1 s), with set-point 1.8 MPa (Savoldi Richard et al., 2012); the controller parameters and set point have been assumed here equal to those in (Savoldi et al., 2018). When the SV opens, the He is released in a Quench Tank (QT) by means of suitable Quench Lines (QL).

The detailed CSM model solves the 1D transient mass, momentum and energy conservation equations, computing the temperature, pressure and velocity distribution, in each of the two regions (cable bundle and central, low impedance channel) of each pancake, as described in detail in (Zanino et al. 1995). Then, the inter-turn and inter-pancake thermal coupling between adjacent turns and pancakes, respectively, is computed considering the insulation as a thermal resistance to evaluate the heat transfer between neighboring conductors (Savoldi et al. 2000).

3 SYSTEM OPERATION REGIMES

During the tests, the facility and the CSM will be operated in different regimes, which can be briefly described as:

a. Cold mode standby operation (e.g. during night or weekend), when the CSM is not charged and kept at nominal ~4.5 K; no dangerous transients are expected from a LOFA in these conditions, so this regime is not analyzed here.
b. Cold mode experimental operation (i.e. during tests), when the CSM is charged at full or partial current (which is the case analyzed in the present paper). In this regime, an accidental temperature increase up to (or above) the so-called *current sharing temperature* T_{CS} may lead to a *quench*, i.e., to a loss of the superconducting state (notice that T_{CS} is defined as the temperature, above which the current starts to flow also in the Cu matrix of the SC strands and in the pure Cu strands, developing a non-zero voltage and causing Joule heat generation in the cable). The consequent fast local Joule heat deposition can induce thermal stresses that may seriously

damage the conductor, causing a degradation of its performance or, in the worst case, the loss of integrity of the conductor. The presence of a *normal* (non-SC) zone and, to some extent, variations in the conductor temperature above T_{CS} can be detected by measuring the voltage at the extremities of the each pancake.

The coil inlet temperature is here taken as the nominal one. The objective of the analysis is to study the response of the system described above (in the operating mode b.) to abnormal conditions, e.g., to accident scenarios driven by stochastic components failures (see the following Section 4). In particular, our interest is mainly devoted to LOFAs (see the previous Section 2). Actually, in absence of helium coolant flow, the heat deposition induced by AC losses (caused by the controlled discharge of the CS circuits) may a priori lead to a dangerous increase in the conductor temperature (with possible quench of the magnet), even in a cold test configuration like the one analyzed here. Two variables are monitored during each transient as "critical indicators" of the state of the system: the cooling helium pressure at the inlet and outlet of the CS magnet and the voltage measured at the coil extremities. Actually, if the pressure in the conductor exceeds 25 MPa, the conductors can be damaged (ITER_D_2NBKXY v1.2, 2009); also, if the voltage on a single pancake goes above 0.1 V for more than 1s, it means that the conductor temperature has exceeded the current sharing temperature T_{CS}, i.e., that the superconducting state of the magnet is lost.

4 FAILURE SCENARIOS GENERATION BY MULTIPLE VALUED LOGIC

The following component failures can occur at random times in the time horizon [0,600] seconds:

1. the Centrifugal Pump (CP) reduces exponentially the rotational speed, directly affecting the mass flow rate that can be reduced to i) 75%; ii) 50%; iii) 25%; iv) 0% of the nominal mass flow rate, i.e. in the last case down to a total loss of pumping capacity.
2. the two Control Valves (CVs) can fail in three different modes: i) stuck (open) at the nominal position; ii) stuck closed at 50% of the nominal position; iii) stuck totally closed.
3. the By-pass Valve (BV) can fail in three different modes: i) stuck (closed) in nominal position; ii) stuck open at 50% of the flow area; iii) stuck totally open.
4. the two Safety Valves (SVs) can fail in three different modes: i) stuck (closed) in nominal position; ii) stuck open at 50% of the flow area; iii) stuck totally open.

It can be shown that the system reaches a steady state condition in ~100 seconds, irrespectively of the failure occurred. Therefore, we set a mission time $T_M = 700$ s.

A Multiple Value Logic (MVL) scheme has been adopted to generate the accidental scenarios, considering the stochastic (discrete) time interval (t) of occurrence of component failures, their (discrete) magnitude (m) and the order (ord) of events along the sequence. The random realizations of the discretized time and magnitudes values are included into a sequence vector that represents a generated scenario to be simulated, [m_{cp}, t_{cp}, ord_{cp}, m_{cv1}, t_{cv1}, ord_{cv1}, m_{cv2}, t_{cv2}, ord_{cv2}, m_{bv}, t_{bv}, ord_{bv}, m_{sv1}, t_{sv1}, ord_{sv1}, ms_{v2}, ts_{v2}, ord_{sv2}] (Di Maio et al., 2017). The following values are considered:

- time (t) discretization: we use the label $t = 1, 2, 3, 4, 5$ and 6, for failures occurring in the intervals [0, 100] s, [101, 200] s, [201, 300] s, [301, 400] s, [401, 500] s, [501, 600] s, respectively; $t = 0$ means that the component does *not* fail within the T_M of the scenario and the value "NaN" is used to identify the respective (non-)failure order (ord) in the sequence vector of the accidental scenario. Notice that, even if the failure order (ord) may seem redundant in the MVL representation, it is actually used to discriminate between scenarios where different components fail in the *same* time *interval t*. Also, it is worth highlighting that, once a time *interval t* is identified by MVL, the *actual* time of component failure (used in the deterministic simulation of the accident scenario) is randomly sampled within the interval.
- Magnitude (m) discretization:
  - the CP magnitude is indicated with the label $m_{cp} = 1, 2, 3$ or 4 for failure states corresponding to an exponential decrease of the rotational speed down to 75%, 50%, 25% and 0% of the nominal value, respectively; if $m_{cp} = 0$, the component does not fail;
  - for each CV, the magnitude is indicated by the label $m_{cv} = 1, 2$ or 3 if the component stays stuck (open) at the nominal position, stuck closed at 50% of the nominal position and stuck closed, respectively; if $m_{cv} = 0$, the component works correctly;
  - the BV magnitude is indicated by the label $m_{bv} = 1, 2$ or 3 if the component stays stuck in (closed) nominal position, stuck open at 50% of nominal flow area and stuck totally open, respectively; if $m_{bv} = 0$, the component does not fail;
  - for each SV, the magnitude is indicated by the label $m_{sv} = 1, 2$ or 3 if the component stays stuck (closed) in nominal position, stuck open at 50% of nominal flow area and stuck totally open, respectively; if $m_{sv} = 0$, the component works in that scenario.

As an example, the accidental sequence vector [4, 6, 5, 0, 0, NaN, 1, 2, 1, 2, 4, 3, 2, 5, 4, 1, 3, 2] represents a scenario where: the CP fails completely to 0% of the nominal value at a time in [501,600] s (fifth event occurring along the sequence); the CV1 correctly works throughout T_M; the CV2 fails stuck (open) at the nominal position at a time in [101,200] s (first event occurring along the sequence); the BV fails stuck open at 50% of the nominal flow area (third event along the sequence) at a time in [301,400] s; the SV1 fails stuck open at 50% of the flow area at a time in [401,500] s (fourth event along the sequence); finally, the SV2 fails stuck (closed) in nominal position at a time in [201,300] s (second event along the sequence).

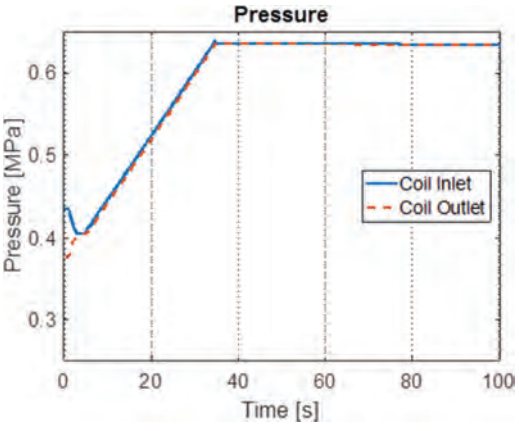

Figure 2. Pressure at the inlet and outlet of the coil (following the CP failure at 0% of the nominal mass flow rate).

5 RESULTS

In principle, the MVL accidental scenario generation procedure described above would entail the creation of 4×10^8 scenarios. We report here only the "bounding analysis" of the system response, analyzing a *reduced set* of MVL sequences, which are *expected* to be the *most challenging* for the system safety. Notice that *none* of the selected accident sequences turns out to be *critical* for the CS module integrity. In particular, the voltage at the extremities of the SC coil will remain far below the threshold of 0.1V (i.e., the temperature of the conductor does not exceed the T_{CS}): this means that the magnet maintains its superconductive properties.

Let us consider the MVL sequence [4, 1, 1, 0, 0, NaN, 0, 0, NaN, 0, 0, NaN, 0, 0, NaN, 0, 0, NaN], which entails the pump to fail according to an exponential decrease of the rotational speed till complete stop; the other components work correctly during the scenario. This sequence has been chosen because in this system no CP redundancies are designed and, therefore, a CP unavailability might lead the CSM to critical conditions. Notice that when the loss of flow is detected (Section 2), in order to protect the CS, a controlled discharge of its electrical circuits is carried out, consisting of a current ramp down to 0 in about 30s. A significant heat is, thus, generated in the conductors, due to the AC losses produced by the fast current variation. Figure 2 shows that when the LOFA occurs, the pressure of the coil both at the inlet (solid line on Figure 2) and outlet (dashed line) increases up to 50% with respect to the nominal value, without however exceeding the pressure safety threshold of 1.8 MPa.

Two additional MVL that might deserve attention are [0, 0, NaN, 0, 0, NaN, 0, 0, NaN, 0, 0, NaN, 3, 1, 1, 0, 0, NaN] and [0, 0, NaN, 0, 0, NaN, 0, 0, NaN, 0, 0, NaN, 0, 0, NaN, 3, 1, 1]. These sequences entail the failure of safety valves SV1 and SV2, located respectively at the inlet and outlet of the coil, that have the function of keeping the pressure of the system below the critical value of 1.8 MPa in accidental situations. In normal operation, the pressure at the inlet of SV1 is equal to 0.433 MPa and at the outlet is 0.42 MPa, corresponding to the assumed pressure of the quench tank. If component SV1 fails, helium starts flowing in the quench line leading to the reduction of the pressure at the inlet of the coil (solid line in Figure 3): both the inlet and the outlet pressure of the coil decrease, the mass flow rate remains at its nominal value and a new steady state situation is reached with large safety margin with respect to the pressure safety threshold 1.8 MPa.

Sequence [0, 0, NaN, 0, 0, NaN, 0, 0, NaN, 0, 0, NaN, 0, 0, NaN, 3, 1, 1], instead, entails SV2 failure. In Figure 4, it can be seen that the pressure at the inlet of the valve is equal to 0.376 MPa (solid line) whereas at the outlet (dashed line) it is equal to the assumed pressure of the quench tank (i.e., 0.42 MPa). When valve SV2 opens, the pressure at the outlet of the coil increases up to 0.42 MPa. Since the CP is working correctly, the nominal pressure drop between the inlet and the outlet of the component is maintained. As a consequence, the increase in the outlet coil pressure is followed by an increase in the inlet coil pressure. Also in this case, a new steady state condition is reached with a large safety margin with respect to the pressure safety threshold of 1.8 MPa.

The relevance of the dynamic features is witnessed by the outcome of sequence [0, 0, NaN, 0, 0, NaN, 0, 0, NaN, 0, 0, NaN, 3, 1, 1, 3, 1, 2], whose evolution is shown in Figure 5. The first failure is represented by the SV1 stuck open. This causes a slight decrease in the pressure at the inlet

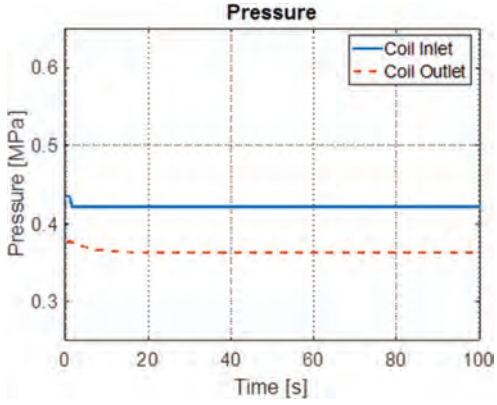

Figure 3. Pressure at the inlet and outlet of the coil following SV1 failure (stuck totally open).

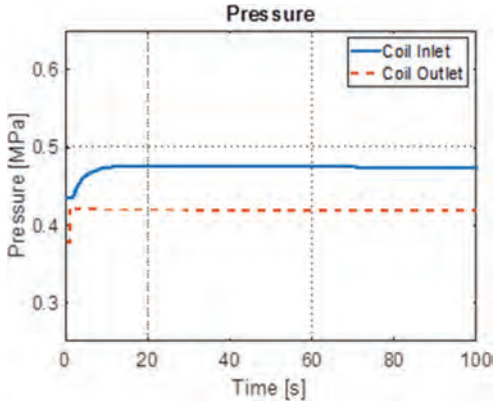

Figure 4. Pressure at the inlet and outlet of the coil following SV2 failure (stuck totally open).

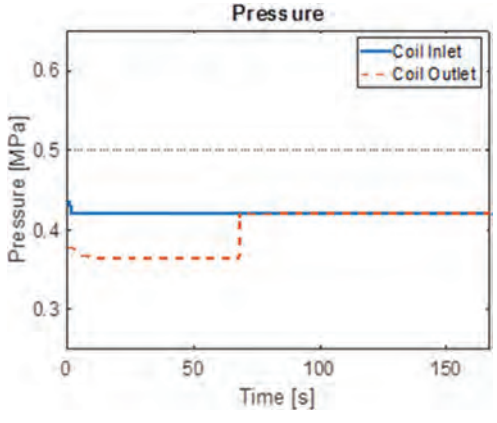

Figure 5. Pressure at the inlet and outlet of the coil along the sequence of failures: SV1 stuck totally open; SV2 stuck totally open.

(solid line) and at the outlet (dashed line) of the coil. Then, also safety valve SV2 fails stuck open, causing an increase in the pressure at the outlet of the coil up to the value of 0.42 MPa, the pressure assumed for the quench line (this is due to the fact that the pressure at the outlet of the coil is lower than that in the quench line). As a result, the pressure at the inlet and at the outlet of the coil equalizes: the LOFA happens (and is detected) and the current is reduced to zero producing AC losses, which lead to heat deposition. Throughout the rest of the transient, the value of the pressure at the boundaries of the coil stabilizes at 0.42 MPa. This response of the system justifies the necessity of a dynamic approach. In fact, if we consider the single failures of the SV1 and SV2 at the most conservative magnitude (see, e.g., Figures 3 and 4), a new steady state condition is reached *without* any *problem* from the point of view of the *availability* of the CSM in the test facility; on the other hand, the combination of failures considered just now leads to a different end state.

In all the scenarios reported here, the pressure at the boundaries of the SC coil is kept below the safety threshold of 1.8 MPa, i.e., with a positive safety margin. In other words, as for the analysis here presented, no critical situations are expected and the coil is not damaged. In addition, the voltage always stays well below the threshold of 0.1 V, which means that the current sharing temperature T_{CS} is not exceeded.

6 CONCLUSIONS

In this paper, we have considered the safety analysis of the simplified cooling system of a *single* module of the ITER Central Solenoid (CS) in a cold *test facility*, subject to a Loss-Of-Flow Accident (LOFA). For this, the deterministic 4C code has been employed to simulate the system behavior and a Multiple Value Logic (MVL) has been adopted for building a comprehensive set of combinations of times and (discrete) magnitudes of components failures to run stochastic accident scenarios. The cooling helium pressure at the inlet and outlet of the SC coil, and the voltage measured across the pancakes have been selected as "critical" safety parameters to monitor during each transient.

The application of the MVL has generated a list of more than 10^8 possible scenarios. However, for the sake of brevity, we have carried out only a "bounding analysis" of the system response by inspecting a *reduced set* of MVL sequences, in particular, those *expected* to be *most challenging* for the system safety. Results have shown that these scenarios are *not critical* for the CS module integrity: in particular, in all the cases considered, the

pressure at the boundaries of the SC coil is below the safety threshold of 1.8MPa, i.e., with a positive safety margin. Also, the voltage keeps well below the threshold of 0.1V, which means that the temperature of the conductor does not exceed the current sharing temperature T_{CS} and the magnet does *not* lose its SC properties.

However, a final remark is in order with respect to the positive results obtained. The CS magnet has been analyzed here in "cold mode experimental operation" (see Section 3), with the coil inlet temperature taken as the *nominal* one. In some cases, this temperature can be artificially increased, in order to perform specific tests (for example, the T_{CS} measurement (Savoldi et al. 2000)). This situation would reduce the temperature *margin* (namely, the difference between the operating cable temperature and the T_{CS}), shifting the operating point closer to the T_{CS} and, thus, reducing the amount of the heat needed to induce a quench. The analysis of such "more severe" operating conditions will be possibly considered in future research.

Reliability-based design optimization by using support vector machines

Niclas Strömberg
Department of Mechanical Engineering, Örebro University, Sweden

ABSTRACT: In this work we perform Reliability-Based Design Optimization (RBDO) by classifying the limit states by using soft non-linear Support Vector Machines (SVM). By adopting the kernel trick in the dual formulation, by using e.g. the Gaussian kernel,we classify non-linear states of fail or safe obtained from design of experiments. The Most Probable Point (MPP) of the SVM is established in the physical space where the distance is minimized in the metric of Hasofer-Lind. The solution to the corresponding optimality conditions is obtained by using Newton's method with an inexact Jacobian and a line-search of Armijo type. At the MPP, we perform Taylor expansions of the SVM using intermediate variables defined by the iso-probabilistic transformation. In such manner, we derive a Quadratic Programming (QP) problem which is solved in the standard normal space. This is done for several probability distributions such as e.g. lognormal, Gumbel, gamma and Weibull. The optimal solution to the QP problem is mapped back to the physical space and new Taylor expansions of the SVM are derived and a new QP problem is formulated and solved. This procedure continues in sequence until we obtain convergence of our RBDO problem. The steps presented above constitute our proposed FORM-based sequential QP approach for RBDO by using SVM. The target of reliability appearing in the FORM-based QP problem might also be adjusted using different SORM formulas such as e.g. Breitung, Hohenbichler or Tvedt, or by applying importance-based Halton or Hammersley sampling. A nice feature of the proposed SVM-based RBDO approach is that several limit state functions can be represented simultaneously by only one single SVM. Thus, the proposed SVM-based RBDO methodology might be considered to be a rational approach for the treatment of RBDO problems including system reliability. This is demonstrated by solving established RBDO benchmarks.

1 INTRODUCTION

The soft non-linear support vector machine (SVM) introduced by Cortes & Vapnik (1995) defines a paradigm shift in machine learning and the paper has been cited more than 15000 times. By adopting the kernel trick and the soft penalization, we are able to classify non-linear separable data including misclassified data points. In this work, we suggest to use a single SVM to represent several limit state functions simultaneously when performing reliability based design optimization. For readers not familiar with SVM, an excellent introduction to this machine learning discipline is found in the textbook by Hamel (2009).

Although the number of papers on SVM-based RBDO is small, the idea of using SVM in order to represent limit state functions in RBDO is not new. Basudhar et al. (2008) solved RBDO problems using SVM and a particle swarm algorithm. Song et al. (2012) performed sampling-based RBDO by using probabilistic sensitivity analysis and virtual support vector machines. Khatibinia et al. (2013) suggested a gravitational search algorithm with a weighted least square support vector machine for RBDO. Wang et al. (2015) proposed a new SORA-based RBDO method using SVM as a surrogate model for the limit state function. Most recently Liu et al. (2017) used SVM-based sampling in order to improve Kriging models for RBDO. Another recent paper is by Yang & Husada (2017), who study seven state of the art methods from data mining in order to improve accuracy and efficiency of a single-loop RBDO method.

In this work, we will adopt the SORM-based sequential quadratic programming (SQP) approach for RBDO recently suggested by Strömberg (2017), where we now represent the limit state functions by using SVM instead of analytical expressions. The main idea of the proposed method is to represent several limit state functions simultaneously with only one single SVM. In such manner, a RBDO problem with several reliability constraints boil down to a problem with only one constraint. We also think that this approach is a step towards a rational method for treating problems with system reliability. Reliability analysis without optimization using a similar idea was recently investigated by Li et al. (2016).

The proposed method might be consider to be a metamodel-based approach for RBDO even though the SVM is not representing the overall behaviour of the reliability constraint function but only is a representation of the limit state or a classification of states in fail or safe. Metamodel-based RBDO is a most powerful approach for treating the reliability constraints of complex models such as non-linear finite element models. Popular metamodels for this kind of applications are e.g. Kriging Kriging (Hu et al. 2016), artificial neural networks (Zhu et al. 2011) and radial basis function networks (Lv et al. 2015). In Strömberg (2016) FORM- and SORM-based RBDO of a underrun protection profile was performed using a new type of radial basis function networks with a priori bias suggested by Amouzgar & Strömberg (2017).

The outline of the paper is as follow: in the next section we review the FORM- and SORM-based SQP approach for reliability based design optimization that recently was suggested in Strömberg (2017), in section 3 we present the theory of the soft non-linear support vector machine by deriving the dual formulation of the maximum margin problem using the Karush-Kuhn-Tucker (KKT) conditions and introducing the soft penalization. In section 4 two RBDO examples are solved using the proposed SVM-based methodology, in particular an established benchmark with three reliability constraints are treated using a single SVM and we also suggest how to apply SVM-based adaptive sampling in order to improve the solution. Finally, some concluding remarks are presented.

2 SQP-BASED RBDO

Most recently a SORM-based SQP approach for RBDO was suggested in Strömberg (2017). A brief presentation of this approach is given in this section.

Let us consider the following RBDO problem:

$$\begin{cases} \mu\min \quad f(\mu) \\ \text{s.t.} \quad \Pr\left[g(\boldsymbol{X}) \le 0\right] \ge P_s, \end{cases} \tag{1}$$

where $\boldsymbol{X}$ is a vector of N_{VAR} uncorrelated random variables X_i. The mean value μ_i of each variable X_i is collected in μ. The functions $f = f(\mu)$ and $g = (X)$ represent the objective function and constraint, respectively. Thus, the reliability constraint reads that the probability that $g \le 0$ must be greater than the target of reliability P_s. In this work, we treat this reliability constraint by representing the limit state $g = 0$ by support vector machines, see the next section. The SVM can also be used to classify states of fail or safe, but that is not the main purpose of using SVM in this work. The main idea is to represent several limit states simultaneously by using a single SVM and then toperform RBDO following the method presented in this section.

The cumulative distribution of each variable is given by

$$F_i(x;\boldsymbol{\theta}_i) = \int_{-\infty}^{x} \rho_i \, \mathrm{d}x, \tag{2}$$

where $\rho_i = \rho_i(x;\boldsymbol{\theta}_i)$ is the probability density function for distributions parameters collected in $\boldsymbol{\theta}_i = \boldsymbol{\theta}_i(\mu_i)$. So far, the following distributions have been implemented: normal, lognormal, Gumbel, gamma and Weibull.

The problem in (1) is solved by the SQP approach as outlined below. At an iterate k with mean values collected in μ^k, we perform Taylor expansions of f and g in intermediate variables Y_i defined by the iso-probabilistic transformation, i.e.

$$Y_i = Y_i(X_i) = \Phi^{-1}\left(F_i\left(X_i;\boldsymbol{\theta}_i\left(\mu_i^k\right)\right)\right), \tag{3}$$

where $\Phi = \Phi(x)$ is the cumulative distribution of the standard normal distribution. In addition, the Taylor expansion of g is done at the most probable point x_i^{MPP} on the limit surface. The Taylor expansion of f becomes $f(\boldsymbol{\eta}) \approx f(\boldsymbol{\mu}^k) +$

$$\sum_{i=1}^{N_{\text{VAR}}} \left.\frac{\partial f}{\partial X_i}\right|_{\boldsymbol{X}=\boldsymbol{\mu}^k} \frac{\phi\left(Y_i^k\right)}{\rho_i\left(\mu_i^k;\boldsymbol{\theta}_i^k\right)} \eta_i + \frac{1}{2} \sum_{i=1}^{N_{\text{VAR}}} \sum_{j=1}^{N_{\text{VAR}}} \tilde{H}_{ij} \eta_i \eta_j, \tag{4}$$

where $\boldsymbol{\eta}$ is the mean of $\boldsymbol{Y}$ and

$$\tilde{H}_{ij} = \left.\frac{\partial^2 f}{\partial X_i \partial X_j}\right|_{\boldsymbol{X}=\boldsymbol{\mu}^k} \frac{\phi\left(Y_i^k\right)}{\rho_i\left(\mu_i^k;\boldsymbol{\theta}_i^k\right)} \frac{\phi\left(Y_j^k\right)}{\rho_j\left(\mu_j^k;\boldsymbol{\theta}_j^k\right)}. \tag{5}$$

Furthrmore, $\tilde{g} = \tilde{g}(Y) \approx$

$$\sum_{i=1}^{N_{\text{VAR}}} \left.\frac{\partial g}{\partial X_i}\right|_{\boldsymbol{X}=\boldsymbol{x}^{\text{MPP}}} \frac{\phi\left(y_i^{MPP}\right)}{\rho_i\left(x_i^{MPP};\boldsymbol{\theta}_i^k\right)} \left(Y_i - y_i^{\text{MPP}}\right), \tag{6}$$

where $y_i^{\text{MPP}} = Y_i\left(x_i^{\text{MPP}}\right)$ is the most probable point defined by

$$\begin{cases} \min\limits_{X} \dfrac{1}{2} \boldsymbol{Y}(\boldsymbol{X})^T \boldsymbol{Y}(\boldsymbol{X}) \\ \text{s.t. } g(\boldsymbol{X}) = 0. \end{cases} \tag{7}$$

In this work, we solve (7) when the limit state $g(\boldsymbol{X}) = 0$ is represented by a soft non-linear SVM as presented in the next section. This is in turn done by solving the necessary optimality conditions by using Newton's method withan inexact Jacobian.

Finally, by inserting (4) and (6) into (1), we derive the following QP-problem:

$$\begin{cases} \min\limits_{\eta_i} \quad f(\boldsymbol{\eta}) \\ \text{s.t.} \quad \begin{cases} \mu_{\tilde{g}} \le -\beta_t \sigma_{\tilde{g}}, \\ -\int \le \eta_i \le \int, \end{cases} \end{cases} \tag{8}$$

where

$$\mu_{\tilde{g}} = \sum_{i=1}^{N_{\text{VAR}}} \left.\frac{\partial g}{\partial X_i}\right|_{\boldsymbol{X}=\boldsymbol{x}^{\text{MPP}}} \frac{\phi\left(y_i^{MPP}\right)}{\rho_i\left(x_i^{MPP};\boldsymbol{\theta}_i^k\right)}\left(\eta_i - y_i^{\text{MPP}}\right),$$
$$\sigma_{\tilde{g}} = \sqrt{\sum_{i=1}^{N_{\text{VAR}}} \left(\left.\frac{\partial g}{\partial X_i}\right|_{\boldsymbol{X}=\boldsymbol{x}^{\text{MPP}}} \frac{\phi\left(y_i^{MPP}\right)}{\rho_i\left(x_i^{MPP};\boldsymbol{\theta}_i^k\right)} \right)^2}. \tag{9}$$

Here, $\beta_t = \Phi^{-1}(P_s)$ is the target reliability index which can be corrected by any SORM approach or Monte Carlo sampling. So far, four SORM approaches have been implemented, e.g. Breitung, Hohenbichler and Tvedt. In addition, Halton- and Hammersley-based importance sampling at the MPP are also implemented. The optimal solution to (8), denoted η_i^*, is mapped back from the standard normal space to the physical space using

$$\mu_i^{k+1} \approx \mu_i^k + \frac{\Phi\left(Y_i^k\right)}{\rho_i\left(\mu_i^k;\boldsymbol{\theta}_i^k\right)}\eta_i^*.$$

Then, a new QP-problem is generated around $\boldsymbol{\mu}^{k+1}$ and this procedure continues in sequence until convergence is obtained. The QP-problem in (8) solved using quadprog.m in Matlab.

3 SUPPORT VECTOR MACHINE

In this section, we present the dual formulation of the soft non-linear support vector machine. First we introduce the original linear SVM, which actually was suggested already in the 60 s by Vapnik, then we apply the kernel trick and, finally, regularize the problem.

Let us consider N sampling points x^i, which take values $y^i = 1$ (fail) or $y^i = -1$ (safe). Furthermore, we assume that it exists hyper-planes

$$w \cdot x + b = 0, \tag{10}$$

which separate these sampling points into two subsets; one that only takes values $y^i = 1$ and the other one with values $y^i = -1$. This is shown in Figure 1, where the SVM-based RBDO methodology is illustrated. We also assume that the following constraints are satisfied:

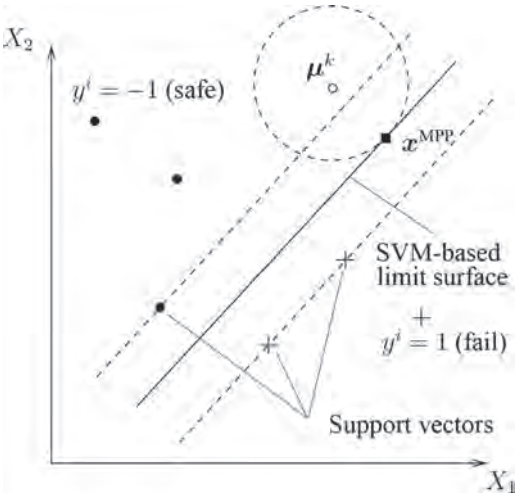

Figure 1. Illustration of the proposed SVM-based RBDO approach.

$$y^i\left(\boldsymbol{w}\cdot\boldsymbol{x}^i + b\right) \ge 1, \qquad i = 1,\ldots,N. \tag{11}$$

The shortest distances to $\boldsymbol{x}^i$ from a hyper-plane defined in (10) is given by

$$\boldsymbol{x}^i = \boldsymbol{x} + \gamma^i \frac{\boldsymbol{w}}{\| \boldsymbol{w} \|}. \tag{12}$$

(12) inserted in (11) yields

$$y^i\left(\boldsymbol{w}\cdot\boldsymbol{x} + b + \gamma^i \| \boldsymbol{w} \|\right) \ge 1. \tag{13}$$

By utilizing (10), one obtains

$$\gamma^i \ge 1/\| \boldsymbol{w} \| \text{ for } y^i = 1, \tag{14a}$$

$$\gamma^i \le -1/\| \boldsymbol{w} \| \text{ for } y^i = -1. \tag{14b}$$

Thus, the lower bound on the shortest distance $|\gamma^i|$ is maximized by minimizing $\| \boldsymbol{w} \|$. This is the key idea of the original linear support vector machine formulation, which reads

$$\begin{cases} \min\limits_{(w,b)} \dfrac{1}{2} \| \boldsymbol{w} \|^2 \\ \text{s.t.}\, 1 - y^i\left(\boldsymbol{w}\cdot\boldsymbol{x}^i + b\right) \le 0, i = 1,\ldots N. \end{cases} \tag{15}$$

Obviously, the closest sampling points to the optimal hyper-plane

$$\boldsymbol{w}^*\cdot\boldsymbol{x} + b^* = 0 \tag{16}$$

are obtained when

$$y^i\left(\boldsymbol{w}^*\cdot\boldsymbol{x}^i+b^*\right)=1. \tag{17}$$

Sampling points satisfying (17) are called support vectors, see Figure 1. It is also obvious that in the region between the optimal hyper-plane defined by (16) and the support vectors is empty of sampling points. Thus, the support vector machine formulation in (15) finds a hyper-plane that maximizes the size of this region. This region is augmented with sampling points in the SVM-based adaptive sampling approach discussed in the next section.

The Karush-Kuhn-Tucker conditions of the support vector machine in (15) are given by

$$\mathbf{0}=\boldsymbol{w}-\sum_{i=1}^{N}\lambda_i y^i\boldsymbol{x}^i, \tag{18a}$$

$$0=\sum_{i=1}^{N}\lambda_i y^i, \tag{18b}$$

$$\lambda_i\geq 0, \tag{18c}$$

$$1-y^i\left(\boldsymbol{w}\cdot\boldsymbol{x}^i+b\right)\leq 0, \tag{18d}$$

$$\lambda_i\left(1-y^i\left(\boldsymbol{w}\cdot\boldsymbol{x}^i+b\right)\right)=0. \tag{18e}$$

The corresponding Lagrangian function is $\mathcal{L}=\mathcal{L}\left(\boldsymbol{\lambda},\boldsymbol{w},b\right)=$

$$\frac{1}{2}\parallel\boldsymbol{w}\parallel^2+\sum_{i=1}^{N}\lambda_i\left(1-y^i\left(\boldsymbol{w}\cdot\boldsymbol{x}^i+b\right)\right). \tag{19}$$

Furthermore, the dual formulation of the support vector machine in (15) reads

$$\max_{\boldsymbol{\lambda}\geq\mathbf{0}}\min_{(w,b)}\mathcal{L}\left(\boldsymbol{\lambda},\boldsymbol{w},b\right). \tag{20}$$

By inserting (18a) in (19), one obtains $\mathcal{L}\left(\boldsymbol{\lambda},w(\boldsymbol{\lambda}),b\right)=$

$$-\frac{1}{2}\sum_{i=1}^{N}\sum_{j=1}^{N}\lambda_i\lambda_j y^i y^j\boldsymbol{x}^i\cdot\boldsymbol{x}^j+\sum_{i=1}^{N}\lambda_i-b\sum_{i=1}^{N}\lambda_i y^i. \tag{21}$$

In addition, the latter part is zero by (18b). In conclusion, the dual support vector machine formulation is given by

$$\begin{cases}\min\limits_{\lambda}\dfrac{1}{2}\sum\limits_{i=1}^{N}\sum\limits_{j=1}^{N}\lambda_i\lambda_j y^i y^j\boldsymbol{x}^i\cdot\boldsymbol{x}^j-\sum\limits_{i=1}^{N}\lambda_i\\ \text{s.t.}\begin{cases}\sum\limits_{i=1}^{N}\lambda_i y^i=0,\\ \lambda_i\geq 0,\boldsymbol{i}=1,\ldots,N.\end{cases}\end{cases} \tag{22}$$

From the optimal solution $\boldsymbol{\lambda}^*$ of the dual support vector machine in (22), we obtain the corresponding support vector machine solution from the Karush-Kuhn-Tucker conditions in (18) as

$$\boldsymbol{w}^*=\sum_{i=1}^{N}\lambda_i^* y^i\boldsymbol{x}^i \tag{23}$$

and

$$b=1/\,y^i-\boldsymbol{w}^*\cdot\boldsymbol{x}^i \tag{24}$$

for any $\lambda_i^*>0$. Notice, by using (23), the optimal hyper-plane in (16) can be written as

$$\sum_{i=1}^{N}\lambda_i^* y^i\boldsymbol{x}^i\cdot\boldsymbol{x}+b^*=0. \tag{25}$$

Notice also that you only need to do the summation over support vector indices, because otherwise λ^* equals zero by the KKT-conditions. This is utilized in the implementation in order to speed up the evaluation of the SVM.

For non-separable sets of sampling points x^i, the support vector machine approach presented above will of course not work. However, one might transform the sample set to a new space where it become separable, let say by $\boldsymbol{\xi}=\boldsymbol{\xi}(x)$. In this new space, the only difference in the derivations of the dual support vector machine in (22) and (25) is the appearance of a new scalar product $\left\langle\boldsymbol{\xi}^i,\boldsymbol{\xi}^j\right\rangle$ instead of $\boldsymbol{x}^i\cdot\boldsymbol{x}^j$. Thus, we donot have to know the explicit expression of the transformation $\boldsymbol{\xi}=\boldsymbol{\xi}(\boldsymbol{x})$, but only the expression of the scalar product of the new space. The explicit expression of this scalar product is known to be the kernel function, i.e.

$$k\left(\boldsymbol{x}^i,\boldsymbol{x}^j\right)=\left\langle\boldsymbol{\xi}^i\left(\boldsymbol{x}^i\right),\boldsymbol{\xi}^j\left(\boldsymbol{x}^j\right)\right\rangle. \tag{26}$$

Consequently, by using an appropriate kernel function in (22) instead of $\boldsymbol{x}^i\cdot\boldsymbol{x}^j$, e.g. the Gaussian kernel

$$k=k\left(\boldsymbol{x},\boldsymbol{z}\right)=\exp\left(-\frac{\parallel\boldsymbol{x}-\boldsymbol{z}\parallel^2}{2\sigma^2}\right), \tag{27}$$

the sample set can be separated by

$$\sum_{i=1}^{N}\lambda_i^* y^i k\left(\boldsymbol{x}^i,\boldsymbol{x}\right)+b^*=0. \tag{28}$$

Another kernel function is the polynomial kernel, i.e.

$$k=k\left(\boldsymbol{x},\boldsymbol{z}\right)=(1+\boldsymbol{x}\cdot\boldsymbol{z})^p. \tag{29}$$

Even if we perform a suitable kernel trick, we might have some misclassified points such that

(22) does not converge to a solution. This can be treated by applying a regularization of (22). The established soft regularization of (15) is

$$\begin{cases} \min\limits_{(w,b,v)} \dfrac{1}{2} \| \boldsymbol{w} \|^2 + C \sum\limits_{i=1}^{N} v_i \\ \text{s.t.} \begin{cases} 1 - v_i - y^i \left(\boldsymbol{w} \cdot \boldsymbol{x}^i + b \right) \le 0, i = 1, \ldots N, \\ v_i \ge 0, i = 1, \ldots N. \end{cases} \end{cases} \tag{30}$$

The Karush-Kuhn-Tucker conditions in (18) then modify by adding the following conditions:

$$C - \lambda_i \ge 0, \tag{31a}$$

$$v_i \ge 0, \tag{31b}$$

$$v_i \left(C - \lambda_i \right) = 0. \tag{31c}$$

The corresponding Lagrangian becomes $\mathcal{L} =$

$$-\frac{1}{2} \sum_{i=1}^{N} \sum_{j=1}^{N} \lambda_i \lambda_j y^i y^j \boldsymbol{x}^i \cdot \boldsymbol{x}^j + \sum_{i=1}^{N} \lambda_i - \sum_{i=1}^{N} \lambda_i v_i + C \sum_{i=1}^{N} v_i, \tag{32}$$

where the two latter terms cancel out due to (31c). Thus, the only difference of the dual support vector machine in (22) for this regularization is the appearance of an upper bound on λ_i, i.e.

$$\begin{cases} \min\limits_{\lambda} \dfrac{1}{2} \sum\limits_{i=1}^{N} \sum\limits_{j=1}^{N} \lambda_i \lambda_j y^i y^j k\left(\boldsymbol{x}^i, \boldsymbol{x}^j \right) - \sum\limits_{i=1}^{N} \lambda_i \\ \text{s.t.} \begin{cases} \sum\limits_{i=1}^{N} \lambda_i y^i = 0, \\ 0 \le \lambda_i \le C, i = 1, \ldots, N. \end{cases} \end{cases} \tag{33}$$

Finally, $0 < \lambda_i < C$ must be satisfied in order for (24) to be valid. Here, we have also introduced the kernel $k(\boldsymbol{x}, \boldsymbol{y})$ in the objective function. The soft non-linear SVM in (33) is solved using quadprog.m in Matlab.

4 EXAMPLES

In this section, we demonstrate by solving two examples that the soft non-linear SVM presented in the previous section can represent the limit states properly such that the SQP-based RBDO methodology can be applied for solving RBDO problems with SVM-basedlimit state functions. The first problem was considered in Strömberg (2016), where SLP-based RBDO was performed by adopting radial basis function networks (RBFN) as metamodels. The second example is a most well-know benchmark for evaluating new RBDO approaches, see e.g. Youn and Choi (2004).

The first example reads

$$\begin{cases} \mu_i \min \quad \sqrt{1000 \left(\dfrac{4}{\mu_1} - 2 \right)^2 + 1000 \left(\dfrac{4}{\mu_1} - 2 \right)^2} \\ \text{s.t.} \begin{cases} \Pr[(X_1 - 0.5)^4 + (X_2 - 0.5)^4 \le 2] \ge P_s, \\ 1 \le \mu_i \le 4, \end{cases} \end{cases} \tag{34}$$

where $P_s = 0.999$ and $\text{VAR}[X_i] = 0.1^2$. The deterministic solution is (1.5,1.5) and the minimum of the unconstrained objective function is found at (2,2). The constraint $g > 0$ $g > 0$ is plotted to the left in Figure 2. The solution to (34) obtained by our SQP-based RBDO approach is (1.2705,1.2705). The corresponding reliability is 99.9%.

Now, let us consider the problem in (34) as a "black-box", which we represent with metamodels for a sample set of 100 Hammersley points as depicted in Figure 4 for the next example. In particular, we let the objective function be represented by a radial basis function network as in Strömberg (2016) and the limit state is represented by a SVM

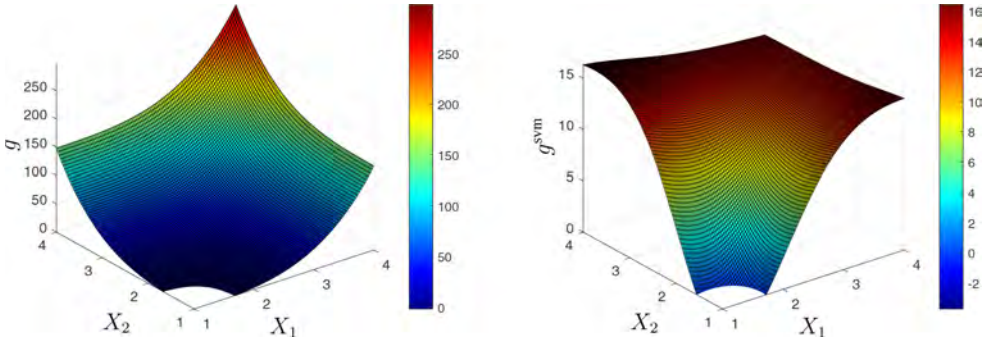

Figure 2. The left plot shows $g > 0$ and in the right plot $g^{\text{svm}} > 0$ is given. Despite the overall behaviour is not captured by the SVM, the limit state is represented properly.

g^{svm}. Figure 2, $g^{\text{svm}} > 0$ is plotted. Notice that g^{svm} only represents the limit state properly but not the overall behaviour. Of course, the classification of fail or safe is obtained by taking sign(g^{svm}). Instead of solving (34), we solve the metamodel-based representation of (34), i.e. the radial basis function taken as our objective function and g^{svm} is the limit state function. The corresponding solution is (1.3410, 1.2315) and the reliability for this solution becomes 99.7%, slightlylower than the target of 99.9%. Histograms for the objective function and the constraint are plotted in Figure 3. Notice the non-symmetric characteristic of the solution. This as well as the reliability of the solution can be improved by adopting adaptive sampling. This is a topic for future work. In fact, the SVM is most appropriate for improving the sample set with data along the limit state in the margin of the SVM. Some ideas of how this can be done is outlined for the next example.

The second example is a most well-known benchmark with three constraints and reads

$$\begin{cases} \mu_i \min \quad (\mu_1 + \mu_2)^2 \\ \text{s.t.} \begin{cases} \Pr\left[g_1 = 20 - X_1^2 X_2 \le 0\right] \ge \Phi(3), \\ \Pr\left[g_2 = 1 - \dfrac{(X_1 + X_2 - 5)^2}{30} - \dfrac{(X_1 - X_2 - 12)^2}{120} \le 0\right] \ge \Phi(3), \\ \Pr\left[g_3 = X_1^2 + 8X_2 - 75 \le 0\right] \ge \Phi(3), \\ 1 \le \mu_i \le 7, \end{cases} \end{cases} \tag{35}$$

where $\text{VAR}[X_i] = 0.3^2$. A small modification of the original problem is done by taking the square of the objective function. This problem was recently considered in Strömberg (2017) by using a SORM-based SQP approach for reliability based design optimization. The example was in that work also generalized to 50 variables and 75 constraints for five different distributions simultaneously (normal, lognormal, Gumbel, gamma and Weibull). The analytical solution for two variables with normal distribution is obtained to be (3.4525,3.2758) with our RBDO algorithm.

In this work we consider (35) to be a "blackbox" for which we setup a design of experiments using Hammersley sampling with 100 points as shown in Figure 4. From this sampling we define a training set g^{train} for our support vector machine in the following manner:

$$g^{\text{train}} = \begin{cases} 1 & \text{if any } g_i > 0, \\ -1 & \text{otherwise.} \end{cases} \tag{36}$$

For this training set, we obtain a SVM g^{svm} according to Figure 4. The plot to the right clearly shows that the the limit state functions are well represented by the global SVM $g^{\text{svm}} = 0$. The corresponding classification of fail or safe using sign(g^{svm}) is given in Figure 6. As in the previous example, we represent the sampling data for the objective function with a RBFN. Thus, our RBDO problem to be solved is this RBFN-based objective function with the reliability constraint on the SVM $\Pr\left[g^{\text{svm}} \le 0\right] \ge \Phi(3)$. In such manner, we reduce the problem size from three constraints to a problem with only one constraint. For this problem, the RBDO algorithm produces the following solution: (3.4247,3.2218). The corresponding reliability indices for the two first active constraints are 2.84 and 2.87, respectively. Histograms for these constraints are given in Figure 5.

Instead of solving (35) using a uniform sampling as presented in Figure 4, we adopt a sequential

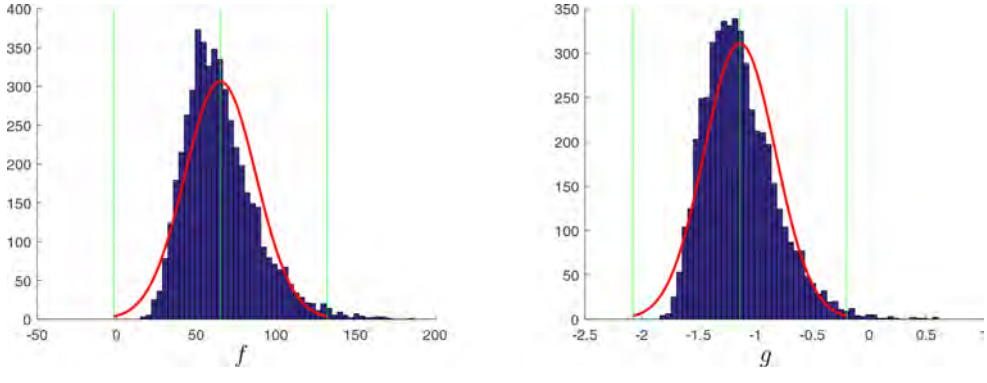

Figure 3. Histogram of the objective function f and the constraint g for the solution obtained by using the SVM. Red lines are showing the corresponding normal distribution, where green lines mark the $\mu \pm 3\sigma$ intervals.

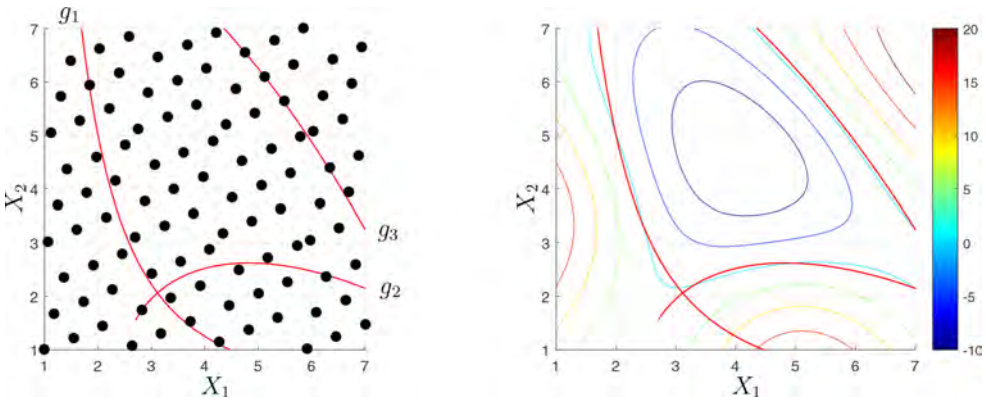

Figure 4. In the left plot the Hammersley sampling of 100 points is shown together with the explicit constraints g_i. To the right the corresponding SVM is depicted. The limit state surface in cyan corresponds well to the actual limit surfaces g_i.

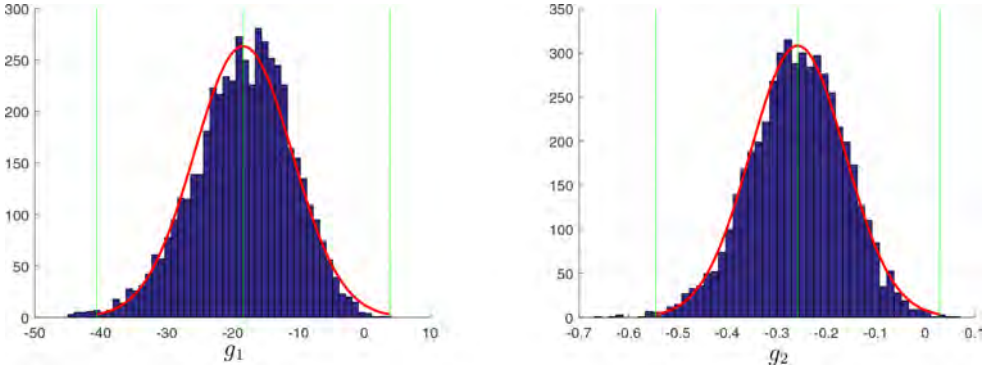

Figure 5. Histograms for the two first active constraints g_1 and g_2, respectively. Red lines are showing the corresponding normal distribution, where green lines mark the $\mu \pm 3\sigma$ intervals.

adaptive sampling approach by distributing points in the margin of the SVM along the limit states as well as adding the deterministic optimum and the most probable point obtained in each sequence. For instance, in Figure 7, we start from a set of 50 Hammersley points and then add 10 points (8 SVM-based points, 1 deterministic optimum, 1 MPP) sequentially five times following this SVM-based sampling approach in order to generate the set of 100 points shown in Figure 7. In this figure the corresponding SVM is also plotted. Comparing the SVMs in Figure 4 and Figure 7, one can see that the latter onebetter capture the local behavior of the limit surface close to the optimal solution. The optimal solution for this SVM-based formulation of the example is (3.4805,3.2585) and the corresponding reliability indices are 3.08 and 2.95, respectively, for the two active constraints. This is rather close to the target of 3. It is clear that this

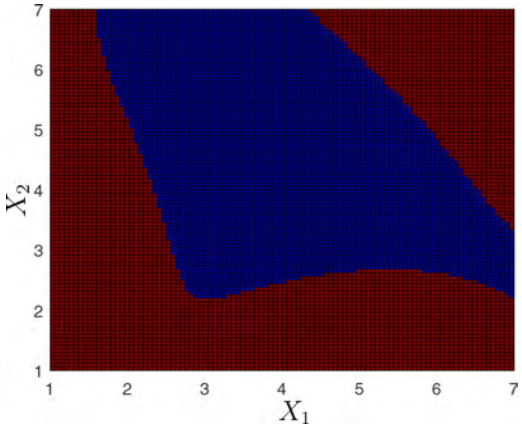

Figure 6. Classification in fail (red) or safe (blue) using the SVM.

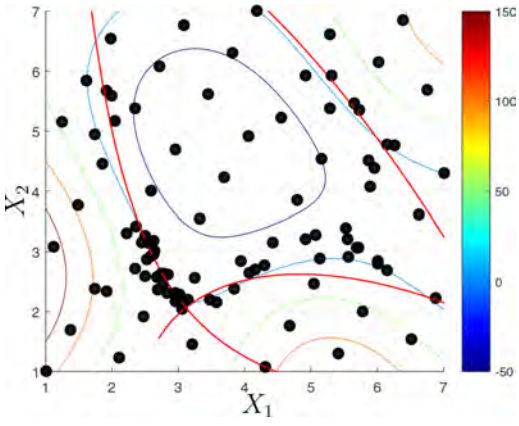

Figure 7. SVM-based adaptive sampling augmented with deterministic optimum and MPP.

is an improvement compared to the previous solution presented above for the same example.

Finally, we solve (35) for all three constraints modelled by three separate SVM models using the adaptive DoE used above. Then, we obtain the following solution (3.4304,3.3053), and the corresponding reliability indices for the active constraints: 2.97 and 3.12.

5 CONCLUDING REMARKS

In this work SVM-based RBDO is investigated by implementing soft non-linear SVM together with a SQP-based RBDO method recently developed in Strömberg (2017). The implementation is done so far for two random variables and the idea is to represent the limit state functions with a single SVM. It is demonstrated that the proposed approach works well for an established benchmark with three reliability constraints. It is also demonstrated how the SVM can be utilized in adaptive sampling. For future work it would beinteresting to investigate the approach for more than two variables with several constraints.

Crisis management in extreme situation: The Model of Resilience in Situation (MRS) as a support to observe the organization with simulation

Q. Baudard, P. Le Bot & C. De la Garza
EDF Research and Development, Human and Organizational Factors Group

ABSTRACT: The traditional approach to safety engineering for a nuclear reactor is mainly focused on its technical dimension, while the Human Factors approach focuses on how to optimize the value added by human to the reliability of the system. Safety management seeks to organize the work as well as possible, train employees, develop their safety culture, and so on. This juxtaposition of approaches to reliability illustrates the recurring dilemma faced by at-risk organizations in choosing between the technical anticipation of pre-defined situations and the optimization of the management of the situations by people who, in real time, through their skills and understanding of the situation going on, will adapt their strategy and actions according to that particular situation. These last three years, we have performed a series of Extreme Situation Simulations on Full Scale Simulators in order to test the resilience of the Crisis Organization of EDF during accidents with characteristics similar to the accident of Fukushima. The realization of these tests was an organizational challenge which required up to 80 people for the simulation, and about 5 months for both the preparation and the analysis of the tests.

1 OBJECTIVE OF THE STUDY

Following the Fukushima accident, EDF implemented additional crisis management measures (organizational, material, etc.) to respond to an accident in an Extreme Situation (ES). An Extreme Situation is a situation in which a nuclear site is isolated and inaccessible as consequences of a large-scale external event which has an impact on all the reactors of the site, and during which the operating teams have limited means of communication. The objective of our works was to study the design of the operating teams in Extreme Situations and the National Crisis Management Organization of EDF, in order to identify the strengths and the areas of improvement for crisis management.

To do this, we observed simulations involving the entire crisis management organization of EDF, which would operate in an ES, from the operating teams on-site, to the experts from the National Technical Support Team, along with members of the National Direction Command Post. External stakeholders (Public Powers, Regulatory Authority…) have not been taken into account in the simulation.

We applied a multidisciplinary approach to these simulations, cross-referencing the analyses of experts in Cognitive Ergonomics, Human Reliability and Nuclear Safety. Our method of analysis of these simulations is based on the Model of Resilience in Situation (Le Bot & Pesme, 2010), which explains how a socio-technical system such as the one we have observed can continue to operate safely using a process of anticipation and a process of adaptation. Therefore, beyond the operational objective of studying the organizational system anticipated in an ES, we examined more closely the link between resilience and crisis management.

The purpose of this communication is to present the method we have developed for the implementation of the Extreme Situation Tests and the one used for their analysis. We will first see how the specific context of an ES is complex to simulate, and how we managed to achieve it. We will then detail the method of observation of the tests and analysis, focusing on the functional analysis of the resilience in accordance with the Model of Resilience in Situation. Finally, we will present some of the conclusions we have drawn from the analyses and the first lessons for the implementation of simulations.

2 TESTS IN EXTREME SITUATIONS

2.1 *What is an extreme situation?*

The concept of Extreme Situations emerged following the accident at Fukushima in 2011. The situation we considered as representative for the study of the crisis organization is a situation with characteristics similar to this one.

We suppose that a nuclear site is hit by a major earthquake leading to the loss of internal and external power supplies on at least two reactors, with the isolation of the site preventing the immediate arrival of the local on-call emergency response teams and the Safety Engineer.

Furthermore, nearly all internal and external communication systems of the site have been rendered unavailable by the event: in the first tests, the control room could not communicate remotely with the field operators when they are working on field manoeuvers. In later tests, an autonomous communication system was available for the teams to communicate with the field operators. In the short-term, the team in the control room can only receive support from the National Emergency Response Team by communicating with the "National Direction Command Post" via an emergency satellite telephone.

2.2 *How to simulate an extreme situation?*

During our study, we observed two series of three tests, each involving complete operating teams on full scale simulators. Four tests were carried out on two simulators in parallel, representing a beyond-design-basis "multi-unit" site accident, simultaneously affecting two reactors on one site. During one of these exercises, the two simulated units were of different technologies. The two remaining tests were focused on thermohydraulic design basis accidents in situations combined with another event (fire or flooding), in order to study the design of the team in a non-isolated site situation.

A multi-disciplinary work group, consisting of representatives of the site operations departments, training instructors on simulators and experts on ergonomics, human reliability and safety, prepared the tests. This group produced the test protocol and defined a scenario able to provide sufficient data to understand crisis organization in a beyond-design-basis extreme situation. The accident scenarios were tested and validated in technical and documentary terms, and lastly, for each test, a prior "dummy" test was used to check the entire simulation system with site operating teams.

This study meant that for the first time within the company, tests could be performed on two full scale simulators in parallel built in the training centre of the sites, a "hardware" one reproducing the control room exactly, and another "digital" one with touch screens representing the devices of the control room. During one of the tests, a third unit was simulated on paper: it was a world's first. The simulation of several units raises numerous problems, for example, certain units are paired and share common equipment. This is not the case for the full scale simulators, they are technically independent. Thus, during tests simulating two paired reactors sharing common systems, the unavailability of shared equipment needed to be simulated for one simulated reactor if the other simulated reactor used it.

Furthermore, following the Fukushima accident, it was decided to equip each reactor with complementary equipment for facing extreme situations, such as emergency unit cooldown diesel generator sets: these were not yet taken into account in the simulators, or in the training of the operating teams at the time of the tests. Since the objective of the simulations is to study the operation of the crisis organization as it would be with this equipment deployed, these devices were provisionally simulated for the tests and the operating teams participating in the tests were specially prepared in their use. The validation of the new procedures was not an objective of the tests.

Lastly, it emerged from our preliminary analyses of the Fukushima accident (Baudard, 2017) that the field actions had played a very important role in the crisis management. We therefore involved the field operators of each operating team in the simulation by asking them to simulate the completion of the actions requested by the control room in a degraded environment (poor lighting, access path blocked, etc.). This participation by the field operators helped to ensure a more realistic simulation, even though they have not simulated their actions directly in the field.

2.3 *The observation system*

To limit as far as possible any technical contingencies in the progress of the test, each scenario was played out twice with different teams before being observed during the final test. The aim of these precautions was to seek possible faults in the procedures

Table 1. Data collection methods.

In-situ observation	Ergonomics	Human reliability
Note taking	Chronologies, actions performed, decision making, communication, difficulties observed.	
Video & audio recording	Detailed subsequent analysis of sequences chosen	Used only in case of doubt
Types of instrumented collection		Process evolution Logbooks
Post-simulation debriefings	Debriefing focused on the Notable Events in the organization, noted during the observation and discussed between observers during the preparation of the debriefing	

which were being designed, but also to allow the trainers to adapt to this unusual scenario.

The tests involved up to 80 people, from its preparation through to the implementation:

- two complete operating teams and one observer per team member
- field operators for each team and one observer per group
- the experts of the national Technical Support Team and two dedicated observers
- members of the National Direction Command Post and two dedicated observers
- Scenario creators and trainers
- In-house specialists and others from outside of the company coming to observe the method of data collection
- etc.

The system observed is adapted to the crisis organization which would take place in an ES in order to represent it as accurately as possible. However, entities from outside of the company (prefecture, regulatory agency, media, etc.) were not simulated. The system is characterized by the six observation posts (two simulators, two teams of field operators, the National Technical Support Team (NTST) and National Direction Command Post) across which the ergonomics, human reliability and safety observers were spread. The simulation takes place over a period of five hours, followed by an on-the-spot debriefing and post-analysis of the simulator logbook. The data collection methods are detailed in the following table:

Five work themes guided the organization, the observation and the analysis of the Extreme Situation Simulations:

- The design of the operating team
- Field actions management
- Information Exchange with the National Crisis Organisation
- The use of the tools and resources available in an ES
- The resilience of the organisation, which we will look at in more detail later.

3 DATA ANALYSIS

3.1 *Analysis method*

The main stages in the analysis method are summarized in Table 2 below:

Following the observation of a test, the multidisciplinary analysis group identifies the favorable and unfavorable factors for the organizational resilience of the socio-technical system in Extreme Situations. The common document base for analysts is as follows:

- The exhaustive chronologies by group (operating team, Technical Support Team, etc.) is reproduced based on the notes taken by each observer, distinguishing the actions carried out by the group (application of procedures, launching field actions, etc.) and events independent of the group (equipment failure, action carried out by an independent group, etc.)
- Identification of "Notable Events" (NE). A Notable Event is an event or the repetition of an event which reveals an action, the absence of an action, a decision made, a collective or individual initiative, a fact that can strengthen the reliability of the organisation of the operating team, and/or the emergency response team, operations, its robustness, facilitating sensemaking, or on the contrary which may make the socio-technical system less reliable and make safety barriers more fragile, damaging sensemaking. The NE are observed during the in situ observation, subsequently during the group debriefing, or during the reconstruction of the overall chronology. NE are the central elements in the analysis of the resilience of the socio-technical system.

The NE are then categorized according to the groups they refer to (control room 1 or 2, emergency response team, management control unit, field operators), and a first level of analysis is used to identify:

- the Technical NE, resulting from operations on the process

Table 2. Contribution of the different disciplines to the analysis of the situations.

					Ergonomics		
					Cognitive analyses and analyses of group operations		
Observers	Human reliability + ergonomics		Human reliability				
Chronology by observer, then by Group, then overall chronology	Raw analysis from observations and debrefings Notable Events	Technical points Summary of notable events by group and overall	Monacos chronologies progress of operations	Functional analysis of resilience	Timing charts of control room activity and Site/ National interactions	Themed analyses of debriefings	Analysis by hypothesis

- the Expertise NE on the assistance that the experts provide for the operations
- the Organizational NE on the operation of the group as a whole.

Lastly, the Human Reliability analysts link together the Notable Events, the characteristics of the system observed, and the resilience functions defined in the MRS.

3.2 *Model of resilience in situation*

The Model of Resilience in Situation (Le Bot & Pesme, 2010) is an empirical model which was build out of analyses of real or simulated accidents, based on the theoretical framework of Social Regulation (Reynaud, 1997). The model serves to reconcile two seemingly opposite rationales: the anticipation of potential situations on the one hand and adaptation to the situation on the other. It is used to dynamically describe the operational management of a crisis situation, alternating between periods of constructing ad'hoc operating rules and periods of application of these rules. Should the rules being applied become obsolete, the process will repeat.

The MRS applies to crisis organization as a whole, as a dynamic network of work groups (operating team, experts, etc.) that interact, cooperate, collaborate and coordinate themselves. Each of these groups, taken within its own environment (procedures, HMI, etc.), is considered a distributed cognitive interactive system. The overall resilience of the organization therefore results from interactions within the groups and interactions between groups.

The model links together two processes: the execution process, and the adaptation process based on Figure 1:

In stable operating conditions, the system executes the operation rules (EXECUTION). The functions to be performed continuously are:

– INFORMATION: selection and sharing of information based on the surveillance criteria
– ACTION: act based on the objectives and their priorities with the corresponding resources
– CONTROL: ensure that the action complies with the operating rules

If the continuous VERIFICATION detects that the rules are not appropriate or are obsolete (objective achieved), the system initiates a Rupture phase after a RECONFIGURATION: interruption of the rules which are not relevant, mobilization of resources, then ADAPTATION in order to readjust the operating rules by carrying out DIAGNOSIS, PROGNOSIS, SELECTION of relevant procedures and parameters, PRIORITISATION of objectives, COLLABORATION to negotiate and define the operating rules, COOPERATION to distribute the tasks and the resources.

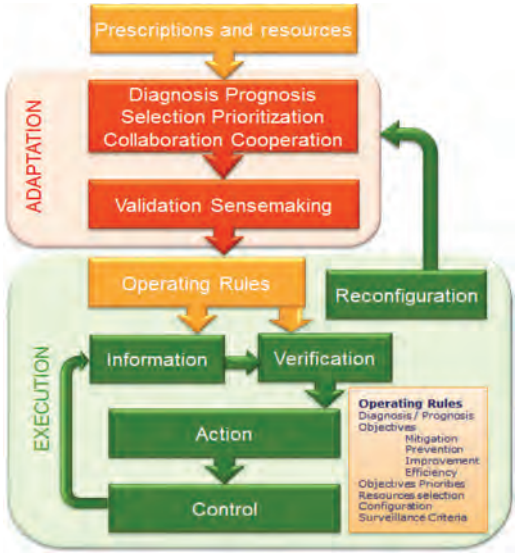

Figure 1. The model of resilience in situation.

The operating rules are validated (VALIDATION) and shared to make the situation relevant, implementing them and linking the past experience, present actions and future projections of the parties involved.

3.2.1 *Definitions of the MRS functions*

Adaptation process:
The adaptation process involves redefining operation: objectives, strategy and resources to achieve the objectives. This means:

– Anticipating the behaviour of the installation and the actions to be carried out (diagnosis and prognosis functions)
– Selecting the relevant information, procedures, instructions and means/resources (selection function)
– Collaborating to adapt them autonomously if necessary, to define the new strategy with the operational objectives and resources (collaboration and prioritisation functions)
– Validating the implementation of the rule by the authorised party (validation function).

Execution process:
The execution process involves robustly implementing the agreed strategy:

– The robustness is obtained by the execution (action function) and the control of the ongoing actions (control function).

– The group constantly checks that this strategy remains appropriate in regard of the situation (verification function)
– These functions are carried out by the acquisition and the sharing of information (information function), and guided by sensemaking (sensemaking function)

3.3 *Functional analysis of resilience*

During our analyses of the tests, we seek to relate Notable Events with these resilience functions and estimate whether they are favorable or unfavorable. For example, the contribution of a member from outside of the operating team to the production of the rules to be followed is a favorable factor for COLLABORATION between groups. On the contrary, the workload of parties involved in Extreme Situations slowed down the management of field actions, which was an unfavorable factor for the ACTION and CONTROL functions to be carried out, as well as for the PRIORITISATION of actions.

Our analysis can be summarized by the diagram on Figure 2. Taking the example of the use of a new field actions management tool, the Field Actions Monitoring Device, we would have the analysis on Figure 3.

This tool was introduced in the second series of tests, trying to resolve the difficulties observed. More specifically, its use in extreme situations allowed us to observe that the tool ensured that the field actions to be carried out were managed correctly. With minimal preparation in this new tool, the team was able to implement organization ensuring effective management of field actions, particularly important in an ES. Furthermore, this tool facilitates the prioritization of field actions and the monitoring of field operators and their optimization in a situation requiring many field actions. Therefore, the Field Actions Monitoring Device was a favorable factor in controlling the state of the reactor in a degraded situation.

4 GENERAL DISCUSSION

The results of our analyses show that the design basis of the crisis management organization in Extreme Situation was not called into question. It also appears that some observed difficulties require more consideration in the preparation of the operating teams in order to strengthen resilience.

4.1 *Management of field actions*

The main observation relates to the management of field actions and of the "field operator" resources. In a design basis accident, if electrical power sources are lost, the necessary number of safety-related equipment items for the facility are backed up by Emergency Diesel Generators and can still be controlled remotely in the control room. Field actions then involve trying to return the systems to service or checking the shutdown of the stopped systems, and therefore these actions are not generally essential for the operation of the reactor. In an Extreme Situation with a beyond-design-basis

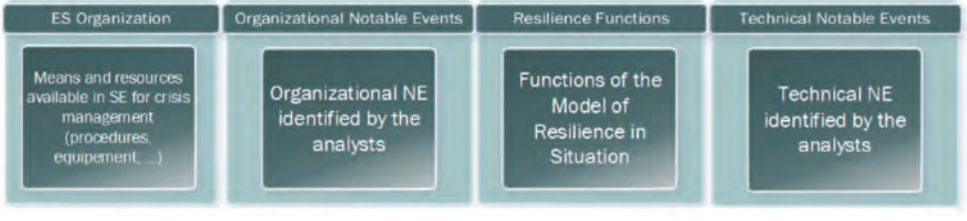

Figure 2. Functional analysis of resilience method.

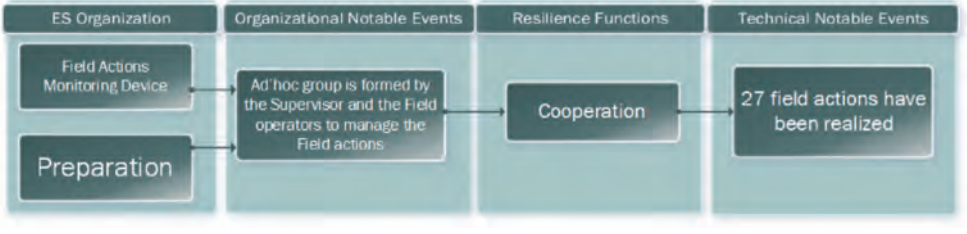

Figure 3. Example of functional analysis of resilience method: Field actions monitoring device.

loss of electrical power sources, these backups may be lost and the operation of the installation may require direct field action to control certain equipment, try to return it to service or take information. The field operators are in fact in high demand. They are sent in the field on a case-by-case basis depending on each action demanded by the team in the control room, with one or more field action sheets, and their actions are not carried out instantly since they need to travel to the premises before executing their sheet, and the action itself must often be executed manually. Each sheet therefore requires human resources, one or more field operators will need time to perform the action demanded.

Prioritizing and re-prioritizing the field action sheets becomes a condition for the success of the crisis management in the control room. This activity has considerable cognitive requirements for the person responsible of it, and an impact on the collective operation of the team. During our tests, this activity takes up a lot of the supervisor's time, therefore leaving them less available for the team and for their own supervision tasks.

To help to manage the field actions and the field operators, a prototype of a Field Actions Monitoring Device has been designed as part of an agile process (De la Garza et al., 2016). This is a triptych panel providing an overview of the actions pending, allowing them to be prioritized and then to see those which are in progress and who is carrying them out, and finally the successes and failures. This system is a support for ES operation, making it easier to monitor and ensure the safety of the field operators who leave to carry out actions. It also allows information to be shared within the operating team and becomes an area for exchanges, or even collective problem-solving.

4.2 *Reflections on the ES simulation system*

The organization and analysis of an Extreme Situation test is costly in terms of time and resources: 60 to 80 people from different entities (operators, engineering, trainers, R&D, etc.) working on the organization and progress of the tests requiring 4 to 6 months of preparation, then 4 to 6 months of analysis… We have adopted a procedure of continuous improvement in the organization of the tests, progress of which has been spread over more than three years, getting the various stakeholders in the preparation involved earlier in the process, and optimizing the analysis method.

However, we can see that there remain questions pending and areas for improvement to be followed in the organization of simulations on such a large scale, and in particular based around four points discussed above relating to the preparation, creation of scenarios and control of certain variables.

4.2.1 *Unpredictability of the scenario*

The scenario we designed for the tests was a succession of equipment failures (loss of off Site Power, Loss of on-site Power…) similar to the damages that the Fukushima Daiichi NPP faced during the crisis. In order to successfully manage the accident, the operating teams have to apply rarely used procedures.

Before the final test, we had to validate the technical aspects of de simulation, like the behavior of the Full Scale Simulator in this situation where it had to cope with a lot of equipment failures, or how well the procedures matched with the situation.

The problem is that, because of the autonomy we gave to the operating teams during the simulations, if we want to validate the adequacy of the procedures, we have to make sure that they are correctly applied by the operating team: operators might choose another procedure to apply, if they consider it more appropriate. Instructors however are trained to strictly apply the procedures, so we preferred having them for the technical validation of the scenarios.

Even though the technical validation is necessary, it does not protect from problems during the test. But since their objective was to study the resilience of the teams, we left them a lot of autonomy in the operations, and we would not have stopped the simulation should they have applied a procedure we had not expected.

4.2.2 *Simulating equipment which is scheduled but not yet installed*

How can the players be prepared to manage a simulation which will require equipment and an organization which are not yet scheduled as part of their training, and at the same time make the situation as close as possible to the target? Here we have a modification of an existing situation.

To train the teams, we offered them preparatory information meetings, during which the objective of the tests, the scheduled progress for the day and the new systems scheduled for crisis management were presented, without giving them any indication of the scenario which would be played out.

Research is in progress at EDF on rapid means of prototyping control room interfaces, which can be combined with the simulator design codes. The equipment scheduled as part of the post-Fukushima project could therefore be integrated into the simulators during extreme situation tests.

4.2.3 *Getting the players involved*

How can the players get involved in the simulation of a faulted condition, in a highly-degraded environment?

It is of course impossible to recreate in the control room or in the field the degraded condi-

tions encountered by the operators during the Fukushima accident. However, using field operators, we regularly provided the control room with information on the degraded state of the facilities. For example, on returning from a simulated field inspection, the field operator drew up for the supervisor the list of inaccessible premises, damaged equipment, etc.

We have seen tests in which the teams attached great importance to the safety of the participants in the field, avoiding sending them for field actions which are irrelevant given the situation, or sending them in pairs. These observations were interpreted as a good understanding of the situation in hand.

It has however not always been clear in the mind of the teams that the site was isolated, to the extent that some were waiting for the arrival of the on call teams in order to launch important actions. The question arises of how to simulate the consequences of the external hazard on the environment of the plant which have a major impact for the operators and their actions.

4.2.4 *Importance of multi-reactor accident simulations*

Our studies into the Fukushima accident highlighted the interactions which took place between the different damaged units on the site (Baudard, 2017): immobilization of resources, focus on one reactor at the expense of the others, transfer of experience, etc.

Thanks to the autonomy we left to the teams, they were able to perform out of the procedures actions, and we identified transfer of experience mechanisms during the simulations. For example, one operating team benefited from the experience of the team from the neighboring plant unit in restoring the power supply using the backup means scheduled in the post-Fukushima provisions.

Our work on the ES tests highlighted favorable factors allowing these beyond-design-basis crisis situations to be managed, but there are also factors which will require progress. Since these simulation of multi-units accidents are relatively recent, we think that it would be helpful, for understanding and improving resilience, to develop these simulation situations, but also simplifying them.

4.3 *Our proposition for future preparations*

Indeed, even though the organization, observation and analysis of the tests have been highly beneficial for the development of knowledge on Extreme Situations management by the parties involved within the company, these tests are too costly and too time consuming.

We have already started investigating lighter simulation methods for the teams involved in crisis management (through Serious Games or Storytelling for example), focusing on one specific group rather than the whole organization, and simulating its environment. A prototype has been tested with the National Technical Support Team (Alengry et al, 2018).

A stochastic-based evacuation model for risk assessment in road tunnel fire accidents and the importance of educating users

P. Ntzeremes
School of Mechanical Engineering, National Technical University of Athens, Greece

K. Kirytopoulos
School of Natural and Built Environments, University of South Australia, Adelaide, Australia

ABSTRACT: Road tunnel management is oriented in protecting tunnels from fire accidents that can evolve to disasters causing several human losses and extended infrastructure destruction. In order to enhance tunnels' safety, analysts usually employ Quantitative Risk Assessment (QRA) models for predicting human losses. However, human behaviour includes significant uncertainties during the evacuation process. This paper aims to address this problem proposing a stochastic-based evacuation model. Employing Monte Carlo approach, a set of simulations is conducted in which users' behaviour modelling is based on data from the existing theoretical framework, post-accident reports, conducted experiments and legislation requirements. Applying the model to a typical Greek tunnel, the outcome highlights a significant proportion of scenarios that exceed losses estimated by traditional approaches revealing also potential fallacies. The model's contribution rests on the provision of a stochastic-based simulation that is closer to describing reality than a simple deterministic model, as far as users' evacuation is concerned.

1 INTRODUCTION

Road tunnels are regarded as a key element of the road network as they connect remote regions since they create short-cuts in mountainous ranges. In addition, the growing concentration of population in large urban areas has inevitably lead to the extended use of underground road tunnels in order to relief the increasing traffic volumes (PIARC, 2016).

Due to the aforementioned implementations, road tunnels are considered critical infrastructures. A critical infrastructure can be defined as "… facilities of key importance to public interest whose failure or impairment could result in detrimental supply shortages, substantial disturbance to public order or similar dramatic impact" (Gheorghe, et al., 2006, p. 6). This criticality was confirmed by the adverse effects in terms of human losses and infrastructure destruction from various past accidents. For instance, the Mont Blanc tunnel accident in 1999, the worst accident in Europe, cost the life of 39 people and around 350 million Euros for the repair (AADT, 1999). Likewise, the Sasago tunnel accident in 2012, the worst tunnel accident in Japanese history, where the tunnel ceiling collapsed causing fire and cost the life of 9 people. Meanwhile, the road network of the region remained closed for almost two months (Maskura, et al., 2015). To this respect, road tunnels, like any complex socio-technical and critical system, must be designed to ensure an acceptable level of safety (Kirytopoulos & Kazaras, 2011). For tunnels specifically this would mean protection against fire accidents considering that can evolve to disasters.

In order to enhance tunnels' level of safety, safety analysts usually apply the risk assessment process based on various Quantitative Risk Assessment (QRA) models (Kirytopoulos, et al., 2010). The ultimate goal of a QRA model is to estimate the tunnel level of safety in case of a fire accident focusing primarily on predicting human losses amongst trapped-users. With this respect, QRA models often examine a subset of some crucial fire scenarios in a deterministic approach based on specific guidelines and regulations that each country has adopted (PIARC, 2012). However, post-accident reports, full-scale and virtual experiments towards the aspect of human behaviour under emergency situations have illustrated significant uncertainties regarding the self-evacuation process of the trapped-users. Despite that, national guidelines as well as QRA models do not take into account this information during the analysis in sufficient detail.

This paper aims to address this problem by proposing a model with a stochastic-based approach. The proposed model employs Monte Carlo

approach for conducting a set of simulations in which users' behaviour during the discrete stages of their self-evacuation process is based on probabilistic data. The probabilistic data used in the model were sourced from various findings from existing theories, post-accident reports, conducted full-scale as well as virtual experiments and legislation requirements. The outcome provides safety analysts with a prediction of the distribution of both successful and non-successful self-evacuations in order for them to estimate the overall tunnel safety and select additional measures, if required. Furthermore, by surfacing the impact of self-evacuation to the evolvement of the accident, it points out the importance that authorities and tunnel managers should give on educating tunnel users in order to react appropriate in such accidents.

2 EVACUATION PROCESS IN TUNNEL FIRE ACCIDENTS

2.1 *General principles of the evacuation models*

The safety ground of the road tunnel system encompasses all the crucial elements of the system and classifies the latter into five basic categories, namely: (a) the facilities, (b) the infrastructure, (c) the traffic, (d) the users and (d) the vehicles (Kirytopoulos, et al., 2017). The risk assessment methods deal with these categories that combine to form the tunnel level of safety as high as reasonable possible.

Users' losses is the representative parameter that provides the preparedness of the tunnel system in confronting fire accidents. Thus, each of the risk assessment methods focuses primarily on estimating the possible losses amongst trapped-users and is concerned about how to reduce them (PIARC, 2012).

Indeed, tunnel users consist the most vulnerable factor of the system. They are the first who confront with the fire consequences in a tunnel and in most of the cases without being adequately experienced in such circumstances. Moreover, they do not have appropriate equipment with them and often they do not have the education of other groups, like the members of the rescue teams, on how to react in critical situations (Kirytopoulos, et al., 2017).

Furthermore, fire in tunnel has much different behaviour than fire in the open road. In particular, it has rapid development, remains in maximum Heat Release Rate (HRR_{max}) longer and releases much more fumes (Beard & Carvel, 2012; PIARC, 2017). As a result, trapped-users have to evacuate themselves in a strictly limited time interval, which does not allow for any delay in the beginning of the self-evacuation process for the anticipation of external rescue teams.

Servicing the principles of managing risks in which users' factor must be taking into account, users' behaviour during the evacuation is in the centre of attention in order to assess and enhance road tunnels' level of safety.

The majority of the evacuation models, like engineering hand calculations and computer tools, are used in order to calculate the time it takes for trapped users to evacuate the tunnel walking away from the fire environment and heading towards a safe place as the emergency exit doors or the tunnel portals (it depends from the fire location) as soon as possible. An important prerequisite in this direction is the establishment of two basic time parameters, the Available Safe Egress Time (ASET) and the Required Safe Egress Time (RSET). ASET is defined as the time which is actually available for trapped users from fire sparking and the time point at which conditions become inadequate for human life, because of the high rates of pollutant concentration and radiation. On the other hand, RSET refers to the time that trapped users actually need for a successful outcome of their self-evacuation. The aim of the safety analysts is to achieve the ASET to be greater than RSET (Kinateder, et al., 2015). To do so, they have to forecast two main things of the evacuation process: the actions that people take and the time it needs for these actions to be performed.

However, most of the risk assessment methods as well as evacuation models implement oversimplified assumptions about the different stages of evacuation process and the behaviour of trapped-users. Furthermore, they have to follow the country-specific regulatory requirements. These approaches might increase the uncertainty of evacuation models that subsequently lead to a considerable uncertainty of the whole safety approach. Hence, it is important to design models taking into account potential information or clues from both real accidents and studies about human behaviour in fire evacuation and adapting them to the models, accordingly. If so, the uncertainties regarding the overall level of tunnel safety could be diminished.

2.2 *Human behaviour in evacuation process*

2.2.1 *Theoretical framework*

Human behaviour in fire evacuation process depends on which phase of the process the user performs. The big picture of the evacuation process in tunnels can be separated in three main phases (Kuligowski, 2013).

Initially, the first phase is the ignition phase. This point has some perturbation as not all the

users perceive the fire location promptly and also at the same time. For this reason, there is possibility for another accident to occur, such as crashing, upstream of the fire location. The second phase is the pre-evacuation phase. In this phase the user receives, collects and processes the cues in order to decide his own self-evacuation strategy. The progress of this phase depends on both the knowledge of the user and user's risk perception, as well. These two phases constitute the no-moving period and the time that elapses can prove fatal for the users. Experiments showed that under certain circumstances even a couple of seconds delay can neutralise the user (Ntzeremes, et al., 2018). The last phase of the evacuation process is the moving period. In this phase, trapped-users begin to walk away from their positions inside the tunnel and heading towards to a safe location. In tunnels, depending on the fire location, emergency exit doors and/or the tunnel portals are considered as safe locations. However, post-accidents reports indicated that not all users were willing to abandon their cars hoping that rescue teams could extinguish the fire soon or underestimating the fire behaviour (AADT, 1999).

With regard to the aforementioned phases of the evacuation process, there are some common theories in order to interpret trapped-users behaviour (Fridolph, et al., 2013). The first theory is the behaviour sequence model, which separates the human behaviour in four distinct mental and physical actions. So, a user initially receives, after interprets, subsequently prepares and in the end acts. The next theory is the role—rule model. This model makes the assumption that every user in a critical situation would behave according to the set of rules steaming from his position. A subsequent theory is the affiliation model, which assumes that a person would head to places or follow people that are familiar to him. The last theory deals with the social influence. This approach considers that the presence of other people would affect the user's evacuation process.

2.2.2 *Evidence from real and virtual cases*

Placed next to theoretical framework, a valuable source on human behaviour in fire accidents is the evidences from real and virtual accidents, both for the no-moving period and also for the moving period.

Regarding the post-accident reports, in the most disastrous tunnel accident in history, the Mont Blanc accident, one of the most important observations is that a significant number of 27 users delayed enough the evacuation process or they did not even started remaining in their vehicles. On the contrary, in Burnley accident in Sydney in 2007, the quick reaction of both the users and the emergency response units reduced the RSET significantly reducing both the causalities and injuries (Fridolph, et al., 2013).

Furthermore, studies based on virtual accidents can also provide analysts with information about users' behaviour. For instance, some studies illustrate the important factor of social influence during evacuation (Kinateder, et al., 2014). Subsequently, some other studies explored the factor of risk perception of users and the relationship between fire and awareness of successful evacuation process (Ronchi, et al., 2015). Other studies explore users' behavioural intentions and knowledge in case of fire accidents. Outcomes were far away from reflecting the expected ones, as users often had totally underestimate the criticality of the accidents (Kirytopoulos, et al., 2017). The aforementioned information illustrates the high perturbation amongst the information on the way that trapped-users might behave during fire accidents. Thus, there is a lack of available data for use by evacuation models as far as the no-moving period of users' self-evacuation process.

However, similar perturbation and lack of data exists in the estimation of the moving period, too. One of the most important factors when assessing safety in tunnels is the users walking speed through smoke, which is the basic evacuation performance characteristic. Smoke caused by fires flows stratified in the tunnel tube and large space during the initial fire, and after the stratification of the smoke is disrupted by the heat absorption by the ceiling wall. Subsequently, it starts to diffuse inside the tunnel, making evacuation activities, rescue activities and fire extinguishing activities extremely difficult. Studies have shown that walking speed does not only steams from the physical ability of the user but also affected from the speed of information exchanged, the experience and the knowledge of the user as well as from the social influence (Ronchi, et al., 2015).

Furthermore, a number of full-scale experiments estimating walking speed have been conducted. In such experiments, researchers examine different group of participants in different smoke situations (irritant and non-irritant smoke). As a result, the outcome shows a strong interrelation between the extinction coefficient, which shows how easily the air can be penetrated by a beam of light, and the estimating walking speed in normal and emergency situations (Seike, et al., 2016).

2.2.3 *Country-specific regulations*

Last but not least, the country-specific regulations, usually determine the context in which a safety analyst should operate affecting the analysis. Often, in these regulations, the walking speed of the user in relation to opacity is provided as a deterministic

number, which is something that does not always reflect reality (PIARC, 2012).

3 METHODOLOGY

In order to estimate the tunnel level of safety, a simulation-based research is used. This approach can aid a better understanding of the phenomenon, the outcome of the self-evacuation process of trapped-users in a fire accident, having the advantage that includes and integrates available data from existing theories and experiments. The structure of the process is as follows:

Initially, the fire scenario along with the fire location are selected. Trapped-users' evacuation is illustrated as a trajectory, depicted as line segments depending on the walking speed, with regard to tunnel length and time. Fig. 1 provides an example of the evacuation process.

Road tunnels have generally simple and straight geometries in which the relative distance of the users from the fire source, the fire characteristics and the time spent inside the tunnel are the main factors affecting life safety. In order to estimate the impact of fire on trapped-users, firstly, the tunnel's airflows (the air temperature and the air opacity) should be estimated. The Computational Fluid Dynamic (CFD) process is performed with the aid of Camatt 2.0 software. The outcome provides two sources of data, the air temperature and the air opacity with regard to the tunnel length and time. Subsequently, these data are used for the estimation of the effect of the heat and pollution on the evacuation trajectories of the users.

Trapped-users safety are affected by accumulating heat of both radiation and convection. The estimation of the Fractional Effective Dose of heat (FED_h) in every time step and location is estimated by the following equation:

$$FED = \Sigma(1/t_{iconv.}+1/t_{irad.})*\Delta t \quad (1)$$

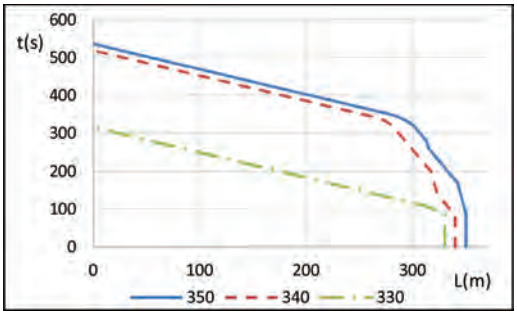

Figure 1. Evacuation process with fire location at 350 m.

where $t_{iconv.}$ is the time duration for convective heat, which is calculated as:

$$t_{iconv.} = (5*107)*T^{-3.4}\text{: for light clothing} \quad (2)$$

where {t} the time in minutes and {T} the temperature in °C, and where $t_{irad.}$ is the time duration for burning of skin by radiation, which is calculated as:

$$t_{irad.} = 4*q^{-1.36} \quad (3)$$

where {t} the time in minutes and {q} the radiant heat flux in kW/m^2 (for q > 2.5 kW/m^2; for q < 2.5 kW/m^2 this time is equal to 30 min).

Along with the effect of heat, trapped-users are also affected by accumulating toxicity by pollutants concentration. Carbon monoxide (CO) is the toxic gas on which toxicity is raised, based on the national standards. The estimation of the Fractional Effective Dose of CO (FED_{co}) in every time step and location is estimated as follows:

$$FED_{co} = \Sigma(0.00083*CO^{-1.036}*\Delta t)/D \quad (4)$$

where {Δt} is the exposure time in minutes, {CO} is the CO concentration in ppm and {D} is the concentration at incapacitation.

In order to estimate the FED of heat and pollution concentration further information is needed regarding the evacuation trajectory of the users. In the presented model, contrasting to the commonly used deterministic approach, the stochastic variables of the evacuation process are defined exhibiting the interrelation amongst current literature and national regulations.

Initially, a time that indicates the no-moving period, is selected. The no-moving period, consisting of the ignition and the pre-evacuation phases, is defined by the stochastic variable of how much time it takes before moving period begins. In Purser's study, this time regarding the Mont Blanc accident was specified between 40s and 90 s. Another study from Japan specified this time between 30 s and 120 s (Seike, et al., 2016). On the contrary, Greek regulations do not determine this time, but the most commonly time used in such analyses is approximately 90 s. Synthesising the existing data along with the Greek provisions, a uniform distribution with 60s as a lower limit and 120 s as an upper limit, is considered in order to be at the safe side.

In addition, the stochastic variable that characterises the moving period is the walking speed of the users. With a view to represent as closer to reality, the process employs existing studies results towards the connection between air opacity and walking speed (Seike, et al., 2016; Ntzeremes, et al., 2018). Synthesising these data with the

Table 1. Users' walking speed.

Speed (m/s)			
Distribution	Normal	Normal	Normal
Mean	1	0.5	0.2
St. Div.	0.067	0.067	0.05
Opacity (m^{-1})	(0, 0.50)	[0.50, 0.70]	[0.70, …)

Greek provisions, three moving intervals are defined (Table 1).

At the beginning, the process estimates human losses using the deterministic values of the Greek provisions (AAT, 2011). These values are the mean points of the aforementioned distributions. As a result, the outcome that safety analysts would estimate according to the current deterministic approach, is provided.

After building the model, the simulation is executed, with the aid of Matlab 2017b software, for 1000 iterations using the time distribution of the no-moving period and Table 1 elements for the moving period. This step forms the "60–120" scenario. Having created the distribution of losses, the results of both the deterministic and the stochastic approach are compared. Afterwards, another two repetitions of the process are conducted changing first the upper limit of the no-moving period, reducing it by 30 s creating a new uniform distribution between 60 s and 90 s ("60–90" scenario). Subsequently, reducing generally the delay time of trapped-users a second new uniform distribution between 30 s and 90 s ("30–90" scenario) is created. These two aforementioned scenarios are related to two user training scenarios, one with the goal to reduce the upper reactive limit and the other decreasing the upper and the lower one.

In the end, the outcome provides a prediction of the distribution of non-successful self-evacuations.

4 ILLUSTRATIVE CASE

4.1 *Case description*

A de-identified road tunnel in Greece fulfilling both the Greek and European safety requirements, is selected. The examined fire scenario, which is a standardised fire scenario of Greek regulations, involves a fire of HRR_{max} 100MW sparking from a HGV without carrying dangerous goods (PIARC, 2017; Ntzeremes, et al., 2018). The location of the fire, 350 m from the entrance of the tunnel, is part of the entry area, which regarded as the most common and one of the most vulnerable locations of the tunnel (PIARC, 2017, p. 12). Tunnel's attributes are shown in Table 2.

Table 2. Tunnel's attributes.

Designing features	One dimension—single sector—rural	
	Total length	3.000 m
	Slope	–1,5%
	Number of exit doors	6
	Number of traffic interruptions	7
	Starting time of traffic lights after fire ignition	5 min
Mechanical ventilation	Number of jet-fan-array	8
	Starting time	2 min
Traffic conditions	Vehicle flux	55 veh./hr.
	Proportion of HGVs	30%

4.2 *Results*

In order to simulate trapped-users trajectories, their initial locations are required. To this respect, the analysis assumes uniform traffic condition and uniform distribution of the stopped-vehicles. So, at the time fire outbreaks, the traffic simulation results in 10 trapped-vehicles shaping one row with 10 m distance in-between. Hence, the model estimates the losses corresponding to the locations that the vehicles have stopped (e.g. Fig. 1), taking into account that each vehicle has two users.

On the one hand, the analysis following the traditional deterministic approach using the mean points of the aforementioned distributions estimates eight losses (there are four fatal trajectories corresponding to the fire location and the three consecutive locations upstream the fire). However, if a more conservative approach is applied, the outcome would be with less losses. For instance, if the time when the evacuation starts is determined at 60 s and the users' speed remain the same, only two losses (only the fire location's trajectory is fatal), are estimated. This outcome highlights how the expert judgment or an incorrect threshold can alter the estimated safety level.

On the other hand, the stochastic approach illustrates a much different outcome. Fig. 2 presents a wider distribution of the scenarios.

Fig. 2 shows that regarding the simulation of "60–120" scenarios set only 18.8% of the scenarios include eight losses. The outcome provides an approximately equal probability amongst the scenarios of four, six, eight, ten and twelve losses arising significant uncertainty. This outcome raises serious concerns about the safety of the tunnel. There is a significant probability of 41.2% scenarios to have ten or more losses (up to fourteen), although there is an equal probability of 40% of

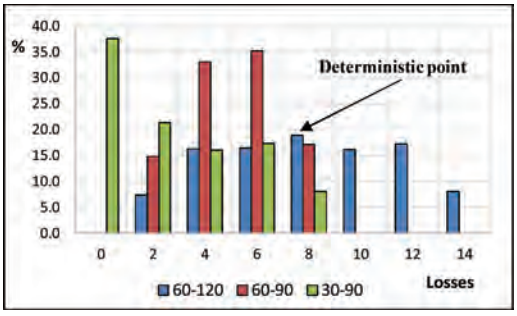

Figure 2. Distribution of evacuation scenarios.

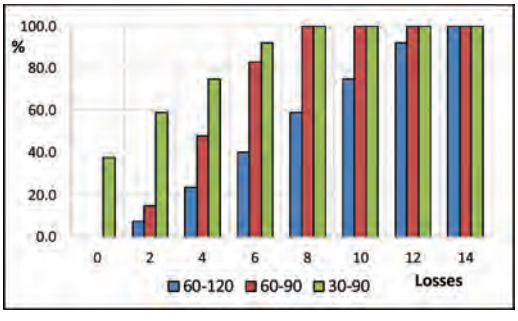

Figure 3. Cumulative function of evacuation scenarios.

scenarios to have less than eight losses, which cannot counterbalance the probability of very adverse consequences. The potential additional measures in case of fourteen losses require quite different additional measures than if there were only four, as this discrepancy raises in 30 m longer the lethal length of backlayering.

Furthermore, the "60–90" simulation shows that if the evacuation starts no longer than 90s, there is 83% probability of having favourable outcome with regard to the deterministic approach and 40% with the "60–120" scenario. In this outcome, the trapped-users corresponding to the fifth, the sixth and the seventh stopped-vehicle are considered totally safe. However, as in the "60–120" case, still all the scenarios include losses.

Only the last case ("30–90" scenario set) has 37.5% probability of including scenarios without losses. However, there is an equal probability of having up to six losses, which indicates that the need for taking additional measures is inevitable.

However, the results indicate also the importance of users' attitude in fire accidents. To this respect, reducing the upper limit of the time corresponding to the no-moving period, trapped-users before the first 40 m are successfully evacuating the tunnel. Nevertheless, the safety problem of the tunnel still remains. So, if the users are educated enough in order to start the evacuation process immediately, the outcome shows that approximately 40% of the scenarios have no losses without changing any other parameter of the system.

In order to illustrate the safety level of the tunnel the cumulative diagram of losses is employed. Based on this, safety level can be a strict threshold (e.g. 2 losses should be not exceed 20%) or can be estimated based on as low as reasonable possible (ALARP) principle.

In addition, the effect of users' education is also reflected in Fig. 3. Consequently, through the simulation one can observe the wider spread of losses in contrast to the deterministic approach. It is remarkable how a small reduction of only 30s in the range of the time of the beginning of the evacuation can benefit the overall safety level. Thus, a huge effort must be given towards the sensitisation of authorities and tunnel users towards safety.

5 CONCLUSIONS

The presented study illustrates that the current safety approach towards road tunnels, which constitute a critical infrastructure of the road network, by applying QRA models should focus further on the users' factor. The existing literature provides safety analysts with the theoretical amendments to interpret human behaviour in fire accidents. Furthermore, the cues from previous accidents as well as the full-scale experiments and virtual reality experiments enlighten better scientists in discovering crucial parameters of the evacuation process.

However, there is lack in data that would assist evacuation models to give outcomes with lower uncertainties. In the presented illustrative case, the use of the deterministic approach together with the country-specific regulatory requirements cannot estimate the tunnel's actual level of safety. The first gives four losses when the stochastic approach estimates 60% of the scenarios above this value. Nevertheless, the outcome provides safety analysts with a prediction of the distribution of non-successful self-evacuations in order to estimate the overall tunnel safety and select additional measures, if required. Hence, this approach is closer to describing reality than a simple deterministic model, as far as users' evacuation is concerned. In a nutshell, it aids risk analysts make better-informed decisions.

Furthermore, the change in the parameter of the beginning of the evacuation process shows the importance of educating tunnel users in confronting with these accidents. The outcome showed that a reduction of time by 30s could result in 40% of

the scenarios be free of losses, when in the basic case all scenarios have from two to fourteen losses.

ABSTRACT: This paper describes the newly-developed damage-based fatigue life model for the long-term reliability assessment of the drawn steel wires and the wire ropes. The methodology is based on the computed local stress field in the critical trellis contact zone of a stranded wire rope by the FE simulation and the degradation of the Young's modulus of the drawn steel wires. The fatigue damage model is based on Lemitaire's damage equations for quasi-brittle material with a damageable microinclusion embedded in an elastic mesoelement. The incremental fatigue damage calculations employing the load-cycle block is described. The routine is integrated into commercially available Finite Element Analysis (FEA) software. A case study using a single strand (1 × 7) steel wire rope with 5.43 mm-dia. drawn wires is employed to illustrate the damage-based fatigue life prediction procedures. The simulated tensile fatigue cycles consist of the load range of 145 kN and load ratio, $R = 0.1$. The peak applied load corresponds to 50% of the maximum breaking load of the steel wire rope. The FE-calculated results indicate that the von Mises stress, maximum principal stress and the contact pressure cycle in-phase, and with an identical stress ratio as the applied axial load. The trellis contact point is relatively small and experiences elastic stresses, thus the fatigue damage prediction for the fretting fatigue condition is appropriate. The damage initiation life at the trellis contact along the core wire is calculated at $N_o = 1050$ cycles. An additional and improved data set of the damage model parameters of the drawn steel wires is required to achieve an accurate and validated life prediction model of the wire ropes.

1 INTRODUCTION

Steel wire ropes have found numerous applications in marine and civil construction including the mooring system for FPSO in the deep sea, bridge suspension elements for suspended and stayed structures, and lifting cranes. In these applications, the wire ropes are subjected to complex loading, often involving tension-tension fatigue induced by both the lifted weight and self-weight of the component, bending over the sheave fatigue, free bending fatigue due to transverse load such as ocean current, and torsion fatigue. The sea operating environment further amplifies the reliability issue through stress corrosion cracking of the wire rope elements. The rated or operating load for the wire rope is often a fraction of the Maximum Breaking Load (MBL) of the wire rope and induces stresses in the elastic range. However, the combination of the relatively high stress amplitude and the positive load ratio, particularly at the trellis contact region, could initiate damage and nucleate fatigue crack at the locality. The subsequent crack propagation leads to fracture of the critical drawn wire, redistribution of stresses in the fracture locality and failure of the neighboring drawn wires thus leading to premature fatigue failure of the wire rope. Considering the associated high cost of installation, and if needed, the very costly and difficult to replace wire rope (Raoof & Davies 2008), an efficient and accurate predictive tool is required for reliability assessment of the wire ropes over their typical design life of 20 years.

The common causes of fatigue failure of the wire rope are due to the contact pressure and slip (Waterhouse 2003). The relatively high contact pressure developed at the trellis contact between the layers of the strand wires in a small contact region. Consequently, this induces partial slip with small displacement amplitude causing the fretting fatigue failure. In a wire rope design having a large lay angle, a line contact is established between the wires in the strand causing a large slip contact region. The relatively large amplitude of

displacement results in gross slip and failure occurs by fretting wear of the wire rope. In both cases, the development of a failure model should account for both the mechanics of deformation and mechanism of failure of the wire rope. The work describe in this paper is limited to wire ropes failing under the fretting fatigue mode.

Fatigue life prediction of the wire rope is a challenging task because the wire rope is a system consisting of many drawn wires arranged in different windings and simultaneously enduring the applied load. Design against failure due to the tensile load that exceeds the breaking strength of the wire rope has been established (Prawoto & Mazlan 2012). Fatigue testing of the wire rope samples to generate the fatigue-life curve seems a straight-forward way of life prediction. Most of the available fatigue-life data for the wire ropes are generated from tests at zero-depth (in-air environment). In this respect, extensive axial fatigue-life test data on sheathed steel spiral strands have been established (Raoof & Davies 2008). The work also quantifies the effects of external hydrostatic pressure, representing the deep-water loading condition, on the fatigue performance of the sheathed wire ropes. Fatigue design of the wire ropes that considers both the high-cycle fatigue of the stranded wires and the inherent fretting effects have been examined (Winkler et al. 2015, Wang et al. 2013, Cruzado et al. 2012, Sasaki et al. 2007). The fatigue-life data for the wire ropes are based on data taken from available standards such as DNV OS-E301 (2004) and open literature (Raoof & Davies 2008, Alani & Raoof 1997, Birkenmaier 1980, Suh & Chang 2000). However, the reported fatigue strength of these wire ropes is relatively low at $(S_{lim} / S_U) = 0.15–0.3$ (Kao & Byrne 1982). The continuum-based high cycle fatigue life model such as the modified Goodman and Soderberg approach could only predict the terminal life of the most critical wire. While fatigue failure of the wire rope is often defined by the area fraction of the fractured wires. Reliability model based on the local stress concentration due to the erosion of the wire material at the contact locations has also been proposed. However, the evolution of the local geometry of the area is difficult to establish.

This paper describes the framework for the development of a damage-based fatigue life model for the steel wire ropes. The methodology for damage and failure assessment of the wire rope materials under the high-cycle fretting fatigue condition is discussed. An incremental calculation routine based on cyclic degradation of the elastic modulus of the drawn wires is deliberated. A preliminary simulation for the case of a single strand (1 × 7) steel wire rope under tensile fatigue loading is demonstrated.

2 FRAMEWORK FOR THE DAMAGE-BASED FATIGUE LIFE PREDICTION

The reliability assessment of the steel wire ropes is aimed at the prediction of the fatigue life of the wire rope when subjected to the general loading conditions. Figure 1 illustrates the framework for the development of a validated damage-based fatigue life prediction model for the wire ropes. The fatigue life of the wire rope is governed by many factors including the design and material of the drawn wires, fabrication process, operating load conditions and environment. The wire rope design also indicates if fretting fatigue at trellis contact or fretting wear causing gross slip is dominating the failure scene. The fretting fatigue failure is being addressed in this paper. Fatigue tests of the wire rope establish the corresponding fatigue life, N_f, represented by *Task (A)*. *Task (B)* constitutes of the tension tests of the drawn steel wires to establish the mechanical properties of the material. Fatigue tests of the drawn wires are performed to establish the strength-life and fatigue limit of the wire material. Damage parameters are also extracted from the resulting S-N curve. The damage-based fatigue life model of the drawn wire material is developed in *Task (C)*. The properties and damage model parameter values obtained in *Task (B)* are employed. The damage model is then incorporated in the finite element analysis (FEA) through user subroutine *UMAT* for the *Abaqus FEA* software employed in this study, in *Task (D)*. The FE-computed fatigue life is compared with the measured life from *Task (A)* to establish the validity of the fatigue life prediction model.

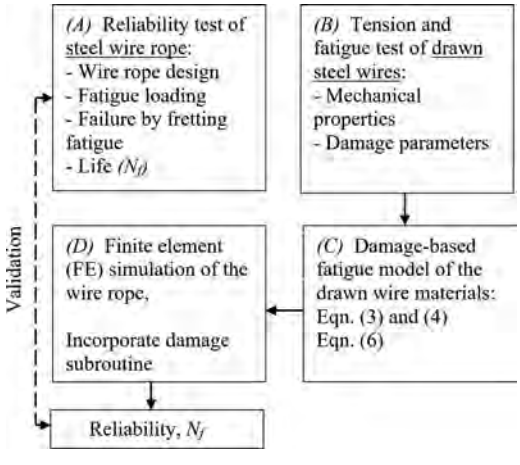

Figure 1. Framework for the damage-based fatigue life prediction of the steel wire ropes.

2.1 *Fatigue damage model*

Damage in a material can originate from the debonding of atoms or the nucleation, growth and coalescence of microcavities or microcracks. It leads to the gradual degradation of stiffness and strength of the material. Although the damage process is discontinuous in nature, it can be modelled by a continuous variable at the mircoscale (Lemaitre 1985, Kachanov 1958). In a representative volume element (RVE) of the material, the damage parameter is defined by scaling the damaged area, A_D by the total cross-sectional area, A of the RVE such that:

$$D = \frac{A_D}{A} \tag{1}$$

The damage parameter is continuous and represents the failure of microdefects over the mesoscale volume element. The value of the scalar damage variable, D is bounded by $0 \le D \le 1$, where $D = 0$ represents the undamaged state while rupture (or separation of the material point) occurs at the value of $D = 1$. Following damage initiation, the effective stress tensor, $\{\tilde{\sigma}\}$ can be represented by:

$$\hat{\sigma}_{ij} = \frac{\sigma_{ij}}{1 - D} \tag{2}$$

where σ_{ij} is the Cauchy stress tensor.

The evolution of this damage variable that depends on the expected value of the micro-defect density can then represent the history of the inelastic strain in the material. In the high-cycle fatigue where the amplitude of the loading is low, the amplitude of the plastic strain is relatively small or negligible at the mesoscale when compared to the elastic strain amplitude. For the drawn steel wires that are assumed to behave in a quasi-brittle manner, the behavior is brittle at the mesoscale but localized damage growth occurs at the microscale. Thus, the material is modeled as a damageable microinclusion embedded in an elastic mesoelement, as illustrated in Figure 2. While the mesoscale matrix is elastic, the microscale inclusion experiences elastic, plastic and damage. In addition, it is assumed that the inclusion is subjected to the same strain state (or strain rate) as the mesoscale matrix.

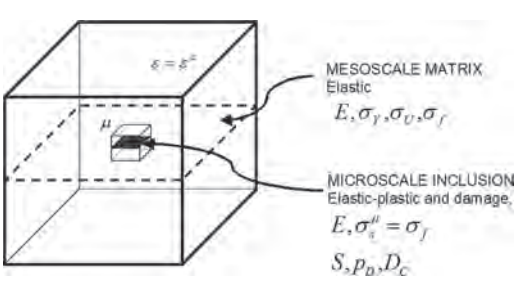

Figure 2. Representative Volume Element (RVE) for the two-scale model (Adapted from Lemaitre (1985)).

The prediction of the rupture or the separation of the material point requires the coupling between the plastic flow and damage at the material constitutive level. Detailed derivation of the damage equation is found in the work of Lemaitre (1996) and employed by the authors (Salleh et al. 2017). Damage initiation occurs when the equivalent strain reaches the damage strain threshold, p_D defined as:

$$p_D = \frac{\sigma_u - \sigma_f}{\sigma_f - \dfrac{\sigma_f^2}{\sigma_Y}} \tag{3}$$

where σ_Y, σ_u and σ_f is the yield stress, tensile strength and fatigue limit of the material, respectively. The number of cycles, N_o needed for the equivalent strain to reach the damage threshold, p_D is given by:

$$N_o = \frac{p_D}{2\Delta\varepsilon} = \frac{E\,p_D}{2\Delta\sigma} = \frac{E\,p_D}{4\left(\sigma_M - \bar{\sigma}\right)} \tag{4}$$

where E is the elastic modulus of the material, σ_M denotes the maximum stress and $\bar{\sigma}$ is the cyclic mean stress in the cycle.

Based on the kinetic damage law for the inclusion, and considering the relatively large plastic strain compared to the elastic component of a micro-volume, μ the evolution of damage is expressed as:

$$\dot{D} = \frac{Y^{\mu}}{S}\dot{p}^{\mu} \tag{5}$$

The superscript, μ refers to quantities for the microelement and S is a material damage parameter. It is desirable to express the damage strain energy release rate, Y^{μ} and the accumulated plastic strain rate, $\dot{p}^{\mu}$ terms as functions of the macroscopic quantities such as strain and stress. The plastic strain rate, $\dot{p}^{\mu}$ of the elastic-perfectly plastic microvolume is equal to the equivalent strain rate of the elastic mesoscale matrix.

We consider pure elasticity at the mesoscale and further approximate the damage rate, $\dot{D} = 0$ if the equivalent stress, $\sigma_{eq} < \sigma_f$, the fatigue limit of the material. In addition, an increase in the mean stress causes a decrease in the corresponding stress amplitude needed to induce fatigue failure at a certain number of cycles. Under these conditions, eqn. (5) can be conveniently written in incremental form as (Salleh et al. 2017):

$$\Delta D = \frac{2\sigma_f^2}{E^2 S}\left[\begin{array}{l}\frac{2}{3}(1+\nu)\left(\sigma_M - \sigma_f\right) \\ +\frac{1-2\nu}{9\sigma_f^2}\left(\sigma_M^3 - \sigma_f^3\right)\end{array}\right](\Delta N) \quad (6)$$

The term, ΔD represents the increment of the fatigue damage accumulated over the elapsed load cycles, ΔN while E and ν is the elastic modulus and Poisson's ratio of the material, respectively. It should be acknowledged that the Young's modulus of the material is likely to degrade with the accumulated load cycles. In addition, the rate of the stiffness degradation is dependent on the magnitude of the acting stress cycles and the stress ratio, as described in the next section. The separation or rupture of the critical material point would occur when the accumulated fatigue damage variable reaches a critical level (denoted by D_C in Table 1).

2.2 *Incremental fatigue damage calculations routine*

Fatigue damage is estimated based on the gradual degradation of strength and modulus of the drawn steel wire over the applied load cycles. Each simulated load cycle represents a block of specified number of cycles on the wire rope. During this load increment, the decrease in the modulus of the drawn steel wire is prescribed as observed experimentally. The calculations of the fatigue damage that occur at a material point during the given increment of the load cycles, ΔN is described by the process flow as illustrated in Figure 3. This constitutes a user-defined *SUBROUTINE UMAT* for the commercially available *Abaqus FEA* software employed in this work. The current stress tensor, σ_{ij} fatigue damage level, D the accumulated fatigue cycles, N residual stiffness, $E(N)$ properties of the drawn steel wire (S, ν, σ_y, σ_u, σ_f) and the load-cycle block size, ΔN are transferred from the main FE program.

STEP2 calculates the simulated load cycle parameter, namely the maximum, σ_M and mean stress, $\bar{\sigma}$. The number of load cycles, N_o required to initiate fatigue damage at this material point is estimated. The calculations proceed to the subsequent steps if the material point experiences damage initiation.

Table 1. Properties and damage model parameters for the drawn steel wires.

Parameter	Symbol	Value
Elastic modulus	E_o (GPa)	202
Yield strength	σ_y(MPa)	1690
Tensile strength	σ_u(MPa)	2164
Poisson's ratio	ν	0.28
Fatigue limit	σ_f(MPa)	305
Damage parameter	S(MPa)	6
Critical damage	D_C	0.8

SUBROUTINE UMAT

STEP1 Transferred from main program:
σ_{ij}, D, N, $E(N)$, ΔN
S, ν, σ_Y, σ_u, σ_f

STEP2 Increment $N = N+\Delta N$
Determine σ_M, $\bar{\sigma}$
Calculate N_o (eqn. (4))
IF $N \geq N_o$, calculate the damage
ELSE RETURN

STEP3 Determine (N_f, σ_f) from S_{max}-N curve (as corrected using Miner's rule)

STEP4 Determine residual $E(N)$ corresponding to N cycles (eqn. (7))

STEP5 Compute ΔD (eq. (6))

STEP6 Update for N:
$D = D+\Delta D$
$\sigma_{ij} = \frac{\sigma_{ij}}{1-D}$

RETURN

Figure 3. Flow chart of the incremental damage calculations over a load-cycle block.

In *STEP3,* the fatigue strength-life curve (see Figure 5) is corrected since the material point has been overstressed for finite number of cycles [Miner 1945]. The number of cycles to failure, N_f corresponding to σ_M is established. It is used in eqn. (7) to establish the residual elastic modulus, $E(N)$ of the drawn steel wire at the end of the load-cycle block in *STEP4.* Next, the increment of the damage parameter, ΔD over the increment of the load cycles is established using eqn. (6).

Finally, in *STEP6* the damage variable and the stress tensor are updated to correspond to the end the load-cycle block. These updated variables are returned to the main program for the next load-cycle block.

3 ILLUSTRATIVE CASE STUDY

A case study employing a single strand (1 × 7) steel wire rope construction and subjected to axial

fatigue loading is considered to illustrate the characteristic fatigue damage evolution and the life prediction of the wire rope. Although the 1 × 7 wire rope is commonly used as stayed cable, the validated fatigue life model could be used for other wire rope designs and loading conditions. The chemical composition of the drawn wires is (in wt.%) 0.83*C*, 0.91*Si*, 0.717*Mn*, 0.0124*P*, 0.0031*S*, 0.015*Cu*, the remaining being *Fe*. The observed preferred orientation of the grains along the drawing direction provides the superior strength of the wires in the axial direction. Since the damage model is developed for fretting fatigue failure, this failure mechanism should be reproduced by the steel wire rope under study.

3.1 *Finite element modeling*

The geometry of the wire rope model is illustrated in Figure 4, along with the design parameters. The core wire is straight. The total length of 330 mm of the wire rope model considered accounts for a full pitch length of 230 mm in the central length region, while the remaining lengths at both end regions are used to apply the load and boundary conditions. One end of the wire rope is fixed in both translational $(U_x = U_y = U_z = 0)$ and rotational $(UR_x = UR_y = UR_z = 0)$ displacements, while the other free end is subjected to an applied axial load, but without rotation $(UR_y = 0)$. An axial fatigue load consisting of the load range, ΔP = 145 kN and load ratio of minimum-to-maximum load, $R = 0.1$ is applied. The peak load cycle is at 50% of the maximum breaking load (i.e. 50% MBL) of the wire rope. The contact condition of the wires is prescribed to follow Coulomb's law with the assumed coefficient of friction, *cof* = 0.5 considering the surface roughness of the drawn wires. Based on the outcome of the mesh convergence study, the single strand (1 × 7) wire rope geometry is discretized into 203208 8-node continuum elements. *Abaqus FEA* software with user-defined *SUBROUTINE UMAT* is employed for the analysis.

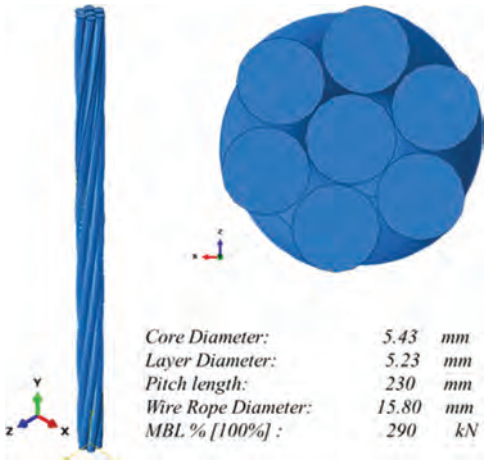

Figure 4. Geometry and the geometrical properties of the single strand (1 × 7) wire rope.

3.2 *Mechanical testing of the drawn steel wires*

The tension test is performed on the drawn steel wire specimens in the as-fabricated condition. The gage length is 100 mm. The resulting mechanical properties are listed in Table 1. The true fracture strength of the drawn steel wires, σ_R = 2.164 GPa with the corresponding true plastic strain at fracture, ε_R = 6.78% are established.

Fatigue life tests were performed on the drawn steel wires in the as-received condition at the load ratio of minimum-to-maximum load, $R = 0.1$ and loading frequency of 30 Hz. The 5.43 mm-diameter drawn wires are tested in the as-fabricated condition. The resulting fatigue strength-life (S-N) curve is shown in Figure 5 (circle symbols). The solid line compares the published fatigue life of 0.9 mm eutectoid steel wires. Effect of size (wire diameter) on fatigue life is consistent in that the larger diameter wires display a relatively shorter fatigue life. This is postulated by the greater number of manufacturing defects or microcracks inherent in a larger volume of the material within the gage section. The fatigue strength of the drawn steel wires is determined at σ_f = 305 MPa, corresponding to $N = 2.5 \times 10^5$ cycles (R = 0.1). The damage model parameter values are approximated based on the limited test data on alloy wires, as shown in Table 1 (Lemaitre 1996).

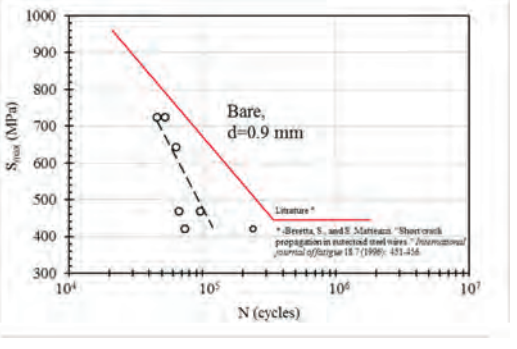

Figure 5. Fatigue strength-life (S-N) curve of the drawn steel wires, d = 5.43 mm, R = 0.1.

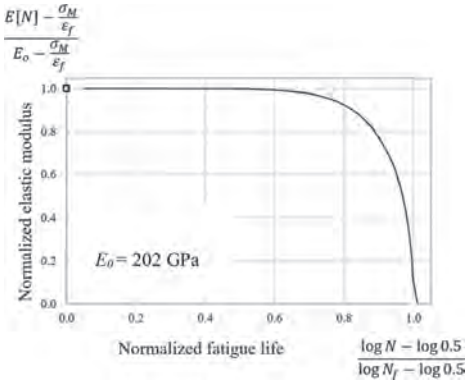

Figure 6. Normalized residual Young's modulus of the drawn steel wires.

The characteristic degradation of the Young's modulus of the drawn steel wires is established through the interrupted fatigue tests of the wire specimens. In each test, the wire specimen is subjected to a specified fatigue loading *(ΔP, R)*. The test is interrupted at every block of fatigue cycle, ΔN and the sample load-displacement response up to the maximum load cycle magnitude is recorded. The interrupted fatigue test is continued until the wire fractured. The loading and unloading residual Young's modulus as function of the accumulated load cycles are then extracted from the slope of the resulting stress-strain curves. Three different combinations of the fatigue loading is employed. The residual Young's modulus data could be presented in terms of the normalized quantities as (Adam et al. 1989, Gathercole et al. 1994):

$$E(N)=\left[1-\left(\frac{\log N-\log 0.5}{\log N_f-\log 0.5}\right)^{\alpha}\right]^{\frac{1}{\beta}}\left(E_o-\frac{\sigma_M}{\varepsilon_f}\right)+\frac{\sigma_M}{\varepsilon_f} \quad (7)$$

where α and β are curve-fitting constants. The effect of different load ratios could be incorporated through the different fatigue life, N_f of the respective specimen. The trend of the normalized residual Young's modulus curve is illustrated in Figure 6. The interrupted fatigue tests conducted by the authors for the drawn steel wires are still on-going.

4 RESULTS AND DISCUSSION

A typical distribution of the maximum principal stress in the wire rope material corresponding to the peak applied load cycle is shown in Figure 7. In the single strand wire rope under tension-tension loading cycles, the core wire experiences the greatest axial displacement under the prescribed iso-strain end condition. This is due to the core wire element having the shortest length within the pitch distance of the wire rope. The surrounding wires stretch around, inducing the contact pressure at selected locations along the core wire during the tensile stressing. However, the computed highest magnitude of 1.27 GPa is artificially induced at the localized end region of the wire rope model due to the applied boundary conditions, thus should not be considered in the fatigue analysis. The highest principal stress occurring in the relatively small trellis contact region of the core wire is about 83% of the yield strength level of the drawn wires at 1.690 GPa, as shown in the figure. Thus, the fretting fatigue model is appropriate for the analysis. Each material point in each drawn wire of the wire rope experiences different stress amplitude but at the same stress ratio of $R = 0.1$, as the applied load cycles. In addition, It is also noted that the equivalent stresses (von Mises and maximum principal stress) and the contact pressure evolve in-phase

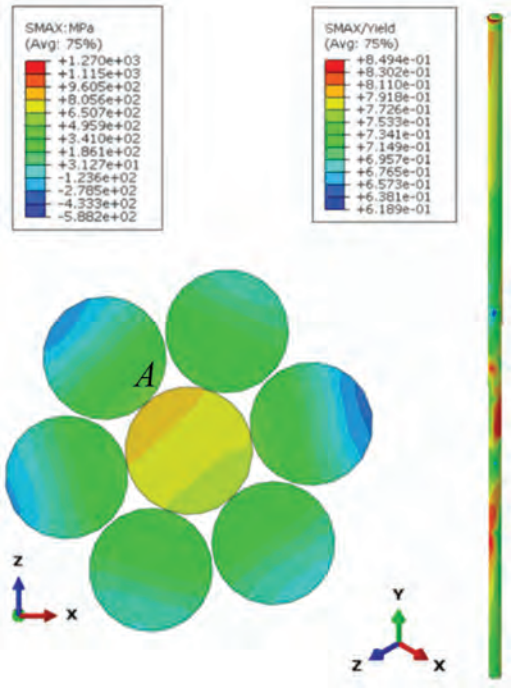

Figure 7. The maximum principal stress distribution across the critical section containing the highest contact pressure (left) and similar normalized distribution in the core wire (right).

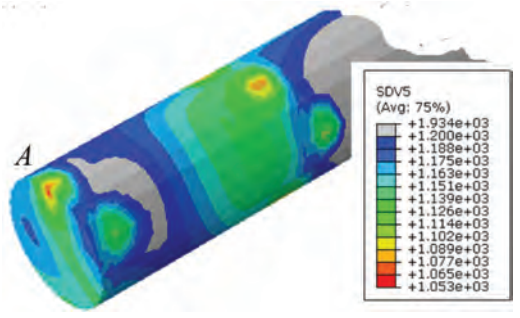

Figure 8. Distribution of the fatigue variable, N_o in part of the core wire showing the critical section (left) with the trellis contact region (marked A).

with the applied sinusoidal axial load. The peak von Mises stress in the trellis region is 1.240 GPa with the stress range of 1.116 GPa.

The calculated number of cycles required to initiate fatigue damage, N_o for the applied load-cycle is shown in Figure 8. The left cross-section represents the critical section of the core wire containing the highly stressed trellis contact region. Fatigue damage is predicted to initiate first in this localized critical region (marked A) of the core wire at $N_o = 1050$ cycles.

The grey region represents material point with $N_o > 1200$ cycles. Following damage initiation, the damage evolves with the continuous redistribution of the stresses in the wire rope to satisfy the force equilibrium and strain-displacement compatibility. The path of damage, thus fatigue crack propagation could fairly be inferred, at this early stage of the analysis, from the high-to-low gradient of N_o as illustrated in the figure.

Once the critical drawn wire fractured, the load carried by the wire is transferred to the neighboring intact wires in the strand. In a wire rope design consisting of large number of drawn wires, the fatigue life of the wire rope could be established based on the prescribed area fraction of intact-to-total load bearing area of the wires.

5 CONCLUSIONS

The framework for the development of a validated damage-based fatigue life model of the steel wire ropes has been presented and discussed. The fatigue damage model is based on the gradual degradation of strength and Young's modulus of the drawn steel wires. FE simulation of the single-strand (1×7) wire rope under axial fatigue loading ($\Delta P =$ 145 kN, $R = 0.1$) indicates that:

– the von Mises, maximum principal stress and contact pressure at the trellis contact point evolve with an identical stress ratio as the applied axial load.
– the trellis contact point is relatively small and experiences elastic stresses, thus the fatigue damage prediction for the fretting fatigue condition is appropriate.
– the critical material point at the trellis contact in the core wire experiences the first damage initiation event at $N_o = 1050$ cycles.

An efficient computational strategy for robust maintenance scheduling: Application to corroded pipelines

E. Patelli & M. de Angelis
Institute for Risk and Uncertainty, Chadwick Building, University of Liverpool, UK

ABSTRACT: The ability to predict correctly the future remaining life time of components is of paramount importance to improve the safety and reliability of systems and networks via an effective maintenance policy. However, simplifications and assumptions are usually adopted to compensate lack of data, imprecision and vagueness, which cannot be justified completely and may, thus lead to biased results. To overcome these issues, an imprecise probabilities approach is proposed for reliability analysis and risk-based maintenance strategy. A novel efficient computational approach is proposed for identifying robust maintenance strategies. The optimal solution is obtained through only one reliability assessment based on Advanced Line Sampling and reusing the outcome of maintenance activities in a force Monte Carlo approach. The proposed methodology remove the huge computational cost of reliability-base optimization making the analysis of industrial size problem feasible. The applicability of the approach is demonstrated by identifying the optimal maintenance policy of buried pipelines and it is shown how this approach can improve the current industrial practice.

1 INTRODUCTION

One of the most important degradation/deterioration mechanisms that affect the long-term reliability and integrity of metallic pipelines is corrosion. Corrosion which leads to metal loss is the most prevailing time dependent threat to the integrity, safe operation and cause of failure for oil and gas pipelines (Caleyo et al. 2002). The corrosion process is affected by large uncertainty making the assessment of pipelines a complex and challenging task (Bazán and Beck 2013, Qian et al. 2011). For instance, uncertainties are in relation to operational data variation, associated to the randomness of the environment, form imperfect measurements of pipeline geometry, in the material strength and from the ageing processes of the pipeline.

The remaining strength of a pipeline with corrosion defects can be assessed using one or all of the international design codes viz: B31G (AMSE 1991), B31Gmod (ASME 2012), Battelle (Leis and Stephens 1997a, Leis and Stephens 1997b), DNV-101 (AS 2015) and Shell-92 (Klever et al. 1995). The associated methods use deterministic values for load and resistance variables, thereby assuming no uncertainty. In the light of the existing inherent uncertainties in the corrosion process, the obtained results are obviously quite coarse approximations, which may deviate from reality significantly. A key challenge in this regard is the probabilistic modelling, which relies on substantial information and data required to define parameter distributions. Sahraoui et al. (2013) proposed a Bayesian modelling to take into account imperfect inspection results while Li et al. (2017) suggested using Bayesian network and Markov process approach to develop an optimal maintenance strategy for corroded subsea pipelines.

However, the amount of data required to define unequivocally those distributions might not be available in practice, assumptions and simplifications are applied and often they cannot be justified completely. To solve this conflict, the use of imprecise probabilities (Beer and Ferson 2013, Beer and Patelli 2015) is proposed to realistically reflect the vagueness of the available information in the probabilistic model. In fact, since these assumptions and simplifications can be quite decisive, an imprecise probabilities approach provides a promising pathway towards a robust maintenance strategy. This paper therefore proposes the use of a novel reliability metric redefined within the framework of imprecise probabilities.

Another challenging task is the identification of optimal inspection interval time in order to reduce the overall costs of pipelines including cost of inspection, repair and failure. For instance, areas needing repairs must be accurately pinpointed as to minimise excavations for verifications. Likewise, early observations of failure mechanisms, and determination of the likelihood of failure in association with the pipeline must be handy.

The identification of optimal maintenance scheduling requires in turn the evolution of the model reliability that can be computational expensive to evaluate (Gomes et al. 2013). Approximate methods, e.g. FORM may not be sufficiently accurate or applicable for large scale problems, and we have to resort to simulation based methods.

In this paper, a novel and efficient computational technique is proposed for the identification of a robust maintenance scheduling taking into account uncertainty and imprecision. More specifically, the proposed approach allows determining the optimal inspection interval and the repair strategy that would maintain adequate reliability level throughout the service life of the pipeline obtained through only one reliability assessment. In turn, the reliability analysis is performed using Advanced Line Sampling (de Angelis et al. 2015). This allows to estimate reliability bounds with only one simulation and, in addition, it efficiency is independent of the reliability level. Hence, the proposed approach is applicable to the analysis of industrial size problem. The proposed reliability strategies are implemented in the general purpose software OpenCossan (Patelli et al. 2018, Patelli 2016, Patelli et al. 2012) and freely available.

2 MODELLING CORRODED PIPELINE

Metal losses due to corrosion affect the ultimate resistance, safety and serviceability of the structure and cause changes in its elastic and dynamic properties. These are major concerns in structural reliability assessment of existing structures and infrastructures, also in the prediction of the safe and serviceable life for both new and existing structures.

2.1 *Failure criteria*

The failure modes considered here are the loss of structural strength of pipelines through reduction of the remaining pressure strength, and pipe wall thickness caused by corrosion defects. The failure pressure are assessed using four international design codes: Shell-92, B31G, DNV-101 and Modified B31G models, respectively. The summary of all the failure pressure models is shown in Tables 1 and 2. In Table 1 W is the pipe wall thickness; L is the longitudinal length of defect; D is the outside diameter of pipe and M is the Folias' factor. In Table 2, F_p is the failure pressure and d represents the defect depth. σ_y and σ_u are the material yield stress and the ultimate tensile strength, respectively.

The assumption and limitation of these models are reflected on the individual flow stresses which

Table 1. Flow stess and Folias' factor according different international design codes.

Model	Flow stress	Folias' factor (M)
B31G	1.1 SMYS	$\sqrt{1+0.893\frac{L^2}{DW}}$
Modified B31G	SMYS + 68.95 MPa	$\sqrt{1+0.6275\frac{L^2}{DW}-0.003375\frac{L^4}{D^2W^2}}$ for $L \le \sqrt{50DW}$
		$0.032*\frac{L^2}{DW}+3.3$ for $L > \sqrt{50DW}$
DNV-101	SMTS	$\sqrt{1+0.31\left(\frac{L}{DW}\right)^2}$
Shell-92	SMTS	$\sqrt{1+0.893\frac{L^2}{DW}}$

Table 2. Failure pressure of pipelines according different international design codes.

Model	Defect (area and shape)	Failure pressure expression (F_p)
B31G	$2/3dL$ Parabolic	$1.11\frac{2\sigma_y W}{D}\left(\frac{1-\frac{2d}{3W}}{1-\frac{2d}{3W}M^{-1}}\right)$
Modified B31G	$0.85dL$ Arbitrary	$\frac{2\left(\sigma_y+68.95\right)W}{D}\left(\frac{1-0.85\frac{d}{W}}{1-0.85\frac{d}{W}\cdot M^{-1}}\right)$
DNV-101	dL Rectangle	$\frac{2\sigma_u W}{D-t}\left(\frac{1-\frac{d}{W}}{1-\frac{d}{W}\cdot M^{-1}}\right)$
Shell-92	dL Rectangle	$\frac{1.8\sigma_u W}{D}\left(\frac{1-\frac{d}{W}}{1-\frac{d}{W}\cdot M^{-1}}\right)$

are the measure of the strength of steel in presence of a defect. Folias' factors, M, is the geometry correction factor to account for the stress concentration due to radial deflection of the pipe surrounding a defect. Failure is assumed to occur as a result of the flow stress, defined by yield strength (in B31G and Modified B31G codes) or ultimate tensile strength (in DNV-101 and Shell-92) as their tensile properties. Further considerations and

assumptions on different shapes and areas of corrosion defect can also be made which might lead to different definition of failure critaria.

The failure criteria is defined as the difference between the failure pressure, F_p, of the pipeline and the maximum allowed operating pressure, ($MAOP$):

$$g = F_p - MAOP \tag{1}$$

where g is the so-called limit state function.

The easiest way to estimate the reliability of pipelines is based on safety factors (also known as level I analysis) calculated using the capacity equations or codes presented in Table 2. Such analysis do not model explicitly the uncertainties that might have occurred and increased over the years of the pipeline service. The effects of the uncertainty are considered in terms of safety margins and factors. Worst-case scenario is used for loads and capacity of the structural system and in turn, this might leads to greater safety/reliability but also to huge costs associated with the overdesign or overmaintenance of pipelines.

Level II analysis based on partial safety factors includes the first and second moment of the parameter distributions. Partial safety factors take care of uncertainties for defect depth and failure pressure (burst) capacity. For instance, DNV-101 code uses analytical expression to derive the values of standard deviation of relative corrosion defect σ_{rd}, and the failure pressure.

In modern engineering systems and critical infrastructures to assure adequate level of safety and reliability an explicit quantification of the uncertainty must be performed. A full probabilistic approach (level III analysis) requires the evaluation of multidimensional integral shown in Eq. 2. The probability of failure, P_f, is defined as:

$$P_f = P(g \le 0) = \int_{g(\boldsymbol{\theta}) \le 0} f(\boldsymbol{\theta}) d\boldsymbol{\theta} \tag{2}$$

where $f(\boldsymbol{\theta})$ represents the multivariate distribution function of the uncertainty vector $\boldsymbol{\theta}$. In realistic application a large number uncertainties need to be considered. Hence, analytical and approximate methods like FORM and SORM result to be inadequate for solving Eq. (2) (Valdebenito et al. 2010). Monte Carlo simulation methods are then required to evaluate the integral of Eq. (2). However, when dealing with rare case events, plain Monte Carlo simulation might become infeasible due to the large number of the samples required to achieve a specific level of accuracy. To overcome this limitation, advanced Monte Carlo techniques such as Line Sampling (de Angelis, Patelli, & Beer 2015) and Subset simulations (Au & Patelli 2016) can be adopted for analysing complex real world problems.

2.2 *Maintenance strategy*

In order to understand the status of pipelines, different inspection tools can be used characterised by different quality and sensitivity. The inspection activities may assess the damage incorrectly or may not even detect any damage at all based on the quality and assiciated inspection costs.

The most common tools for metal loss and crack inspection are based on the Magnetic Flux Leakage or Ultrasonic techniques (Version 2009). Pigging data is gathered through in-line inspection activities using Magnetic Flux Leakage intelligent pig, whereby the values of parameters in the model is as a result of the operations and inspection histories of the pipeline. Geometry tools are available for detecting and sizing of deformations and mapping tools for localization of a pipeline and/or pipeline features (Version 2009).

In this paper the probability of detection (PoD) associated with the non-destructive inspection techniques is modelled as (Pandey 1998):

$$PoD = 1 - \exp^{-qd} \tag{3}$$

where d represents the defect depth and q the quality of inspection.

Following an inspection, if a defect is detected, it can be repaired or not. In fact, repairing a buried pipeline is an expensive process because it requires the excavation and the replacement of part of the pipeline. For this reason, the repair is perform immediately after an inspection only if the pipe defects produce a failure pressure safety factor lower than a prescribed threshold otherwise the pipe is left unrepaired. In this case a useful remain life is estimated and a preventive maintanance can be scheduled. The threshold level of the safety factor is between 1.25 and 1.5 (Pandey 1998). These values are in agreement with the level of integrity established by actual pipeline hydro testing, and corresponds with the repair factor for a class 2 pipeline in Canadian code (Association 2007).

3 MODELLING THE UNCERTAINTIES

A full probabilistic analysis requires the proper characterisation of the uncertainties. In other words, each variable is associated with a proper probabilistic distribution function. For instance, it is practice to describe the variability of measurements as a Gaussian process characterised by its mean and standard deviation. A proper estimation

of the characteristic of the distribution (or even the shape of the distribution itself) requires the availability of data. When the amount of data is not enoughfor unambiguous characterisation of the uncertainties, expert judgement and often unjustified assumptions. This is the case in many practical situations where very limited data are available. To avoid the inclusion of subjective hypothesis, the imprecision and vagueness of the data can be treated combining probabilistic and set theoretical components in a unified construct allowing the identification of bounds on probabilities for the events of interest in order to give a different prospective to the resultss (Beer and Patelli 2015).

For the treatment of imprecise knowledge, nonconsistent information and both epistemic and aleatory uncertainty multiple mathematical concepts can be used including intervals (Augustin 2004), probability boxes (Ferson et al. 2003), normalized fuzzy sets (also known as possibility distributions) (Verma et al. 2007), Dempster-Shafer structures (Dempster 1967, Shafer 1976), Bayesian frameworks (Faber 2005) and Random Set theory. In particular, Random Set theory is a general framework suited to model uncertainty represented as cumulative distribution functions (CDFs), without making any implicit or explicit assumption at all. Explanatory examples of such flexible frameworks are provided in (Patelli et al. 2015, Rocchetta et al. 2018).

In this paper, the concept of probabilistic boxes (P-boxex) is used (Ferson, Kreinovich, Ginzburg, Myers, & Sentz 2003). P-boxes can be seen as a generalization of the Dempster-Shafer structures where the sets are represented by distributions. Hence, P-boxes are sets of Cumulative Distribution Functions (CDFs) for which lower and upper bounds are assigned $\left[\underline{F}_X, \overline{F}_X\right]$. The probability distribution associated to the random variable x can be either specified or not. The former are generally named distributional P-boxes, or parametric P-boxes, the latter are named distribution-free P-boxes, or non-parametric P-boxes. In literature the upper bound on probability is referred as plausibility and the lower bound as belief.

Distributional p-boxes appear when there is indetermination in the representations of the parameters of a given CDF. These parameters are imprecisely specified as intervals. For instance, consider a quantity that is known to be Gaussian with mean within the interval [1,2] and standard deviation somewhere in [3,4]. All CDFs that are normal and have means and standard deviations inside these respective intervals will belong to this probability box. The upper and lower CDF bounds $\underline{F}$ and $\overline{F}$ of the p-box enclose many non-normal distributions, but these would be excluded from the p-box by specifying the normal CDF as the *parental distribution family*.

The calculation of the bounds of the quantity of interest such as the probability of failure requires significant computational resources. This because it will be necessary to estimate the integral of Eq. (2) for all the possible probabilistic model considered and then identify the bounds of the response. Fortunately in many engineering applications the response of the model is monotonic with respect to the imprecision of the input parameters. In general, this allows to estimate the bounds of the probability of failure with only 2 full probabilistic analysis (Rocchetta et al. 2018). Advanced Line Sampling (de Angelis et al. 2015) method can further reduce the computational cost allowing the estimation of the bonds of the probability of failure with only 1 efficient probabilistic analysis (de Angelis et al. 2014).

4 ROBUST MAINTENANCE STRATEGY

Inspection and monitoring of pipelines is necessary in order to ensure their continued fitness for purpose, which entails protection from any time-dependent degradation processes, such as corrosion. Also, pipeline failures have significant impact on the economic, environmental and social aspects of the society. Therefore, the proper assessment and maintenance of such structures are crucial; negligence will lead to serviceability loss, failure and might lead to catastrophic environmental and financial consequences. On the other hand, maintenance is an expensive activity and the availability of robust maintenance scheduling is of paramount importance. The premise for these decisions is supplied by reliability estimation inculcating the impact of inspection scheduling and reparation activities over the pipeline's service life.

4.1 *Optimization problem*

In reliability-based optimization, the total expected costs in relation to maintenance and failure is the objective function that needs to be minimised, see e.g. (Beer et al. 2014). The time and number of the inspections represents the design variables of the optimization problem while the expected monetary costs associated with inspection, repair and failure form the objective function that can be formulated as:

$$\underset{N_I, q, t_i}{\arg\min} \quad E\left[C_T\left(N_I, q, t_i\right)\right] \tag{4}$$

where N_I, q, t_i and C_T denote the number of inspections, the qualities of inspections, the i-th time of inspection and the expected total cost, respectively. The expected total costs are defined as:

$$E\left[C_T\left(N_I,q,t_i\right)\right]=E\left[C_I\left(N_I,q,t_i\right)\right]+E\left[C_R\left(N_I,q,t_i\right)\right]+E\left[C_F\left(N_I,q,t_i\right)\right] \quad (5)$$

where C_I, C_R and C_F are the costs of inspection, repairs and failure, respectively.

In addition, the optimisation problem must satisfy some constraints. For instance, it might be necessary to guarantee a minimum level of reliability, i.e.:

$$R(t)=1-P_f(t)\geq\beta \qquad \forall t\in\left[0,T_m\right] \quad (6)$$

where $P_f(t)$ is the probability of failure at time t and T_m represents the so-called mission time. Hence, reliability based maintenance strategy requires the evaluation of the reliability over the time as summarised in Section 2.1. Constrained optimisation techniques are then adopted to identify the minimum of the objective function, Eq. (4), satisfying the constrain of Eq. (6).

4.2 *Inspection costs*

The expected inspection costs $E(C_I)$ are calculated as the product of the unit inspection cost, c_I, that depends on the quality of inspection q, corrected by the discount rate, r, and the probability that inspection will take place at time t_i: $1 - P_f(t_i)$. In other words, the pipeline has not to be failed before the i-th inspection time scheduled at t_i. This expected costs are expressed in mathematical form as:

$$E\left[C_I\right]=\sum_i \frac{c_I(q)}{(1+r)^{t_i}}\cdot\left(1-P_f\left(t_i\right)\right) \quad (7)$$

4.3 *Repair costs*

The evaluation of the expected costs associated with repair, $E\left[C_R\right]$, is quite challenging since depends on the probability of performing a repair after the i-th inspection, $P_R(t_i)$. This, in turn depends on the probability of detection (POD) (i.e. the probability to detect a defect). The expected repair costs are modelled as:

$$E\left[C_R\right]=\sum_{i=1}^{N_I} c_R P_R\left(t_i\right)\frac{1}{(1+r)^{t_i}} \quad (8)$$

where c_R, is the unit cost of a repair. The probability of repair is calculated by computing the reliability analysis of the pipeline where the repair threshold represents the limit state function weighted by the probability to detect the crack, i.e.

$$P_R(t)=\int_{1.25\leq g(\boldsymbol{\theta},t)\leq 1.5} f(\boldsymbol{\theta})\cdot PoD(d,t)\,d\boldsymbol{\theta} \quad (9)$$

4.4 *Failure costs*

The total capitalized expected costs, $E[C_F]$, due to failure are the costs associated with failure over the region of the corresponding demand functions. Hence, the calculation of the failure costs requires the estimation of the probability of failure of the pipeline over the time. Teh computational strategy proposed in the next Section allows to estimate these costs by performing a single reliability analysis and the reusing the results in the optimisation loop.

The cost of failure at a specific inspection time is calculated as the cost of the failure of i-th time t_i (that is proportional to $P_F\left(t_i\right)$ minus the cost of failure at previous time t_{i-1}: $\propto P_F\left(t_{i-1}\right)$. This allows to take into account the fact that the system has survived till the time t_{i-1}. Taking into account all the inspection times and the discount costs, the expected failure cost becomes:

$$E\left[C_F\right]=\sum_{i=1}^{N_I} c_F\frac{\left(P_f\left(t_i\right)-P_f\left(t_{i-1}\right)\right)}{(1+r)^{t_i}} \quad (10)$$

5 COMPUTATIONAL STRATEGY

5.1 *Reliability analysis*

The estimation of the probability of failure requires in general significant computation efforts. In particular for highly reliable pipelines, the number of model evaluations easily exceed the computational resources available. In addition, the presence of imprecision adds another level of complexity because the propagation of intervals and p-boxes requires the adoption of an additional optimization loop making the required computational cost quite challenge. For this reason, the Advanced Line Sampling (de Angelis et al. 2015) method is adopted to estimate the bounds of the probability of failure. One of the key feature of this approach is the ability to estimate different probabilities of failure (associated to different levels of the performance function) with only one analysis. For instance this can be used to estimate with only one reliability analysis the bounds of probability of failure due to imprecision in the inputs and the probability of repairs as well.

5.2 *Robust maintenance*

The robust maintenance is computed adopting a novel computational strategy that allows to reuse

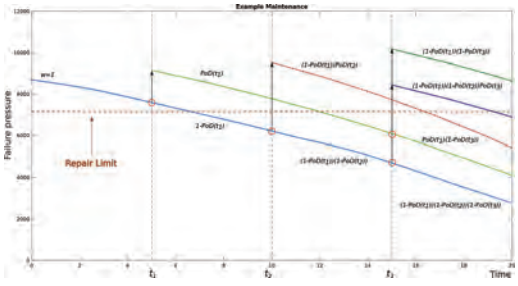

Figure 1. Effect of maintenance (repairs) on the weights associated with realisations of evolution on the time of the failure pressure.

the results of the reliability analysis in the optimisation problem.

In order to explain the simulation approach, we first consider a simplified model without imprecision and solved using plain Monte Carlo method. The idea is to first simulate the evolution of defects/cracks in pipelines without considering inspections and repairs. This is performed by sampling the parameters of the model and then solving the equations in Tables 1–2 till the time of interest. At this point we have a number of possible cracks evolution (or failure pressures) over the time. Then, we add the effect of maintenance and update the corresponding pipeline reliability as shown in Figure 1 by calculating the weights associated to each possible event outcome. The procedure is repeated for all the simulated cracks evolution. The computed weights are then used to calculate the probability of failure at time of interest. For instance, the probability of failure at time t_i is estimated by the summation of the weights associated to the failure events divide by the total numberof simulations.

Finally an optimisation tools is used to identify the number and time of inspections that minimise Eq. (4). When a new inspection time is proposed, it is necessary to recompute the weights starting from the original simulation but thisstep does not require the re-analysis of the model (i.e. evaluating the evolution of the crack/defect till the time of interest).

6 EXAMPLE APPLICATION

The optimal maintenance scheduling of a pipeline with characteristics shown in Table 4 is performed.

6.1 *Reliability analysis of pipelines*

First, the probability of failure of the pipeline as a function of time has been computed using the DNV-101, Shell-92, B31G and B31Gmod codes without considering inspection and maintenence. The uncertainties are modelled as shown in Table 5. Different level of imprecision on the parameter vaules has also been condidered.

Advanced Line Sampling (de Angelis et al. 2015) is adopted to estimate the reliability of the pipelines with 20 lines resulting in 120 model evaluations. Advance Line Sampling is able to deal with imprecision in the parameter values and it allows to compute the bounds of the reliability. In addition, the number of model evaluations are independent of the reliability level. As expected, the probability of failure of the corroded pipeline increases with time as shown in Figure 2. The Figures shows lower and upper bounds of the probability of failure when 10% of imprecision is considered on the input variables. Shell-92 and the DNV-101 are the most conservative models followed by Modified B31G and the least conservative is the B31G model. than 0.6) respectively. This is in accordance with results from literature obtained without considering imprecision (see e.g. Caleyo et al. (2002)). The results of the analysis are also summarised in Table 3.

6.2 *Robust maintenance*

Maintenance is a very effective way to improve the safety of corroded pipelines. The aim of this section is to identify the optimal number of inspections that are able to minimise the overall costs. Maintenance is only performed is a defect is detected. The typical minimal detectable depth of a high resolution Magnetic Flux Leakage tool for uniform corrosion is 0.1 W with a POD of 0.9 (Version 2009). Using these values and the pipeline wall thickness $W = 9.52\ mm$, the quality of inspection can be estimated as $q = 2.42$ (from Eq. 3). However, if the length of the defect is $l < 30mm$ we have a pitting defect. In this case the quality of inspection is reduced to $q = 1.61$.

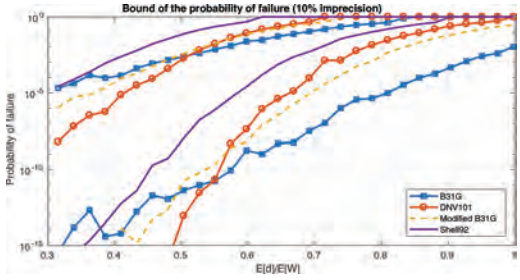

Figure 2. Lower and upper bounds of the probability of failure of a pipeline with 10% of imprecision on the variables using Shell-92, B31G, Modified B31G and DNV-101 failure pressure models.

In this example, it is assumed that the inspection time are equally spaced from the initial time till the final time of 50 years (mission time). Figure 3 shows the pipeline failure probability at mission time against the number of inspections for different models and parameter imprecision. From the results presented in the Figure 3, it can be deduced that using B31G model and 3 inspections suffice reducing the probability of failure of the pipeline below 10^{-6}. However, when the modified B31G model is used more than 6 inspections are required (using the upper bounds of the parameters). These results allows to identify the minimum number of inspections required to guarantee a prescribed level of safety. The very small probability of failure have been calculated adopting the approach presented in Section 5.

Figures 4 and 5, show the total expected cost as a function of the number of inspection obtained using DNV-101 model. Obviously, the costs of inspection increases with the number of inspections performed during the lifetime of the pipeline. Costs of failure decreased with the number of inspections. For very small number of inspections the total costs are governed by the costs associated with failure while for large number of inspections, the total maintenance costs are due to the costs associated with repairs. The optimal number of inspection is always a trade-off between costs of failure and costs of repairs. Using the DNF-

7 CONCLUSIONS

In this paper, an efficient numerical approach for robust optimal pipeline inspection time scheduling has been proposed. This allows to determine the optimal inspection interval and the repair strategy that would maintain adequate reliability throughout pipeline service life. The computational framework allows to take into account the uncertainties of the model and imprecisions on the knowledge of model parameters. The proposed approach is efficient since allows to perform reliability based optimisation with only one reliability analysis.

ABSTRACT: Reliability and safety issues of mooring chains are causing concern in recent years. Accordingly, some efforts have been made for detecting the structural integrity of mooring chains. However, a fully successful mooring chain condition monitoring technique has not been achieved today. This is largely due to the fact that mooring chains are submerged in water and the currently available non-destructive testing technologies are difficult to apply in wet environment. To overcome this issue, a new mooring chain condition monitoring method is studied in this paper with the aid of thermography technique. The research is conducted based on two philosophies, i.e. (1) the mooring chain material has much higher thermal conductivity than that of water. Therefore, when the mooring chain is heated, the thermal energy will transmit mostly inside the chain, rather than dispersing in water; (2) the defects occurring in the mooring chain will disturb the transmission of thermal flow inside the mooring chain and consequently change the distribution of the temperature in the adjacent area. To demonstrate the effectiveness of the proposed method, both numerical and experimental researches are conducted in this paper. The research results have shown that thermography is indeed valid in detecting the integrity of mooring chains.

1 INTRODUCTION

There are a variety of non-destructive testing techniques that have been developed for addressing various structural integrity testing and assessment issues in different fields, such as those depicted in References (see Blitz 2012, Sanjeev et al. 2013, Amenabar 2011 and Garcia-Martin et al. 2011). However, few of them is applicable to monitoring the structural integrity of mooring chains as the mooring chains are full submerged in the water located in harsh marine and offshore environment.

In order to tackle this issue, much effort has been made by the scholars and industrialists in recent years, although a cost and technically effective mooring chain condition monitoring technique has not been successfully achieved till today. This is because so far, almost all the existing mooring chain condition monitoring techniques and systems (see AVT Reliability 2017, Seatools 2017, Lugsdin 2017), with the exception of the ultrasonic guided wave technique developed by TWI (see TWI 2013), are originally designed for detecting a broken mooring line rather than detecting and monitoring the growth of the defects occurring in it. In reality, a defective mooring chain may but is not necessary lead to broken of the mooring line when it is subject to extreme loads. For example, Remotely Operated Vehicle (ROV) inspection has been popularly adopted for inspecting typical damage and loss of integrity of marine structures. It can be equally applied to the inspection of mooring chains. However, ROV inspection only provides snapshot of the surface of mooring chains, which could be covered by thick layer of marine lives. Therefore, visual inspection via ROV is unable to provide the operator with reliable information about the actual structural health condition of mooring chains. Moreover, the application of ROV inspection is limited by weather windows and access, it is unlikely to realize the continuous monitoring of the mooring chain. In order to obtain continuous monitoring data from mooring chains, AVT Reliability attempted to use strain gauge to monitor the integrity of mooring chains and applied the devised strain gauge based measurement system to assessing the integrity of the 9 mooring chains installed on a 870,000 barrel oil storage tanker (AVT Reliability 2017). The novelty of such a system is that it does not

directly measure the chain tensions but instead, monitors the stresses in the buoy structural steelwork in reacting those same chain tensions. This has the advantage that the instrumentation can be mounted internally inside the buoy in a clean dry environment. However, the measured stresses from the buoy structural steelwork are not only dependent on the integrity of mooring chains, but also affected by the motions of the storage tanker and the external loads acting on it. Therefore, the AVT system is effective in detecting a broken mooring line, however ineffective in detecting and monitoring the incipient defects occurring in it. Apart from AVT Reliability, the other companies also develop mooring chain integrity monitoring systems using different techniques. For example, Seatools developed the mooring chain inclination measurement technique (Seatools 2017), Tritech International Ltd developed a multi-beam sonar technique (Lugsdin 2017), and so on. But they all for detecting whether the mooring lines are well connected to the floating structures, rather than for detecting the defects occurring in the chains. To tackle this issue, TWI developed an automated ultrasonic guided wave technique for monitoring mooring chains (TWI 2013). Laboratory test has shown that such a technique does work in improving the accuracy, consistency and repeatability of inspection results. But it requests to make minimal surface preparation before conducting inspection. However, this is very difficult to implement in the practical application. Additionally, the high cost of the associated robotic delivery system also limits the extensive application of such an ultrasonic guided wave technique. In view of this, a new mooring chain condition monitoring technique is studied in this paper with the aid of thermography technique. The details of the numerical and experimental research are given below.

2 HYPOTHESES

According to the fundamental theory of thermodynamics, the rate of heat flow can be described as (Borgnakke et al. 2003):

$$\frac{Q}{t} = \frac{\kappa A}{d}\Delta T \tag{1}$$

where Q = the amount of heat transferred in a time t; κ = the thermal conductivity constant for the material; A = the cross sectional area of the material transferring heat; d = the thickness of the material; and ΔT = the difference in temperature between one side of the material and the other.

From (1), there are two hypotheses can be inferred that: (1) since the thermal conductivity κ for steel is 46 Watts/meter–°C, which is much higher than the thermal conductivity of water (i.e. κ for water is only 0.58 Watts/meter–°C), the heat flow will be transferred much faster in steel than in water. Accordingly, when the steel mooring chain is heated from one end, the majority of heat flow will be transferred inside the steelwork of the chain rather than being dissipated in the water around it; (2) equation (1) shows that the cross sectional area A is inversely proportional to the temperature difference ΔT. That means when the same amount of heat is transferred inside the chain, the defect resulted change in the cross sectional area A will be indicated by the change in temperature or temperature distribution. In the meantime, the heat flow will be transferred automatically along the path which has smaller thermal resistance.

If the above two hypotheses are true, the integrity of the mooring chain then can be detected via observing the distribution of mooring chain temperature. In other words, the discontinuity in temperature distribution may indicate the presence of defect in the structure of mooring chain.

3 NUMERICAL RESEARCH

In order to demonstrate the aforementioned two hypotheses and investigate the transferring process of the heat flow insider a mooring chain when it is heated, the numerical model of mooring chains is developed in ANSYS 15. In each chain, the center to center distance is 24 mm, the width is 18 mm. The radius of the side circle is 4 mm. Then, different types of defects were artificially made on the model through changing its geometries. The mooring chains with different sizes of cracks with 0.5 mm clearance are shown in Figure 1.

In ANSYS 15, the steady state thermal analysis are conducted. In the engineering data section of the analysis, steel was chosen as the material for the mooring chain. In the calculation, the mooring chains are meshed and moreover, mesh refinement properties were used for building finer meshes particularly in the vicinity areas of the defects, such as the example given in Figure 2.

In the numerical calculations, both environmental temperature 22 Celsius and heating temperature

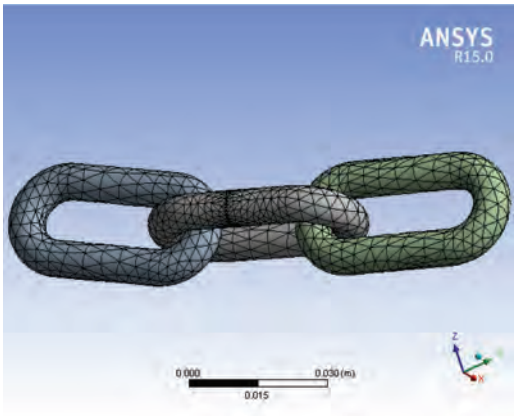

Figure 2. Mesh and mesh refinement of the mooring chains.

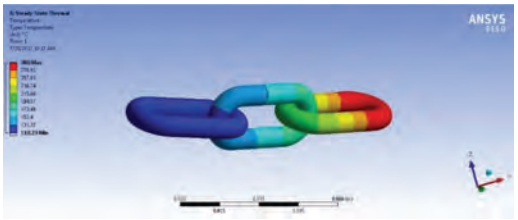

Figure 3. Numerical result obtained when a partially cracked mooring chain is heated from one end.

300 Celsius are specified in the steady state thermal column. The convection film coefficient is also defined in this section. The value is taken as 22 W/m^2°C. When the heating temperature is applied at one end of the mooring chains while the other end is fixed and no temperature is applied, the numerical calculation results for a partially cracked mooring chain are graphically shown in Figure 3.

From Figure 3, it is found that: (1) the discontinuity of the temperature observed from the upper part of the defective mooring chain proves that the defect in the mooring chain does disturb the transfer of heat flow, thus may cause visible temperature difference in the vicinity area of the defect; (2) the asymmetric distribution of the temperatures of the upper and lower parts of the defective mooring chain proves that heat flow is more easily to be transferred along the path that has smaller thermal resistance; (3) although in the numerical simulation, the mooring chain is assumed to be placed in air rather in water, the visible temperature differences prove that when the steel mooring chain is heated from one end, the majority of heat flow will be transferred inside the steelwork of the chain rather than being dissipated outside the chain as the thermal conductivities of air and water are similar and much smaller than that of steel mooring chain; and (4) moreover, the profile of the temperature distribution around the defect indicates the size of the defect. In order to further verify the findings from Figure 3, a fully cracked mooring chain is heated from both ends, as shown in Figure 4.

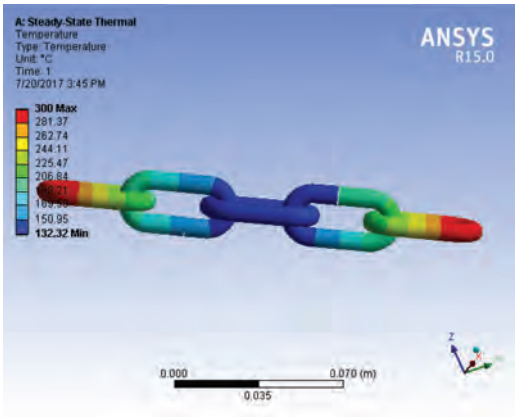

Figure 4. Numerical result obtained when a fully cracked mooring chain is heated from both ends.

From Figure 4, it is clearly seen that the aforementioned four findings are also valid when the mooring chain is completely cracked and heated from both ends. This indicates that, in the sense of theory, the thermography do have potential to be applied to detect and monitor the defects occurring in mooring chains.

4 EXPERIMENTAL RESEARCH

In order to physically demonstrate the interesting findings observed in numerical research, experimental research is organized in laboratory. The perfect and defective chains with different sizes of cracks are shown in Figure 5. Where, the chain cracks are artificially made using hacksaw.

In the experiment, the influences of the cracks on the chain temperature distributions in their vicinity areas are investigated in two scenarios in order to find a better heating method that can lead to more reliable condition monitoring result. In the first scenario, the mooring chain being investigated is heated from the both ends of it; while in the second scenario the mooring chain is headed from only one end. The experimental results obtained in the first scenario are shown in Figure 6.

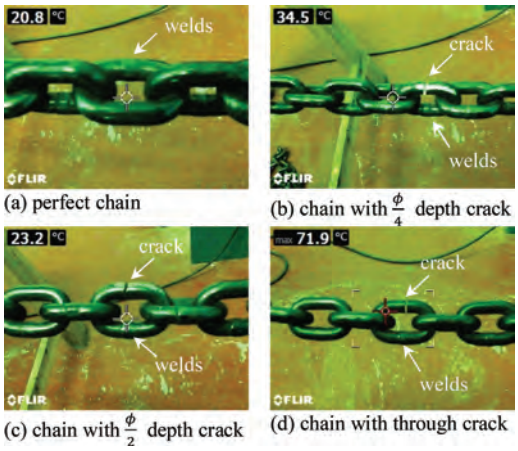

Figure 5. Mooring chains used in the experiments.

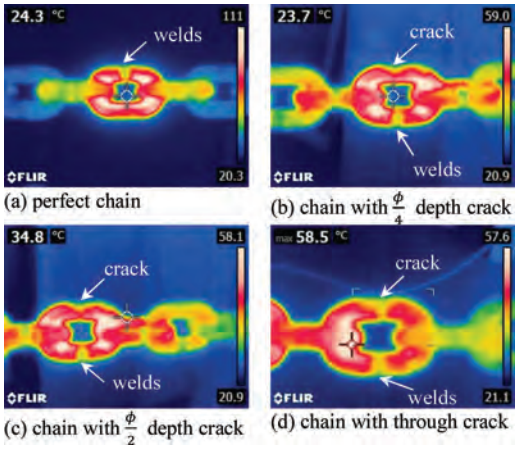

Figure 6. Experimental results obtained when the chains are heated from both ends.

From Figure 6, it is found that when the mooring chain is perfect and has no any defect inside the chain structure, the temperature is distributed evenly and smoothly over the chain except at welds, where the temperature is obviously smaller than in others due to the much higher thermal conductivity of the welding material. But when a crack is present in the chain, the even distribution of the temperature over the chain will be discontinued. Consequently, a concave profile can be observed from the cracking area in the thermal image. Moreover, it is found that the larger the size of the crack, the deeper the concave profile tends to be. This is because the air or water in the clearance of the crack has lower thermal conductivity than that of the mooring chain material. Therefore, the air or water temperature in the crack clearance is lower than that of the steelwork of the chain. From such an observation, it can be inferred that a partial through crack can partially stop the transfer of heat flow, although the heat flow is still able to be transferred through the un-cracked section. But when the crack continues to propagate and finally becomes a full through crack in the end, the transfer of heat flow will be significantly limited by the crack. In this worst case, the heat flow in the cracking area is transferred only via the air or water in the clearance of the full through crack. In general, from these experimental results obtained in the first scenario, it can be concluded that the crack occurring in the mooring chain can be readily detected using thermographic technique. Moreover, the size of the crack can be approximately understood through observing the concave depth of the temperature profile in the vicinity area of the crack. However, more accurate evaluation of the crack is difficult to achieve due to the limitation of observation.

In order to further improve the accuracy of the crack evaluation, the experiment is repeated in the second scenario. But the difference from the first scenario is the mooring chains being investigated are heated from only one end. The corresponding experimental results are shown in Figure 7.

From Figure 7, it is found that the similar phenomena observed from the first scenario (see Figure 6) also can be observed. But the assessment of the crack is not easy to achieve through observing the concave depth of the temperature profile because the concave feature caused by the crack cannot be clearly observed in the second scenario. Accordingly, a quantitative assessment method is developed in the following by using the temperature reading function of the thermographic camera. In addition, it is noticed that there is a temperature value displayed at the top left of the picture, such as $80.8°C$ in Figure 7a, $26.6°C$ in Figure 7b, $25.2°C$ in Figure 7c, and $33.8°C$ in Figure 7d. These values indicate the temperatures at the positions located by the circle with a cross. With the aid of this special temperature reading function provided by the thermal camera, the temperature at any position in the thermal image can be readily obtained. Then, the temperatures at two specific positions are measured for developing the quantitative assessment criterion. One is the temperature T_h measured at the heating source position, another is the temperature T_c measured at the other side of the crack. Since the temperature at the heating source position is the highest temperature in the thermal image, the value of T_h is usually the maximum value shown in the grey scale of the image, i.e. $T_h = 216\,^oC$ for Figure 7a, $192\,^oC$ for Figure 7b, $263\,^oC$ for Figure 7c, and $99.6\,^oC$ for

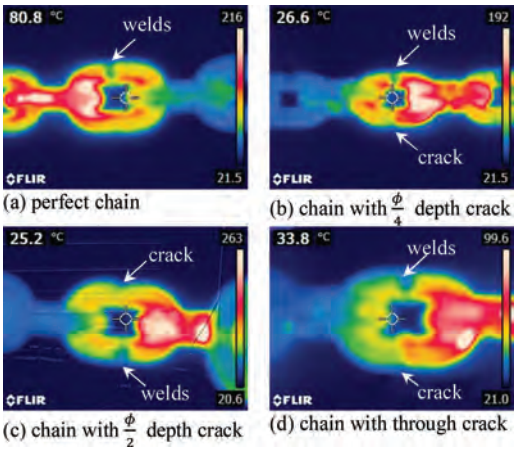

Figure 7. Experimental results obtained when the chains are heated from one end.

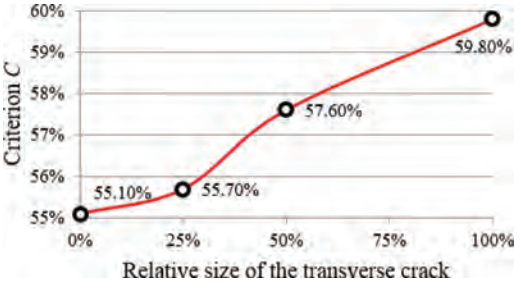

Figure 8. Quantitative assessment of the crack occurring in the mooring chain.

Figure 7d. Therefore, in fact T_c is the only value that needs to be measured by moving the circle with a cross to the other side of the crack. Once the value of T_c is obtained, the following quantitative assessment criterion can be calculated, i.e.

$$C = \frac{T_h - T_c}{T_h} \times 100\% \qquad (2)$$

In essence, the criterion C measures the significance that the crack disturbs the heat transfer along the mooring chain. When the crack increases in size, the local heat transfer ability of the chain will decrease due to the reduced contact area of the metal. This will lead to a small value of T_c and consequently a large value of criterion C when the heating temperature T_h is constant. Therefore, the criterion C can be used to quantitatively assess the size of a transverse crack occurring in the mooring chain. In the experiment, the values of T_c have been read from the images shown in Figure 7. They are $T_c = 97\,^oC$ for Figure 7a, $85\,^oC$ for Figure 7b, $111.5\,^oC$ for Figure 7c, and $40\,^oC$ for Figure 7d. Substitute the values of T_h and T_c into (2), the criterion C is calculated and the results are shown in Figure 8.

From Figure 8, it is clearly seen that as expected, the value of criterion C does increase gradually with the increasing depth of the crack. This means that the larger the size of the crack, the more significant the influence of the crack tends to be in the heat transfer process. This fully demonstrates that the proposed quantitative evaluation method does work in assessing the crack occurring in the mooring chain.

5 CONCLUSIONS

In order to explore a feasible method for monitoring the health condition of mooring chains, both numerical and experimental researches are conducted in the paper to investigate the potential of thermography technique in detecting transverse cracks occurring in mooring chains. From the work reported above, the following conclusions can be drawn:

1. When the mooring chain is perfect in structural integrity, the temperature is smoothly distributed over the chain except at welds, where the temperature is smaller than in other chain parts due to the higher thermal conductivity of welding materials in comparison of that of the steel material of mooring chain;
2. When the mooring chain is heated from its both ends, a clear concave will appear in the temperature profile in the presence of a transverse crack in the mooring chain. Moreover, the larger the size of the crack, the deeper the concave tends to be. Therefore, the concave in the temperature profile is a good indicator of the crack and its propagation when the mooring chain is heated from the both ends of it;
3. In comparison of the scenario that the mooring chain is heated from the both ends of it, more accurate assessment of the crack can be achieved when the mooring chain is heated from only one end. Experiment has shown that the proposed quantitative evaluation method can successfully predict the presence and growth of the crack when the chain is heated from only one end;
4. The aforementioned numerical and experimental researches have demonstrated that thermography technique does have potential to be applied to condition monitoring mooring chains. However, further research is still required to develop an appropriate method to heat the mooring chain in a completely wet environment.

Bayesian updating of stochastic process-based models for corroding gas pipelines based on imperfect inspection information

K. Pesinis & K.F. Tee
Department of Engineering Science, University of Greenwich, UK

ABSTRACT: This paper presents an efficient approach for Bayesian analysis of corroding gas pipelines containing metal-loss corrosion defects subjected to internal pressure. The methodology considers stochastic dependence among individual defects. The Nataf model is used to model the interdependence (correlation) among the defects. The generation of new defects and the growth of existing ones are included in the stochastic modelling, by employing a Non-Homogeneous Poisson Process (NHPP) and a Homogeneous Gamma Process (HGP), respectively. Information on a corroding pipeline obtained through multiple In-Line Inspections (ILIs) is used for the Bayesian updating of stochastic models. The Probability of Detection (PoD) and measurement error of the inspection tools are also taken into consideration. The Bayesian updating is conducted by using Structural Reliability Methods (SRM), a recently proposed method in literature that sets an analogy between Bayesian updating and a reliability problem. The SRM adopted herein is Subset Simulation (SuS) and the whole analysis is referred to as BUS-SuS. The updating is conducted in conjunction with the Data Augmentation (DA) technique which accounts for both detected and undetected defects, by treating the undetected ones as the missing data. Multiple simulated corrosion defects from different ILI inspections are employed for the implementation and validation of the methodology. A parametric study that examines the impact of correlations among defects on the posterior stochastic models is also included in the numerical example.

1 INTRODUCTION

Metal-loss corrosion is the most predominant gradual deterioration process for gas pipelines, based on historical failures. Reliability-based integrity management programs are increasingly adopted by pipeline operators to ensure the safe operation of pipelines against metal-loss corrosion (Khan & Tee 2016). In the literature, stochastic growth models are considered the most efficient modelling option for metal-loss corrosion in gas pipelines (Maes et al. 2009, Zhang & Zhou 2013, Pesinis & Tee 2017). However, a comprehensive analysis requires the modelling of the generation of new crack features too. Moreover, the dependence (or correlation) among individual defects should be considered, to express the spatial dependence among them. This is typically due to the similar corrosive environment, similar pipe properties at the defects' location and the fact that defects are subjected to the same loading conditions (Zhou et al. 2012, Khemis et al. 2016).

In Maes et al. (2009) and Zhang & Zhou (2013) gamma process was employed to characterize the growth of corrosion defects on the pipeline. In Qin et al. (2015) the generation of new metal-loss corrosion defects was taken into consideration in the analysis, using a stochastic process-based model. In all three studies, the hierarchical Bayesian analyses updated the stochastic models based on ILI data by means of Markov Chain Monte Carlo (MCMC) simulation, without considering correlations among defects. In fact, there is only limited information available on modelling correlations of deterioration in energy pipelines (Qian et al. 2013, Zhou et al. 2017) and to the best of the authors' knowledge, none when it comes to Bayesian updating. Furthermore, when it comes to MCMC simulation, this is thought to involve an underlying uncertainty around ensuring the final samples have reached the posterior distribution and has limited capacity in ultimately quantifying small failure probabilities (Straub et al 2016). An alternative method to MCMC is Bayesian Updating with Structural reliability methods (BUS), which sets an analogy between Bayesian updating and a reliability problem (Straub & Papaioannou 2014). This formulation enables the use of established SRM to conduct the Bayesian updating. The SRM adopted in this study is Subset Simulation (SuS).

Thus, hierarchical Bayesian updating is conducted herein, by using BUS-SuS in conjunction with the Data Augmentation (DA) technique. Simulated data corresponding to a gas pipeline

subjected to internal pressure loading are used to illustrate and validate the proposed methodology. The growth of multiple metal-loss corrosion defects is characterized through adopting a Homogeneous Gamma Process (HGP) model and incorporating it into the hierarchical Bayesian framework based on multiple ILI data, accounting for the associated measurement errors as well. Furthermore, the interdependence among different defects is considered using the Nataf model, also known as the Gaussian copula. The generation of new metal-loss corrosion defects is realised in the analysis by means of Non-Homogeneous Poisson Process (NHPP). At the end, the impact of different dependence scenarios is investigated.

The contributions of this paper include first the development of a robust hybrid hierarchical Bayesian framework for the updating of both generation and growth stochastic model, with respect to metal-loss corrosion. The proposed methodology, based on BUS-SuS and DA technique, eliminates the uncertainty regarding whether the final samples have reached the posterior distribution. Then, the methodology efficiently accounts for different spatial correlation scenarios among individual defects, which has not been conducted before in Bayesian updating for energy pipelines. The contents of this paper are structured as follows. Section 2 defines the uncertainties concerning the inspection data. The formulations of the NHGP and HGP models for the defect generation and growth, respectively, are presented in Section 3. The hierarchical Bayesian method for updating the model parameters by means of BUS-SuS and DA are presented in Section 4. An application based on simulated ILI data corresponding to a gas pipeline is presented in Section 5, in order to illustrate and validate the proposed methodology. Finally, conclusions are drawn in Section 6.

2 UNCERTAINTIES OF INSPECTION DATA

2.1 *Measurement error*

Inspection data for corrosion defects on gas pipelines are subject to random measurement errors because of the accuracy limitations of the ILI tool. Thus, the measured size of a defect is expected to differ from its actual size. Based on a measured size, the actual defect size can be evaluated through the following (Qin et al. 2015, Zhang and Zhou 2013):

$$d_{ki} = a_i + b_i c_{ki} + \varepsilon_{ki} \tag{1}$$

for a corrosion defect k (k = 1, 2,…, n) that is detected in the ith (i = 1, 2, …, m) inspection, where a_i and b_i denote the constant and non-constant biases, respectively, associated with the defect depth and ε_{ki} is the random scattering error associated with the measured depth. It should be noted that if $a_i = 0$ and $b_i = 1$ the tool is unbiased. The random scattering errors associated with different defects for a given ILI tool were assumed to be mutually independent and those associated with different ILI tools for a given defect were also assumed to be mutually independent (Stephens & Nessim 2006).

Given a measured defect k, the probability distribution of the random scattering error ε_{ki} in the ith inspection can be determined from tool specifications that characterize the sizing accuracy in terms of the probability that the error will fall within prescribed bounds e_{min} and e_{max}. Then, the mean value (μ) and standard deviation (σ) of the random scattering error can be determined, for any distribution type. Assuming that the mean and standard deviation of the error are from a multivariate normal distribution as follows:

$$\mu = (e_{\min} + e_{\max})/2 \tag{2}$$

$$\sigma = (e_{\max} - \mu)/\left[\Phi^{-1}\left(\frac{1+p_e}{2}\right)\right] \tag{3}$$

where Φ^{-1} is the inverse standard normal distribution function (Stephens & Nessim, 2006).

2.2 *Probability of detection*

Probability of detection (PoD) is related to the capacity of an ILI tool to detect a metal-loss corrosion defect (Zhang & Zhou 2013). It can be defined as a function of the defect size together with constants that refer to the tool's accuracy. The following exponential function can be defined (Qin et al. 2015):

$$\text{PoD} = 1 - e^{-q(c-c_{th})} \quad \text{for } c \geq c_{th} \tag{4}$$

The value of q refers to the inherent tool detection capacity and can be specified from vendor-supplied tool specifications. In addition, c denotes the actual defect depth and c_{th} is the detection threshold, i.e. the minimum detectable defect depth.

3 DEFECT GENERATION AND GROWTH

3.1 *Stochastic defect generation*

The non-homogeneous Poisson process stochastic process-based model was employed for the generation of new defects on a pipe segment over time (Qin et al. 2015, Tee & Pesinis 2017).

The total number of defects in a time interval [0, t] is assumed to follow a Poisson distribution with a probability mass function (PMF), $f_p(N(t)|\lambda(t))$:

$$f_p(N(t)\Big|\lambda(t)) = \frac{(\lambda(t))^{N(t)} e^{-\lambda(t)}}{N(t)!} \left(t \geq 0\right) \tag{5}$$

$N(t)$ is the expected number of defects generated over the time interval [0, t] and $\lambda(t)$ is the instantaneous generation rate:

$$\lambda(t) = \int_0^t \lambda_o \tau^{\delta} d\tau \tag{6}$$

with the parameters λ_0 and δ quantified from the ILI data.

In case of m ILIs that have taken place over a certain period, it was assumed that each inspection can detect new and existing defects, in terms of their spatial positions (Qin et al. 2015). The total number of defects X_i on the time of the ith inspection (i = 1, 2, ... m) t_i, can be divided into those defects that have initiated prior to the (i-1) th inspection, X_i^0 and those ones that have initiated between the (i-1)th and ith inspections X_i^s. The value of X_i^s can be evaluated by assuming that it follows a Poisson distribution with PMF given by:

$$f_p(X_i^s\Big|\lambda_0, \delta) = \frac{(\lambda_i)^{X_i^s} e^{-\lambda_i}}{X_i^s!} \tag{7}$$

The detected defects are typically less than the actual ones and that is due to the imperfect detectability of the ILI tool. If X_i^{sd} and X_i^{su} are the detected and undetected values, respectively, of the total number X_i^s. Following the Poisson splitting property (Qin et al. 2015, Kulkarni 1995), X_i^{sd} and X_i^{su} are assumed to follow the Poisson distributions with the respective PMFs:

$$f_p(X_i^{sd}\Big|\lambda_0, \delta) = \frac{(\overline{\text{PoD}}_i \lambda_i)^{X_i^{sd}} e^{-\overline{PoD}_i \lambda_i}}{X_i^{sd}!} \tag{8}$$

$$f_p(X_i^{su}\Big|\lambda_0, \delta) = \frac{[(1-\overline{\text{PoD}}_i)\lambda_i]^{X_i^{su}} e^{[-(1-\overline{\text{PoD}}_i)\lambda_i]}}{X_i^{su}!} \tag{9}$$

where PoD_i with the overline refers to the average PoD that corresponds to the X_i^s defects and can be evaluated from:

$$\overline{\text{PoD}}_i = \int \text{PoD}(x) f_{X_i^s}(x) dx \tag{10}$$

where $f_{Xi}^s(x)$ denotes the probability density function (PDF) of the depths of the X_i^s defects at time t_i.

3.2 *Stochastic defect growth*

The depth $c(t)$ of a defect at year t, (i.e. $t = 0$ corresponds to the installation year of the pipeline) was assumed to follow a homogeneous gamma process (Zhang & Zhou 2014). The PDF of $c(t)$ is gamma distributed:

$$f_{c(t)}(c(t)\Big|\gamma(t), \omega) = \frac{\omega^{\gamma(t)} c(t)^{\gamma(t)-1} e^{-c(t)\omega}}{\Gamma(\gamma(t))} \mathrm{I}_{(0,\infty)}(c(t)) \tag{11}$$

with $\gamma(t)$ representing the time-dependent shape parameter which is a linear function with time:

$$\gamma(t) = \alpha_1 (t - t_0) \tag{12}$$

where t_0 denotes the initiation time of a defect. In addition, ω ($\omega > 0$) is the time-independent rate parameter or the inverse of the scale parameter, $\Gamma(\bullet)$ denotes the gamma function and $I_{(0,\infty)}(c(t))$ is the indication function (i.e. it is equal to unity if $c(t) > 0$ and zero otherwise). The quantity α_1/ω represents the mean of the defect depth. The parameters α_1 were assumed to be common for all defect depths, whereas t_0 and ω were assumed to be defect-specific. t_{0z} and ω_z were defined with respect to the initiation time and rate parameter for the zth defect, as opposed to the index k that was used to characterise detected defects, i.e. z refers to the total number of defects (both detected and undetected).

The growth of the jth defect among the (i-1)th and ith inspections Δc_{iz} is gamma distributed with a time-dependent shape parameter $\Delta\gamma_{iz}$ as follows:

$$\Delta\gamma_{iz} = \alpha_1 (t_i - t_{0z}) \quad \left(i = y\right) \tag{13}$$

where y is a quantity that satisfies $t_{y-1} < t_{iz} < t_y$. The depth of each defect z at the time of each inspection i c_{iz}, is the sum of consecutive incremental depths between the (i-1)th and ith inspections:

$$c_{iz} = c_{i-1,z} + \Delta c_{iz} \tag{14}$$

4 BAYESIAN ANALYSIS

4.1 *Likelihood functions*

Given the number of detected defects in a total of m inspections and assuming a defect k first detected in the ith (i = 1, 2, … or m) inspection, $\mathbf{d}_k = (d_{ik}, d_{i+1,k}, \ldots, d_{i+y,k}, \ldots, d_{mk})'$ and $\mathbf{c}_k = (c_{ik}, c_{i+1,k}, \ldots, c_{i+y,k}, \ldots, c_{mk})'$ can be defined that denote the vector of the actual depths for defect k and the vector of the corresponding ILI-reported depths of defect

k, respectively. Considering the measurement error, the likelihood of $\boldsymbol{d}_k$ conditional on $\boldsymbol{c}_k$ can be defined as follows:

$$L(\mathbf{d}_k|\mathbf{c}_k) = (2\pi)^{-\frac{(m-i+1)}{2}} \left|\Sigma_{\mathbf{E}_k}\right|^{-\frac{1}{2}} \exp[-\frac{1}{2}(\mathbf{d}_k - \alpha - \mathbf{bc}_k)' \Sigma_{\mathbf{E}_k}^{-1}(\mathbf{d}_k - \alpha - \mathbf{bc}_k)] \quad (15)$$

where $\boldsymbol{\alpha} = (a_i, a_{i+1},\ldots,a_m)'$ and $\mathbf{b}$ is an $m - i + 1 \times m - i + 1$ diagonal matrix with the yth element equal to a_{i+y}.

The updating of the number of detected defects inherently contains the possibility that some of the newly detected defects in the ith inspections might have been generated prior to the previous inspection (i-1)th but remain undetected until then. However, it was assumed that the newly detected depths in the ith inspection, have initiated between the (i-1)th and ith inspections. That is a conservative approach, since it finally leads to overestimation of the instantaneous rate of the generation model (Qin et al. 2015). The likelihood function for the newly detected defects in m inspections X_i^{sd} (i = 1, 2, …, m) was defined as follows:

$$L(X_i^{sd}|\lambda_0,\delta) = \prod_{i=1}^{m} \frac{\left[\overline{PoD}_i \lambda_0 (t_i^{\delta} - t_{i-1}^{\delta})\right]^{X_i^{sd}}}{S_j^{kde}} \exp\left\{-\left[\overline{PoD}_i \lambda_0 (t_i^{\delta} - t_{i-1}^{\delta})\right]\right\} \quad (16)$$

where the PoD_i with the overline, includes both detected and undetected defects in the ith inspection. The undetected defects were treated as the missing data and the data augmentation (DA) technique was employed to incorporate these in the Bayesian analysis (Tanner & Wong 1987). This technique is described in more detail in Section 4.4. Thus, the PoD serves as a link in the Bayesian updating, between the generation and growth models.

4.2 *Prior distributions*

The gamma distribution was selected as the prior distributions of α_1, ω_k parameters of the growth model and also for the λ_0 and δ parameters of the generation model. The truncated normal distribution with an upper bound equal to the time of the inspection that each defect is detected for the first time and a lower bound equal to the time of the previous inspection was chosen as the prior distribution of t_{0j}. The prior distributions for t_{0k}, α_1 and ω_k for individual defects were assumed to be mutually independent. The shape (rate) parameters of the gamma prior distributions for α_1, ω_k and λ_0, δ were defined as $\xi_1(\xi_2)$, $\kappa_1(\kappa_2)$ and $\varphi_1(\varphi_2)$, $\zeta_1(\zeta_2)$, respectively. Dependence among defect behavior is modelled through correlation coefficients among the HGP model parameters. In this study, the model parameters ω_k were considered equi-correlated among all defects (k = 1, 2,…, n) with correlation coefficients θ. The correlation coefficient represents the statistical dependence due to common fabrication quality, common material characteristics and common loading characteristics. The joint distribution of all model parameters is subsequently modelled through a Nataf (Gaussian copula) model (Qian et al. 2013).

4.3 *Updating with BUS-SuS and DA technique*

Bayes' rule enables updating the joint prior distribution of the parameters $\boldsymbol{\eta}$ that correspond to both generation and growth models, based on the inspection data $\mathbf{C}$. The prior distribution is $f(\boldsymbol{\eta})$ and is converted into a 'posterior' distribution $f'(\boldsymbol{\eta}|\mathbf{C})$, based on the following (Straub & Papaioannou 2014):

$$f'(\boldsymbol{\eta}|\mathbf{C}) = \frac{L(\mathbf{C}|\boldsymbol{\eta}) f(\boldsymbol{\eta})}{\int_{\Omega} L(\mathbf{C}|\boldsymbol{\eta}) f(\boldsymbol{\eta})} \quad (17)$$

where $\boldsymbol{\Omega}$ denotes the domain of definition of $\boldsymbol{\eta}$.

In this study, the Bayesian updating was conducted with BUS-SuS along with the aforementioned DA technique which constitutes a robust hybrid simulation technique, in an effort to numerically evaluate the complex denominator of Eq. 17, since an analytical evaluation would not be feasible. Bayesian updating with BUS-SuS is an extension of the classical rejection sampling approach to Bayesian analysis (Straub & Papaioannou, 2014, Straub et al. 2016). It is more advantageous over MCMC, which is typically used in the energy pipeline literature, since it diminishes the uncertainty around ensuring that the final samples have reached the posterior distribution and therefore provides more accurate samples of the posterior. The simple rejection sampling algorithm however, is quite inefficient and therefore subset simulation is employed that can compute very small probabilities. Thus, the Bayesian updating becomes very efficient, while maintaining the advantages of the simple rejection sampling algorithm (Straub & Papaioannou 2014, Straub et al. 2016).

A set of random samples of the prior distribution $\boldsymbol{\eta}$ are generated and then accepted as samples of the posterior distribution. The prior samples are accepted with a probability $p = cL(\boldsymbol{\eta})$, where c is a positive constant that ensures $cL(\boldsymbol{\eta}) \leq 1$ for all $\boldsymbol{\eta}$. If c is selected too small, this might decrease the efficiency of the method, since the acceptance

rate is a linear function of c. If c is too large, the resulting samples might not follow the posterior distribution. An optimal choice of c is considered to be (Straub & Papaioannou 2014):

$$c = \frac{1}{\sup L(\boldsymbol{\eta})} \tag{18}$$

For a single ILI with error ε, $\sup L(\boldsymbol{\theta})$ is equal to maximum of the PDF of ε. For the multiple ILIs of this study, $\sup L(\boldsymbol{\eta})$ was thought to be equal to the maximum of the multivariate PDF of the error ε_{ki}. This is spatially independent, following a multivariate normal distribution with a zero mean and known covariance matrix Σε associated with the total number of inspections m.

After defining the augmented outcome space [$\boldsymbol{\eta}$; p] and the domain $\{p \le cL(\boldsymbol{\eta})\}$ a structural reliability problem results, with the posterior distribution obtained by censoring the joint distribution of p and $\boldsymbol{\eta}$ to $\{p \le cL(\boldsymbol{\eta})\}$ and marginalizing $\boldsymbol{\eta}$:

$$f'(\boldsymbol{\eta}|\mathbf{C}) \propto \int_0^1 I([\boldsymbol{\eta}, p] \in \{p \le cL(\boldsymbol{\eta})\}) f(\boldsymbol{\theta}) dp \tag{19}$$

where I is an indicator function which takes value 1 if $\{p \le cL(\boldsymbol{\eta})\}$ and 0 otherwise (p is a standard uniform random variable). In the structural reliability convention, the domain $\{p \le cL(\boldsymbol{\eta})\}$ describes an observation event (in terms of the Bayesian updating) through a limit state function r, such that it corresponds to a respective domain $\{r(p,\boldsymbol{\eta}) \le 0\}$:

$$r(p, \boldsymbol{\eta}) = p - cL(\boldsymbol{\eta}) \tag{20}$$

The probability of the observation event can be efficiently computed by a robust method such as SuS. It is typically efficient to apply SuS in the standard normal space, therefore in this study the outcome space of the original random variables p and $\boldsymbol{\eta}$ was transformed to a space with independent standard normal random variables $\mathbf{V}$ (p and $\boldsymbol{\eta}$ are independent and thus they can be transformed separately). The transformed observation domain is a function U:

$$U(\mathbf{v}) = v_0 - \Phi^{-1}(cL(\mathbf{T}(\mathbf{v}))) \tag{21}$$

where Φ is the standard normal CDF.

An algorithm based on SuS can generate samples from the transformed observation domain subsequently. SuS is a well-established method and a detailed step-by-step presentation of the method can be found in Au & Beck (2001) and Straub & Papaioannou (2014). It should be noted that the final finding of interest in this study is the samples that belong to the posterior distribution. As a result, a final step should be defined. In that extra step, J additional samples conditional on Y from the output domain $\{p \le cL(\boldsymbol{\eta})\}$ are produced, so that a total number of (at least) Z samples from the posterior distribution is obtained.

Both the detected and undetected defects were considered for the Bayesian updating in this study. The depths of the detected defects were related to the ILI-reported depths through the likelihood function given by Equation 15, while the real depths of the undetected defects were treated as the missing data and imputed using the DA technique (Tanner & Wong 1987). As a result, the joint posterior distribution of the model parameters was evaluated from the depths of the total defect population (both detected and undetected). It should be noted that it is straightforward to couple DA in BUS-SuS. DA is an iterative process that in each iteration contains two steps; the imputation and the posterior step. The imputation step generates the samples of the missing data from its corresponding probabilistic distribution conditional on the current state of model parameters, whereas the posterior step is used to generate new samples of model parameters, from their corresponding posterior distributions conditional on both the observed and missing data. More information and details of the DA process can be found in Tanner & Wong (1987), Rubin (2004) and Little & Rubin (2014).

5 APPLICATION

5.1 *Case study*

Simulated data are used to illustrate and validate the methodology. A gas pipe segment is considered, with 609 mm diameter and 7.9 mm wall thickness, from pipe material API 5 L grade X52. Five future ILIs were assumed to take place on years t = {4, 7, 9, 11, 15} after the installation of the pipeline. The growth of individual defects was assumed to be a linear random variable corrosion growth model, with the rate of defect growth for each defect selected from a uniform distribution with lower bound 0.29 mm/year and upper bound 0.50 mm/year. Metal-loss corrosion defects were assumed to initiate based on the NHHP model by deterministically setting the parameters $\lambda_0 = 0.2$ and $\delta = 1.0$ and to grow with the aforementioned individual random rate.

Furthermore, a depth detection threshold of >1 mm deep was considered and a PoD of 98.3%. The measurement error was assumed to fall within the bounds of ±1 mm with 90% probability. Therefore $q = 4.0785$ in Equation 4 and measurement error follows a multivariate normal distribution with mean zero and standard deviation $\sigma_r = 7.29\%wt$. The constant and non-constant

biases included in the measurement error given by Equation 1 were assumed to be equal to zero and unity for all inspections respectively, while the random scattering errors associated with different inspections were defined as mutually independent with the same standard deviation of unity. Table 1 summarises the simulated data.

5.2 *Validation of Bayesian formulation*

The Bayesian analysis was carried out for the defect generation and growth models, based on the ILI data. The shape and scale parameters of the gamma prior distributions for the parameters of the models α_1, ω_k and λ_0, δ were all set to unity. A total of 20,000 samples were generated to evaluate the probabilistic characteristics of the model parameters. The means, medians and standard deviations of the posterior marginal distributions of the parameters λ_0, δ of the NHPP model, together with the average PoD for the defect generated prior to the first inspection year and among the rest of inspection years respectively, are summarised in Table 2. Furthermore, the same information for the HGP parameters α_1 that are common for all defects is also presented in Table 2. When compared with the actual (i.e. simulated) values, the posterior mean and median values of δ and λ_0 are considered to be in good agreement, which validates the Bayesian formulation described in Section 4. This is further illustrated in Figure 1 and Figure 2 for the NHPP and HGP models, respectively.

In Figure 1, results for a period from when the generation of new defects initiates to the last inspection year (i.e. 15), are presented. The mean values of the number of generated defects were estimated, with the values λ_0, δ set equal to their corresponding posterior medians. For comparison, $\lambda(t)$ evaluated by the actual values of λ_0 and δ, the simulated total number (i.e. detected and undetected) of defects, along with the simulated numbers of detected defects on the five ILIs are also illustrated in Figure 3 $\lambda(t)$ agrees with the actual mean very well, which proves the validity of the Bayesian model.

Next, the depths of the detected defects at year 15 were evaluated and compared with the corresponding actual defect depths. Each predicted defect depth was set equal to the corresponding mean derived from the HGP growth model, with the parameters of the model (i.e. α_1, ω_k and t_{0k}) equal to the respective posterior medians. In the Bayesian updating, constant c of Equation 18 was evaluated on each inspection year, based on the procedure described in Section 4.4 and the respective

Parameter	NHPP		PoD				
	λ_0 (0.2)	δ (1.0)	1	2	3	4	5
Mean	0.30	0.81	0.03	0.99	0.41	0.72	0.73
Median	0.30	0.80	0.03	0.97	0.41	0.72	0.73
Std	0.28	0.17	0.08	0.12	0.07	0.07	0.07

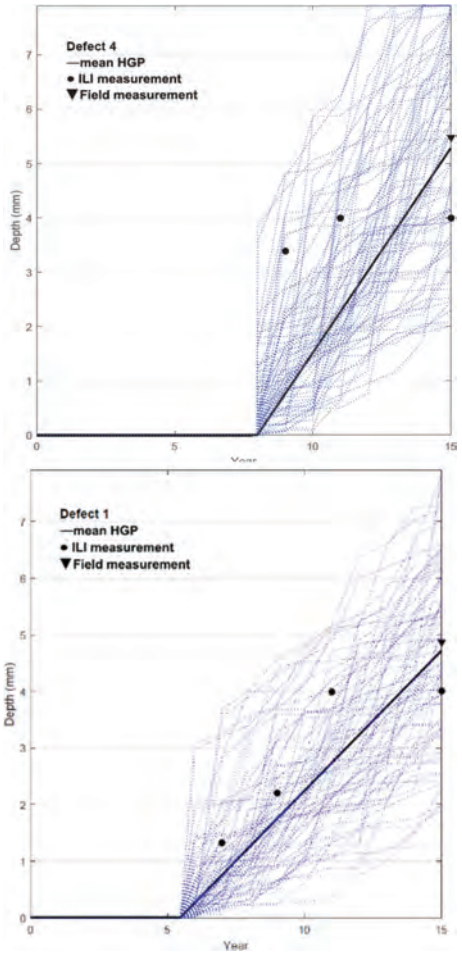

Figure 3. Predicted growth paths of defects 1 and 4 based on the HGP model.

values are illustrated in Table 3. From Figure 2 it can be observed that the model predictions are in good agreement with actual values. In fact, all defect depths fall within the range of ±10%wt of the corresponding actual depths, which is a commonly adopted confidence interval for ILI tools' accuracy in industry (Zhang & Zhou 2013). In summary, the methodology is validated against the corresponding actual data and its accuracy is verified.

For illustration purposes, two defects were chosen for analysis and their means were estimated, based on the results of BUS-SuS for the same 15-year period. The mean and standard deviation of defect depths were defined as $\alpha_1(t-t_{0k})/\omega_k$ and $(\alpha_1(t-t_{0k})/\omega_k^2)^{0.5}$ respectively for each defect, based on the HGP corrosion growth model. The parameters α_1, ω_k and t_{0k} were set equal to the deterministic median values from their corresponding marginal

Table 3. Constant c values for different ILI years.

Time of inspection	Year 4	Year 7	Year 9	Year 11	Year 15
Constant c	0	6.2796	4.3460	3.0084	2.0840

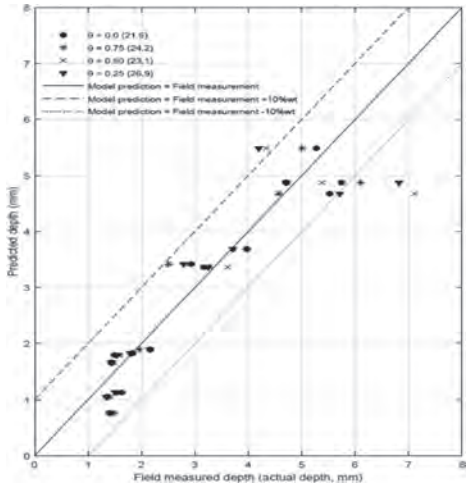

Figure 4. Comparison of the predicted depths and actual depths at year 15 for different correlation coefficients among defects.

posterior distributions derived from BUS-SuS. Also, 80 random realisations of the HGP model are illustrated for each defect. It is observed that for both defects, the BUS-SuS predicted depths and actual depths are in very good agreement, even though the ILI data is not in great proximity with the actual depths. Thus, the proposed model can account successfully for the imperfections of the inspection data and capture the actual initiation times and growth rates of the defects.

Furthermore, in order to investigate the effect of the correlations of defects on the growth model, different dependency scenarios were examined. It was assumed that c_{ik} $(i = 1, 2, ..m)$, $(k = 1, 2,\ldots, n)$ are identically distributed and equi-correlated with the corresponding coefficient θ, set equal to 0.25, 0.5, 0.75 and 0.0 (i.e. 0.0 corresponds to independent and identically distributed samples).

Figure 4 compares the predictions of the growth model (i.e. HGP) at year 15 corresponding to different correlation scenarios. The Mean Squared Error of Prediction (MSEP), defined as:

$$1/n\sum_{k=1}^{n}(c_{pr}-c_{ar})^2 \qquad (22)$$

quantitatively evaluated the predicting accuracy of the growth model, where c_{pr} and c_{ar} denote the predicted

and actual depths of the *k*th defect. The MSEP values are illustrated in brackets on Figure 4 and it is given that the higher the accuracy the lower the corresponding MSEP value is expected to be. It is observed that the most accurate correlation scenario is $\theta = 0.0$. Nevertheless, there is not a clear tendency indication with respect to different correlation scenarios, by either the depth predictions or the MSEP results. In fact, for almost half defects, the depth predictions are negligibly different among correlation scenarios. However, for all correlation scenarios the methodology proposed for updating of the growth model is validated against the actual data. It should be noted that for all correlation scenarios the posterior NHPP generation model results remained unchanged. Therefore, it is thought that correlations do not impact the updating of the methodology significantly, but the selection of a specific correlation structure is likely to affect the accuracy of the growth model upon updating.

6 CONCLUSIONS

A stochastic process-based hierarchical Bayesian methodology was proposed for corrosion management of gas pipelines. The metal-loss corrosion defect generation was characterised by a NHPP and the growth by a HGP. Furthermore, the Nataf model was used for the spatial dependence among defects. The hierarchical Bayesian framework proposed, captured the imperfect detectability of the ILI tool as defined by the PoD and also the measurement errors associated with the ILI data. The Bayesian updating was performed by employing BUS-SuS in conjunction with the data augmentation technique.

The proposed model was applied on simulated defects and multiple ILI inspections. Different defects were assumed identically distributed and equi-correlated with the coefficient θ equal to 0.25, 0.5, 0.75 and 0.0. Results from the Bayesian updating of the generation and growth models, indicate that the predicted overall defect population corresponding to the base case (i.e. $\theta = 0.0$) is in good agreement with the actual defect population, which validates the proposed methodology. The other three correlation scenarios also lead to predictions of good agreement with the actual data and therefore the Bayesian methodology is accurate irrespective of the correlation scenario. There are some discrepancies in the accuracy of predictions among the different scenarios nonetheless, identified by the MSEP. The most accurate among all four scenarios was the one with θ equal to 0.0.

Effect of the manufacturing defects on the reliability of disposal packages for high level radioactive waste

A. Persoons, P. Beaurepaire & A. Chateauneuf
CNRS, SIGMA Clermont, Institut Pascal, Université Clermont Auvergne, Clermont-Ferrand, France

F. Bumbieler
Andra, Rue Jean Monnet, Châtenay-Malabry, France

ABSTRACT: In the deep geological disposal facility for radioactive waste to be built in France, it is planned to encapsulate high level waste in carbon-steel overpacks before inserting them into horizontal micro-tunnels. The main function of the overpack is to isolate the waste from the environment long enough for its radio-toxicity and heat to significantly decrease. Several phenomena affect the overpack during its lifetime. The prediction and modelling of these phenomena are subjected to many uncertainties due to their complexity and their extrapolation over long time periods (several centuries). This paper presents an overall framework for the estimation of the failure probability of the overpacks over time. The failure scenario considered is the fracture of the overpack. The analysis is based on a parameterized finite element model taking into account the evolution of the geometry due to the non-uniform corrosion process, the evolution of the mechanical loading and their variability. In addition the manufacturing process may induce defects which are modeled as cracks and included in the model of uncertainty. The whole process is run for several time steps until the complete failure of the overpack. The reliability estimation is based on a two-level Monte Carlo analysis and according to a fracture mechanics criterion based on a probabilistic critical stress intensity factor.

1 INTRODUCTION

Nuclear plants are one of the principal sources of electricity in many countries and are responsible for most of the electricity production in France. Nuclear industry produces 60% of the French radioactive waste, 27% are from research activities, 9% from defense, 3% from industry and 1% from medical activities (ANDRA 2015). Radioactive waste are categorized by their level of hazardousness. The European council directive 2011/70/EURATOM states that, at this time, deep geological storage is the safest option as the end point of management of high-level waste. Cigeo is the French project of deep geological disposal facility for radioactive waste. Safety and reliability are major goals of the project and it is necessary to guarantee that the radioactive material will not be in contact with water during the early time of storage. In the project, high level waste are planned to be conditioned in carbon-steel overpacks before being inserted into horizontal micro-tunnels. The main function of the overpack is to isolate the waste from the environment long enough for its radio-toxicity and heat to significantly decrease. This period is estimated at 500 years. Therefore, the reliability of overpacks is an important element in the safety assessment of the overall Cigeo project.

For this project, studies are lead on the evolution of corrosion processes (type and kinetics), the properties of the steel grades and their behavior in repository conditions, the thermos-hydro-mechanical properties and behavior of the rock, the prediction and characterization of failure mode of the steel structures (the buckling of the lining, cracking of the overpack). Reliability methods have not been explored yet in this project although they are already widely used in other fields with comparable constraints such as oil and gas industry (Dundulis et al. 2016). The interest of the study is to estimate the failure probability of the overpacks taking into account the aging process and uncertainties of the system. The failure probability is investigated considering a fracture mechanics criterion to take into account an eventual Stress Corrosion Cracking (SCC) sensitivity of the steel.

The analysis presented in this paper proceeds as follows: a realization of the random variables is generated and the finite element analysis of the degraded model is performed for all the time steps over the lifetime. The stress field is recovered and the stress intensity factor is calculated at each time

step for numerous randomly simulated cracks. The reliability of the system over time is estimated by a Monte-Carlo method using two levels of simulations. At the first level, a limited sample of the random variables affecting the finite element analysis is evaluated. For each of them (second level) the stress intensity factor of the random crack requires only post processing. This strategy allows us to analyze a large number of crack configuration with moderate numerical efforts. The reliability is then evaluated for every time step facing a random critical stress intensity factor criterion.

2 STATEMENT OF THE PROBLEM

The repository will take place 500 meters below ground in an impermeable argillaceous rock (Callovo-Oxfordian claystone) able to contain radioactivity over a very long period (ANDRA 2005). High Level Wastes (HLW) disposal cells consist of horizontal micro-tunnels cased with a steel liner (Fig. 1). A cement-based filling material that imposes corrosion-limiting environmental conditions is also injected between the rock and the lining. HLW are vitrified and sealed in stainless steel containers conditioned in low-alloy overpacks which are inserted in the lining (Figs. 2–3). The whole system may be compared to Russian nesting dolls, in the center is the waste, then the container, the overpack, the lining, the filling material and finally the rock.

The corrosion and the evolution of the mechanical loading could affect the structural integrity and the reliability of the overpack. Therefore, it is important to describe and model the in-situ conditions of the system along its lifetime, the possible variations of this scenario and the possible failure causes.

Overpacks are made of low-alloy steel to promote general corrosion in repository conditions. Water coming from the host rock will progressively fill the HLW cell implying that two corrosion rates (either under or above water) affect the overpack.

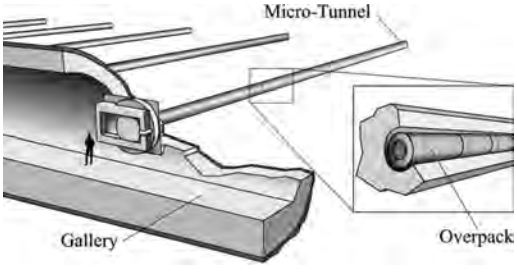

Figure 1. Overview of the storage facility.

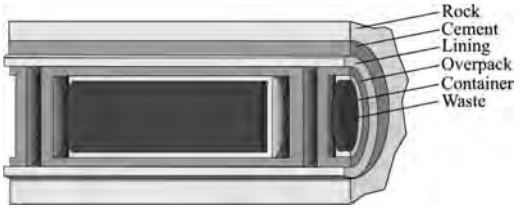

Figure 2. Schematic cross-section of the system studied.

Figure 3. R7-T7 vitrified waste disposal package.

These two corrosion rates lead to non-uniform corroded thickness around the overpack.

The evolution of the water level over time is the equilibrum result of several hardly predictible phenomena, involving the saturation and water flow in the rock and the gas production by the corrosion processes. Therefore, uncertainties remain about the long term stabilized height of the water level. A liquid water extraction system avoids the water filling of the micro-tunnel during the 100 years operating phase, so that the water level is null for this period. The equilibrium of the gas and liquid phases has been studied for intermediate level waste disposal facilities of the same project i.e. the same rock in (Croisé et al. 2011; Brommundt et al. 2014). It has been stated that once the repository is sealed, the rock saturation will increase and water will flow in. After a while, an equilibrium between water and gas pressure will be reached and the water level will stabilize. This study focuses only on the case of the water level stabilizing at an intermediate value filling half of the micro-tunnel (Fig. 4).

Corrosion also affects the steel lining which is under the pressure of the rock. The reduction of its operational thickness will eventually cause buckling, it will come into contact with the overpack

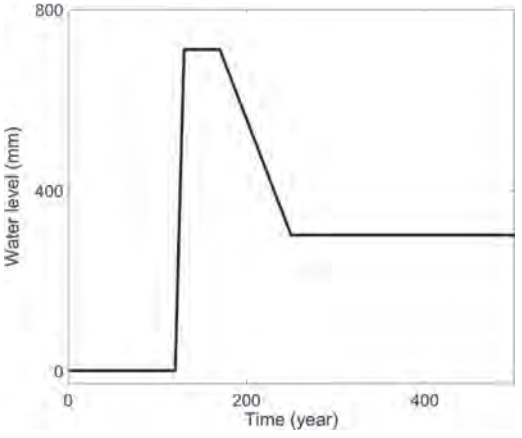

Figure 4. Water level over time.

and transmit the pressure. The contact area will progressively expand until it completely covers the overpack which will be directly subjected to the pressure of the rock. Once the micro-tunnel is sealed, it is also subjected to a fluid pressure.

The overpack is made of 3 forged parts welded by electron beam. Each overpack is inspected for defect from either the welding or the forge process, but defects such as surface cracks may remain undetected, being too small for the precision of detection. In this study, only the case of cracks with a constant depth over time is considered.

Various processes affect the geometry of the overpack and the mechanical loading. It is therefore important to model all of these processes with their variability to use them as input parameters of a finite element model. The study focuses only on the reliability facing a fracture criterion, to take into account a potential SCC sensitivity of the steel which is a conservative approach. To this end, a parameterized finite element model of the overpack has been developed. The corrosion process and its variability have been modeled as well as the mechanical loading over time. Cracks are positioned and numerically simulated in the highest tensile stress concentration area and the stress intensity factor is estimated using analytical equations.

3 MODEL OF UNCERTAINTY

Various uncertainties should be considered because of the novelty of the whole project, the complexity of the system and the long periods of time studied. These uncertainties can affect significantly the lifetime of the overpack. Therefore, it is important to quantify and to properly model them.

Two different strategies have been used to describe the variability of the system. Uncertain parameters are modelled by random variables. For corrosion rates and water level over time, the evolutions of the phenomena are uncertain because of the inherent complexity of the whole system. Sets of possible scenarios are described and each case can be studied individually.

The corrosion rates are the result of several chemical processes which are hardly predictable. The in situ corrosion process of the overpack has been studied in (Schlegel et al. 2014; Necib et al. 2017). It has been stated that the corrosion rates are decreasing as a result of the pseudo-passivation of the metal surface. However, the precise path that this decrease follows is uncertain, this study focus only on a very severe estimated scenario (Fig. 5). In this one the corrosion rates are steady for 100 years because of a potential oxygen inflow from the access gallery during operating phase of the HLW cell. Once the micro-tunnel is closed and the access drift backfilled, the corrosion rates decrease until they reach a new equilibrium. The uncertainty considered in this paper is related to the overall chemical activity of the system, where both of the corrosion rates are fully correlated. From expert opinion, the corrosion rates have a nominal value c and the interval which is the most likely to contain their actual value is $[\frac{1}{1.5}c;1.5c]$. Therefore, it has been modelled by a multiplying factor A following a lognormal distribution with the median equal to one and affecting both corrosion rates. This way, the probability for the variable to be larger than 1.5 is equal to the probability for it to be less than $\frac{1}{1.5}$. The standard deviation is then fitted so that 99.7% of the realizations are in the interval.

The contact pressure P_c transmitted by the lining after buckling is uncertain. Three different

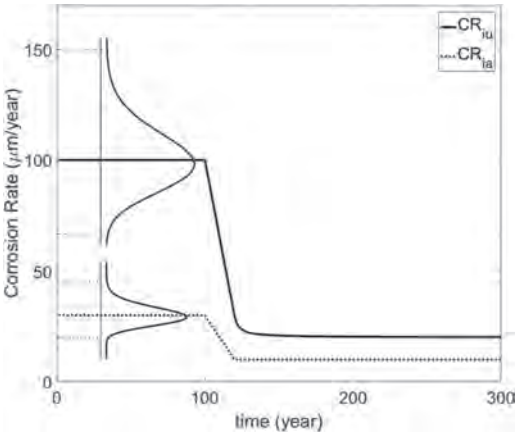

Figure 5. CR_{ia} and CR_{iu} evolutions over time.

studies have been carried out on the contact pressure transmitted by the lining after buckling. The dispersion of the results have been simplified by the confidence interval [$0.5P_{nominal}$;$2P_{nominal}$] which is used for this study. The same strategy as described for the corrosion rates have been used to model the contact pressure with lognormal distribution.

The reliability analysis is performed using a fracture mechanics criterion. An uncertain semi-elliptical crack is simulated on the external surface. The size of the crack is taken deterministic with both crack depth and length of 2 mm. These values have been chosen according to the biggest acceptable crack of the best quality of control described in the European standard EN 10228-3 about non-destructive testing for the forged parts. To reduce the calculation time, the crack is considered at a deterministic coordinate value in the axis of the cylinder (z_c). Preliminary simulations have highlighted a tensile stress concentration localized at this specific position. The position of the crack on the cross-section profile at $z = z_c$ is defined by the angle θ_1, the angle with respect to the circumferential direction. The orientation of the crack on the surface is defined by the angle θ_2. It is assumed that the crack does not have any preferential position or orientation, and that all the configurations are equally likely. Therefore, both of these parameters are taken as independent random variables following a uniform distribution defined by the interval [0; 180]. Early studies (Necib et al. 2017) have been performed to estimate the fracture toughness of the overpack under representative corrosion conditions K_{1scc}. CT specimens have been loaded to 40 $MPa\sqrt{m}$ during 4000 hours exhibiting very limited propagation (<150 µm). Further studies are in progress but no statistical data are currently available. By default, a normal distribution has been defined by the following parameters:

- mean value of $K_{1scc} = 40MPa\sqrt{m}$
- coefficient of variation of 0.1

4 FINITE ELEMENT MODEL

The reliability analysis is based on a finite element model that should be representative of the geometry and loading of the system in operational conditions for all its lifetime. To reduce calculation time, the finite element analysis is limited to the elastic behavior of the material. The goal is to retrieve the stress field in the whole area where cracks will be simulated. This model is evaluated for time steps of 100 years until complete failure. This occurs when the corroded thickness at one location reaches the initial thickness. All these evaluations correspond to one realization of the random variables affecting the finite element model. In order to perform a reliability analysis, many of these realizations are required. Therefore, the model must be as fast as possible and completely parameterized to be automatically generated.

Corrosion is taken into account as a reduction of the thickness, implying that the geometry of the overpack is changing over time. The corroded thickness is non-uniform around the overpack and depends on the time, the history of the water level, and the corrosion rates. The exact thickness of the cross-section can be evaluated at any point of the profile. However, the water level is supposed steady after a period and the corrosion process is highly simplified. These simplifications lead to strong thickness discontinuities implying sharp edges on the corroded cross-section profile. These sharp edges are not representative of the real geometry of the corroded overpack and would lead to stress concentrations in the finite element analysis. To define a continuous smooth cross-section profile representative of the thickness loss by corrosion, the exact corroded thickness is calculated for 16 points on the profile, every 22.5° as described in Equation (1).

$$CT(i,t) = \int_0^T \left(I^a(i,t) CR_{ia}(t) + I^u(t,i) CR_{iu}(t) \right) dt \quad (1)$$

with CT(i,t) the corroded thickness at the i^{th} point at time t, $CRia$(t) and $CRiu$(t) are the values of the corrosion rates above and under water at time t, I^a and I^u are defined as follow:

$$I^a(\boldsymbol{i},\boldsymbol{t}) = \begin{cases} 1 \text{ if } h_{wat}(t) < h(i) \\ 0 \text{ if } h_{wat}(t) \geq h(i) \end{cases} \quad (2)$$

$$I^u(\boldsymbol{i},\boldsymbol{t}) = 1 - I^a(\boldsymbol{i},\boldsymbol{t}) \quad (3)$$

with h_{wat}(t) the height of the water level at time t and h(i) the height of the i^{th} point. The radius of the points are reduced by the corroded thickness and a closed spline curve is defined passing through the points (Fig. 6). For each time increment, the spline is calculated and used as the corroded cross-section profile to generate the geometry of the part.

The mechanical loading is composed of a constant fluid pressure and a contact pressure. The contact pressure over time depends on the date at which the lining buckles. This date is calculated by an empirical equation determined by previous experimental and numerical studies lead at Andra (Nguyen 2017). The equation is based on the rock pressure value and the corrosion rates. The contact area where the pressure is applied is defined by a contact angle α (Fig. 7). The angle

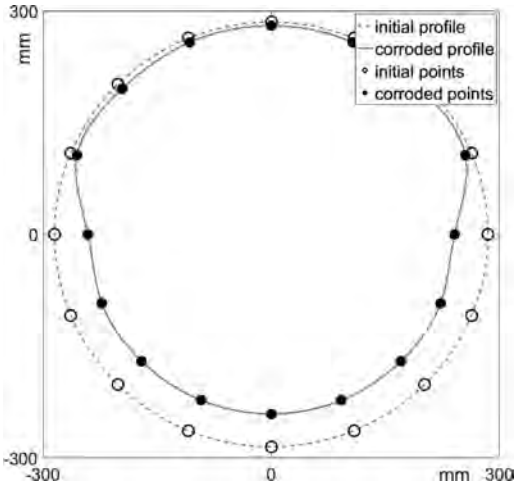

Figure 6. Sample of corroded cross-section profile.

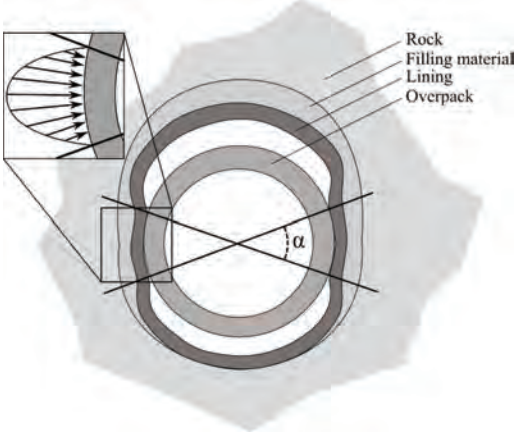

Figure 7. Schematic drawing of the contact angle.

defines two contact areas modelling the case of a two lobes buckling. The contact angle evolution is very difficult to predict due to the complexity of the system (post-buckling behavior of the lining, long term mechanical loading applied to the rock) and as a first approximation, it is assumed that it increases linearly with time and is expected to reach complete contact is about 3000 years. The pressure profile over the contact surfaces is taken as parabolic, such that pressure is equal to zero at the edges and nominal at the middle. The nominal pressure is governed by the random variable P_c as discussed in section 3. Once α reaches 180°, it is necessary to adapt the pressure profile such that its evolution is smooth. At this time, the two contact areas are joined and the pressure is null at the two edges separating them. The overall pressure profile is close to an ellipse. However, the long-term profile pressure is a circle because minor horizontal and vertical stresses in the rock are almost equal. Therefore, to ensure continuity of the loading over time, α is considered increasing even after 180° and the pressure profile is updated following the same evolution. The difference being that the profile pressure is still applied on the two 180° areas, this way the stress values at the edges increase and the pressure profile get closer to a circle (Fig. 8).

The finite element analysis is performed on the uncracked model, the stress field around the crack position is then analyzed to estimate the stress intensity factor as described in (Pommier, Sakae, and Murakami 1999). These equations are a generalization of the work of Newman & Raju (1981). In these equations the stress field around the crack is defined as a polynomial of the geometrical coordinates. The order and parameters of the polynomial are input parameters of the equations. They provide good evaluations of K_I for semi-elliptical surface cracks with a wide range of shapes given by the two input parameters, the crack depth and length. The stress field is exported from the finite-element analysis on a grid with five points in the axial direction centered on z_c, five points in the radial direction and 500 points in the circumferential direction. Once the position of the crack associated with θ_I is determined, the stress field at several points around the crack and the coordinates of these points are retrieved. The area where the data are retrieved is the slice of the scan area that is centered on the crack position (5 axial points, 5 radial points, 6 circumferential points). The components of the stress field are modelled

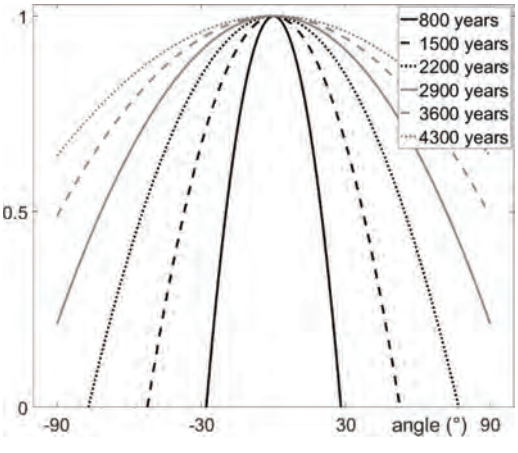

Figure 8. Pressure profile for several time steps after buckling.

with a linear regression in the global coordinate system. Then, the parameters of the fitted linear model of the stress field are calculated in the local coordinate system attached to the crack. These parameters are used to estimate the stress intensity factor associated with the opening mode along the crack edge. This way all positions and orientation of cracks can be simulated with a single finite-element analysis.

5 RELIABILITY ANALYSIS

The results of the finite element model are used to perform the reliability analysis using Monte-Carlo simulations. The failure probability P_f is expressed as follows (Lemaire 2013):

$$P_f = \int_{-\infty}^{+\infty} I(\boldsymbol{X})\, f(\boldsymbol{X})\, d\boldsymbol{X} \tag{4}$$

where f is the joint probability density function of the random variables $\boldsymbol{X}$ and I is defined as:

$$I(\boldsymbol{X}) = \begin{cases} 1 \text{ if } g(\boldsymbol{X}) \le 0 \\ 0 \text{ if } g(\boldsymbol{X}) > 0 \end{cases} \tag{5}$$

with g is the performance function which is an auxiliary function introduced to define the failure event. The failure domain is associated with the negative values of g, as discussed in Equation (5). In Monte-Carlo simulations, realizations of the random variables are generated and the integral expressed in Equation 4 is estimated by:

$$P_f \approx \frac{1}{N} \sum_{j=1}^{N} I\left(\boldsymbol{X}^{(j)}\right) \tag{6}$$

where N is the number of simulations and $\boldsymbol{X}^{(j)}$ denotes samples of the uncertain parameters obtained using a (quasi-)random number generator. This approximation is valid for N sufficiently large, usually for $N \ge 100/P_f$.

In this study, random variables are managed following two different strategies depending on how time consuming they are to evaluate. The random variables affecting the finite element model (A, P_c) are associated with considerable numerical efforts because for each realization the finite element analysis has to be performed for the whole lifetime. The random variables affecting only the crack $(\theta_1, \theta_2, K_{1c})$ are easy to evaluate because they only require post processing without further evaluation of the finite element model. Therefore, to maximize the simulations and to use the advantage of the variables associated with moderate numerical effort, the Monte-Carlo simulations are lead on two levels with two different numbers of simulations. The random variable set can be divided into two sets $\boldsymbol{X} = (\boldsymbol{X}_1, \boldsymbol{X}_2)$. where $\boldsymbol{X}_1 = (\theta_1, \theta_2, K_{1c})$ and $\boldsymbol{X}_2 = (A, P_c)$. The previous equation can be written as:

$$P_f = \int \int_{-\infty}^{+\infty} I(\boldsymbol{X}_1, \boldsymbol{X}_2)\, d\boldsymbol{X}_1\, d\boldsymbol{X}_2 \tag{7}$$

The Monte-Carlo simulation is applied twice in order to transform both integrals into sums.

$$\begin{aligned} P_f &\approx \int_{-\infty}^{+\infty} \frac{1}{N_1} \sum_{j=1}^{N_1} I\left(\boldsymbol{X}_1^{(j)}, \boldsymbol{X}_2\right) d\boldsymbol{X}_2 \\ &\approx \frac{1}{N_1 N_2} \sum_{k=1}^{N_2} \sum_{j=1}^{N_1} I\left(\boldsymbol{X}_1^{(j)}, \boldsymbol{X}_2^{(k)}\right) \end{aligned} \tag{8}$$

In this study, 100 simulations of the variables related to the finite element model (N_2) have been evaluated and 100,000 cracks (N_1) have been simulated for each of them. Therefore the failure probability is expressed as follow:

$$P_f(t) \approx \frac{1}{N_1 N_2} \sum_{k=1}^{N_2} \sum_{j=1}^{N_1} I\left(\theta_1^{(j)}, \theta_2^{(j)}, K_{1c}^{(j)}, A^{(k)}, P_c^{(k)}, t\right) \tag{9}$$

and I defined with the performance function g:

$$g\left(\boldsymbol{X}^{(j,k)}, t\right) = K_{1c}^{(j)} - K_1\left(\theta_1^{(j)}, \theta_2^{(j)}, A^{(k)}, P_c^{(k)}\right) \tag{10}$$

Once complete failure is reached (i.e. corrosion of all the thickness of the overpack), the finite element model can no longer be created. Therefore, stress intensity factor and the sign of g cannot be evaluated. The system is then considered defective regardless of the sign of g and the failure probability over time is estimated with:

$$\text{if } t \ge t_{cf} \text{ then } I(\boldsymbol{X}_1, \boldsymbol{X}_2, t) = 1$$

6 RESULTS

The stress intensity factor K_1 have been evaluated every 100 years until complete failure for the $N_2 * N_1$ simulations. The results have been represented by the median curve and confident interval bounds at 95% (Fig. 9). The estimation of the stress intensity factor gives negative values as response of compressive stresses. These values have been considered as equal to zero which does not affect the median curve or the estimation of the failure probability. The results show that the dispersion

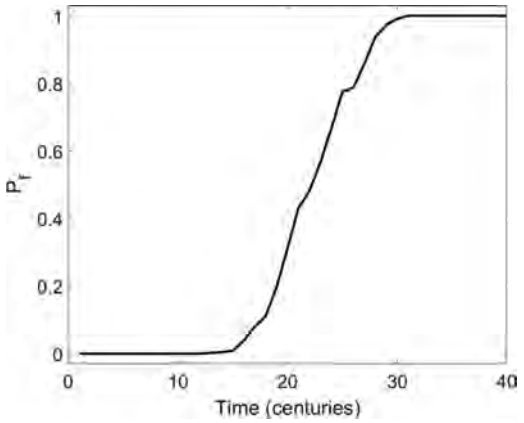

Figure 10. Estimated failure probability over time.

increases with time while the median value remains almost unchanged. This result can be explained by three phenomena. First, with time increasing, the average thickness shrinks and the overall stresses slowly increases. Second, the stress concentration area as discussed in section 3 is only local in the area where cracks are simulated but it may lead to high stress intensity factors. This area grows with time and the stress values involved increase rapidly, thus increasing the extreme values of stress intensity factor. Finally, depending on their orientation, the cracks are almost equally likely to be subjected to tension than to be subjected to compression. Therefore, even with increasing stresses involved, the median value of the stress intensity factors remain balanced. Because of the impossibility to evaluate K_1 once compete failure is reached as discussed in section 5, with time increasing the number of samples available to estimate the variability of K_1 decreases, explaining the increasing irregularities of the upper bound of the confident interval.

The failure probability over time estimated by the Monte-Carlo simulation is represented in Fig. 10. The first failures occurs after 1100 years and the failure probability at this date is 10^{-6}. Therefore, the failure probability at 500 years which is the minimum required lifetime is less than 10^{-6}.

7 CONCLUSION

The failure probability of the overpacks for HLW is estimated taking into account the evolution of the operational conditions and the aging of the system. The presented study is based on assumptions made to ensure conservationism and reduce computation time. The failure probability at 500 years is smaller than 10^{-6} which is in good agreement with the lifetime requirement of the overpack. This study gives a first estimation of the reliability of the design choices made for the Cigeo project. The reliability and safety of the infrastructures are major issues of the project and these results are relevant for the validation and improvement of the design choices.

This study could be completed by more simulations and the implementation of a metamodel to reduce numerical efforts. Further improvement would be to take into account a wider range of parameters involved in the problem. For example the other corrosion cases and water level evolution scenarios could be evaluated, as well as cracks on a wider surface area and the possibility of internal cracks in the overpack thickness.

ABSTRACT: Three sizes are important for the characterization of the propagation of fatigue cracks—initial size, detectable size and acceptable size. The theoretical model of a fatigue crack progression can be based on a linear elastic fracture mechanics. Depending on location of an initial crack, the crack may propagate in structural element that could be described by calibration functions. Single edge-cracked steel element with rectangular cross-section under relative short edge fatigue damage under pure tension, pure bending, three and four point bending load have been chosen for applications of the theoretical solution suggested in the studies. When determining the required level of reliability, it is possible to specify the time of the first inspection of the construction which will focus on the fatigue damage. Using a conditional probability and Bayesian approach, times for subsequent inspections can be determined based on the results of the previous inspection. For probabilistic calculation of fatigue crack progression, the original and new probabilistic method—the Direct Optimized Probabilistic Calculation (DOProC), which uses a purely numerical approach based on optimized numerical integration without any simulation techniques or approximationapproach. This provides more accurate solutions to probabilistic tasks, and, in some cases, allows to considerably fasten completion of computations with the taking into account the statistical dependence of random input variables.

1 INTRODUCTION

Fatigue phenomenon is one of the main factors influencing the life of steel structures and bridges subjected to cyclic loading. A substantial increase in the overall weight load from vehicle axles and crossing frequencies leads to higher fatigue damage than considered during the design of bridges. Due to above mentioned reasons, it is highly relevant to develop methods for the calculation and assessment of the residual fatigue life and time-dependent analysis of the reliability of existing steel structures, e.g., Soliman et al. (2016), Maljaars & Vrouwenvelder (2014) and Partov & Kantchev (2014). Numerous numerical methods, mostly based on the Finite Element Method (FEM), e.g., Major et al. (2017), Nemec et al. (2017), Vican et al. (2015) Cajka (2013) and Kormanikova and Kotrasova (2011), have been developed to aid in the understanding of the behavior of the fatigue phenomena.

In the design of structures, information related to time-variable load and detection of cracks from measurement during the operational period of the structure should be incorporated into reliability calculations. The essential tools for these calculationsare provided by fracture mechanics and the reliability theory, e.g., Hradil et al. (2017) and Michalcova & Lausova (2017). Some of approaches used for the fatigue crack prediction are based on stochastic methods, e.g., Kralik (2016), Antucheviciene et al. (2015) and Fedorik

et al. (2015). Insight into the stochastic interactions among random factors (load, geometric and material characteristics), e.g., Krivy & Konecny (2013), affecting the reliability of steel bridges is namely essential and crucial to understanding the progress of failure probability of steel structures over time, e.g., Schneider, Thons, & Straub (2017). Moreover, due to the presence of significant uncertainties associated with crack initiation and propagation, inspection, monitoring and/or repair actions planning should be performed and applied to prevent sudden failures of damaged structural components and their associated consequences, e.g., Lotsberg, Sigurdsson, Fjeldstad, & Moan (2016).

The paper focuses on the probabilistic approach based on optimized numerical integration—the newly developed Direct Optimized Probabilistic Calculation method (DOProC), published in details, e.g., in Janas et al. (2017). The DOProC method is distinguished by higher accuracy than the other probabilistic methods. Another advantage is the easy implementation on platforms with multiple processing units or cores, enabling the parallel computing of this probabilistic procedure, e.g., on supercomputers – (Krejsa et al. 2016). This new probabilistic approach has allowed to describe and implement a very precise methodology for stochastic prediction of fatigue damage of steel structures and bridges exposed to cyclic loading. Probabilistic modeling of fatigue crack progression leads to designing a system of regular inspections of structures and is based on linear elastic fracture mechanics and Paris-Erdogan's law, e.g., Seitl et al. (2017). This article describes this approach with a particular focus on the demonstration of using the above mentioned methodology for the single edge-cracked steel element with a rectangular cross section under relatively short edge fatigue damage.

2 THEORETICAL BACKGROUND

2.1 *Fatigue crack propagation*

When investigating the propagation, the fatigue crack that deteriorates a certain area of the structure component is described with one dimension only—fatigue crack length a. In order to describe the propagation of the crack, the linear elastic fracture mechanics is typically used. This method uses Paris-Erdogan's law and defines relation between propagation rate of the crack size a, and range of the stress rate coefficient, ΔK, in the tip of the crack:

$$\frac{da}{dN} = C \cdot \Delta K^m , \tag{1}$$

where C, m are material constants, that are determined experimentally, N is the number of loading cycles and ΔK is range of the stress intensity factor in front of the crack tip and it is defined as follow:

$$\Delta K = \Delta\sigma \cdot \sqrt{\pi \cdot a} \cdot F\left(\frac{a}{h}\right), \tag{2}$$

where $\Delta\sigma$ is constant stress range (the value of $\Delta\sigma$ corresponding to each way of loading, see Fig. 1, is shown in Table 1), h is the height of the rectangular cross-section of the component and $F(a/h)$ is the calibration function which represents the course of propagation of the crack (e.g., at the edge or on the surface of the component) and various boundary conditions.

Three sizes are important for the description of the characteristics of the propagation of fatigue cracks. The fatigue crack will propagate in a stable way only if the initial crack a_0 exists in the place where the stress is concentrated. Existence of the initiation cracks during the propagation should be revealed, along the detectable length of the crack a_d, e.g., during inspections. The crack propagates in a stable way until it reaches the third important size—acceptable length of the crack a_{ac}, which is a limit for the required reliability.

2.2 *Stochastic reliability assessment*

The main assumption is that the primary design should take into account the effects of the extreme loading and the fatigue resistance should be assessed. The probabilistic methods should be used for the investigation of the propagation rate of the fatiguecrack until the acceptable size is reached because the input variables include uncertainties and reliability should be taken into account. The resistance of the structure can be evaluated using Eqs. (1) and (2) as:

$$R(a_{ac}) = \int_{a_0}^{a_{ac}} \frac{da}{\left(\sqrt{\pi \cdot a} \cdot F\left(\frac{a}{h}\right)\right)^m} \mathrm{d}a \,. \tag{3}$$

If the upper integration limit a_d is used, the resistance of the structure $R_{(a_d)}$ can be specified similarly. Similarly, it is possible to define the cumulated effect of loads that equals to:

$$E(N) = \int_{N_0}^{N} C \cdot \Delta\sigma^m \mathrm{d}N = C \cdot \Delta\sigma^m \cdot (N - N_0), \tag{4}$$

where N is the total number of oscillations $\Delta\sigma$ for the change of the length from a_0 to a_{ac}, and N_0 is the number of oscillations in the time of initialization of the fatigue crack (typically, the number of oscillations is zero). For details see, e.g., (Krejsa, Koubova, Flodr, Protivinsky, & Nguyen 2017).

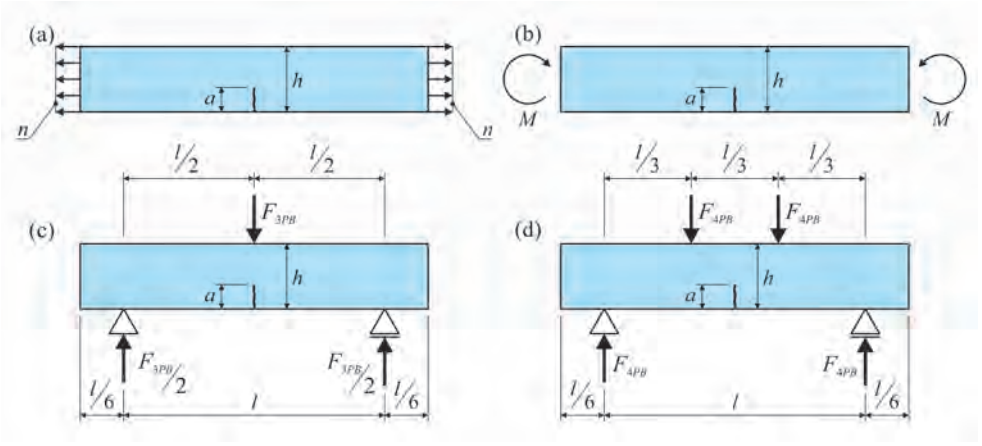

Figure 1. Static scheme for single edge-crack steel specimens: (a) loaded by tension, (b) loaded by pure bending, (c) loaded by three-point bending, (d) loaded by four-point bending.

Table 1. Stress range $\Delta\sigma$ and the acceptable length of the crack a_{ac} for single edge-crack steel specimens and various loads according Fig. 1; l is span of the element, w and h are width and height of the rectangular cross-section, n is flat load [N/m²], N is axial force and f_y is yield stress.

Type of load	Stress range $\Delta\sigma$	Acceptable length of the crack a_{ac}
Tension	$\frac{N}{w\cdot h}, N = n\cdot w\cdot h$	$h-\frac{N}{w\cdot f_y}$
Pure bending	$\frac{6\cdot M}{w\cdot h^2}$	$h-\sqrt{\frac{6\cdot M}{w\cdot f_y}}$
Three-point bending – 3PB	$\frac{3\cdot F_{3PB}\cdot l}{2\cdot w\cdot h^2}$	$h-\sqrt{\frac{3\cdot F_{3PB}\cdot l}{2\cdot w\cdot f_y}}$
Four-point bending – 4PB	$\frac{2\cdot F_{4PB}\cdot l}{w\cdot h^2}$	$h-\sqrt{\frac{2\cdot F_{4PB}\cdot l}{w\cdot f_y}}$

The probability of failure P_f equals to:

$$P_f = P\left(G_{fail}(\boldsymbol{X})<0\right) = P\left(R(a_{ac})-E(N)<0\right), \quad (5)$$

where G_{fail} is reliability function and **X** is a vector of random physical properties such as mechanical properties, geometry of the structure, load effects and dimensions of the fatigue crack.

2.3 *Inspections planning*

When the probability of failure P_f according to Eq. (5) exceeds the specified designed probability, P_d, the inspection should be performed. On the basis of the results of the first inspection, a system of following inspections can be established using conditional probability, as e.g. in Krejsa et al. (2017).

Because it is not certain in the probabilistic calculation whether the initiation crack exists and what the initiation crack size is and because other inaccuracies influence the calculation of the crack propagation, a special inspection is necessary to check the size of the measurable crack in a specific period of time. The acceptable crack size influences the time of the inspection. If no fatigue cracks are found, the analysis of inspection results give conditional probability during occurrence.

While the fatigue crack is propagating, it is possible to define following random phenomena that are related to the growth of the fatigue crack and may occur in any time, t, during the service life of the structure. Then:

- $U_{(t)}$ **phenomenon:** No fatigue crack failure has been revealed within the t-time and the fatigue crack size $a_{(t)}$ has not reached the detectable crack size a_d. This means:

$$a_{(t)} < a_d\,, \quad (6)$$

- $D_{(t)}$ **phenomenon:** A fatigue crack failure has been revealed within the t-time and the fatigue crack size $a_{(t)}$ is still below the acceptable crack size a_{ac}. This means:

$$a_d \le a_{(t)} < a_{ac}\,, \quad (7)$$

- $F_{(t)}$ **phenomenon:** A failure has been revealed within the t-time and the fatigue crack size $a_{(t)}$ has reached the acceptable crack size a_{ac}. This means:

$$a_{ac} < a_{(t)} . \tag{8}$$

If the crack is not revealed within the *t*-time, this may mean that there is not any fatigue crack in the construction element. This might be also an initiative phase of nucleation of the fatigue crack (when a crack appears in the material) and this phenomenon is not taken into account in the fracture mechanics. Even if the fatigue crack is not revealed it is likely that it exists there but the fatigue crack size is so small that it cannot be detected under existing conditions.

Using the phenomena above, it is possible to define following probabilities:

- The probability that the failure is not detected within the *t*-time, this means the probability that the fatigue crack size $a_{(t)}$ is below the measurable crack size a_d:

$$P\left(U_{(t)}\right) = P(a_{(t)} < a_d) , \tag{9}$$

- The probability that the failure detected within the *t*-time has the crack size $a_{(t)}$ that is less than the acceptable size a_{ac}:

$$P\left(D_{(t)}\right) = P(a_d \le a_{(t)} < a_{ac}) , \tag{10}$$

- The probability that the failure occurs within the *t*-time, this means the probability that the fatigue crack size $a_{(t)}$ reaches the acceptable size a_{ac}:

$$P\left(F_{(t)}\right) = P(a_{ac} < a_{(t)}) . \tag{11}$$

Those three phenomena cover the complete spectrum of phenomena that might occur in the *t*-time. This means:

$$P\left(U_{(t)}\right) + P\left(D_{(t)}\right) + P\left(F_{(t)}\right) = 1 . \tag{12}$$

In order to specify the time for the next inspection, it is necessary to determine the conditional probabilitie which can be expressed using the full probability rule:

$$P(F_{(T)} \mid U_{(t_I)}) = \frac{P\left(F_{(T)}\right) - P\left(F_{(t_I)}\right)}{P\left(U_{(t_I)}\right)} - \frac{P\left(D_{(t_I)}\right) \cdot P(F_{(T)} \mid D_{(t_I)})}{P\left(U_{(t_I)}\right)} \tag{13}$$

and

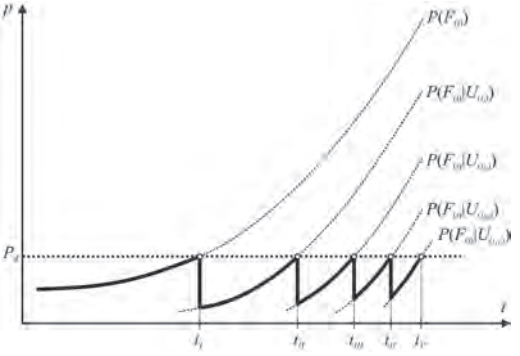

Figure 2. Probabilities of failure P_f calculated according Eqs. (5) and (13) with the times of 5 inspections.

$$P(F_{(T)} \mid D_{(t_I)}) = \frac{P\left(F_{(T)}\right) - P\left(F_{(t_I)}\right)}{P\left(D_{(t_I)}\right)} - \frac{P\left(U_{(t_I)}\right) \cdot P(F_{(T)} \mid U_{(t_I)})}{P\left(D_{(t_I)}\right)} \tag{14}$$

For details see Fig. 2 and, e.g., (Krejsa, Brozovsky, & Mikolasek 2017), (Krejsa, Kala, & Seitl 2016).

3 APPLICATION

The demonstration of using introduced methodology was made for the single edge-cracked steel element with rectangular cross-section under short edge fatigue damage defined according scheme in Fig. 1(c). Calibration curves $F(a/h)$ were experimentally derived for a specimens with relative crack length a/h: 0.01–0.3 loaded by tension, pure, three-point and four-point bending.

The resulting calibration functions, e.g., for 3PB test and ration $l/h = 2$ is according to Seitl et al. (2017):

$$F(\frac{a}{h})^{\frac{l}{h}=2}_{3PB} = +1.0259 - 1.4659 \cdot \left(\frac{a}{h}\right) + 4.9318 \cdot \left(\frac{a}{h}\right)^2 - 2.4637 \cdot \left(\frac{a}{h}\right)^3 , \tag{15}$$

for ration $l/h = 4$ is:

$$F(\frac{a}{h})^{\frac{l}{h}=4}_{3PB} = +1.0691 - 1.3496 \cdot \left(\frac{a}{h}\right) + 5.1865 \cdot \left(\frac{a}{h}\right)^2 - 3.3509 \cdot \left(\frac{a}{h}\right)^3 , \tag{16}$$

for ration $l/h=8$ is:

$$F\left(\frac{a}{h}\right)_{3PB}^{\frac{l}{h}=8}=+1.0963-1.3052\cdot\left(\frac{a}{h}\right)+5.2829\cdot\left(\frac{a}{h}\right)^2-3.5972\cdot\left(\frac{a}{h}\right)^3, \quad (17)$$

for ration $l/h=16$ is:

$$F\left(\frac{a}{h}\right)_{3PB}^{\frac{l}{h}=16}=+1.1079-1.2328\cdot\left(\frac{a}{h}\right)+5.0551\cdot\left(\frac{a}{h}\right)^2-3.2837\cdot\left(\frac{a}{h}\right)^3 \quad (18)$$

and for ration $l/h=80$ is:

$$F\left(\frac{a}{h}\right)_{3PB}^{\frac{l}{h}=80}=+1.1180-1.1964\cdot\left(\frac{a}{h}\right)+5.0176\cdot\left(\frac{a}{h}\right)^2-3.3127\cdot\left(\frac{a}{h}\right)^3. \quad (19)$$

The value of the calibration function $F(\frac{a}{h})_{3PB}$ for intermediate ratio values of *l*/*h* is determined by linear interpolation.

Eqs. (3), (4) and (5) allow for effective computation of the inspection times for each single edge-cracked steel components using DOProC method using FSCProbCalc code with exactly defined random input quantities.

The allowable crack size a_{ac} for the single edge-crack steel specimen loaded by three-point bending can be expressed by a relationship in Table 1 considering the derived weakening of the cross-sectional area of the element (with the limit length defined by ratio $a/h = 0.3$), similarly as in (Wang, Zhai, Duan, & Wang 2015):

$$a_{ac}=h-\sqrt{\frac{3\cdot F_{3PB}\cdot l}{2\cdot w\cdot f_y}}. \quad (20)$$

Deterministic and random input quantities are given in Table 2 and Table 3.

If a period of time t is specified and the time step is 1 year, it is possible to determine resistance of the construction $R_{(a_{ac})}$ and $R_{(a_d)}$ pursuant to Eq. (3) – see Figs. 3 and 4, load effects, $E(N)$, pursuant to Eq. (4) – see Fig. 5, and reliability function $G_{fail}(\boldsymbol{X})$ according Eq. (5) – see Fig. 6, as well as the probability of elemental phenomena, *U*, *D* and *F*, pursuant to Eqs. (9) through (11) for each year of the structural operation – see Fig. 7, which are the basis for specification of inspection times.

Table 2. Overview of deterministic input quantities.

Quantity	Value
Material constant m	3
Material constant C	$2.2\cdot10^{13}$ MPa^{m}m$^{(m/2)+1}$
Height of the rectangular cross-section h	0.1 m
Width of the rectangular cross-section w	0.01 m
Span of the element l	0.4 m
Target probability of failure P_d	0.02277 ($\beta=2$)

Table 3. Overview of random input quantities expressed in a bounded histograms.

Quantity	Type of parametric probability distribution	Mean value	Standard deviation
Total number of stress peaks per year N	Normal	10^6	10^5
Yield stress f_y	Lognormal	200 MPa	20 MPa
Loading force in three-point bending test F_{3PB}	Normal	6 kN	0.6 kN
Initial size of the crack a_0	Lognormal	0.2 mm	0.05 mm
Smallest detectable size of the crack a_d	Normal	2 mm	0.2 mm

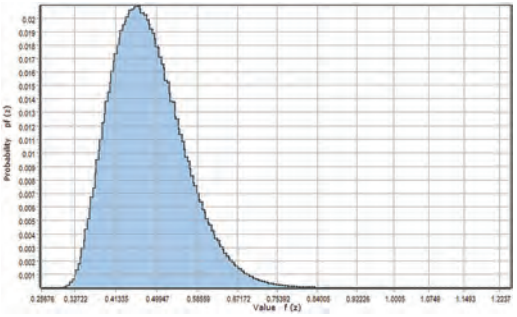

Figure 3. Resulting histograms of the structural resistance $R_{(a_d)}$.

When the probability of failure P_f according Eq. (5) exceeds the specified designed probability, P_d, the inspection should be performed. The Table 4 include numerical values for the final inspection times—for the first inspection and subsequent inspections resulting from the conditional probability pursuant to Eq. (13).

4 CONCLUSION

The article demonstrates the probabilistic calculation of the fatigue damage prediction of relatively short edge crack under various loading using the newly developed Direct Optimized Probabilistic Calculation (DOProC), which appears to be a very efficient tool to make probabilistic assessment of the structural reliability on the basis of the exact definition of the acceptable size of the fatigue crack. The theoretical model of fatigue crack progression is based on a linear fracture mechanics and Paris-Erdogan law. The computational procedure is capable to make probabilistic assessment of the structural reliability on the basis of the exact definition of the acceptable size of the fatigue crack. The probabilities were obtained for three basic phenomena, which are related to propagation of the fatigue cracks. On the basis of those data, the probability of failure can be calculated for each year of operation of the structural element. When determining the required degree of reliability, it is possible to specify the time of the first inspection of the structure, which will focus on the fatigue damage. Using a conditional probability, times for subsequent inspections can be determined. The article describes how to design the system of regular structural inspections in case of the simple demonstration example.

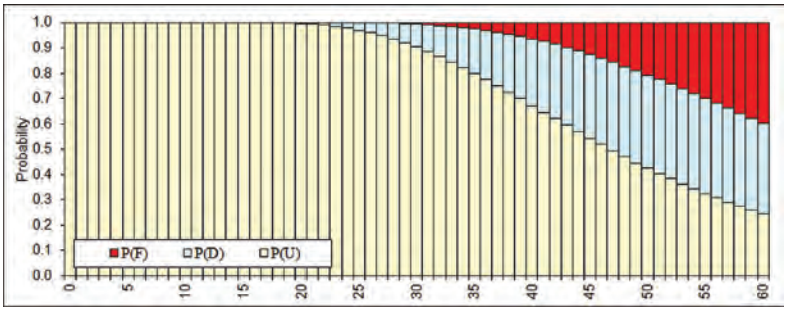

Figure 7. Resulting probabilities of random events U, D and F for first 60 years of structural operation under various load.

The DOProC method and its application in probabilistic prediction of fatigue crack damage can considerably improve estimation of maintenance costs for the structures and bridges subject to cyclic loads. This methodology is developed further. The goal of investigations seems to be, in particular, application of Bayesian networks in the computational model, such as e.g. in Mahadevan et al. (2001), which describes propagation of fatigue cracks in the system.

Reliability analysis of structural health monitoring systems

E. Etebu & M. Shafiee
Cranfield University, College Road, Bedfordshire, UK

ABSTRACT: Structural Health Monitoring (SHM) systems are comprised of a grid of sensors installed at a fixed location on structures to detect the presence of defect, localize the detected defect, quantify its severity, and estimate the Remaining Useful Life (RUL). SHM system performance is currently assessed based on Probability of Detection (POD) of defects, which is a function of defect size. This performance parameter was inherited from Non-Destructive Testing (NDT), where a human operator performs inspection on a structure at a given location, with mobile sensors. For SHM systems, POD and Probability-of-False-Alarm (PFA) are a measure for only detection of defects. Furthermore, these parameters could vary over time as sensors degrade. This paper presents a methodology to characterize the performance of SHM systems with respect to damage detection, localization, and assessment. Probability theorem is used to characterize uncertainties associated with the SHM process, and Bayes theorem is employed to determine its reliability. The methodology is then tested on vibration-based modal strain energy SHM technique applied to a numerical Finite Element Analysis (FEA) study conducted on an offshore energy structure.

1 INTRODUCTION

Structural health monitoring (SHM) is a technique used to assess the integrity of in-service structures that are exposed to operational and environmental loads on a continuous basis, with the goal of improving the monitored structure's reliability, reducing inspection cost, and emergency repair expenditure (Doebling *et al.* 1998). SHM systems are typically comprised of a grid of sensors installed at a fixed location on monitored structure, where signals measured from the structures response are transferred though a communication network, processed to extract damage sensitive features, after which a damage detection algorithm is employed to determine the structure's integrity. In overall, the four functions of SHM systems include detection of defect, localizing the detected defect, quantifying its severity, and estimating the structure's remaining useful life (RUL).

SHM system performance is currently assessed based on probability of detection (POD), which describes the probability of detecting defects as a function of their size at the time of inspection (Annis, 2009). This performance parameter was inherited from non-destructive testing (NDT), where POD is a function of replicability achieved by the human operator, instruments and sensors used at a given location. Moreover, the instruments and sensors can be transported to multiple locations for inspection. This is vastly different from SHM where a human operator is absent; instruments and sensors are placed at an unchanging location after installation. For a SHM system, the replicability of POD is influenced by the environment, measurement noise, deterioration of sensors and communication network.

Statistical characterization of SHM systems performance based on POD was established in earlier works (see Thompson, 2007; Aldrin, 2010; Aldrin *et al.*, 2011; Etebu and Shafiee, 2017) to alleviate the number of experiments associated with SHM operational parameters, by implementing a validated model to assess the changes in SHM outcome at varying damage severity, location, as well as operational conditions. Outcomes from these models are used to generate POD curves using the Hit/Miss data fitted to a binary regression model, where the POD curve is generally plotted with 95% confidence interval (CI).

In addition to POD, the probability of false alarm (PFA) has also been applied to evaluate SHM performance, where PFA is a performance measure of detecting defect in the absence of defect [3]. Although these two parameters are indicators of SHM performance, POD and PFA are associated with only damage detection. Hence, these parameters do not evaluate SHM performance with respect to localization, and damage assessment.

In this paper, a methodology is presented to characterize the performance of SHM systems with respect to damage detection, localization, and assessment using the Model Assisted Probability

approach, and Vibration based SHM technique to assess varying levels of damage on multiple members of a fixed offshore platform in operational conditions.

The rest of the paper is organized as follows. Section 2 develops an assessment framework for SHM system performance. In Section 3, the proposed approach is applied to a numerical study and the results are analysed in Section 4. Finally, the research is concluded in Section 5.

2 SHM PERFORMANCE: DAMAGE DETECTION, LOCALIZATION AND ASSESSMENT

The statistical characterization of SHM systems performance based on POD and PFA has been established by previous studies (Annis, 2009; Aldrin *et al.*, 2011; Thompson, 2008), where the output O_{dd} of a SHM damage detection system either generates an event that indicates the occurrence damage D_d in a structure, or no damage detected D_{nd}. The classification of damage occurrence O_{dd} for SHM is based on a minimum detectable damage size known as the damage threshold D_{th} which separates D_d and D_{nd}. POD and PFA are then expressed as

$$POD(t) = P(O_{dd} \mid D_d - D_{th} \geq 0), \tag{1}$$

$$PFA(t) = P(O_{dd} \mid D_d - D_{th} < 0). \tag{2}$$

In order to address the performance of SHM systems with respect to localizing damage and estimating its severity, two additional performance functions are required to be developed. The performance of a SHM system with respect to locating damage on a structure—in the event of damage being detected—is characterized using the Probability of Accurate Localization (POAL), which is constructed based on the zone of true damage location (ZTDL) and the predicted location of damage occurrence (PLD). The zone of true damage location is characterized by the true damage location (TDL) and an allowable localization tolerance (ALT) corresponding to a specific TDL. Based on the given definition, the limit state function (LSF) for POAL is expressed mathematically as:

$$g(\mathrm{x,y,z,t}) = |\mathrm{TDL} - \mathrm{PLD}| - \mathrm{ALT}. \tag{3}$$

When the LSF is less than zero, then an accurate location of damage will be attained from the SHM system. An event where the LSF is greater than zero indicates the occurrence of an error in damage localization; this error either indicates a false positive or false negative location. The Probability of Accurate Localization (POAL) can be expressed in Cartesian coordinates using the localization LSF as follows:

$$\mathrm{POAL(t)} = P\Big[\, O_{dd} = Dd \,|\, \big\{ \big| TDL(x,y,z,t) - PLD(x,y,z,t) \big| \big\} - ALT(x,y,z,t) \leq 0 \Big]. \tag{4}$$

Evaluation of damage severity is conducted by either quantifying or qualifying its magnitude. The error between the predicted damage severity (PDS) and actual damage severity (ADS) is implemented to construct a damage assessment LSF. In order to construct a suitable range of error associated with damage assessment, an acceptable damage severity threshold (DST) is required. The Probability of Accurate Assessment (POAA) is constructed using conditional probability as:

$$POAA(t) = P\Big[\, O_{dd} = Dd \,|\, \big\{ \big| ADS - PDS \big| \big\} \leq DST \Big]. \tag{5}$$

3 SIMULATED CASE STUDY

The proposed approach is applied to a numerical study in order to evaluate SHM performance. Vibration based Modal strain energy (MSE) by Stubbs *et al*. (1995) is employed to assess the integrity of fixed offshore platform with varying degrees of damage at its structure members. The topology and foundation stiffness of the fixed offshore platform are given in detail by Karadeniz (2001); the operational and environmental loads applied are presented in Table 1.

Finite element model of the fixed offshore platform was constructed using beam elements, where damage was modeled by reducing the stiffness of a given structure member. Steel was assigned as the material property of all members in the structure. Baseline response of the fixed offshore platform condition was initially attained where no damage was present in the fixed offshore platform, after which cracks were simulated at 8 different locations, where 10 levels of damage severities were

Table 1. Environmental and operational loads applied in the numerical simulation.

Mass of Deck	4800 ton
Water Depth	50 m
Significant wave height	2.5 m
Drag coefficient	1.3
Inertia Coefficient	2.0
Sea spectrum	Pierson-Moskowitz

simulated at each location. In this work only the first 3 modes of vibration are implemented during the SHM process.

Damage detection is conducted by MSE based on the observed change in each structure member j at vibrational mode i using the following equation:

$$MSE_j = \frac{\sum_{i=1}^{3}\left[\phi_i^{dT} K_{j0} \phi_i^d + \sum_{j=1}^{118} \phi_i^{dT} K_{j0} \phi_i^d\right] \phi_i^T K \phi_i}{\sum_{i=1}^{3}\left[\phi_i^{T} K_{j0} \phi_i + \sum_{j=1}^{118} \phi_i^{T} K_{j0} \phi_i\right] \phi_i^{dT} K \phi_i^d}. \quad (6)$$

At each mode, λ_i represents the eigenvalue, ϕ_i represents the mode shape, K_{j0} represents the stiffness matrix of a structure member, and K is the global stiffness matrix (Stubbs *et al.*, 1995).

Damage localization in the structure is based on the normalization of the modal strain energy based on its mean σ_{MSE} and standard deviation $\overline{MSE}$ as (Li *et al.*, 2016):

$$ZMSE_j = \frac{MSE_j - \overline{MSE}}{\sigma_{MSE}}. \quad (7)$$

Assessment of damage in each element is conducted by quantifying the damage magnitude using the cross modal relationship in Equation (8), written in matrix form. Parameter α is the reduction factor in the stiffness of a given structure member. The magnitude of α varies from 0 to –1, where –1 indicates a total loss in stiffness (Li *et al.*, 2007):

$$[\alpha] = \left([\gamma]^T [\gamma]\right)^{-1} [\gamma]^T [\varphi], \quad (8)$$

where

$$\varphi = \left[\frac{\lambda_j^d}{\lambda_i} - 1\right] \phi_i^T K \phi_j^d, \gamma = \sum_{n=1}^{DE} \phi_i^T K_n \phi_j^d. \quad (9)$$

The values of O_{dd} attained from $ZMSE_j$ at different levels of damage are used to create a POD curve based on a fixed value of D_{th} which was set as 1. A hit/miss graph was plotted and fitted to the logistic binary regression model to calculate POD.

The performance function POAL was also assessed by implementing ALT, as a function of braced members sharing the same node with the damaged member. Furthermore, non-connected load sharing members on the same floor with the damaged member were also implemented to calculate ALT. The position of PDL was attained from $ZMSE_j$, which in conjunction with TDL, and ALT were used to generate hit/miss graph which was fitted to attain a POAL curve. A similar process was applied to achieve the POAA curve, where PDS was quantified using α, and DST was set at 20% of ADS.

4 RESULTS

The undamaged structures modal frequencies were 7.328 Hz, 7.328 Hz and 33.193 Hz for the first 3 modes respectively. The directions of excitement for the first two modes exhibited translation motion in the diagonal direction of the X-Y plane, while the third mode displayed torsional motion.

The 80 scenarios of damage assessed with indexes in Stubbs *et al.* (1995) resulted in at least one member element with $ZMSE$ value greater than 1, thus indicating the presence of damage for all damage scenarios. The performance of damage localization and severity were observed to be dependent on the extent of damage, type of structure member, and orientation of damaged structure member. Platform legs were most sensitive structure members to damage; a 0.5% decrease in stiffness was accurately localized. Furthermore, the estimated loss of stiffness was within 80% of the true stiffness value (see Figure 1). For diagonal structural members lying horizontal to the floor

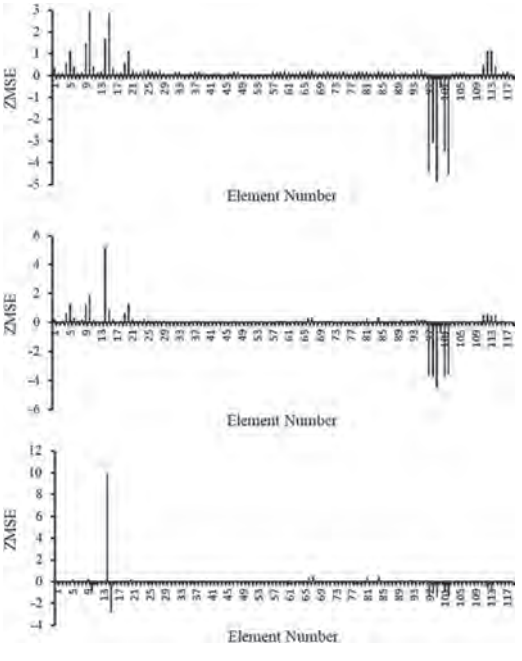

Figure 1. ZMSE outcome on structure member 5 (platform leg) at (top) 0.5% (middle) 10% (bottom) 50% reduction in member stiffness.

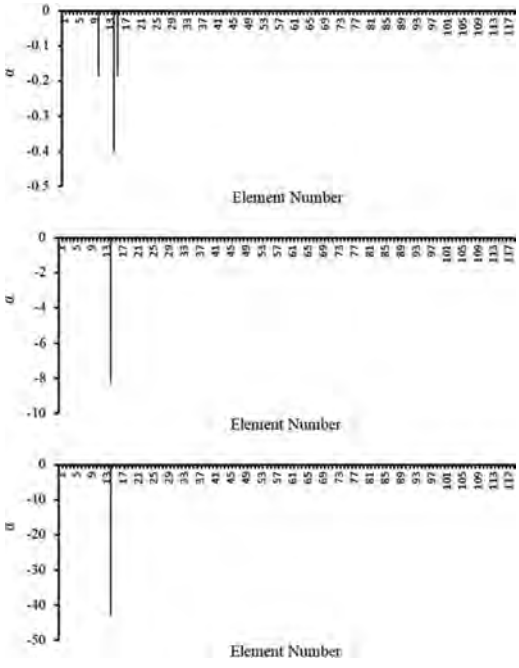

Figure 2. PDS outcome on structure member 14 (platform leg) at (Top) 0.5% (Middle) 10% (Bottom) 50% reduction in member stiffness.

plain, damage localization and severity estimation was unsuccessful across all damage scenarios. Damage in vertical bracings were accurately localized and estimated for damage scenarios where the reduction in member stiffness was 5% or greater. For horizontal bracings, a reduction in member stiffness of 15% resulted in accurate localization and estimation of damage.

Further analysis of all structure members with simulated damage indicated a correlation between the orientations of mode shape excitement, and the location of damaged structure member. Damaged structure members positioned in the diagonal planes of mode shape excitement were correctly localized with an acceptable PDS at lower magnitudes of ADS in comparison to equivalent structure members on the same floor (see Figure 2).

The data compiled from all 80 outcomes of ZME, and α were used to attain a model assisted POAL, and POAD via the hit/miss technique. A logit model was employed to generate both probability curves. The attained hit/miss data for damage localization and damage severity were equivalent in this study, when damage was not localized within the ALT, the magnitude of PDS was less than 80% of TDS.

The attained POAL and POAD curve represented in Figure 3 indicates that the vibration

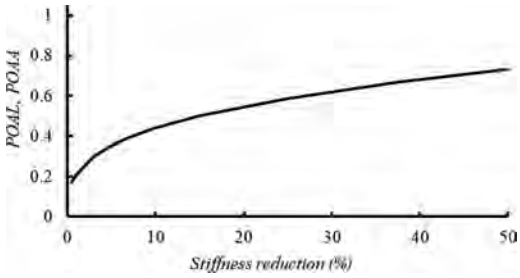

Figure 3. Probability of Accurate Localization (POAL), and Probability of Accurate Assessment (POAA) generated from hit/miss data.

modal strain energy method was able to correctly localize and assess 18% of damage that result in a 0.5% reduction in stiffness, as well as 75% of damage that generate a 50% reduction in element stiffness.

5 CONCLUSIONS

Two performance functions were presented for SHM systems with regards to its ability to accurately predict the location of damage and the damage severity. For a given damage magnitude, the Probability of Accurate Localization (POAL) quantifies the SHM systems ability to localize damage, while Probability of Accurate Assessment (POAA) is a measure of the predicted damage severity in comparison to the actual damage severity. These performance functions work in conjunction with the widely used probability of detection (POD) performance function to characterize three of the four major objectives for SHM systems.

Numerical studies were conducted to detect, localize and quantify damage on a fixed offshore platform under operational loads at varying damage magnitudes and locations using the Modal strain energy (MSE). The results indicate that MSE was able to detect damage in all simulated scenarios, thus leading to constant POD curve across all extent of damage. The POAL and POAA curves were identical, as all damage correctly localized also generated a satisfactory estimate for damage severity. The performance of MSE method with respect to POAL and POAA varied based on the type of member with an assigned damage, damage magnitude and its location with respect to the orientation of mode shape excitement.

The current numerical study did not include errors associated with Eigen value and Eigen vectors attained from the finite element model vibration data. However, noise is always present in real world measurements of vibration data. Hence,

future studies will include the addition of noise in vibration parameters.

Serviceability criteria for structural design in prescriptive documents

J. Markova & M. Holicky
Klokner Institute, Czech Technical University in Prague, Czech Republic

L. Navarova
College in Ceske Budejovice, Czech Republic

ABSTRACT: The reliability of structures in the serviceability limit states is analysed. The Eurocode EN 1990 for basis of structural design provides general recommendations which should be further supplemented including classification of irreversible serviceability limit states with respect to assumed consequences of construction works. Further harmonisation of National Annexes to Eurocodes and other prescriptive documents is needed. The standards recommend almost identical serviceability criteria for similar environment which are further compared with differently calculated characteristic values of stresses, deflections or crack widths based on different analytical models and combinations of actions. An example of verification of the serviceability limit states of crack width for a reinforced concrete member indicates that the resulting crack width might be found in a rather broad range. The probabilistic methods are applied for the verification of the reliability of the structural member and also of crack width model. It is shown that the reliability level of the structural member designed according to Eurocodes fulfils the recommended target reliability level given in EN 1990.

1 INTRODUCTION

Construction works are designed using methods recommended in national, European or international standards. The first generation of Eurocodes allows the national selection of about 1600 Nationally Determined Parameters (NDPs) including alternative design approaches, load combinations, values of partial factors for actions and material properties and other reliability elements, and also serviceability constraints. Therefore, the reliability of a designed structure depends on applied national codes or specified parameters NDPs in the National Annexes to nationally implemented Eurocodes in CEN Member States (MS). It is expected that in the second generation of Eurocodes the number of NDPs will be reduced and most procedures harmonised.

The load-bearing capacity and serviceability of a structure designed in accordance with national codes or nationally implemented Eurocodes could be expected within a broad range. The actual structural resistance depends not only on used theoretical models and selected partial factors and other reliability elements, but also on prescriptive rules including structural detailing. Moreover, in some cases the theoretical models given in various standards for determining structural resistance provide different probability of over-crossing the specified design value.

It is shown that the reliability of structural members designed for the serviceability limit states according to current national standards, Eurocodes and also fib Model Code have a considerable scatter which should be analysed and further harmonised.

2 DESIGN PROCEDURES IN CODES

The partial factor method which is a basic method for the structural design in Eurocodes, in international standards including ISO 2394 (2015) and also in many national standards, deals with uncertainties of basic variables by means of design values assigned to the variables. The design limit state function may be expressed in terms of the set of design values of a vector $\boldsymbol{x}$ of basic variables given as

$$g(\boldsymbol{x}_\mathbf{d}) = \mathrm{g}(F_\mathrm{d}, f_\mathrm{d}, a_\mathrm{d}, \theta_\mathrm{d}, C_\mathrm{d}) \quad (1)$$

where F_d = the design value of action, f_d = the design material property, θ_d = the design model of uncertainty, a_d = the design value of geometrical quantity and C_d = the serviceability constraint.

The design condition is given as

$$g(\boldsymbol{x}_\mathbf{d}) \geq 0 \quad (2)$$

for the design vector of basic variables in the limit state function which is commonly obtained on the

basis of the characteristic values of basic variables and a set of partial factors for actions and material properties.

For the verification of the serviceability limit states, the following inequality is given

$$E_d \leq C_d \tag{3}$$

determined on the basis of relevant combination of actions following EN 1990 (2002). The limiting serviceability constraints are not defined here, however they are newly proposed in the final draft of revised prEN1990 (2017).

For the verification of various serviceability requirements, the characteristic or quasi-permanent combinations of actions are often applied for which some serviceability constraints are provided in material oriented Eurocodes. It should be noted that further guidance for serviceability constraints are commonly given in the National Annexes of nationally implemented Eurocodes of CEN MS taking into account the effects of short-term and long-term duration of actions and various design situations. However, the serviceability constraints (e.g. the limit deflection, the limit crack width) are themselves subjected to uncertainties, and should be therefore included in the probabilistic assessment.

3 RELIABILITY ANALYSIS

The knowledge of the reliability level of the structure designed according to the national codes or nationally implemented Eurocodes and also the reliability (credibility) of prescriptive analytical models can be used for optimisation of design procedures or for further harmonisation of standards.

The structural member or theoretical model may be considered as reliable, if the condition $p_{F<}$ p_t is satisfied where the failure probability p_F is given as

$$p_F = \int_{g(x)<0} \varphi_x(x)\,\mathrm{d}x \tag{4}$$

The failure probability can be expressed by the reliability index $\beta = -\Phi^{-1}(p_F)$, where Φ is the distribution function of standardised normal variable. The failure probability p_t is the target value that should not be exceeded during the intended reference period.

The reliability differentiation of structures in EN 1990 (2002) is based on three different levels of failure consequences with respect to the ultimate limit states (Consequence Classes CC1 to CC3).

However, for the serviceability limit states similar differentiation has not been provided yet. In some cases this differentiation of structures in serviceability limit states might also be useful for distinguishing potential consequences.

EN 1990 (2004) recommends for the reversible serviceability limit states the target reliability index $\beta_t = 0$ and for the irreversible limit states $\beta_t = 1{,}5$ (for the fifty year reference period). Some further recommendations for the target values of reliability indices in the serviceability limit states are given in the JCSS Probabilistic Model Code (2014) where three consequence classes are proposed. Therefore, for structures categorized to reliability class RC1 the target reliability index $\beta_t = 1{,}3$ and for structures in class RC3 the target value $\beta_t = 1{,}7$ could be considered.

The reliability analysis of structural members for the ultimate or serviceability limit states can be determined through the probability p_{F1} of the action effects $E(\boldsymbol{X})$ randomly exceeding the structural resistance $R(\boldsymbol{X})$ according to the following relationship

$$p_{F1} = \mathrm{P}\{(\xi_R\, R(\boldsymbol{X}) - \xi_E\, E(\boldsymbol{X})) < 0\} \tag{5}$$

where $\boldsymbol{X}$ = vector of basic variables, ξ_R and ξ_E = coefficients of model uncertainty of resistance and action effects.

The reliability (credibility) of theoretical models given in standards can be analysed by means of the credibility of specified design value $v_d(\boldsymbol{x}_d)$ (e.g. deformation, crack width) determined on the vector of design variables.

The probability p_{F2} of exceeding the design value $v_d(\boldsymbol{x}_d)$ specified according to relevant theoretical formulae and recommendations of prescriptive design procedure, can be analysed

$$p_{F2} = \mathrm{P}\{(v_d(\boldsymbol{x}_d) - \xi_E\, v(\boldsymbol{X})) < 0\} \tag{6}$$

The serviceability requirements in the limit states of crack width are analysed for an example of a selected reinforced concrete member as follows.

4 CRACK WIDTH VERIFICATION

Cracking in reinforced concrete members due to the load effects can be controlled by applying theoretical (analytical) crack width model recommended in Eurocodes or other codes or fulfilling appropriate practical rules. In common cases the prescriptive rules for detailing and stress control are applied according to nationally implemented Eurocodes. However, in some cases the calculation of crack width is needed e.g. for the design of water retaining structures.

Presently various theoretical models exist for predicting the characteristic crack width w_k. Some crack width model may be found nearly in any standard for the design of concrete structures. The preliminary ENV Eurocode for the design of concrete structures and also the Eurocode EN 1992-1-1 (2004) provide different models for the assessment of crack width. The Model Code 2010 (2012) currently introduces different theoretical crack width model than the previous MC 1990 (1998). Presently a new crack width model is proposed in the second generation of EN 1992-1-1 which is presently under development. Evidently the theoretical models have not been well established till now.

The design of the structural members for the serviceability limit states of crack width is based on the inequality between the analyzed crack width and the crack width limit given as

$$w_k(\boldsymbol{x}_k) \leq w_{lim} \tag{7}$$

where the characteristic value of crack width $w_k(.)$ for a vector of characteristic values $\boldsymbol{x}_k$ of basic variables is specified on the basis of a prescriptive formula and w_{lim} is the crack width limit.

For the analysis of crack width, the basic variables are commonly taken into account as deterministic ones where the geometric properties are mostly considered by nominal values, the actions and material properties by characteristic values. Therefore, the calculated values of crack width might have different statistical meaning (mean, characteristic, extreme). The variability of the basic variables may considerably influence the resulting value of crack width. It appears that the design value of crack width may be estimated only with certain reliability.

Moreover, the specification of the required limit w_{lim} for crack width is mostly based on past experience without appropriate scientific backgrounds. The crack width limits should be determined on the basis of given performance requirements, taking into account commonly adverse environment of the structure and possible consequences of excessive cracking.

5 ANALYSIS OF SLAB CRACK WIDTH

As an example, for the analysis of the theoretical models of crack width, a reinforced concrete member subjected to bending moment due to external forces is presented. A simply supported reinforced concrete slab having thickness from 0,19 to 0,29 m, span of 5 m is considered to be loaded by permanent and recommended imposed load of category B (office areas) given in EN 1991-1-1 (2002).

The slab is designed for the Ultimate Limit States (ULS) according to the Eurocodes, but in some cases considering also rules of selected national standards (in those cases the national values of partial factors are applied). The limit states of crack width of concrete slab are verified with respect to the theoretical crack width models given in Eurocodes, Model Code 2010 and also in some national standards. The common crack width limit w_{lim} = 0,3 mm is considered here. It may be noted that the requirement of various standards for limit crack width is almost identical for the similar type of environment. However, different combinations of actions are in some cases recommended in national standards for verification of serviceability limit states of crack width (e.g. quasi-static or serviceability loads combinations). Thus, different values of crack width w_k determined on the basis of a broad range of prescriptive recommendations are being compared with the same limiting value w_{lim}.

The resulting values of crack width of a reinforced concrete slab based on different models given in the Eurocode EN 1992-1-1 (2006) and its prestandard ENV, in Model Code 2010 (2012) and also in the previous document Model Code 1990, in ACI 318 (1989), BS 8110 (1989) and CSN 73 1201 (1986) are illustrated in Figure 1, partly based on the previous works Holicky 2007, Markova & Holicky (2014). It should be noted that the names of standards are shorten in all Figures (the standard in parenthesis indicate that the slab is designed for the ultimate limit states according to national recommendations with respect e.g. to thickness of concrete cover and load combination.

It is shown that the value of crack width is influenced by selection of theoretical crack width model and also previous design of structural member for the ultimate limit state. Prescriptive documents give different requirements for material properties,

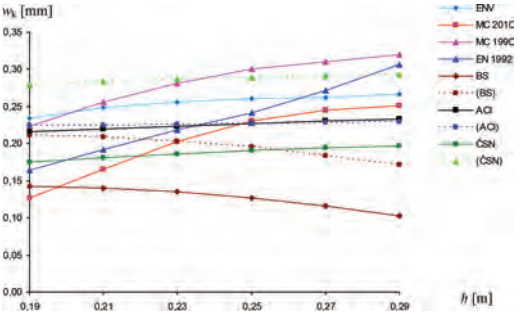

Figure 1. Characteristic values of crack width w_k of a reinforced concrete slab based on selected models in Eurocodes, Model Code documents and selected national standards.

geometrical parameters, loading, structural detailing, stress limitation, minimum area of reinforcement and its cover thickness.

6 PROBABILISTIC CRACK WIDTH VERIFICATION

The time-independent reliability analysis of the slab for the limit state of crack width is dealing with the probability p_{F1} of the random crack width $w(\boldsymbol{X})$ over-crossing the required constraint w_{lim} expressed by

$$p_{F1} = P\{\xi_{lim}\, w_{lim} - \xi_w\, w(\boldsymbol{X}) < 0\} \tag{8}$$

where $\boldsymbol{X}$ is a vector of basic variables and ξ_{lim}, ξ_w are the model uncertainties of the requirements on the crack width limit and the model of crack width, respectively. The structure is assumed to be reliable if the inequality is satisfied

$$p_{F1}\,(\boldsymbol{X}) \le p_{Ft} \tag{9}$$

where p_{Ft} = the target probability of failure that should not be exceeded during the design working life of the structure. Three different levels of the serviceability performance of structures should be distinguished—irreversible, reversible and long-term.

The probabilistic models of basic variables entering the equation (6) are based on recommendations of PMC (2014) and previous reliability analyses developed in the Klokner Institute CTU. Some of the models applied in the reliability analyses are assumed to be deterministic values, while the others are considered as random variables having the normal, lognormal, beta or gamma distribution. Statistical properties of basic variables are described using the moment characteristics (by mean, standard deviation), lower and upper bounds.

The theoretical models assume different probabilities of exceeding the characteristic value of crack width, or the maximum crack spacing. The probability of over-crossing the characteristic crack width w_k is 5% according to Eurocodes [1,3], Model Code 2010 and CSN 73 1201 (1986), 10% in CEP FIP Model Code 1990 and 20% in BS 8110 (1989). The limit state function is based on the theoretical model of mean crack width. Therefore, it is excluded that the theoretical models take into account different probability of over-crossing design value of crack width, or specified maximum distance of cracks.

The results of reliability analysis of the reinforced concrete slab for the limit state of crack width are illustrated in Figure 2.

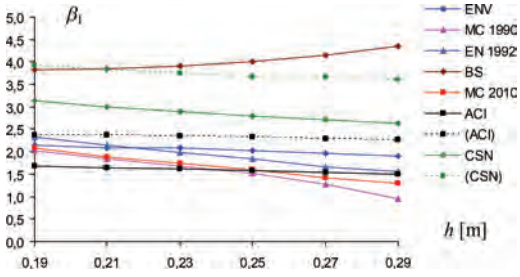

Figure 2. Reliability of reinforced concrete slab of height h for the limit states of crack width.

Analysis of the sensitivity factors α of basic variables indicates that the significant basic variables influencing the design crack width include permanent and variable loads, thickness of the cover of reinforcement, tensile strength of concrete and influence coefficients (e.g. expressing the bond strength, duration of the loading, shape of the strain across cross-section).

7 CREDIBILITY ANALYSIS OF CRACK WIDTH MODELS

The credibility (reliability) of the specified characteristic value of crack width w_k is verified. The probability of the random variable $w(\boldsymbol{X})$ exceeding the crack width w_k determined in accordance with relevant theoretical model of particular standard is expressed as

$$p_{F2} = \mathrm{P}\{w_k(\boldsymbol{x}_k) - \xi_w\, w(\boldsymbol{X}) < 0 \tag{10}$$

where $\boldsymbol{x}_k$ is the vector of characteristic values of basic variables and the coefficient ξ_w represents uncertainties of action effects and inaccuracy of the crack width model.

The probability p_{F2} of the random crack $w(\boldsymbol{X})$ over-crossing the crack width w_k according to relationship (7) for the slab expressed here by reliability index β_2 is illustrated in Figure 3.

Analysis of the credibility of specified crack width w_k indicates, that the reliability index β_2 determined for a reinforced concrete slab appears to be low for the theoretical models introduced in national American and British standards and rather high in Czech standard. The credibility of theoretical models seems to be sufficient in EN 1992–1-1 (2004), and a little bit higher than the credibility of the model provided in Model Code 2010.

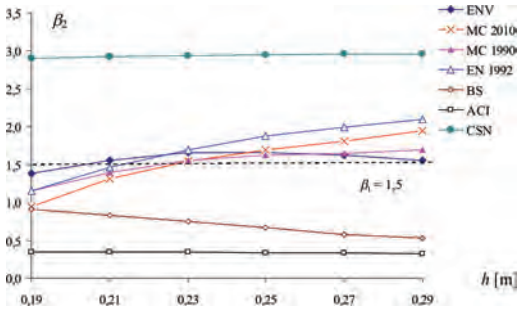

Figure 3. The credibility of the determined crack width w_k for selected theoretical models.

8 CONCLUDING REMARKS

Presently the basic Eurocode EN 1990 for the design of structures introduces general recommendations for the verification of the serviceability limit states. The development of supplementary provisions is needed including classification of structures based on the consequences of failure. Deterministic methods of structural analysis commonly used for the verification of structures in the serviceability limit states do not enable objective evaluation of structural reliability. The probabilistic methods facilitate comprehensive analysis of the reliability of a structure and assessment of credibility of used theoretical models.

An example of verification of a reinforced concrete slab with respect to the limit state of crack width indicates that the same limiting serviceability constraints (crack width limit) is compared with characteristic values of crack widths obtained on the basis of a broad range of normative recommendations and also having different statistical meaning.

The methods of structural reliability enable realistic analysis of concrete members with respect to the crack width. Reliability indices β assessed in the analysis of the credibility of the analytical crack width formulae and the reliability of reinforced concrete slab with respect to limit crack width have a significant scatter and in some cases seem to be rather low.

The credibility of theoretical models for crack width is independent on the previous design of a reinforced concrete slab for the ultimate limit states of Eurocodes or relevant national standards and may be applied for calibration purposes.

Analysis of sensitivity factors α indicates the significant basic variables influencing the reliability index and the credibility of the design crack width including permanent and variable loads, thickness of the cover of reinforcement, tensile strength of concrete and influence coefficients (expressing the bond strength, duration of loading).

It appears that the probabilistic methods can be effectively used for the development and calibration of new theoretical models applied in design and verification of structures. They may be applied for further harmonisation of parameters NDPs in Eurocodes.

ABSTRACT: The soft-packed power battery is becoming a promising power source because of its high energy density and light weight. The duration of sealing has a significant impact on the service life of the soft-packed battery. However, currently there is no effective test method or theoretical models to evaluate its sealing life. In this paper, an Accelerated Degradation Test (ADT) is designed and performed to investigate the sealing strength degradation. The testing is conducted to measure the degradation rates and residual tearing strengths of the standard specimens under the different accelerated stresses. Based on the testing data and membrane theory, a modified Cohesion Zone Model (CZM) is proposed to describe the tearing curve and strength degradation. This model is validated by the testing data well.

1 INTRODUCTION

The soft-packed power battery, as the heart part of electric vehicles, has become the focus of study because of its light weight and high energy density compared with the traditional hard-shell battery (Gallagher, K.C. 2016, Lu, L. 2013, Lee, H. 2014). However, the sealing of soft-packed battery is still has to face some challenges. The sealing duration becomes one of the key factors severely restricting the reliability and safety of the battery, because the sealing is always subjected to tearing load due to slow and constant increase of the inner gas pressure. So, this paper is devoted to investigating the tearing behavior of the sealing and developing an effective testing method and analytical model for its life prediction.

Many methods are proposed to describe film tearing behavior, such as Kim model (Kim, K.S. 1988), Wei-Hutehinson model (Wei, Y. 1998) and cohesion zone model (Barenblatt 1959, Dugdale 1960). Among them, cohesion zone model (CZM) is a more perfect and significant mathematical tool for characterizing crack propagation. In the study of elastic and plastic materials, it can effectively simulate plastic deformation and creep behavior ahead of the crack tip (Barenblatt 1959, Dugdale 1960, Needleman 1987, 1990). Needleman proposed a unified theoretical framework for the cohesion zone from initial degumming to complete detachment (Needleman 1987). Kent used the trapezoidal cohesion model to study the composite cracking process of the film adhesive layer (Kent 2008). Zhao used the CZM to simulate the tearing process between metal film and ceramic substrate (Zhao, H.F. 2008). However, these methods can just describe the instantaneous tearing strength. They do not consider the strength degradation due to viscous deformation of the polymer material under the constant load over a long time period. The theoretical analysis concerns about the tearing strength degradation with time and the size of any moment. Therefore, the models need to be modified considering degradation characteristics of product performance. It is deserved to develop a CZM-based method for the tearing strength degradation of sealing.

To obtain the information of degradation, accelerated degradation test (ADT) is adopted in this study. It is applicable to products with long life and strength degradation. ADT accelerates performance degradation by increasing the level of stress under the condition of keeping the degradation mechanism unchanged and collect performance degradation data (Fallou, B. 1979). These data are then used to estimate the reliability of the product and to predict the life of the product at normal stress levels. Nelson first studied the accelerated degradation test, analyzed the accelerated degradation test data of the insulation material, and obtained the service life of the insulation material under the normal stress (Nelson, W. 1990). Constant stress accelerated degradation test is widely applied in product life assessment, the operation of

which is simple and whose data statistics method is mature (Ma, X.B. 2011). This is obviously suitable for lithium-ion batteries that is a long-life and highly reliable product (Meeker, W.Q. 1995). It is considered that there is a significant degradation characteristic for the behavior that the residual strength of the sealing decreases, for the result that the polymer layer of hot-adhesive soft-packed will have a viscous deformation and be eventually torn under continuous stress. Most of the study still focuses on the correlation between strength and displacement of the sealing, which directly results in deficiency in the mature life evaluation method of the sealing. There is no study of the degeneration of the sealing tearing strength.

In this study, first, the behavior and mechanism of sealing tearing strength degradation are analyzed. A constant stress ADT is designed and implemented. Then, a modified CZM is developed to evaluate strength degradation using testing data. Finally, some conclusions and discussions are given based on the current research.

2 TESTING

2.1 *Specimens and experiment set-up*

The product tested in this study is outsourcing aluminum-plastic film of the soft-packed lithium-ion battery—PA/AL/CPP composite film. The innermost layer is CPP (Cast Polypropylene), which has a high thermal viscosity and is used for fusion when the upper and lower heads are pressurized at high temperature; The middle layer is AL (Aluminum Foil) layer, which is the carrier of the heat-sealing material and prevents water penetration; The outermost layer is PA (nylon), which has a certain anti-puncture performance and plays a decorative role. Fig. 1 and Fig. 2 show the product and product stress diagram respectively. The battery will produce the gas inside in the process of storage or application. The gas pressure causes the sealing of the aluminum plastic film to be torn, that results in the failure of the battery.

The standard specimens are cut out of the seal side with a spill area as shown in Fig. 3. The width W is 8 mm and the length L is 40 mm.

Test system consists of two parts: in situ fatigue test bench and optical measurement microscope, shown in Fig. 4. The test stage manufactured by Care Test Company is mounted on a stage of a measuring microscope and the sample was clamped by the stage. During loading/unloading, images were captured at high resolution using an industrial miniature camera. At the same time, experimental data was recorded and analyzed by Care-Test-fatigue system.

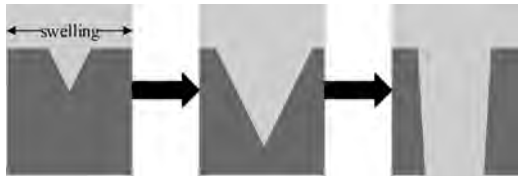

Figure 2. Sealing tearing process caused by the inner gas pressure.

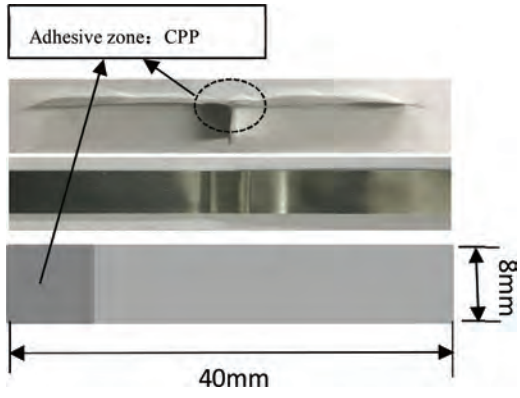

Figure 3. The illustration of specimen.

2.2 *Experimental procedure*

2.2.1 *Strength CURVE measurement*

In order to standardize the tearing strength of the sealing and define the stretch rate of the accelerated degradation test, perform direct tearing test first. The specimen is fixed as shown in Fig. 5. The displacement control of the fatigue stretch test machine was carried out, and several tests were performed at different stretch rates. Tearing direction is perpendicular to the adhesive area and tearing angle is 90 degree. It is known that the tearing process of polymeric materials is influenced by

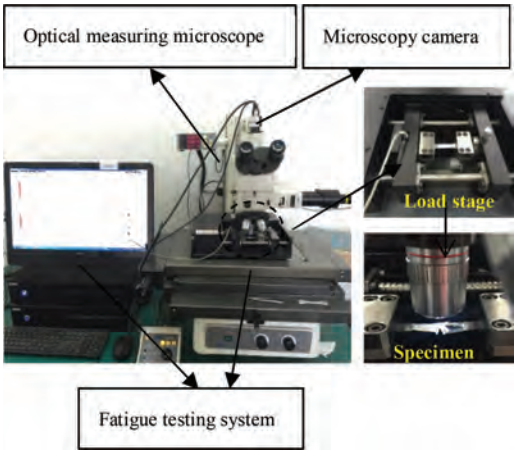

Figure 4. In-situ optical microscopy fatigue testing system.

Figure 5. Specimen installation method.

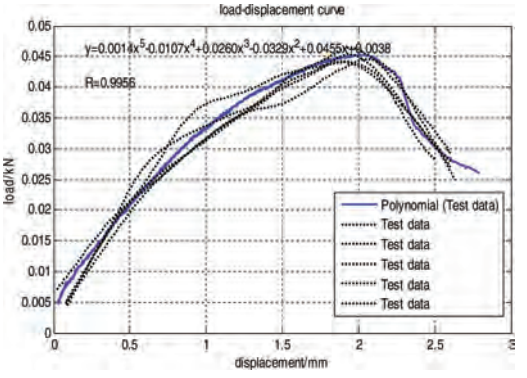

Figure 6. Schematic illustration of curve fit to test results.

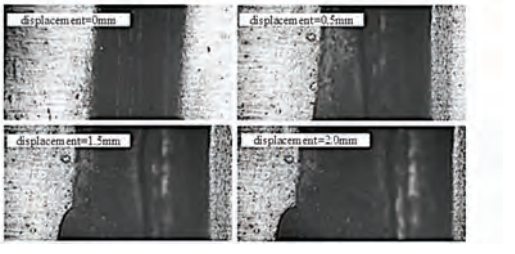

Figure 7. The physical photo of sealing tearing process.

temperature and load (Zhang, G.J. 1996). The test is usually carried out at room temperature and the load is a more sensitive factor. Therefore, only the tearing behavior at room temperature and strength degradation behavior under different constant loads are studied in this paper. The test temperature controlled at 25 degrees. Record the maximum tensile load. According to GB/T 22638.7-2008 ⟨⟨Test Method for Aluminum Foils—Part 7: Tearing strength⟩⟩, the tearing strength is defined as the maximum tensile load at a fixed width. Five specimens were tested repeatedly at each tearing speed, and taking the average value as the tearing strength at that speed.

The load-displacement curves are obtained by Care-Test-fatigue system. The tearing curves can converge when the stretch rate drops to 1 N/mm. Therefore, the ADT stretch rate is defined as 1 N/mm. In Fig. 6, the load-displacement curves obtained from the five sets of data are different. Fig. 7 indicates the process of the sealing tearing. Therefore, average the test results. The maximum in five sets of the load data are 45.37, 44.92, 44.96, 45.61, 44.14 N and the average is 45.00 N. The corresponding displacements are 2.03, 2.18, 1.99, 2.00, 1.80 mm and the average is 2.00 mm. In order to illustrate the general mechanics of the sealing adhesive interface, the five groups of curves are fitted to a standard curve using the least squares method, as shown in Fig. 6.

There is almost no change in the displacement when the load is less than 5 N; when the load is between 5 and 20 N, the displacement increase is approximately linear and can be regarded as the elastic stretching stage; when the load is more than 20 N, the displacement change rate gradually increases. After the load reaches a maximum of 45 N, the sealing is torn rapidly until it is completely torn. Therefore, this sealing tearing strength is calibrated as 45 N. According to the above test results, combined with the principle of degeneration, the constant load of ADT can be controlled between 5 and 20 N and the tests under different load conditions are carried out.

2.2.2 *Accelerated degradation test*

Without changing the failure mechanism of the product, the test conditions are increased to accelerate the failure of the specimens, and the performance degradation data under the high stress level are used to extrapolate the service life of the product under normal use stress. This is the basic principle of the ADT. The specific method is: under

different loads: 5, 10, 20 N; different duration: 20h, 40h, test sealing degradation rate of tearing strength. According to the relationship between time and tearing displacement, the regression curve equation and judgment coefficient are obtained. Under different constant loads, the curves of tearing strength degradation of sealing are shown in Fig. 8 when the duration is 20 h. It can be seen that the sealing is slowly torn with time even if the load is constant. This shows that the tearing strength has been degraded. As the constant load increases, the degradation rate gradually increases.

In order to measure the residual strength after degradation, displacement control was used to perform the tearing test based on the ADT. The result is shown in Fig. 10. And Fig. 9 indicates the process of the sealing tearing.

As it can be seen from the above figure, the maximum tearing strength gradually decreases as the constant load increases while the time is the same. That is when the load time is 20 h and the constant load is 5 N and 10 N respectively, the corresponding

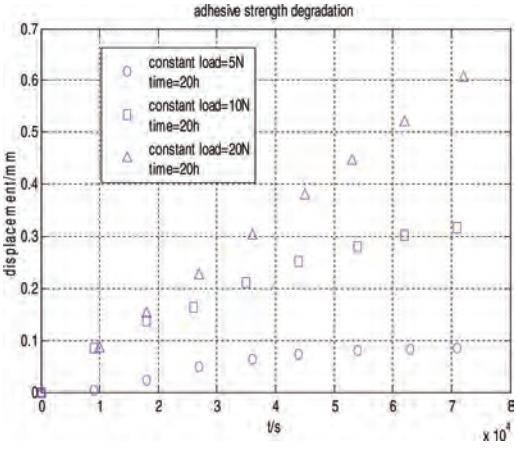

Figure 8. Schematic illustration of relationship between the displacement and time.

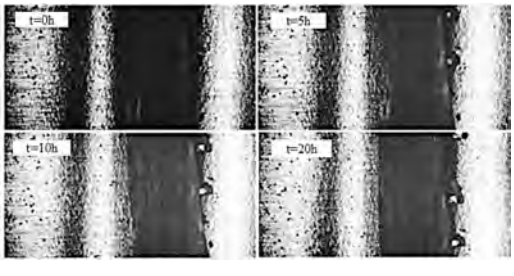

Figure 9. The physical photo of sealing tearing process.

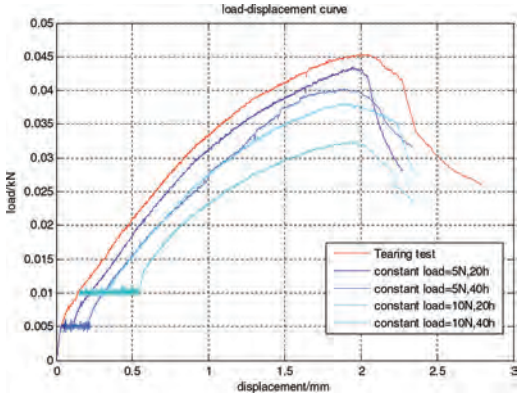

Figure 10. Schematic illustration of curve fit to test results.

tearing strength peak are: 43 N, 38 N; Maintaining a constant load unchanged, with the loading time gradually increases, the maximum tearing strength decreased. That is when the constant load is 10 N and the loading time is 20 h and 40 h respectively, the peak of the tearing strength corresponding to complete tearing is 38 N and 33 N respectively. This shows that the cumulative effect of load has a significant effect on the sealing tearing. It is that a constant load applied to the sealing for a period of time causes the tearing strength to decrease.

3 THEORETICAL ANALYSIS

3.1 *Exponent cohesion zone model*

The mechanical response of polymer materials always shows the combination of elasticity and viscous property, which is called viscoelasticity (Bower, D.I. 2002). CPP is subjected to thermomechanical treatment, such as stretching, at a temperature that is under the melting point and above a glass transition temperature (the glass transition temperature of the polypropylene material is –35°C). In this case, the orientation process of the polymer may occur. As a result of the orientation, the tensile strength and flexural fatigue strength of the polymer material significantly increase in the orientation direction. At the same time, the orientation perpendicular to the orientation direction significantly decreases. The macro performance is torn.

The CZM is based on elastic-plastic fracture mechanics and is used to investigate the elastic-plastic region of the crack tip. The constitutive relation of the cohesion zone is defined by the cohesion and the open displacement at the interface. On the basis of the test, the interface is characterized as a thin layer of the constitutive relation of the exponential cohesion zone model and the exponential

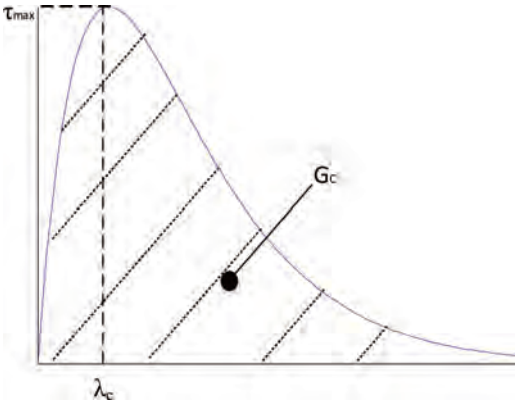

Figure 11. Tearing strength—displacement curve.

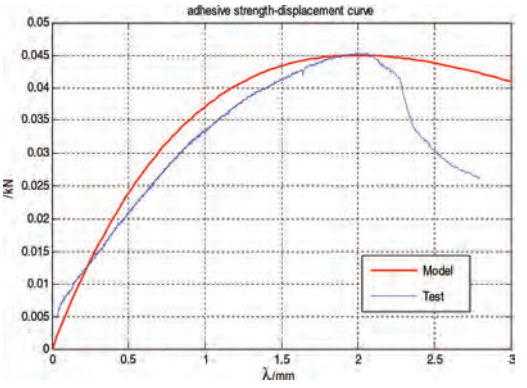

Figure 12. Comparison of tearing curve in CZM model and test result.

CZM is chosen to simulate the separation of the sealed boundary. The tearing strength is given by:

$$\tau = \tau_{max} \frac{\lambda}{\lambda_c} exp\left(1 - \frac{\lambda}{\lambda_c}\right) \tag{1}$$

In Fig 11, the displacement characteristic value λ and the tearing strength value τ are two independent parameters. However, the energy required to separate within a unit area is often used as a parameter. It is equal to the sum of the area under the tearing strength-displacement curve, expressed as follows:

$$G_c = \int_0^{\infty} \tau(\lambda) d\lambda \tag{2}$$

It can be determined by tearing test. If we use the energy required for separation G as a model parameter, then equation (1) can be expressed as:

$$\tau = \frac{G_c}{\lambda_c} \frac{\lambda}{\lambda_c} exp\left(-\frac{\lambda}{\lambda_c}\right) \tag{3}$$

In this paper, the required energy G (N/mm) and displacement eigenvalue λ /mm are two independent constitutive parameters. The relationship between tearing strength and displacement was measured by the test. The peak of strength was 45.00 N and the displacement was 2.0 mm. The calculated interfacial fracture energy was 244.66 N/mm. Fig. 12 shows the predicted results that experimental data on specimen are used to validate the CZM. Obviously, this CZM can give a satisfactory prediction. The sealing CZM expression is as follows:

$$\tau = \frac{0.24466}{2.0} \frac{\lambda}{2.0} exp\left(-\frac{\lambda}{2.0}\right) = f(\lambda) \tag{4}$$

3.2 *Modified CZM*

The change in the displacement of the adhesive area under a constant load is shown in Fig. 9. With the degradation of strength is considered, time and constant load are taken as degradation factors to modify the equation (4). Tearing process can be divided into three stages: to reach a constant load stage, to maintain a constant load loading stage, rapid tearing stage. Assumptions: the constant load is τ_0 /N: the displacement reached to constant load is $f'(\tau_0)$: the constant load loading time is t/s; the degradation rate is (determined by the degeneration rate curve)v; the displacement at the start of rapid tearing is $f'(\tau_0) + vt$. Then, the modified CZM can be written as:

A. to achieve a constant load phase: $\tau = f(\lambda)$
B. to maintain a constant load loading stage: $\tau = \tau_0$
C. rapid tearing stage: $\tau = f(\lambda) - f(vt)$

$$\tau(t, \tau_0, \lambda) = \begin{cases} f(\lambda) & 0 \le \lambda \le f'(\tau_0) \\ \tau_0 & f'(\tau_0) < \lambda \le f'(\tau_0) + v \times t \\ f(\lambda) - f(vt) & f'(\tau_0) + v \times t < \lambda \end{cases} \tag{5}$$

In ADT, different constant loads can change the rate of tearing strength degradation. To obtain the degradation rate under different constant loads, calculate the slope of the straight line in Fig. 8. The result is given in Table 1. Then, the simulation curve of the relationship between degradation rate and constant load is obtained as shown in Fig. 13 and expressed by the following equation:

Table 1. Tearing strength degradation rate under different constant load.

τ_0	v
N	$\times 10^{-6}$ mm/s
0	0
5	1.4
10	4.1

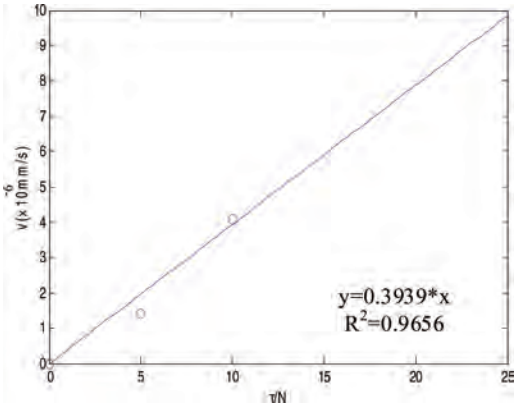

Figure 13. Schematic illustration of curve fit to test data.

$$v = 0.3939\tau_0 = g(\tau_0) \tag{6}$$

Substituting Equation (6) into Equation (5), the modified CZM can be expressed as:

$$\tau(t,\ \tau_0,\ \lambda) = \begin{cases} f(\lambda) & 0 \le \lambda \le f'(\tau_0) \\ \tau_0 & f'(\tau_0) < \lambda \le f'(\tau_0) + 0.3939\tau_0 \times t \\ \mathrm{f}(\lambda) - \mathrm{f}(0.3939\tau_0 \mathrm{t}) & f'(\tau_0) + 0.3939\tau_0 \times t < \lambda \end{cases} \tag{7}$$

4 MODEL VALIDATION

In this section, experiental datas on specimen with under different constant load and duration are used to validate the proposed modified CZM.

In Figure 14, the model predictions are compared to testing data under constant loading and duration. The horizontal axis is the tearing displacement and the vertical axis is the tearing strength. The red line is testing data and the blue line represent predictions of our proposed model. The constant load is 5 N and duration is 40 h in (a). And the (b) is a validation when the constant load is 10 N and duration is 40 h. The (c) is a validation when the constant load is 20 N and duration is 20 h. It is clear that the predictions are in good agreement with the testing data. Obviously, for the residual strength, the modified model can give satisfactory predictions. The strength degradation phenomenon due to constant loading is described well using the proposed model. Good agreements are observed between the model predictions and experimental data. Overall, this model can predict the strength degradation under constant loading and the duration.

5 CONCLUSION AND FUTURE WORK

In this paper, a modified CZM considering degeneration is proposed to evaluate the tearing strength of sealing and calculate the residual strength by ADT. The modified model and the testing data have a good match. It is beneficial to solve the effect of constant loading on the real-time tearing strength of the sealing. Then, the most use security problems will be avoided in a large part. Based on current research, the following conclusions can be given:

1. An ADT is designed to simulate the tearing process of the sealing by using standard specimen on the in-situ tensile machine. The tearing strength of the sealing degrades under a small static tensile load, and the sealing is torn over a long period of time. A positive correlation is observed between the degradation rate and load.
2. A modified exponent CZM considering degradation is proposed to depict the tearing strength degradation curve and residual strength curve of the sealing. The different strength degradation data are used for model validation. Good agreements can be seen between the testing data and model predictions.

The current study considers the stress only, and the effect of temperature and electrolyte will be investigated in the future.

Probabilistic analyses of existing power producing facilities

J. Markova & K. Jung
Klokner Institute, Czech Technical University in Prague, Czech Republic

K. Stastna
Institute of Applied Mechanics, Brno, Czech Republic

ABSTRACT: Assessment of existing components of power producing facilities is based on the probabilistic methods of the theory of structural reliability provided in Eurocodes and ISO standards. An example of quick-closing valves in a selected hydroelectric power plant indicates the assessment of reliability and prediction of remaining working life of a structural component for the considered model of corrosion. Moreover, assessment of reliability level of main steel structural members of existing industrial bridge for two alternatives of a cleaning machinery reveals rather low reliability level of some significantly deteriorated structural members of the industrial bridge in the power plant, and additional measures are to be applied.

1 INTRODUCTION

Various existing construction works in power-plants built in the Czech Republic are gradually deteriorating due to the effects of adverse factors having significant impact on their reliability. The main factors include adverse surrounding environment, chemical attacks, physical effects and repeated actions due to technological processes.

Actual technical state of power producing facilities needs to be regularly evaluated enabling optimal decision regarding their repairs, strengthening or replacement. Simplified conservative procedures for the reliability assessment of existing structures based on the methods commonly used in current codes for the design of new structures may lead to their expensive repairs.

That is why the assessment of existing structures of power-plants are based on the probabilistic methods of the theory of structural reliability given in the international standards ISO 13822 (2010) and ISO 13823 (2008).

The probabilistic assessment of existing energetics devices evoked by necessity of the assessment of their current reliability level, estimation of their remaining life time and also change of technological procedure evoked by need for more effective, however heavier machine in a selected hydroelectric power-plant in the Czech Republic given here as an example shows the procedure for the estimation of reliability, bearing capacity and residual life of existing structures for assumed corrosion models.

2 VERIFICATION OF WORKING LIFE

The reliability requirements for existing structures as well as for new ones may be expressed in terms of the failure probability P_f or reliability index β. The relationship between the both reliability indices is given as

$$\beta = \Phi^{-1}(P_f) \tag{1}$$

where $\Phi(.)$ denotes the standardized normal distribution function. The following reliability condition is required

$$P_f \le P_{ft} \text{ or } \beta \ge \beta_t \tag{2}$$

where P_{ft} and β_t are the target values of the failure probability and reliability index.

The target reliability level which should be used for the verification of existing structures may be based on calibrations taking into account the concept of the minimum expected costs and social risks. The recommended values of the target reliability index β_t for the verification of various limit states given in ISO 13822 (2010) are illustrated in Table 1.

More detailed target reliability indices depending on the consequences of failures and the relative costs for safe design are provided in ISO 2394 (2015).

EN 1990 (2002) gives principles of reliability differentiation in Annex B. Three reliability classes RC are recommended and the target values of reli-

Table 1. Indicative target reliabilities for existing structures.

Limit states	Target reliability index β_t
Serviceability—irreversible	1.5
Ultimate with failure consequences	
– very low	2.3
– low	3.1
– medium	3.8
– high	4.3

Table 2. Reliability differentiation of hydro-technical structures according to CSN EN 1990 (2011).

Reliability class	Examples of construction works
RC3	Dam, weir higher than 5 m, main conduit of potable water to town agglomeration
RC 2	Sewage disposal plant, accumulating pumping plant, water reservoir, aqueduct, hydro-electric power station, weir height up to 5 m, nautical channel
RC 1	Swimming pool, melioration structure

Table 3. Partial factors for actions.

	CSN 75 6303 (2012)		
Type of action	RC1	RC2	RC3
Hydrostatic pressure	1.0	1.1	1.2
Hydrodynamic pressure	1.2	1.3	1.4
Permanent action	1.2	1.35	1.4
Variable action	1.35	1.5	1.65

ability indices β_t proposed including examples of construction works. Presently hydro-technical construction works are not given in the scope of the current generation of Eurocodes and they need to be based on supplementary national prescriptive provisions.

Reliability differentiation of hydro-technical construction works is illustrated in Table 2 as recommended in the recently developed National Annex to CSN EN 1990 (2011) of the Czech Republic.

Partial factors for hydrostatic and hydrodynamic pressures, permanent and variable actions recommended in CSN 75 6303 (2012) for reliability classes RC1 to RC3 are given in Table 3.

Application of probabilistic methods for specification of working life of an existing structure

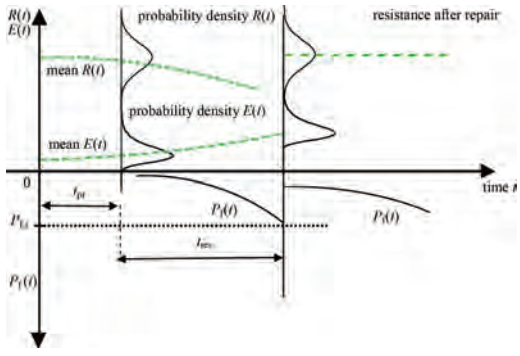

Figure 1. Probabilistic assessment of remaining working life.

is illustrated in Figure 1, Holický & Marková (2007).

It is assumed that the assessment (inspection) of an existing component of a power producing facility is performed in time t_{pr} from the beginning of the structure completion. In case that the time-dependent resistance $R(t)$ of a component and load effects $E(t)$ are known, the remaining working life of the component may be specified.

For estimation of the residual working life t_{res} of the component, the following expression is given as

$$P_f(t_{res}) = P\{R(t_{res}) - E(t_{res}) < 0\} \approx P_{f,t} \quad (3)$$

facilitating decision about its repair or replacing.

The general requirements for the assessment of structural reliability and safety for users are applied for reliability analysis of quick-closing steel valves and also for existing industrial steel bridge in the hydroelectric power plant operating about 50 years.

3 VERIFICATION OF QUICK-CLOSING STEEL VALVES

3.1 *Inspection of state of the quick-closing valves*

The inspection of the quick-closing valves of hydroelectric power plant revealed deterioration of the components including steel cover plates as illustrated in Figure 2.

3.2 *Reliability analysis based on partial factor method*

Firstly, the partial factor method given in EN 1990 (2002) and ISO 13822 (2010) is applied for verification of a cover plate of quick-closing steel valves which is one of main components.

The steel cover plate having thickness of 0,018 m is supported by stiffeners 0,8 m spaced.

Figure 2. Deterioration of a steel cover plate.

Hydrostatic and hydrodynamic components are considered for determination of water pressure on the plate given as

$$q = q_{hs} + q_{hd} = \rho g\, h + \rho Q\, v/A \tag{4}$$

where ρ = water density; h = depth; Q = flow rate; v = water speed; A = area of the cover plate.

The basic condition $M_{Rd} > M_{Ed}$ between the design value of bending moments for resistance and effects of actions should be satisfied. The reliability of the structural component is verified with respect to the ultimate limit state given as

$$M_{Rd} = \gamma_u\, b\, d^2\, f_{yk}/(4\, \gamma_M) \tag{5}$$

where γ_u = coefficient of model uncertainty of resistance, d = plate thickness, b = plate length, f_{yk} = characteristic yield strength, γ_M = material factor.

The characteristic yield strength is considered f_{yk} = 235 MPa, the partial factor γ_M = 1.15 and the coefficient γ_u = 0.85 according to CSN 75 6303 (2012).

The maximum water pressure is considered for determination of load effects for continuously supported cover plate given as

$$M_{Ed} = \delta\,(\gamma_{Qhs}\, q_{hs,k} + \gamma_{Qhd}\, q_{hd,k})\, L^2/12 \tag{6}$$

where γ_{Qhs} = partial factor for hydrostatic pressure, γ_{Qhd} = partial factor for hydrodynamic pressure which are considered here according to Table 3 for structures in class RC2. The dynamic amplification factor δ = 1.3 is considered here as recommended in CSN 75 6303 (2012).

The serviceability limit state of the component is also verified

$$M_{Ed} \le C_d \tag{7}$$

where C_d = limiting deformation.

Results of time dependent reliability analyses of a steel component with respect to both the ultimate (ULS) and serviceability (SLS) limit states are illustrated in Figure 3. The reliability of the cover plate significantly decreases with decrement Δd of plate thickness due to steel corrosion.

In case that the partial factor method is applied for verification of existing structural member in the common consequence class CC2, it is shown that its bearing capacity is exhausted after about 53 years and some measures are needed to be taken, e.g. strengthening or replacement.

3.3 *Application of probabilistic methods*

The probabilistic methods are applied for evaluation of the reliability level of the steel component, Holicky (2009).

The time-dependent corrosion $d_{corr}(t)$ of the steel cover plate is based on the relationship

$$d_{corr}(t) = A\, t^B \tag{8}$$

where A and B = parameters of analytical model which are considered for parameter A in a range from 0,03 to 0,13, and for parameter B from 0.6 to 0.7. It is assumed here for non-uniform corrosion

$$A = 0{,}06 \text{ mm};\ B = 0{,}7 \tag{9}$$

which is based on the results of inspection of the actual state of steel quick-closing valves. Pitting corrosion with pits up to 1 mm is shown in Figure 4.

It is considered that the steel cover plate of quick-closing valves (about 50 years old) is deteriorating due to non-uniform corrosion with average

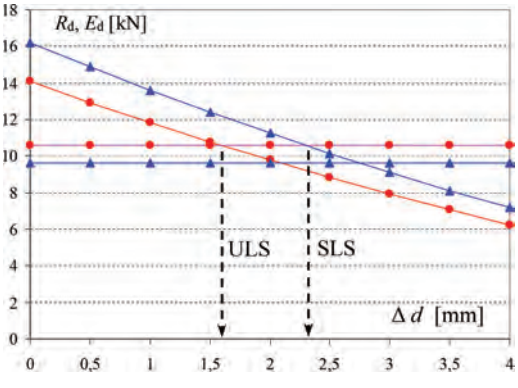

Figure 3. Progressive reduction of the component bearing capacity and serviceability with decrease of slab thickness Δd.

Figure 4. Pitting corrosion of a steel cover plate.

Table 4. Probabilistic models of basic variables.

Basic variable	Symbol	Distr.	Mean μ	C.V. V
Yield strength [MPa]	f_y	LN	280	0.08
Plate span [m]	L	DET	0.75	–
Plate thickness [m]	d	N	0.018	0.03
Plate width [m]	b	DET	1	–
Water pressure [kN/m^2]	q	N	157.6	0.1
Dynamic factor	δ	DET	1.3	–
Parameter A [mm]	A	N	0.06	0.10
Parameter B	B	DET	0.7	–
Resistance uncertainty	ξ_R	DET	0.85	–

one-side decrease up to 1 mm and about 30% probability of simultaneous weakening at opposite side of the cover plate. The model of corrosion given in equation (8) considering parameters in equation (9) leads after 50 years to actual average depth of corrosion of 1.3 mm.

The ultimate limit state is expressed as the difference $\Delta M(t)$ between the time-dependent resistance moment $M_R(t)$ and the bending moment M_E due to the water pressure q

$$\Delta M(t) = \xi_R b\,(d - 1{,}3 d_{\mathrm{corr}}(t))^2 f_y/4 - \delta q L^2/12 \qquad (10)$$

The probabilistic models of basic variables are given in Table 4 assuming normal (N) or lognormal (LN) distributions. Some of the basic variables are considered to be deterministic (denoted DET).

The reliability of the steel cover plate decreases in time due to the reduction of its thickness $d_{\mathrm{corr}}(t)$. The value of the target reliability index $\beta(80) = \beta_t = 3.7$ for considered 80 year working life of the cover plate is specified on the basis of required reliability index for a reference period of one year $\beta(1) = 4.7$ given as

$$\Phi(\beta(80)) = (\Phi(\beta(1))^{80} = (\Phi(4.7))^{80} = \Phi(3.7) \qquad (11)$$

The probabilistic reliability assessment of the steel member is based on own software tool developed in software Mathcad.

Initial reliability of the cover plate non-affected by corrosion (reliability index $\beta = 5.2$) satisfies the target reliability level $\beta_t = 3.7$ for considered reference period of 80 years. For one-side corrosion of 1 mm and cover plate 53 years old (current state), the reliability index decreases to $\beta = 4$, see Figure 5.

It appears that the working life of the cover plate may be estimated to approximately 70 years. Thus, the residual working life of a cover plate is considered to be approximately about next 20 years.

In case that a more effective protection level of cover-plate is provided (currently planned) then lower rate of corrosion may be considered (e.g. parameter $B = 0.6$ only, see case 1 in Figure 6).

New estimation of the residual working life is shown in Figure 6 when new protective coating of

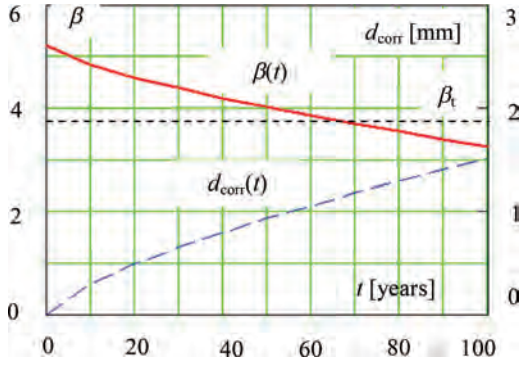

Figure 5. Time-dependent reliability index $\beta(t)$ and one-side corrosion depth $d_{\mathrm{corr}}(t)$.

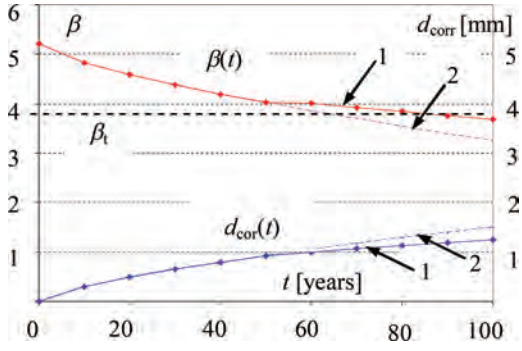

Figure 6. Time-dependent reliability index $\beta(t)$ and one-side corrosion depth $d_{corr}(t)$ for considered increased maintenance level (Case 1), and common maintenance level (Case 2).

steel member is provided leading to extended residual working life from 70 to 90 years.

4 VERIFICATION OF INDUSTRIAL BRIDGE

4.1 *Inspection of the state of bridge*

Existing industrial steel bridge supported by massive concrete columns being used for running of cleaning machine for trash racks in the power station are assessed for possibility of their further usage assuming two alternatives of a new machine (Fig. 7).

Industrial steel bridge is composed of two main structural members—steel longitudinal main rolled beams (I 280) stiffened by cross beams (I 140).

The longitudinal main beam is stiffened in the location of concrete columns by two supporting lateral diagonals (rolled U profiles) built in columns. The beams are supported at their ends by rather not enough suitable U profiles embedded in abutments. Visual inspection of steel structures revealed significant deterioration of load bearing members, mainly in locations of their joints and also in connections with steel bridge deck made from corrugated steel plate (Fig. 8).

Figure 7. Existing industrial bridge with a cleaning machine.

Figure 8. Significant deterioration of bridge structural members.

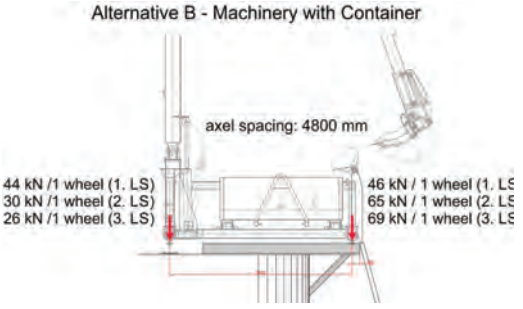

Figure 9. Illustration of new cleaning machinery, alt. B.

Table 5. Load effects and resistances of main structural members of the industrial bridge, in kNm.

Basic member	E	R	R_{red}
Alt. A – main beam	76.6	141.5	99
Alt. B – main beam	73.4	141.5	99
Alt. A – cross beam	14.6	19.8	13.9
Alt. B – cross beam	13.3	19.8	13.9

Reliability of the main structural members of the industrial bridge is verified for two alternatives of the new cleaning machinery for trash racks, see Fig. 9 where the alternative B is illustrated. Firstly, the reliability is verified by partial factor method and commonly applied procedure according to current standards ČSN ISO 13822 (2010), ČSN 73 0038 (2014) and ČSN EN 1990 (2004) (see also 3.1), secondly applying probabilistic methods and the Probabilistic Model Code (PMC 2014) of the Joint Committee on Structural Reliability (JCSS).

Results of reliability verification based on the partial factor method is given in Table 5 considering two alternatives of machinery with different self-weight, total load effects and geometry including supports.

4.2 *Verification by partial factor method*

The reliability of the existing industrial bridge is verified by the partial factor method given in ČSN ISO 13822 (2010) and ČSN 73 0038 (2014).

Self-weight, permanent loads and imposed loads evoked by new machinery are considered. The load bearing capacity of main structural members without any deterioration, and also for estimated actual 30% reduction of resistance is taken into account.

The results indicate that the structures are less loaded when the machinery B is used in comparison to machinery A. For non-deteriorated structure, and also for partly deteriorated structure

Table 6. Reliability of basic bridge steel members.

Basic member	β	$\beta_{red,1}$	$\beta_{red,2}$
Alt. A – main beam	6.5	5.6	4.7
Alt. B – main beam	6.7	5.8	4.9
Alt. A – cross beam	4.7	3.5	2.8
Alt. B – cross beam	5.1	3.9	3.3

(assumed reduction of resistance) the basic reliability condition is fulfilled.

However, low reliability level reveal inclined struts supporting longitudinal beams in regions of concrete columns. Requirement on limiting deflection of steel longitudinal main beams is also not satisfied.

4.3 *Probabilistic structural analyses*

Probabilistic methods are applied for structural verification based on the principles of the Probabilistic Model Code (PMC 2014) and expressions (1,2). The reliability analyses of two basic members, of a longitudinal main beam and cross beam for three cases: a structural member without any deterioration, and also for estimated 20% reduction ($\beta_{red,1}$) and 30% reduction ($\beta_{red,2}$) of resistance is taken into account for two alternative machinery A and B. The results of reliability analysis are given in Table 6.

In case that the main structural members of the industrial bridge are without any deterioration, the resulting reliability indices fulfil the required target reliability index given in EN 1990 (2002).

However, in case that 20%, resp. 30% reduction of resistance is assumed due to the corrosion of steel members, the reliability level of such deteriorated cross beams might be rather low and additional measures (repair, strengthening) should be undertaken.

Moreover, joints of steel members should be checked and repaired if needed.

5 CONCLUDING REMARKS

It is shown that application of partial factor method for the assessment of existing structures might lead in some cases to conservative estimations.

The probabilistic assessment of existing structures make it possible to effectively estimate remaining working life of structures and to plan their maintenance and required economic resources.

The assessment of the quick-closing valves has shown that their remaining life-time is about additional 20 years provided that regular maintenance will be made. Protective layers of steel components should be renovated and regularly inspected. When the reliability index would decrease below the target reliability index 3.7 (estimated to 20 years), a new reliability assessment of cover plates should be made on the basis of updated material characteristic.

Assessment of existing industrial bridge for new technology of cleaning reveals need for regular maintenance. Machinery B appears to be more suitable for cleaning of racks.

Probabilistic methods represent suitable tool for decision about alternative technological procedures and evaluation of actual conditions of structures.

Thermal fatigue lifetime prediction of BGA solder joint via a novel fatigue crack propagation model

W. Men, Y. Chen & R. Kang
Reliability and System Engineering School, BeiHang University, Beijing, China

ABSTRACT: Solder joint thermal fatigue is a major mechanism of electronic products failure. Previous studies had proposed several physics-of-failure models for thermal fatigue life prediction based on stress, strain, or energy. However, few models considered fatigue crack propagation. From that point of view, this paper presented a novel fatigue crack propagation model for ball grid array package solder joint thermal fatigue life prediction. Due to the difficulty of crack length measurement, experiment was conducted to explore the relationship of fatigue crack propagation and daisy chains resistances growth, where the daisy chains were created by solder joint network. Furthermore, the finite element simulation method was used to extend this model for solder joints with different dimensions and materials and the final form of the fatigue crack propagation model was obtained.

1 INTRODUCTION

In electronic package structure, solder joints have the functions of electronic connection, mechanical connection between chips and substrate and thermal dissipation tunnel. Reliability of solder joint has a big impact on the function of the whole electronic product. Due to a mismatch of the coefficient of thermal expansion, electronic solder joint experiences cycle shear strain, which ultimately leads to fatigue failure. Predictions of solder joint thermal fatigue life are mainly based on statistical method or Physics-of-Failure (PoF) models. However, the statistical data is often confidential or difficult to obtain for aerospace electronic products. Consequently, the PoF models are widely used for predicting solder joint life in engineering.

The earliest low-cycle fatigue model was Coffin-Manson model, which presented an expression of fatigue lifetime by exploring the relationship of stress cycle damage and plastic deformation (Manson 1965). Smith et al. (1970) improved Coffin-Manson model by taking energy changes into account and raised model accuracy and effectiveness. Engelmaier-Wild model considered the combined influence of tress relaxation, plastic deformation, and creep, and had been widely used in standards IPC-SM-785 and IPC-D-279 (Engelmaier 1983, Socie 1987).

These models were mainly based on stress, strain, or energy. Darveaux model took hysteresis energy theory and fracture mechanics theory into account to predict crack growth rate, thus the failure cycle numbers could be obtained (Darveaux 1997, Darveaux 2002). However, the parameters in the model couldn't be obtained directly, which limited the applicability of this model (Akay et al. 1997, Perkins 2007). New strategies need to be developed. In this study, a fatigue crack propagation model has been developed for Ball Grid Array (BGA) package solder joint life prediction. Experimental and simulation methods were adopted to determine the parameters and to extend it for more general conditions.

The remainder of this paper is organized as follows. Section 2 presents the fatigue crack propagation model considering stress intensity factor. Section 3 discusses the experimental procedures and results of data analysis to form the complete crack propagation model. Section 4 investigates the relationship between solder joint dimension and material with the proposed fatigue crack propagation model via Finite Element Analysis (FEA) simulation. Section 5 provides conclusions as well as directions for future work.

2 FATIGUE CRACK PROPAGATION MODEL

The thermal failure of electronic devices is a kind of fault phenomenon that mainly occurs in the interconnected parts under the action of long-term temperature cycling. Typical failure mechanisms include thermal fatigue of solder joints and thermal fatigue of plated-through holes, which are mainly caused by cyclical switching of circuits and periodic changes of ambient temperature, which eventually lead to thermal fatigue of solder joints.

For the BGA package solder joints, fatigue can be divided into two phases during the failure process:

– During the forming phase of the fatigue source, the initial crack appears at the solder joint surface with the maximum stress;
– Under the shear stress, the initial crack tip experiences repeated plastic deformation and continuous expansion until fatigue fracture occurred.

Previous studies (Forman & Shivakumar 1986, Manson et al. 1966) have shown that there is an exponential integral relationship of crack length difference Δl and stress intensity difference Δk during the crack propagation stage, and the exponent is related to the cycle number to fatigue failure N_f:

$$\Delta l = \int_{l_0}^{l_f} (\Delta k)^{aN_f{}^b} dl \tag{1}$$

where l = crack length; l_0 = initial crack length; l_f = crack length when fatigue failure occurs; k = stress intensity factor; a and b are constants to be defined.

The stress intensity factor k is a parameter that reflects the strength of the stress field at the crack tip of an elastic object, which can be defined as follow:

$$k = \sigma\sqrt{M} \tag{2}$$

where σ = shear stress and M = bending moment of crack cross section. For BGA package solder joints, the tip shear stresses corresponding to different crack lengths are different; however, the bending moment for the same crack location is constant. Consequently, stress intensity difference can be defined as follow:

$$\Delta k = \Delta\sigma\sqrt{M} \tag{3}$$

Through a large number of statistical data fitting, it is found that $\Delta\sigma$, M, and failure cycle number N have a certain relationship:

$$\frac{N_l}{\sqrt{M}} = \Delta\sigma N_f \tag{4}$$

where N_l = cycle number when the crack length reaches l and N_f = cycle number to fatigue failure. Then Equation (1) can be replaced by:

$$\Delta l = \int_{l_0}^{l_f} \left(\frac{N_l}{N_f}\right)^{aN_f{}^b} dl \tag{5}$$

After the integral is simplified:

$$l = l_0 + (l_f - l_0)\left(\frac{N_l}{N_f}\right)^{aN_f{}^b} \tag{6}$$

When the solder joint falls off, the crack length is equal to the diameter of the solder joint, which denotes failure in principle. However, in order to leave a security margin, the solder joint is considered to have failed when the crack length reaches 70% of the diameter of the solder joint based on GB/T6398. Generally, initial crack length $l_0 = 10^{-8} \sim 10^{-10}$ m, which is small compared to the expansion crack length; consequently, we assumed that $l_0 = 0$. Then the general form of the fatigue crack propagation model can be defined as follow:

$$l = 0.7D\left(\frac{N_l}{N_f}\right)^{aN_f{}^b} \tag{7}$$

where D = solder joint diameter. N_l and N_f can be obtained via experiment or simulation; however, constants a and b are unavailable directly due to the difficulty of crack length measurement. Therefore, the following sections will show a new approach to solve this problem and the fatigue crack propagation model of Equation (7) is determined.

3 EXPERIMENT

This section mainly shows the experimental procedures for obtaining N_l and N_f, as well as the new approach to replace crack length measurement for data fitting to calculate coefficients a and b according to a real-life case.

3.1 *Temperature profile*

The temperature profile used in this study is used in an engine control system of a helicopter, which involves parking, taxi, takeoff, ascent, level-flight, descent, and landing phases. During hot day, the ground temperature can reach 55°C, and since the electronic device was installed inside, considering a temperature difference of 15°C, this would be 70°C. During the flight phase, it will drop to 20°C due to a combination of various factors that influence temperature. The resulting life temperature profile is shown in Figure 1, where the off-time is omitted in this case due to its small impact on system life.

The detailed values of the temperature profile are shown in Table 1. The lower dwell was at 20°C for 115 min, while the upper dwell was at 70°C for 30 min. The overall cycle duration was

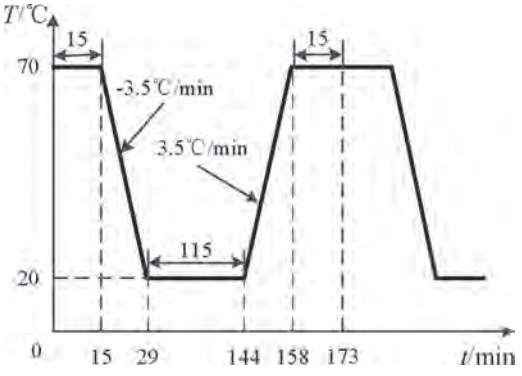

Figure 1. Temperature profile.

Table 1. Detailed values of the temperature profile.

	Temperature (°C)	Duration time (min)
1	70	15
2	Decreasing	14

4	Increasing	14
5	70	15

173 min, and the rate of temperature change was 3.5°C/min.

3.2 *Test specimen*

Due to the difficulty of crack length measurement, experiment was conducted for BGA package solder joints to explore the relationship of fatigue crack propagation and daisy chains resistances growth, where the daisy chains were created by solder joint network.

The first step was to produce test specimens. Chips were surface-mounted on printed circuit boards (PCBs) with 0.5 mm diameter Sn62Pb36 Ag2 solder joints. There were two test boards (A1 and A2) each had six BGA package chips (U1-U6) with an electrical resistance network that could be monitored for failure, which is shown in Figure 2. The solder joint network created three daisy chains named T1, T2, and T3. The resistance of the daisy chain was equal to the sum of the resistances of all solder joints contained within. The solder joints of different daisy chains were under different thermal expansion mismatch conditions. Among them, the daisy chain under the most severe condition would be the first one to fail and its resistances were representations of the solder joints' fatigue crack lengths.

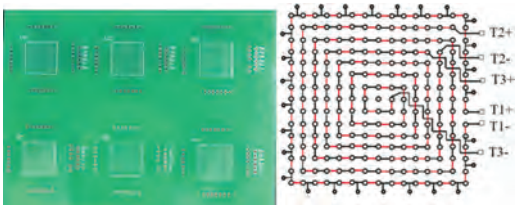

Figure 2. Test specimen and three daisy chains.

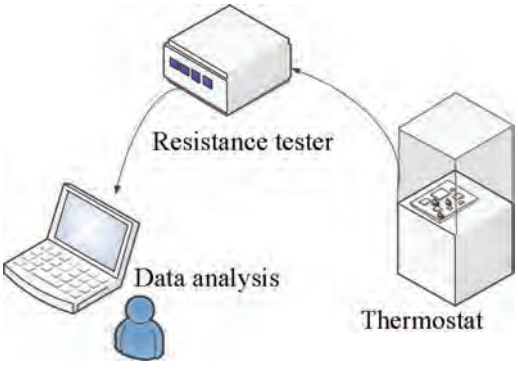

Figure 3. Devices of thermal fatigue experiments.

3.3 *Device setup and parameter conversion*

The temperature cycling profile was achieved with a temperature chamber. And the resistance values of daisy chains were measured with a resistance tester. The experiment and test devices were organized as shown in Figure 3.

Then the thermal fatigue failure cycle numbers N and daisy chains resistances r were obtained. IPC-9701 had shown that there was an exponential relationship of daisy chain resistance r and fatigue crack length l of BGA package solder joints, which is shown as follow after deduction and simplification:

$$r = mi(D - l)^{-n} \tag{8}$$

where i = solder joint number within the daisy chain; D = solder joint diameter; m and n are constants to be defined. Then the relationship of daisy chain resistance r and thermal fatigue failure cycle number N can be derived by combining Equations (7) and (8):

$$r = miD\left[1 - 0.7\left(\frac{N_r}{N_f}\right)^{aN_f{}^b}\right]^{-n} \tag{9}$$

where $N_r = N_l$.

3.4 *Results and discussion*

Twelve resistance values (two test boards with six chips each) of each type of daisy chain had been obtained within this experiment. The results of T1 daisy chains are shown in Figure 4.

Interconnecting failure was defined as a 20% increase in nominal resistance of the daisy chains, which means that at least one of the solder joints had failed ($l_f = 0.7D$). It can be found from Figure 4 that the resistance value of the T1 daisy chain reached 20% increase at about 500 cycles. Consequently, the subsequent data was useless for data fitting due to the overstepping of security margin. Generally, these twelve groups of data had good uniformity. The medium value of these twelve groups of data was used to analyze the fatigue crack propagation model.

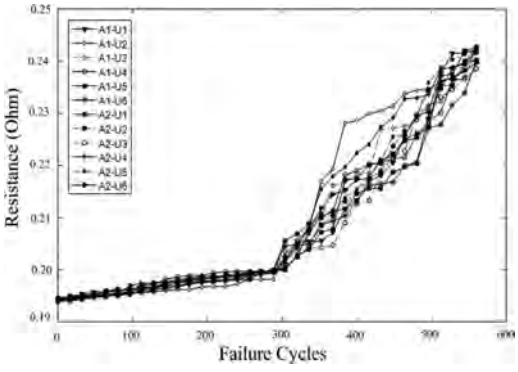

Figure 4. Resistance of the T1 daisy chain in twelve chip samples.

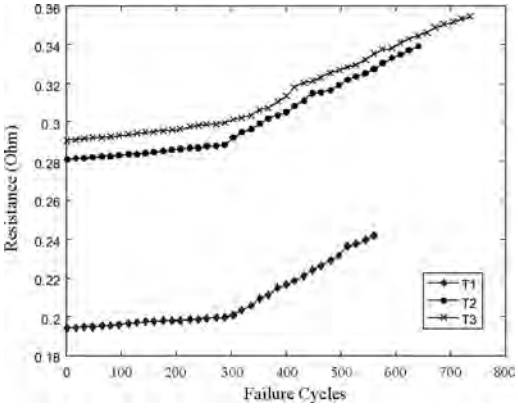

Figure 5. Resistance of daisy chains T1, T2, and T3.

Figure 5 shows the resistances of daisy chains T1, T2, and T3 of the experiment after integration.

The initial resistance values of three daisy chains were diverse due to the difference of solder joint numbers within. Figure 5 shows that the daisy chain T1 was the first one to fail. The reason is that daisy chain T1 was installed on the outermost side of the chip of Figure 2, which has maximal strain under the same thermal stress. As mentioned in section 3.2, daisy chain T1 was under the most severe thermal expansion mismatch conditions, and its resistances represented the thermal fatigue lives of solder joints of the chips. The resistances and failure cycles of daisy chain T1 had been recorded for data fitting purposes.

3.5 *Data fitting*

The experimental data were verified and N and r were picked up, which is shown in Table 2.

Table 2 shows that when resistance r reached a 20% increase for the first time, cycle number N was 508, which represents the fatigue failure cycles N_f in Equation (9). The diameter of solder joints is 0.5 mm and the solder joint number within daisy chain T1 is 56.

Data fitting has been processed with Matlab and a, b, m, and n in Equation (9) are shown in Table 3.

Here, SSE represents the sum of squares due to error, while R-square represents the coefficient of

Table 2. Failure cycles and resistance values of daisy chain T1.

	N (cycles)	r (Ohm)
1	0	0.1942
2	16	0.1946

15	352	0.2098
16	396	0.2197
17	424	0.2211
18	460	0.2298
19	508	0.2394

Table 3. Values of a, b, m, and n and goodness of fitting.

Parameter	Value
a	0.6637
b	0.4053
m	0.0032
n	0.1795
SSE	0.0240
R-square	0.9397
Adjusted R-square	0.9305
RSME	0.0736

determination. Adjusted R-square represents the degree-of-freedom adjusted coefficient of determination, and RMSE represents the root mean squared error.

Then, the relationship of daisy chain resistance r and thermal fatigue failure cycle number N of BGA package Sn62Pb36 Ag2 solder joints with 0.5 mm diameter could be integrated as:

$$r = 0.0032iD\left[1 - 0.7\left(\frac{N_r}{N_f}\right)^{0.6637N_f^{0.4053}}\right]^{-0.1795} \quad (10)$$

where r = resistance of the first failed daisy chain; i = solder joint number within the daisy chain; D = solder joint diameter; N_r = cycle number when the resistance reaches r and N_f = cycle number to fatigue failure. And the fatigue crack propagation model for the certain solder joint can be obtained:

$$l = 0.7D\left(\frac{N_l}{N_f}\right)^{0.6637N_f^{0.4053}} \quad (11)$$

where l = crack length and $N_l = N_r$ = cycle number when the crack length reaches l.

4 FEA SIMULATION

Experimental results were most realistic; however, both time and cost of the experiment were quite significant for aviation products due to the large failure cycle numbers. Therefore, simulation is still the main technology applied for engineering. This section is mainly to show the simulation method for solder joint thermal fatigue, and to explore the relationship between parameters a, b, m, and n with the material and dimension of solder joint; then, the final form of the fatigue crack propagation model could be obtained.

4.1 *Modeling*

A typical BGA package was modeled with the finite element method using ANSYS; the results are shown in Figure 6. The model contained solder joint, chip, substrate, encapsulated layer, and PCB layer. In ANSYS, element type Visco107 was used to describe the solder joint material.

To evaluate the impact of solder joint material and dimension on the crack propagation model, four types of solder joint materials were selected. These were Sn62Pb36 Ag2, Sn96.5 Ag3Cu0.5, Sn60Pb40, and Pb97.5Sn2.5, and the diameters of the solder joint were selected as 0.25 mm, 0.4 mm, 0.5 mm, and 0.6 mm.

4.2 *Simulation results*

The solder joint strain could be calculated via FEA. With the relationship of strain and thermal damage resistance, the daisy chain resistance could be obtained. Figure 7 shows the resistance of T1 obtained via experimental and FEA.

Figure 7 shows that the simulation result was not as smooth as the experimental result; however, the error was controlled within 5%, which was considered to be reasonable within 20%.

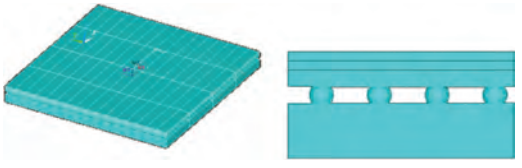

Figure 6. FEA model and solder joint model.

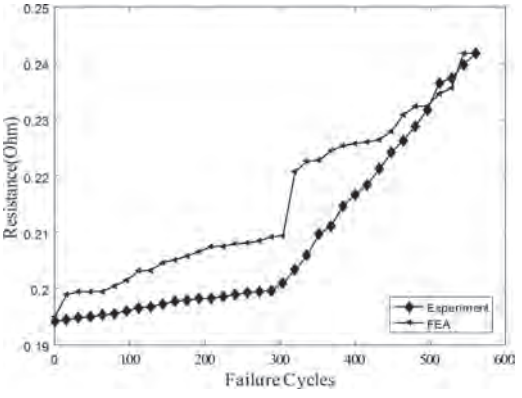

Figure 7. Resistance of the T1 daisy chain via experimental and FEA.

4.3 *Crack propagation model considering material and dimension*

Using these simulation results, the parameter *a*, *b*, *m*, and *n* in Equation (9) for four material types and four diameters of solder joints could be calculated, and the results are shown in Table 4. The material of the solder joint was expressed with Young's Module E and fatigue strength factor σ_f, which are the most critical parameters of the material for fatigue failure. Figure 8 shows the relationship between parameters *a*, *b*, *m*, and *n* depending on diameter and material of the solder joint.

Table 4. Parameter values of different solder joint diameters and materials.

	D (mm)	E (GPa)	σ_f (GPa)	*a*	*b*	*m*	*n*
Sn62	0.25	30	1.97	0.649	0.391	0.0033	0.181

Cu0.5	0.5	35	2.25	1.180	0.412	0.0259	0.178
	0.6	35	2.25	1.180	0.401	0.0258	0.182
Sn60	0.25	32	2.01	0.872	0.408	0.0110	0.179
Pb40	0.4	32	2.01	0.875	0.401	0.0114	0.178
	0.5	32	2.01	0.873	0.411	0.0112	0.178
	0.6	32	2.01	0.874	0.407	0.0111	0.182
Pb97.5	0.25	40	2.55	1.567	0.389	0.0448	0.180
Sn2.5	0.4	40	2.55	1.564	0.406	0.0450	0.180
	0.5	40	2.55	1.569	0.394	0.0451	0.182
	0.6	40	2.55	1.564	0.387	0.0450	0.180

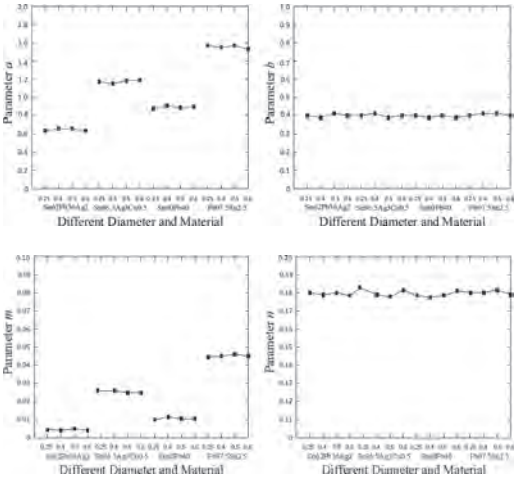

Figure 8. Relationships of parameters with diameter and material of solder joints.

Figure 8 shows that the material and dimension of solder joints have no effect on parameters *b* and *n*. The mean values are 0.400 and 0.180 respectively after testing. Figure 8 furthermore shows that parameter *a* and *m* only changed with changing material. With the simulation results of FEA, the relationships between parameter *a* and *m* with Young's Module E and fatigue strength factor σ_f were fitted via Matlab:

$$a = 0.1109E - 0.3123\sigma_f - 2.0448 \tag{12}$$

$$m = 0.0035E + 0.0118\sigma_f - 0.1246 \tag{13}$$

Consequently, Equation (9) can be expressed as:

$$r = miD\left[1 - 0.7\left(\frac{N_r}{N_f}\right)^{aN_f{}^{0.4}}\right]^{-0.18}$$

$$\begin{aligned} m &= 0.0035E + 0.0118\sigma_f - 0.1246 \\ a &= 0.1109E - 0.3123\sigma_f - 2.0448 \end{aligned} \tag{14}$$

And the final form of the fatigue crack propagation model can be obtained:

$$l = 0.7D\left(\frac{N_l}{N_f}\right)^{aN_f{}^{0.4}}$$

$$a = 0.1109E - 0.3123\sigma_f - 2.0448 \tag{15}$$

where Young's Module E and fatigue strength factor σ_f can be directly found within a material handbook.

5 CONCLUSION AND FUTURE WORK

This paper presented a fatigue crack propagation model for solder joint thermal fatigue life prediction from the perspective of stress intensity factor. To determine the constants within the model, experiment was conducted and a new approach with daisy chain was used to solve the problem of crack length measuring difficulty. The model for a certain solder joint was obtained. To study the relationship of the coefficients of the fatigue crack propagation model with the dimension and material of the solder joint, the Finite Element method was used to simulate more cases. And a more general form of the model was achieved.

A further study may focus on additional FEA simulations and study other factors that may affect fatigue crack propagation models, such as different

mounted styles of the chip and different conductivities of the solder joint.

Reliability of the aircraft in the Polish operational aviation

M. Zieja & M. Woch
Division for IT Support of Logistics, Air Force Institute of Technology, Warsaw, Poland

J. Tomaszewska
Faculty of Aviation, Polish Air Force Academy, Dęblin, Poland

ABSTRACT: This paper is an outgrowth of an investigation to determine what is the main source of failure in the Polish operational aviation. The proper understanding of failure data is valuable in prediction of the future needs in a specified planning horizon or for specified operational hours. The major effort of the study was the reliability analysis for two types of aircraft, which are used in the Polish operational aviation. As the main results the value of the number of hours between failures is presented and this distribution is tested with some mathematical models. The description of the data by Weibull distribution, which is one of the most frequently used functions in reliability analysis, has been tested. Then, the same test has been performed for another mathematical distributions. It has been observed that for an aircraft of first type the best description can be given by different distribution as for the second type and that the standard Weibull distribution is not always the best reliability model. The potentially causes of this behavior are discussed in the article. Additionally, the change of the number of the failures as a function of time is presented. It is observed that this behavior varied for the different types of aircraft.

1 INTRODUCTION

1.1 *Formulation of the problem*

Aircrafts system may be designed with redundancy of components in order to improve their overall reliability. Such approach can increase the reliability of the whole system, however, the improved reliability is not the only factor that contributes to the effectiveness of a task performance. If the system fails and has to be repaired, then the time to repair is also an important factor in effectiveness. One of the most important factors of the high efficiency of the system usage is the appropriate estimation of the expected time to failure, proper planning and efficient performing of inspections and any possible repairs (Tloczynski 2017b). The time to failure can be estimated by knowledge of the behavior of a data from the exploitation process. Data can be described by the different statistical models. Proper selection of the model is externally important which will be presented in this contribution by comparison of data with the selected models. The advantage of this method over the calculation of mean and standard division is the reduction of reparation costs. Failure rate function shows exactly when early failures occurs, constant failure rate may describes random failures, whereas increasing failure rate tells about wear-out failures (Babiarz 2016).

2 FORMULATION OF THE PROBLEM

2.1 *Basics definitions*

A failure rate function is defined as the limit, if it exists, of the ratio of the conditional probability that the instant of time, T, of a failure of an item falls within a given time interval $t + \Delta t$ and the length of this interval, Δt, when Δt leads to zero, given that the item is in an up state at the beginning of the time interval, which can be described as (Koucky and Valis 2007, Valis et al. 2014):

$$\lambda(t) = \lim_{\Delta t \to 0^+} \frac{P\{t < T \le t + \Delta t \mid T > t\}}{\Delta t} \tag{1}$$

where T is a continuous positive random variable of device operation time.

If T has a density $f(t)$ and the distribution $F(t)$ equation (1) will take the form:

$$\lambda(t) = \frac{f(t)}{1 - F(t)} \tag{2}$$

where $F(t) = \int_0^t f(u)\,du = P\{T \le t\} = 1 - P\{T > t\}$.

2.2 *The Weibull distribution*

The Weibull distribution is one of the most widely used lifetime distributions in reliability engineering

(Tloczynski 2017a). It is a versatile distribution, that can take on the characteristics of other types of distributions, based on the value of the shape parameter, β.

Weibull Probability Density Function can be described by the following formula (Hinz, Hienzsch, & Bracke 2017a):

$$f(t)=\frac{\beta}{\eta}\left(\frac{t-\gamma}{\eta}\right)^{\beta-1} e^{-\left(\frac{t-\gamma}{\eta}\right)^{\beta}} \tag{3}$$

where:

η - scale parameter, or characteristic life,

β - shape parameter (or slope),

γ - location parameter (or failure free life).

The Weibull Failure Rate Function is given by:

$$\lambda(t)=\frac{\beta}{\eta}\left(\frac{t-\gamma}{\eta}\right)^{\beta-1} \tag{4}$$

2.3 *The Burr distribution*

In probability theory, statistics and econometrics, the Burr Type XII distribution or simply the Burr distribution[1] is a continuous probability distribution for a non-negative random variable. It is also known as the SinghMaddala distribution[2] and is one of a number of different distributions sometimes called the generalized log-logistic distribution.

Burr Probability Density Function can be described by the following formula (Mueller, Hinz, & Bracke 2017):

$$f(t)=\frac{\alpha k\left(t-\gamma/\beta\right)^{\alpha-1}}{\beta\left[1+\left(t-\gamma/\beta\right)^{\alpha}\right]^{k+1}} \tag{5}$$

where:

k - continuous shape parameter ($k>0$),

α - continuous shape parameter ($\alpha>0$),

β - continuous scale parameter ($\beta>0$),

γ - continuous location parameter ($\gamma\equiv 0$ yields the three-parameter Dagum distribution).

The Burr Failure Rate Function is given by:

$$\lambda(t)=\frac{f(t)}{1-F(t)}=\frac{\dfrac{\alpha k\left(t-\gamma/\beta\right)^{\alpha-1}}{\beta\left[1+\left(t-\gamma/\beta\right)^{\alpha}\right]^{k+1}}}{1-\left[1+\left(t-\gamma/\beta\right)^{\alpha}\right]^{-k}} \tag{6}$$

2.4 *The Dagum distribution*

The Dagum distribution is a continuous probability distribution defined over positive real numbers. It is named after Camilo Dagum, who proposed it in a series of papers in the 1970s. The Dagum distribution arose from several variants of a new model on the size distribution of personal income and is mostly associated with the study of income distribution.

Dagum Probability Density Function can be described by the following formula (Vintr & Valis 2011):

$$f(t)=\frac{\alpha k\left(t-\gamma/\beta\right)^{\alpha k-1}}{\beta\left[1+\left(t-\gamma/\beta\right)^{\alpha}\right]^{k+1}} \tag{7}$$

where:

k - continuous shape parameter ($k>0$),

α - continuous shape parameter ($\alpha>0$),

β - continuous scale parameter ($\beta>0$),

γ - continuous location parameter ($\gamma\equiv 0$ yields the three-parameter Dagum distribution).

The Dagum Failure Rate Function is given by:

$$\lambda(t)=\frac{f(t)}{1-F(t)}=\frac{\dfrac{\alpha k\left(t-\gamma/\beta\right)^{\alpha k-1}}{\beta\left[1+\left(t-\gamma/\beta\right)^{\alpha}\right]^{k+1}}}{1-\left[1+\left(t-\gamma/\beta\right)^{-\alpha}\right]^{-k}} \tag{8}$$

2.5 *The log-logistic distribution*

In probability and statistics, the log-logistic distribution (known as the Fisk distribution in economics) is a continuous probability distribution for a non-negative random variable. It is used in survival analysis as a parametric model for events whose rate increases initially and decreases later, for example mortality rate from cancer following diagnosis or treatment. It has also been used in hydrology to model stream flow and precipitation, in economics as a simple model of the distribution of wealth or income, and in networking to model the transmission times of data considering both the network and the software.

The log-logistic distribution is the probability distribution of a random variable whose logarithm has a logistic distribution. It is similar in shape to the log-normal distribution but has heavier tails. Unlike the log-normal, its cumulative distribution-function can be written in closed form.

Log-logistic Probability Density Function can be described by the following formula (Hinz, Hienzsch, & Bracke 2017b):

$$f(t)=\frac{\alpha}{\beta}\left(\frac{t-\gamma}{\beta}\right)^{\alpha-1}\left[1+\left(\frac{t-\gamma}{\beta}\right)^{\alpha}\right]^{-2} \tag{9}$$

where:

α - continuous shape parameter ($\alpha > 0$),

β - continuous scale parameter ($\beta > 0$),

γ - continuous location parameter ($\gamma \equiv 0$ yields the two-parameter Log-logistic distribution).

The Log-logistic Failure Rate Function is given by (Valis, Zak, Pokora, & Lansky 2016):

$$\lambda(t) = \frac{f(t)}{1-F(t)} = \frac{\frac{\alpha}{\beta}\left(\frac{t-\gamma}{\beta}\right)^{\alpha-1}\left[1+\left(\frac{t-\gamma}{\beta}\right)^{\alpha}\right]^{-2}}{1-\left[1+\left(\frac{\beta}{t-\gamma}\right)^{\alpha}\right]^{-1}} \quad (10)$$

3 EXPERIMENTAL STUDY OF STATISTICAL METHODS

3.1 *Input data*

This analysis uses data on one type of aircraft used in Polish Air Force for a selected group of pilots. Data were obtained from the operation and maintenance. The analysed data are presented in the form of graph of average flight hours between failure as a function of years in Figures 1 and 2. These figures show the data for the years 2011 and 2017. It was noted that data for 2013 are concentrated at lower values, while for 2017 at higher. Such behavior may indicate that at some point there was an improvement of procedures to control the aircraft, which resulted in fewer aircraft failures. It may also be the result increasing the maintained.

Based on Figures 1 and 2, the division into two groups of data can be observed: the first one covers the years 2011–2015, for which the average time between failures is about 15 hours, second contains years 2016–2017 for which the average time between failures increases twice.

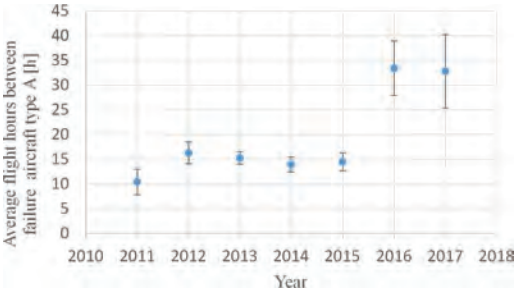

Figure 1. Average flight hours between failure for 4th generation fighter aircraft type A as a function of years.

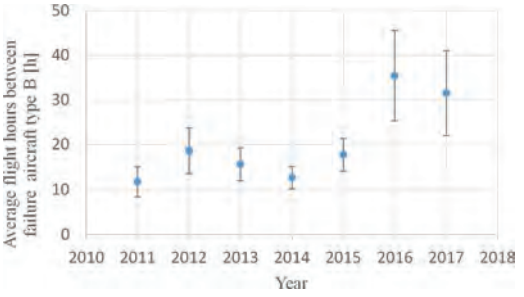

Figure 2. Average flight hours between failure for 4th generation fighter aircraft type A as a function of years.

Comparison of distributions of probability density function with data obtained during the operation process is shown in Figure 7. In addition, Figure 8 summarize the fitting parameters for failure rate function distributions. It can be observed that the for aircraft type A the shape is more narrow. The Weibull's distributions for both type of aircraft have similar shapes, but for type B the most expected value is shifted to lower value. Because no significant differences between the failure time for two types of aircraft have been observed, for better precision of the fit, has been done for all collected data together.

3.2 *Quality of the fit*

To determine the quality of the fit and to determine whether the analysis distribution describes the data, the following tests were used:

- Kolmogorov-Smirnov,
- Anderson-Darling,
- Chi-kwadrat,

which are based on the empirical distribution function (EDF).

3.2.1 *The Kolmogorov-Smirnov statistic*

The Kolmogorov-Smirnov statistic is defined as:

$$D = \sup_x \left| F_n(x) - F(x) \right| \quad (11)$$

The Kolmogorov-Smirnov statistic belongs to the supremum class of EDF statistics (Chakravarti, Laha, & Roy 1967). This class of statistics is based on the largest vertical difference between $F(x)$ and $F_n(x)$. The Kolmogorov-Smirnov statistic is computed as the maximum of D^+ and D^-, where D^+ is the largest vertical distance between the EDF and the distribution function when the EDF is greater than the distribution function, and D^- is the largest vertical distance when the EDF is less than the distribution function.

$$\begin{aligned} D^{+} &= \max_i\left(\frac{i}{n}-U_{(i)}\right), \\ D^{-} &= \max_i\left(U_{(i)}-\frac{i-1}{n}\right), \\ D &= \max\left(D^{+},D^{-}\right). \end{aligned} \tag{12}$$

3.2.2 *The Anderson-Darling statistic*

The Anderson-Darling Statistic belongs to the quadratic class of EDF statistics (Stephens 1974). The Anderson-Darling statistic is defined as:

$$A^2 = n\int_{-\infty}^{+\infty}\left(F_n(x)-F(x)\right)^2 \left[F(x)\left(1-F(x)\right)\right]^{-1} dF(x) \tag{13}$$

Here the weight function is $\psi(x) = [F(x)(1-F(x)]$. The Anderson-Darling statistic is computed as

$$A^2 = -n-\frac{1}{n}\sum_{i=1}^{n}\left[\left(2i-1\right)\log U_{(i)} + \left(2n+1-2i\right)\log\left(1-U_{(i)}\right)\right] \tag{14}$$

3.2.3 *The Chi-Squared statistic*

The Chi-Squared statistics belongs to the quadratic class of EDF statistics (Snedecor & Cochran 1989). This class of statistics is based on the squared difference $(F)_n(x)-F(x))^2$. Quadratic statistics have the following general form:

Table 2. Goodness of fit—summary for 4th generation fighter aircraft type B.

$$Q = n\int_{-\infty}^{+\infty} \left(F_n(x) - F(x) \right)^2 \Psi(x)\, dF \tag{15}$$

The function weights $\Psi(x)$ the squared difference $(F)_n(x) - F(x))^2$.

The Tables 1–3 presented that the goodness-of-fit tests reject the null hypothesis that the number of hours between failures can be approximated by any of the distribution. It is merely because the *p-value* is greater than 0.01.

4 CONCLUSION

This contribution stands at the beginning of research program projecting risk at the Air Force Institute of Technology for 4th generation fighter aircraft and subsequent development will be the subject of future papers. The risk profile of an aircraft is changing and, as such as, it is essential that we will continue to define and monitor desired performance outcomes in line with the risk profile. In order to be able to create such profile, it is necessary to select a probability distribution that will facilitate the construction of reasonably precise probability statements of the type that one wishes to make. In this analysis, the number of hours between failures has been used as the main variable for taking the conclusion about the dependability of the aircraft. It was concluded, from the quality of fitting, that the distribution of Dumm and Darum are the best descriptions of the gathered data. Commonly used in reliability the Weibull distribution, in this particular scenario, did not meet the expected requirements. This can be the result of the relatively small statistic of the incidents of the 4th generation fighter aircraft.

Buffered environmental contours

K.R. Dahl & A.B. Huseby
Department of Mathematics, University of Oslo, Norway

ABSTRACT: The main idea of this paper is to use the notion of buffered failure probability from probabilistic structural design, first introduced by Rockafellar & Royset (2010), to introduce buffered environmental contours. Classical environmental contours are used in structural design in order to obtain upper bounds on the failure probabilities of a large class of designs. The purpose of buffered failure probabilities is the same. However, in constrast to classical environmental contours, this new concept does not just take into account failure vs. functioning, but also to which extent the system is failing. For example, this is relevant when considering the risk of flooding: We are not just interested in knowing whether a river has flooded. The damages caused by the flooding greatly depends on how much the water has risen above the standard level.

1 INTRODUCTION

Environmental contours are widely used as a basis for e.g., ship design. Such contours allow the designer to verify that a given mechanical structure is safe, i.e, that the failure probability is below a certain value. A realistic model of the environmental loads and the resulting response is crucial for structural reliability analysis of mechanical constructions exposed to environmental forces. See Winterstein et al. (1993) and Haver & Winterstein (2009). For applications of environmental contours in marine structural design, see e.g., Baarholm et al. (2010), Fontaine et al. (2013), Jonathan et al. (2011), Moan (2009) and Ditlevsen (2002).

The traditional approach to environmental contours is based on the well-known *Rosenblatt transformation* introduced in Rosenblatt (1952). This transformation maps the the environmental variables into independent standard normal variables. Using the transformed environmental variables a contour with the desired properties can easily be constructed by identifying a sphere centered in the origin and with a suitable radius. More specifically, the sphere can be chosen so that any non-overlapping convex failure region has a probability less than or equal to a desired exceedence probability. The corresponding environmental contour in the original space can then be found by transforming the sphere back into the original space.

Alternatively, an environmental contour can be constructed directly in the original space using Monte Carlo simulation. See Huseby et al. (2013), Huseby et al. (2015a) and Huseby et al. (2015b). Contours constructed using this approach will always be convex sets. This yields a more straightforward interpretation of the contours. Another advantage of this approach is a more flexible framework for establishing environmental contours, which for example simplifies the inclusion of effects such as future projections of the wave climate related to climatic change. See Vanem & Bitner-Gregersen (2012).

In the present paper we introduce a new concept called buffered environmental contours. This concept is based on the notion of buffered failure probability from probabilistic structural design, first introduced by Rockafellar & Royset (2010). Contrary to classical environmental contours, this new concept does not just take into account failure vs. functioning, but also to which extent the system is failing. For example, this is relevant when considering the risk of flooding: We are not just interested in knowing whether a river has flooded. The damages caused by the flooding greatly depends on how much the water has risen above the standard level.

The structure of this paper is as follows: In Section 2, we recall the classic definition of failure probability in probabilistic structural design and compare this to the concept of buffered failure probability, as defined in Rockafellar & Royset (2010). Furthermore, we recall some of the arguments favoring the buffered failure probability over the regular failure probability. Then, in Section 3, we recall the concept of environmental contours and how such contours are used in structural design in order to find upper bounds on the failure probabilities of a large class of designs. In Section 4, we introduce the new concept of buffered environmental contours, and argue that these contours are better suited than the classical ones in

cases where the level of malfunctioning is important. Finally, in Section 5, we apply the proposed contours to a real life example, and compare the contours to the classical environmental contours.

2 STRUCTURAL DESIGN AND THE BUFFERED FAILURE PROBABILITY

In probabilistic structural design, it is common to define a *performance function*[1] $g(x,V)$ depending on some design variables $x=(x_1,x_2,\ldots,x_m)'$ and some environmental quantities[2] $V=(V_1,V_2,\ldots,V_n)'\in\mathcal{V}$, where $\mathcal{V}\subseteq\mathbb{R}^n$. The design variables can be influenced by the designer of the structure, and may respresent material type or layout. The quantities are usually random, and cannot be directly impacted by the designer. Hence, they may describe environmental conditions, material quality or loads. To emphasize the randomness of the quantities, we denote them by captial letters. In contrast, the design variables are controlled by the designer and hence denoted by small letters.

For a given design x s, $g(\boldsymbol{x},\boldsymbol{V})$ represents the performance of the structure, and is called the *state of the structure*. A given mechanical structure can withstand environmental stress up to a certain level. The *failure region* of the structure is the set of states of the environmental variables that imply that the structure fails. The performance function is defined such that if $g(\boldsymbol{x},\boldsymbol{V})>0$, the structure is *failed*, while if $g(\boldsymbol{x},\boldsymbol{V})\le 0$, the structure is *functioning*. Moreover, for a given $\boldsymbol{x}$ the set $\mathcal{F}(\boldsymbol{x})=\{\boldsymbol{v}\in\mathcal{V}: g(\boldsymbol{x},\boldsymbol{v})>0\}$ is called the *failure region* of the structure[3].

2.1 *The failure probability, reliability and approximation methods*

The failure probability, denoted by $p_f(\boldsymbol{x})$, of the structure is the probability that the structure is failed. That is, $p_f(x)=P(g(\boldsymbol{x},\boldsymbol{V})>0)$. If $f_{\boldsymbol{V}}(v)$ is the joint probability density function for the random vector $\boldsymbol{V}$, the failure probability is given by:

$$p_f(\boldsymbol{x})=\int_{\mathcal{F}(x)} f_{\boldsymbol{V}}(v)\,d\boldsymbol{v}. \tag{1}$$

For a given $\boldsymbol{x}$ the *reliability*, $R(\boldsymbol{x})$, of the system is defined as the probability that the system is functioning, i.e.:

$$R(\boldsymbol{x})=1-p_f(\boldsymbol{x}) \tag{2}$$

A classic problem is to compute the reliability of the system. In order to do so, we need to compute the integral (1). In many cases it is difficult to obtain and analytical solution to this. To overcome this issue various approximation methods have been proposed. Two traditional methods for doing this are the *first-order reliability method* (FORM) and the *second-order reliability method* (SORM). The basic idea of the first-order reliability method is to approximate the failure boundary at a spesific point by a first order Taylor expansion. The idea behind SORM is similar, but using a second order Taylor expansion instead. In both cases, the approximated failure probability can be used to optimize the structural design, i.e. determine a feasible design which has an acceptable failure probability.

2.2 *Return periods*

As is common in structural design models, we view $\boldsymbol{V}$ as representing the average value of the relevant environmental variables in a suitable time interval of length L. Based on this and knowledge of the performance function g it is possible to compute the so-called *return period*. This is done as follows:

We consider the environmental exposure of the given design from time $t\ge 0$. The time axis is divided into intervals of some specified length L, and we let $\boldsymbol{V}_i$ denote the average environmental quantity in the ith period, $i=1,2,\ldots$. It is common to assume that $\boldsymbol{V}_1,\boldsymbol{V}_2,\ldots$ are independent and identically distributed. This is a fairly strict assumption, but as it is so frequently used in structural design, we assume this as well. We then let $T:=\min\{i: g(\boldsymbol{x},\boldsymbol{V}_i)>0\}$. By the assumptions it follows that T is geometrically distributed with probability $p_f=P(g(\boldsymbol{x},\boldsymbol{V})>0)$. The *return period* is defined as $E[T]=1/p_f$. Thus, the return period can be interpreted as a property of the distribution of g($\boldsymbol{x}$, $\boldsymbol{V}$). Hence, it suffices to analyze this distribution, which is what we will focus on in this paper.

2.3 *The buffered failure probability*

The approximations made by FORM and SORM can sometimes be too crude and ignore serious risks. Therefore, we will consider the buffered failure probability, introduced by Rockafellar & Royset (2010) as an alternative to the failure probability. This concept relates closely to the conditional value-at-risk (also called expected shortfall, average

1. 1The performance function is sometimes called the limit-state function.
2. Environmental quantities should here be understood in a broad sense. E.g., for marine structures such quantities typically includes wave height and period. For other types of structures, one may consider e.g., material quality, effects of erosion or corrosion as environmental quantities.
3. In some papers, such as Huseby et al. (2013), the failed states are defined as the states such that $g(\boldsymbol{x},\boldsymbol{V})<0$. This is just a matter of choice of notation.

value-at-risk or expected tail loss), which is a notion frequently used in mathematical finance and financial engineering, see Pflug (2000), Rockafellar (2007) as well as Rockafellar & Uryasev (2000).

Recall that for any level of probability α, the α-quantile of the distribution of a random variable is the value of the inverse of its cumulative distribution function at α. For the random variable $g(\boldsymbol{x},\boldsymbol{V})$, we let $q_\alpha(\boldsymbol{x})$ denote its α-quantile. Similarly, for any probability level α, the α-superquantile of $g(\boldsymbol{x},\boldsymbol{V})$, $\bar{q}_\alpha(\boldsymbol{x})$, is defined as:

$$\bar{q}_\alpha(\boldsymbol{x}) = E\left[g(\boldsymbol{x},\boldsymbol{V}) \middle| g(\boldsymbol{x},\boldsymbol{V}) \rangle q_\alpha(\boldsymbol{x})\right]. \tag{3}$$

That is, the α-superquantile is the conditional expectation of $g(\boldsymbol{x},\boldsymbol{V})$ when we know that its value is greater than or equal the α-quantile. Rockafellar & Royset (2010) then define the buffered failure probability, $\bar{p}_f(\boldsymbol{x})$, as follows:

$$\bar{p}_f(\boldsymbol{x}) = 1-\alpha, \tag{4}$$

where α is chosen so that $\bar{q}_\alpha(x)=0$. Note that from the previous definitions we have:

$$\bar{p}_f(\boldsymbol{x}) = P(g(\boldsymbol{x},\boldsymbol{V}) > q_\alpha(\boldsymbol{x})) = 1-F\left(q_\alpha(\boldsymbol{x})\right) \tag{5}$$

where F denotes the cumulative distribution function of $g(\boldsymbol{x},\boldsymbol{V})$.

In order to show how to calculate the buffered failure probability $\bar{p}_f(\boldsymbol{x})$, we consider the plot shown in Figure 1. The curve in the plot represents the cumulative distribution function of the performance function, $g(\boldsymbol{x},\boldsymbol{V})$. As an example we have chosen a Gaussian distribution with mean value –2.5 and standard deviation 1.5. For this distribution we have $F(0) = 0.952$, as can also be seen in the figure by considering the right-most vertical dashed line starting at 0 on the x-axis, and the corresponding upper horizontal dashed line starting at

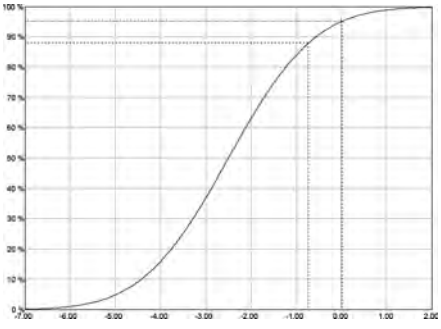

Figure 1. Buffered failure probability calculation where: $p_f(\boldsymbol{x}) = 0.048$, $q_\alpha(\boldsymbol{x}) = -0.743$, $\alpha = F\left(q_\alpha(\boldsymbol{x})\right) = 0.879$, and $\bar{p}_f(\boldsymbol{x}) = 1-\boldsymbol{\alpha} = 0.121$.

0.952. Hence, we get that $p_f(\boldsymbol{x}) = 1-F(0) = 0.048$. In the figure $p_f(\boldsymbol{x})$ is the distance between 100%-line and the upper horizontal dashed line.

Using e.g., Monte Carlo simulation it is easy to estimate $q_\alpha(\boldsymbol{x})$, and we find that $q_\alpha(\boldsymbol{x}) = -0.743$. In the figure $q_\alpha(\boldsymbol{x})$ is represented by the leftmost vertical dashed line. By following this line until it crosses the cumulative curve, we find that $\alpha = F\left(q_\alpha(\boldsymbol{x})\right) = 0.879$. Finally, the buffered failure probability is found to be $\bar{p}_f(\boldsymbol{x}) = 1-\alpha = 0.121$. In the figure $\bar{p}_f(\boldsymbol{x})$ is the distance between 100%-line and the lower horizontal dashed line.

It is easy to see that we always have $q_\alpha(\boldsymbol{x}) \le 0$, and thus, it follows that $\alpha = F\left(q_\alpha(\boldsymbol{x})\right) \le F(0)$. This implies that:

$$\bar{p}_f(\boldsymbol{x}) = 1-\alpha \ge 1-F(0) = p_f(\boldsymbol{x}).$$

Hence, it follows that the buffered failure probability is more conservative than the failure probability. See Rockafellar & Royset (2010) for a detailed discussion of this.

Rockafellar & Royset (2010) present several advantages of using the buffered failure probability instead of the regular failure probability. The following are some of the key arguments:

- In general, the failure probability $p_f(\boldsymbol{x})$ cannot be computed analytically, and the techniques commonly used to approximate it, such as FORM or Monte Carlo methods, can sometimes ignore serious risks. This makes it problematic to apply standard non-linear optimization algorithms in connection to structure design. In contrast, non-linear optimization algorithms are directly applicable when using the buffered failure probability instead.
- The buffered failure probability contains more information about the tail behaviour of the distribution of $g(\boldsymbol{x},\boldsymbol{V})$ than the failure probability.
- The buffered failure probability can lead to more computational efficiency in design optimization when the performance function $g(\boldsymbol{x},\boldsymbol{V})$ is expensive to evaluate.

The *buffered reliability*, $\bar{R}(\boldsymbol{x})$, of the structure is defined as $\bar{R}(\boldsymbol{x}) = 1-\bar{p}_f(\underline{\boldsymbol{x}})$. Since $p_f(\boldsymbol{x}) \le \bar{p}_f(\boldsymbol{x})$, it follows that $R(\boldsymbol{x}) \ge \bar{R}(\boldsymbol{x})$. That is, the reliability of the system is greater than or equal to the buffered reliability. Again, this essentially says that the buffered reliability is more conservative than the reliability.

3 ENVIRONMENTAL CONTOURS

Environmental contours are typically used during the early design phases where the exact shape

of the failure region is typically *unknown*. At this stage it it may not be possible to express a precise functional relationship between a set of design variables $\boldsymbol{x}$ and the performance of the structure. Instead we skip $\boldsymbol{x}$ in the notation and let the design options be embedded in the performance function $g(\boldsymbol{V})$ itself. In particular we denote the failure region simply by $\mathcal{F}$, while the corresponding failure probability, $P(\boldsymbol{V} \in \mathcal{F})$, is denoted by $p_f(\mathcal{F})$.

Although $\mathcal{F}$ is unknown, it may still be possible to argue that $\mathcal{F}$ belongs to some known family, $\mathcal{E}$, of failure regions. As in the previous sections we consider cases where the environmental conditions can be described by a stochastic vector $\boldsymbol{V} \in \mathbb{R}^n$ with a known distribution. An important part of the probabilistic design process is then to make sure that $P(\boldsymbol{V} \in \mathcal{F})$ is acceptable for all $\mathcal{F} \in \mathcal{E}$.

In order to avoid failure regions with unacceptable probabilities, it is necessary to put some restrictions on the family $\mathcal{E}$. This is done by introducing a set $\mathcal{B} \subseteq \mathbb{R}^n$ chosen so that for any relevant failure region $\mathcal{F}$ which do not overlap with $\mathcal{B}$, the failure probability $P(\boldsymbol{V} \in \mathcal{F})$ is *small*. The family $\mathcal{E}$ is chosen relative to $\mathcal{B}$ so that $\mathcal{F} \cap \mathcal{B} \subseteq \partial\mathcal{B}$ for all $\mathcal{F} \in \mathcal{E}$, where $\partial\mathcal{B}$ denotes the boundary of $\mathcal{B}$. This boundary is then referred to as an *environmental contour*. See Figure 2.

Following Huseby et al. (2017) we define the *exceedence probability* of $\mathcal{B}$ with respect to $\mathcal{E}$ as:

$$P_e(\mathcal{B}, \mathcal{E}) := \sup\{p_f(\mathcal{F}) : \mathcal{F} \in \mathcal{E}\}. \tag{6}$$

For a given *target probability* P_e the objective is to choose an environmental contour $\partial\mathcal{B}$ such that:

$$P_e(\mathcal{B}, \mathcal{E}) = P_e$$

We observe that the exceedence probability defined above represents an upper bound on the failure probability of the structure assuming that the true failure region is a member of the family $\mathcal{E}$. Of particular interest are cases where one can argue that the failure region of a structure is *convex*. That is, cases where $\mathcal{E}$ is the class of all convex sets which do not intersect with the interior of $\mathcal{B}$. In the remaining part of the paper we will assume that $\mathcal{E}$ satisfies this.

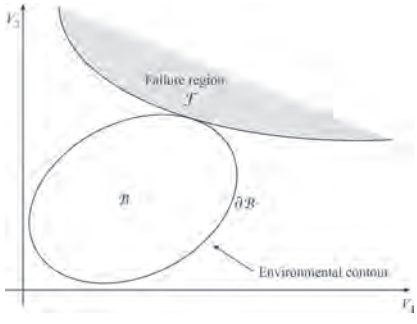

Figure 2. An environmental contour $\partial\mathcal{B}$ and a failure region $\mathcal{F}$

3.1 *Monte Carlo contours*

There are many possible ways of constructing environmental contours. In this paper we focus on the Monte Carlo based approach first introduced in Huseby et al. (2013), and improved in Huseby et al. (2015a) and Huseby et al. (2015b).

Let $\mathcal{U}$ be the set of all unit vectors in $\mathbb{R}^n$, and let $\boldsymbol{u} \in \mathcal{U}$ We then introduce a function $C(\boldsymbol{u})$ defined for all $\boldsymbol{u} \in \mathcal{U}$ as:

$$C(\boldsymbol{u}) := \inf\{C : P(\boldsymbol{u}'\boldsymbol{V} > C) \le P_e\} \tag{7}$$

Thus, $C(\boldsymbol{u})$ is the $(1-P_e)$-quantile of the distribution of $\boldsymbol{u}'\boldsymbol{V}$. Given the distribution of $\boldsymbol{V}$, the function $C(\boldsymbol{u})$ can easily be estimated by using Monte Carlo simulation. Thus, let $V_1, \ldots, V_N$ be a random sample from the distribution of $\boldsymbol{V}$. We then choose $\boldsymbol{u} \in \mathcal{U}$, and let $Y_r(\boldsymbol{u}) = \boldsymbol{u}'\boldsymbol{V}_r$, $r = 1, \ldots, N$. These results are sorted in ascending order:

$$Y_{(1)} \le Y_{(2)} \le \cdots \le Y_{(N)}$$

Using the sorted numbers we first estimate $C(\boldsymbol{u})$. Since $C(\boldsymbol{u})$ is the $(1-P_e)$-quantile in the distribution, a natural estimator is:

$$\hat{C}(\boldsymbol{u}) = Y_{(k)},$$

where k is determined so that:

$$\frac{k}{N} \approx 1 - P_e.$$

Note, however, that this estimator can be improved considerably by using importance sampling. See Huseby et al. (2015b) for details.

For each $\boldsymbol{u} \in \mathcal{U}$, we also introduce the halfspaces:

$$\Pi^-(\boldsymbol{u}) = \{\boldsymbol{v} : \boldsymbol{u}'\boldsymbol{v} \le C(u)\},$$
$$\Pi^+(\boldsymbol{u}) = \{\boldsymbol{v} : \boldsymbol{u}'\boldsymbol{v} > C(u)\}.$$

We then define the environmental contour as the boundary $\partial\mathcal{B}$ of the *convex set* set $\mathcal{B}$ given by:

$$\mathcal{B} := \bigcap_{u \in \mathcal{U}} \Pi^-(u) \tag{8}$$

It follows that the exceedence probability of $\mathcal{B}$ with respect to $\mathcal{E}$ is given by:

$$P_e(\mathcal{B},\mathcal{E}) = \sup\{p_f(\mathcal{F}) : \mathcal{F} \in \mathcal{E}\}$$
$$= \sup\{p_f(\Pi^+(\boldsymbol{u})) : \boldsymbol{u} \in \mathcal{U}\}$$
$$= \sup_{u\in\mathcal{U}} P(\boldsymbol{u}'\boldsymbol{V} > C(\boldsymbol{u})) = P_e,$$

where the second equality follows since we have assumed that $\mathcal{F}$ is convex and hence contained in $\Pi^+(u)$ for all $\mathcal{F} \in \mathcal{E}$ In fact for all $u \in \mathcal{U}$ we have $\Pi^+(u) \in \mathcal{E}$ as well, and these halfspaces are the maximal sets within ε. Moreover, the last equation follows by the definition of $C(\boldsymbol{a})$ given in (7). Thus, we conclude that the contour $\partial\mathcal{B}$ indeed has the correct exceedence probability with respect to ε. See Huseby et al. (2017) for further details regarding this.

4 BUFFERED ENVIRONMENTAL CONTOURS

In this section, we introduce a new concept called *buffered environmental contours*. This combines the ideas behind buffered failure probabilities and environmental contours. Before we introduce the main results we review a result on superquantiles which will be essential in our approach (See Rockafellar (2007).)

Proposition 1. Let g_1 and g_2 be two performance functions such that $g_1(V) \le g_2(V)$ *almost surely, and let* $\bar{q}_{1,\alpha}$ *and* $\bar{q}_{2,\alpha}$ *denote the* α*-superquantiles of* g_1 *and* g_2 *respectively. Then* $\bar{q}_{1,\alpha} \le \bar{q}_{2,\alpha}$.

As a corollary of this result we get the following result on buffered failure probabilities:

Corollary 2. *Let* g_1 *and* g_2 *be two performance functions such that* $g_1(V) \le g_2(V)$ *almost surely, and let* $\bar{p}_{1,f}$ *and* $\bar{p}_{2,f}$ *denote the buffered failure probabilities of* g_1 *and* g_2 *respectively. Then* $\bar{p}_{1,f} \le \bar{p}_{2,f}$.

For a given performance function g its failure probability, p_f, can be computed based on the failure region of g alone. In contrast, computing the buffered failure probability, $\bar{p}_f$, requires more detailed information about the distribution of g. We indicate this by expressing $\bar{p}_f$ as a function of g and denoted $\bar{p}_f(g)$.

Just as for classical environmental contours, a *buffered environmental contour* is the boundary $\partial\mathcal{B}$ of some suitable set $\bar{\mathcal{B}} \subseteq \mathbb{R}^n$. We shall now describe how the set $\bar{\mathcal{B}}$ can be constructed. As in the previous section we let $\mathcal{U}$ be the set of all unit vectors in $\mathbb{R}^n$, and let $u \in \mathcal{U}$ Moreover, we let P_e be a given target probability, and let $C(\boldsymbol{u})$ be defined by (7). In order to introduce buffering, we let:

$$\bar{C}(\boldsymbol{u}) := \mathrm{E}[\boldsymbol{u}'\boldsymbol{V} \,|\, \boldsymbol{u}'\boldsymbol{V} \rangle C(u)]. \tag{9}$$

Given the distribution of V, the function $\bar{C}(u)$ can easily be estimated by using Monte Carlo simulation. As in Subsection 3.1, we let $V_1, \ldots, V_N$ be a random sample from the distribution of $\boldsymbol{V}$, and choose $u \in \mathcal{U}$. Based on the sorted values $Y_{(1)} \le Y_{(2)} \le \cdots \le Y_{(N)}$ we first estimate $C(\boldsymbol{u})$ by $Y_{(k)}$ as previously explained. We then estimate $\bar{C}(u)$ by computing the average value of the sampled values which are greater than $Y_{(k)}$. Thus, we estimate $\bar{C}(u)$ by:

$$\hat{\bar{C}}(\boldsymbol{u}) = \frac{1}{N-k}\sum_{r>k} Y_{(r)}.$$

For each $u \in \mathcal{U}$, we also introduce the halfspaces:

$$\bar{\Pi}^-(\boldsymbol{u}) = \{\boldsymbol{v} : \boldsymbol{u}'\boldsymbol{v} \le \bar{C}(\boldsymbol{u})\},$$
$$\bar{\Pi}^+(\boldsymbol{u}) = \{\boldsymbol{v} : \boldsymbol{u}'\boldsymbol{v} > \bar{C}(\boldsymbol{u})\},$$

similar to what we did in the previous section. Finally, we define the buffered environmental contour as the boundary $\partial\bar{\mathcal{B}}$ of the *convex set* set $\bar{\mathcal{B}}$ given by:

$$\bar{\mathcal{B}} := \bigcap_{u\in\mathcal{U}} \bar{\Pi}^-(\boldsymbol{u}) \tag{10}$$

We observe that by (12) we obviously have that $\bar{C}(\boldsymbol{u}) > C(\boldsymbol{u})$. . By comparing (8) and (10), it is easy to see that this implies that:

$$\mathcal{B} \subset \bar{\mathcal{B}}.$$

Thus, given that the same target probability P_e is used to construct both contours, the buffered environmental contour is more conservative than the classical environmental contour.

The next step is to identify a family $\mathcal{G}$ of performance functions defined relative to the set $\mathcal{B}$ such that $\bar{p}_f(g) \le P_e$ for all $g \in \mathcal{G}$ We recall that for the classical environmental contour we chose to let ε be the family of all convex failure regions which do not intersect with the interior of $\mathcal{B}$. Thus, one might think that the natural counterpart for buffered environmental contours would be to let $\mathcal{G}$ be the family of performance functions with convex failure regions which do not intersect with the interior of $\bar{\mathcal{B}}$. In this case, however, we need more control over the distributions of the performance functions. In order to do so we choose $u \in \mathcal{U}$ and introduce the performance function $\Gamma(u,\cdot)$ given by:

$$\Gamma(\boldsymbol{u},\boldsymbol{V}) = \boldsymbol{u}'\boldsymbol{V} - \bar{C}(\boldsymbol{u})$$

By (12) we have:

$$\mathrm{E}\left[\Gamma(\boldsymbol{u},\boldsymbol{V})\Gamma(\boldsymbol{u},\boldsymbol{V}) > C(\boldsymbol{u}) - \bar{C}(\boldsymbol{u})\right]$$
$$= \mathrm{E}[\boldsymbol{u}',\boldsymbol{V} \mid \boldsymbol{u}',\boldsymbol{V} > C(\boldsymbol{u})] - \bar{C}(\boldsymbol{u}) = 0.$$

Moreover, by (7) we have:

$$\begin{aligned}\bar{p}_f\left(\Gamma(\boldsymbol{u},\cdot)\right) &= P(\Gamma(\boldsymbol{u},\boldsymbol{V}) > C(\boldsymbol{u}) - \bar{C}(\boldsymbol{u})) \\ &= P(\boldsymbol{u}',\boldsymbol{V} > C(\boldsymbol{u})) = P_e\end{aligned}$$

Since the unit vector u was arbitrarily chosen, we conclude that the performance function $\Gamma(u,\cdot)$ has the desired buffered failure probability P_e for all $u \in \mathcal{U}$

We will use these performance functions as a basis for constructing the family $\mathcal{G}$ where the $\Gamma(u,\cdot)$-functions serve as *maximal* elements in this family. Note that the $\Gamma(u,\cdot)$-functions now play a similar role as the halfspaces $\Pi^+(u)$ played in the construction of the family $\mathcal{F}$. Thus, we let $\mathcal{G}$ be the family of all performance functions g for which there exists a $u \in \mathcal{U}$ such that $g(\boldsymbol{v}) \le \Gamma(\boldsymbol{u},\boldsymbol{v})$ for all $v \in \mathcal{V}$. By the above discussion the following result is immediate:

Theorem 3. For all $g \in \mathcal{G}$ we have $\bar{p}_f(g) \le P_e$..

Proof: Assume that $g \in \mathcal{G}$. Then there exists a $u \in \mathcal{U}$ such that $g(\boldsymbol{V}) \le \Gamma(\boldsymbol{u},\boldsymbol{V})$ almost surely. Hence, by Corollary 4.2 and the above calculations we have:

$$\bar{p}_f(g) \le \bar{p}_f\left(\Gamma(\boldsymbol{u},\cdot)\right) = P_e.$$

□

Having constructed both the set $\bar{\mathcal{B}}$ and the family $\mathcal{G}$ we are now ready to introduce the *buffered exceedence probability* of $\bar{\mathcal{B}}$ with respect to $\mathcal{G}$ defined as:

$$\bar{P}_e\left(\bar{\mathcal{B}},\mathcal{G}\right) := \sup\{\bar{p}_f(g) : g \in \mathcal{G}\}. \tag{11}$$

We note that by the definition of $\mathcal{G}$ it follows that $\Gamma(\boldsymbol{u},\cdot) \in \mathcal{G}$ for all $u \in \mathcal{U}$. Hence, we get:

$$\begin{aligned}\bar{P}_e\left(\bar{\mathcal{B}},\mathcal{G}\right) &= \sup\{\bar{p}_f(g) : g \in \mathcal{G}\} \\ &= \sup\{\bar{p}_f\left(\Gamma(\boldsymbol{u},\cdot)\right) : \boldsymbol{u} \in \mathcal{U}\} = P_e,\end{aligned}$$

Thus, we conclude that the contour $\partial\bar{\mathcal{B}}$ indeed has the correct buffered exceedence probability with respect to $\mathcal{G}$.

If $g \in \mathcal{G}$ and $g(\boldsymbol{v}) \le \Gamma(\boldsymbol{u},\boldsymbol{v})$ for all $v \in \mathcal{V}$, we have:

$$\begin{aligned}\mathcal{F}(g) \subseteq \mathcal{F}\left(\Gamma(\boldsymbol{u},\cdot)\right) &= \{\boldsymbol{v} : \boldsymbol{u}'\boldsymbol{v} - \bar{C}(\boldsymbol{u}) > 0\} \\ &= \{\boldsymbol{v} : \boldsymbol{u}'\boldsymbol{v} > \bar{C}(\boldsymbol{u})\} = \bar{\Pi}^+(u)\end{aligned}$$

Thus, the failure region of a performance function $g \in \mathcal{G}$ does not overlap with the interior of the set $\bar{\mathcal{B}}$, but is contained within a halfspace supporting $\bar{\mathcal{B}}$. This is similar to the relation between failure regions in the family ε and the set $\mathcal{B}$ for the classical environmental contours. However, as already pointed out, knowledge about the failure region of a performance function is not sufficient to ensure that the performance function has the correct buffered failure probability.

It may be argued that the choice of the $\Gamma(\boldsymbol{u},\cdot)$-functions as maximal elements in the family $\mathcal{G}$ is too restrictive. In order to have a more flexible framework, it is possible to consider a slightly more general approach where we define:

$$\bar{C}_a(\boldsymbol{u}) := \mathrm{E}[a\boldsymbol{u}'\boldsymbol{V} \,|\, \boldsymbol{u}'\boldsymbol{V} \rangle C(\boldsymbol{u})] = a\bar{C}(\boldsymbol{u}), \tag{12}$$

where a is a positive constant. By increasing the a-factor, the contour may be inflated so that it can be used for steeper performance factors.

On the other hand it should be noted that to ensure that a given performance function g has the correct buffered failure probability, it is not necessary that $g(v)$ is dominated by some $\Gamma(\boldsymbol{u},\cdot)$-function for *all* $v \in \mathcal{V}$. It is sufficient that this holds for v-values corresponding to the upper tail area of g.

5 NUMERICAL EXAMPLE

In this subsection we illustrate the proposed method by considering a numerical example introduced in Vanem & Bitner-Gregersen (2015). More specifically, we consider joint long-term models for *significant wave height*, denoted by H, and *wave period* denoted by T. A marginal distribution is fitted to the data for significant wave height and a conditional model, conditioned on the value of significant wave height, is subsequently fitted to the wave period. The joint model is the product of these distribution functions:

$$f_{T,H}(t,h) = f_H(h) f_{T|H}(t \,|\, h)$$

Simultaneous distributions have been fitted to data assuming a three-parameter Weibull distribution for the significant wave height, H, and a lognormal conditional distribution for the wave period, T. The three-parameter Weibull distribution is parameterized by a location parameter, γ, a scale parameter α, and a shape parameter β as follows:

$$f_H(h) = \frac{\beta}{\alpha}\left(\frac{h-\gamma}{\alpha}\right)^{\beta-1} e^{-[(h-\gamma)/\alpha]^\beta}, \quad h \ge \gamma.$$

The lognormal distribution has two parameters, the log-mean μ and the log-standard deviation σ and is expressed as:

$$f_{T|H}(t \,|\, h) = \frac{1}{t\sqrt{2\pi}} e^{-\left[(\ln(t)-\mu)^2/(2\sigma^2)\right]}, \quad t \ge 0,$$

where the dependence between H and T is modelled by letting the parameters μ and σ be expressed in terms of H as follows:

$$\mu = E\left[\ln(T) \mid H = h\right] = a_1 + a_2 h^{a_3},$$

$$\sigma = SD\left[\ln(T) \mid H = h\right] = b_1 + b_2 e^{b_3 h}.$$

The parameters a_1, a_2, a_3, b_1, b_2, b_3 are estimated using available data from the relevant geographical location. In the example considered here the parameters are fitted based on a data set from North West Australia. We consider data for two different cases: *swell* and *wind sea*. The parameters for the three-parameter Weibull distribution are listed in Table 1, while the parameters for the conditional log-normal distribution are listed in Table 2. In all the examples we use a return period of 25 years. The models are fitted using sea states representing periods of 1 hour. Thus, we get 24 data points per 24 hours. Thus, the desired exceedence probability is given by:

$$P_e = \frac{1}{25 \cdot 365.25 \cdot 24} = 4.5631 \cdot 10^{-6}.$$

For more details about these examples we refer to (Vanem & Bitner-Gregersen 2015).

The classical environmental contours are estimated based on the methods presented in Huseby et al. (2013). More specifically, we have used Method 2 presented in this paper. The buffered environmental contours are estimated in exactly the same way, except that $\hat{C}(\boldsymbol{u})$ is replaced by $\hat{C}(\boldsymbol{u})$ for all $\boldsymbol{u} \in \mathcal{U}$.

In Figure 3 and Figure 4 the resulting environment contours are shown. As one expected, the classical environmental contours are located inside their respective buffered contours. Thus, since the target probability P_e is the same for both types of contours, the buffered contours are more conservative than the classical contours.

Table 1. Fitted parameter for the three-parameter Weibull distribution for signifcant wave heights.

	α	β	γ
Swell	0.450	1.580	0.132
Wind sea	0.605	0.867	0.322

Table 2. Fitted parameter for the conditional log-normal distribution for wave periods.

		$i = 1$	$i = 2$	$i = 3$
Swell	a_i	0.010	2.543	0.032
	b_i	0.137	0.000	0.000
Wind sea	a_i	0.000	1.798	0.134
	b_i	0.042	0.224	–0.500

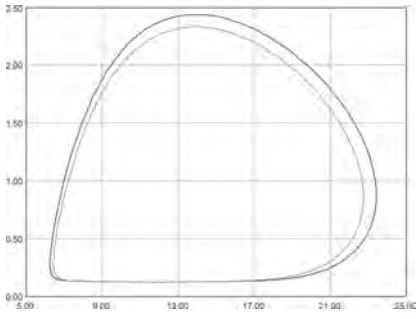

Figure 3. Buffered environmental contour (black) and classical environmental contour (gray) for North West Australia Swell with return period 25 years.

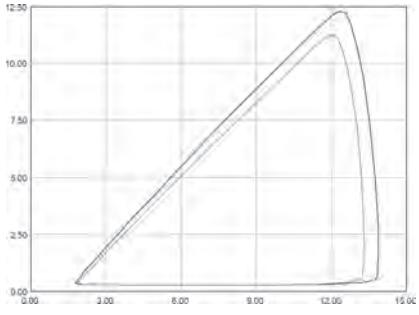

Figure 4. Buffered environmental contour (black) and classical environmental contour (gray) for North West Australia Wind sea with return period 25 years.

6 CONCLUSIONS AND FUTURE WORK

In the present paper we have introduced the concept of buffered environmental contours, and shown how such contours can be estimated using Monte Carlo simulations. Such contours do not just take into account the probability of failure, but also the consequences of a failure. This is relevant e.g., when analysing the risk of flooding at a given location. While it may not be possible to prevent floodings from occurring, the damage caused by such an event can vary a lot depending on how much the water has risen above the normal level. In some cases only minor damages may be the result. In other cases the consequences can be catastrophic.

For a given target probability, P_e buffered environmental contours are generally more conservative than the classical environmental contours. However, in cases where the consequences are more important than the triggering event itself, a higher target probability might be acceptable as long as the damages are manageable. Thus, in real-life applications a buffered environmental contour may not be so conservative after all. At the same time these contours provide much more information

about the tail area of the environmental variables. This may be very useful when a design is optimized.

The buffered environmental contours proposed in this paper are the natural extension of the Monte Carlo contours introduced in Huseby et al. (2013). In particular both contour types are boundaries of convex sets. Sometimes this restriction may lead to contours which include areas of very low probability. Thus, it would be of interest to investigate other ways of constructing buffered contours. In particular, it is possible to modify contours obtained by using the Rosenblatt transformation so that they include buffering. To make this work, however, evaluating the resulting contours becomes very important. The evaluation framework described in Huseby et al. (2017) may serve as a starting point.

Future work in this area also includes the use of buffered environmental contours in design optimization, but with additional design constraints. The question is how such additional constraints can be dealt with. An initial idea is to apply a Lagrange duality method in order to transform the problem into a previously known form.

It would also be interesting to compare buffered environmental contours to the conservative environmental contours defined by Leira (2008). The contours defined in Leira (2008) are typically larger sets than the environmental contours considered in Section 3, which means that they are more conservative when it comes to classifying structures as safe.

Another idea which requires further investigation is how time can be introduced into this model in a less restrictive way. As mentioned in Subsection 2.2, we consider average stochastic environmental conditions $V_1, V_2, \ldots$ over some specified time intervals and assume independence and identical distributions of the V_i s. A more realistic approach would be to introduce a stochastic process in continuous time modelling the environmental situation. It is interesting to see how this affects the model and what consequences this has for the design optimization.

Technical service life prediction of deteriorating structures

O. Lukoševičienė & R. Kliukas
Department of Civil Engineering, Vilnius Gediminas Technical University, Vilnius, Lithuania

ABSTRACT: The technical service life as a quantitative durability parameter of deteriorating structural members is studied. The probabilistic analysis and prediction of durability of deteriorating structures subjected to recurrent extreme service and climate actions is discussed. The strategy of this prediction is based on the concept that not only a performance but also a safety margin of deteriorating members of load-carrying structures are time-dependent random variables. The effect of coincident recurrent extreme actions on their survival probabilities is analysed. The instantaneous and time-dependent survival probabilities of particular members may be assessed by the method of transformed conditional probabilities. The technical service life t_t, as a quantitative durability parameter of deteriorating members is related with the target value of generalized reliability index. The presented methodology on durability prediction of structures may help engineers to calculate the technical service life of deteriorating structures.

1 INTRODUCTION

The load-carrying structures of buildings and construction works must be designed, constructed, erected and operated in such a way that they maintain safety and all quality parameters during an explicit or implicit period of time without requiring unforeseen costs for their maintenance, repair and reconstruction. Higher serviceability and durability requirements are applied to structures which routine or preventive maintenance and repair require great efforts (Lukoševičienė and Kudzys 2009). Timely maintenance and repairs may prolong their technical service life effectively. Qualitative and quantitative inspections in a standard format present the performance of materials and components. The contemporary standard ISO/CD 15686 (1997) recommends using inspections data for assessment and prediction of the durability of deteriorating and ageing members by deterministic and semi-probabilistic methods.

Stewart and Val (1999), Czarnecki and Nowak (2008), Cheung *et al.* (2009) developed probabilistic design approaches and models, describing gradually deteriorating concrete and steel structures of construction works. The random gradual deterioration of load-carrying systems and decrease in their structural reliability are caused by heterogeneous actions of dynamically changing environmental service loads, and aggressive accumulation of chemicals on concrete or steel surfaces of system members. Besides, a predictive reliability analysis of deteriorating members and systems is required to prevent structures from premature damage and to avoid losses and accidents.

But the technical service life, t_t, as basic durability factor of structural members has a big random scatter and should be treated as a stochastic variable which values may be assessed by probability-based approaches and methods. Besides, using deterministic and semi-probabilistic approaches, it is inconceivable to fix a real reliability index of a deteriorating member the failure domain of which changes with time. A durability as time-dependent probabilistic reliability of elements may be prolonged by repairs of materials and components. The standard differentiation in the reliability of structures is based only on classes of failure consequences (EN 1990 2002). However, the methodology of sustainable durability predictions requires taking into account future repair and replacement abilities of deteriorating structural members. The minimum values for reliability index, β_T, associate with the structures or structural members.

Purpose of this study is to suggest approaches of the probability-based prediction of a time-dependent safety, reliability index and technical service life of deteriorating members of structures when they are affected by aggressive actions and recurrent extreme loads.

2 RELIABILITY ANALYSIS OF DETERIORATING STRUCTURES

2.1 *Deterioration of load-carrying structures*

The probability-based reliability analysis of structural systems (frameworks, truss, carcasses) or their subsystems i.e. structural members (beams, slabs,

columns, joints) as physically distinguishable part of a building or civil engineering work may be objectively assessed and predicted only knowing survival probabilities of particular members (normal, cross or oblique sections, connections, deflections). The reliability prediction of deteriorating members and their systems will account for all extreme action combinations. Predicted durability parameters for deteriorating structures depend on chemical or physical diagnosis and the acceptable risk of serviceability failure associated with the damage levels and losses.

Aggressive actions induced by concrete carbonation, chloride penetration and other chemical attacks are the main factors determining the deterioration of concrete members and their systems (Lukoševičienė and Kudzys, 2009). The aggressive environmental conditions cause the degradation of concrete covers and reinforced bars lead to the irreversible limit state of load-bearing members. A process of concrete carbonation leading to global depassivation of reinforcement bars is initiated by carbon dioxide. The highly alkalinous environment with the pH value larger than 12 protects steel members from corrosion, when carbon dioxide, CO_2, reaches the reinforcing bars and the corrosion product, $Fe(OH)_2$, begins to cover their surfaces (CEB Bulletin 238, 1997). The values of deterministic durability parameters of members due to their deteriorating are assessed and presented at design codes or standards by deterministic implicit recommendations and related with long-term experience of designers (EN 1990, 2002; ISO 2394, 1998; EN 12500, 2000).

According to JCSS (2000), in any case, it is expedient to divide the life cycle t_n of deteriorating structures into the initiation, t_{in}, and propagation, t_{pr}, periods (Figure 1). Using hierarchical models, the time-dependent resistance and action effect are presented in Figure 1 (b). The resistance of particular members in the propagation may be defined as (Mori and Ellingwood, 1993)

$$R(t) = \varphi(t) R_{in} \tag{1}$$

where $\varphi(t)$ denotes the deterioration function; R_{in} is the initial value of member resistance.

The deterioration function of particular members caused by corrosion may be presented in the form:

$$\varphi(t) = 1 - a(t - t_{in})^b \le 1; \tag{2}$$

where a is a degradation intensity factor; b defines a non-linearity of the deterioration function; t – time being considered; t_{in} – time of corrosion initiation (Mori & Ellingwood, 1993; Zhong & Zhao, 2005). Deterioration function is close to rectlinear ($b \approx 1$) and parabolic ($b \approx 2$) when corresponding degradation mechanisms are a steel corrosion and aggressive environmental attacks. Marine corrosion process of steel structures is not linear function of time (Melcher et al., 2008). The deterioration function by Eq. (2) analysis are shown in Figure 2, when b = 1 and $a = 0.00125, 0.0025, 0.00375$ (rectlinears *2*, *3*, *4*), respectively. The coefficient of variation of deteriorating member resistance may be expressed as $\boldsymbol{\delta} R(t) = \left[\boldsymbol{\delta}^2 R_{in} + \boldsymbol{\delta}^2 \varphi(t)\right]^{1/2}$. Its components $\boldsymbol{\delta} R_{in} = \sigma R_{in} / R_{in,m}$ and $\boldsymbol{\delta} \varphi(t) = \sigma \varphi(t) / \varphi_m(t) = a_m (t - t_{in}) \times \boldsymbol{\delta} a / \left[1 - a_m (t - t_{in})\right]$ characterize the variations of initial resistance R_{in} and rectilinear deterioration function from Eq. (2). When the parameters of a factor a of this function $a_m < 0.005$, $\boldsymbol{\delta} a = 0.3 - 0.5$ and $\boldsymbol{\delta} R_{in} = 0.08 - 0.20$ the random value $\boldsymbol{\delta} R(t_{pr})$ insignificantly exceeds the coefficient of variation $\boldsymbol{\delta} R_{in}$. Therefore the variances of time-dependent and initial resistances of deteriorating particular members are very close in their values, i.e. $\boldsymbol{\sigma}^2 R(t) \approx \boldsymbol{\sigma}^2 R_{in}$.

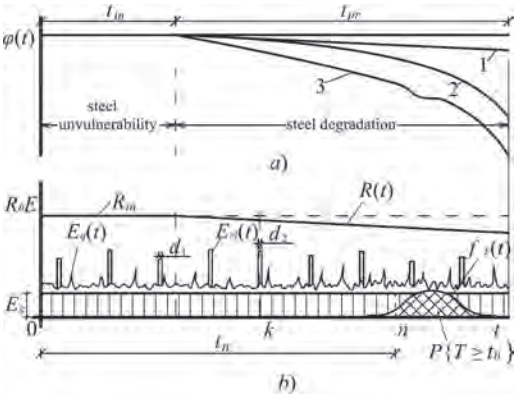

Figure 1. Degradation function $\varphi(t)$ (*a*) and dynamic model (*b*) for time-dependent reliability analysis: *1* – unloaded members, *2* – loaded columns, *3* – loaded beams (Kudzys & Lukoševičienė, 2009).

According to Stewart and Val (1999) also Enright and Frangopol (1998) studies of reinforcement corrosion of reinforced concrete bridge beams, it has led to propose several resistance deterioration functions (Figure 2) that relate to low, medium and high deterioration (curves 1, 5, 6), respectively:

$$\varphi(t) = 1 - at + a_1 t^2; \tag{3}$$

when

$$a = \begin{cases} 0.0005 & a_1 = 0 \;\; t_{in} = 10 \, years \;\; as \; low \\ 0.005 & a_1 = 0 \;\; t_{in} = 5 \, years \;\; as \; medium \\ 0.01 & a_1 = 0.00005 \;\; t_{in} = 2.5 \, years \;\; as \; high \end{cases}$$

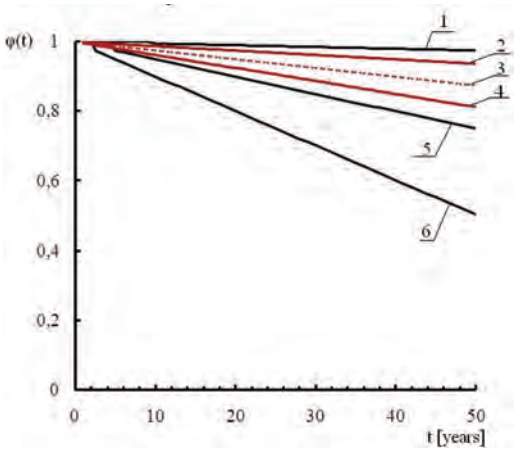

Figure 2. Deterioration function calculated using curves (*1*, *5*, *6*) from Eq. (3), rectlinears (*2*, *3*, *4*) from Eq. (2).

where a, a_1 – degradation intensity parameter. It is assumed that a_1 is a random variable with the coefficient of variation equal to 0.2.

The deterioration function in initiation and propagation periods of reinforced concrete and steel structures is shown in Figure 1 (a).

2.2 *Random safety margin of particular members*

Using the hierarchical dynamic model for time-dependent reliability analysis, the time-dependent safety margin of deteriorating particular members exposed to permanent and variable action effects may be written in the form:

$$Z(t) = g\left[\, \boldsymbol{X}(t), \boldsymbol{\theta} \right] = \theta_R R(t) - \theta_g E_g - \theta_q E_{q_s} - \\ - \theta_q E_{q_e}(t) - \theta_s E_s(t) - \theta_w E_w(t) \tag{4}$$

here $\boldsymbol{X}(t)$ and $\boldsymbol{\theta}$ are the vectors of basic physical and additional variables, representing random components (resistances and action effects) and their model uncertainties; $R(t)$ – time-dependent resistance of deteriorating members; $E_g, E_{q_s}, E_{q_e}, E_s$ and E_w are the action effects caused by permanent, sustained, extraordinary service (live), snow and wind loads, respectively; $\theta_R, \theta_g, \theta_{q_s}, \theta_{q_e}, \theta_s, \theta_w$ are additional random variables containing the design model uncertainties associated with resistances and action effects of particular members. The mean values and standard deviations of additional variables are: $\theta_{Rm} = 0.99 - 1.10$, $\boldsymbol{\sigma}\theta_R = 0.05 - 0.10$ and $\theta_{gm} = \theta_{q_s m} = \theta_{q_e m} = \theta_{sm} = \theta_{wm} \approx 1.00$, $\boldsymbol{\sigma}\theta_g = \boldsymbol{\sigma}\theta_{q_s} = \boldsymbol{\sigma}\theta_{q_e} = \boldsymbol{\sigma}\theta_s = \boldsymbol{\sigma}\theta_w \approx 0.10$ (Hong and Lind 1996, JCSS 2000);

The resistance as static or dynamic structural response for which a probability distribution can be described by normal or lognormal distribution laws (ISO 2394 1998; EN 1990 2002). According to JCSS (2000), EN 1990 (2002), ISO 2394 (1998), Mori and Kato (2003) recommendations, a Gaussian distribution law is to be used for permanent actions, when lognormal, Gaussian, Weibull and gamma distributions may be assumed for sustained live loads. Imposed intermittent extraordinary service and industrial actions may be assumed to be distributed by exponential law (Vrowenvelder 2002). The Gumbel cumulative distribution function is quite appropriate for the probability analysis of structures subjected to climate annual extreme wind and snow loads (ISO 4354 1998, JCSS 2000).

The structural safety analysis of deteriorating members may be based on the limit state criteria:

$$Z_k = R_k - E_k, k = 1, 2, ..., n-1, n, \tag{5}$$

where $R_k = \varphi_k \theta_R R_{in}$ is the resistance of deteriorating members at the sequence cut *k;* E_k is action effects at the same sequence cut k.

The means and variances of these components of the safety margin Z_k given by Eq. (5) may be expressed:

$$\left(\theta_R R_k\right)_m = \theta_{Rm}\left[1 - \alpha_m (t - t_{in})^{\beta}\right] R_{in,m} \tag{6}$$

$$\boldsymbol{\sigma}^2\left(\theta_R R\right) = \theta_{Rm}^2 \boldsymbol{\sigma}^2 R + R_m^2 \boldsymbol{\sigma}^2 \theta_R \tag{7}$$

$$\theta_{Em} E_m \tag{8}$$

$$\boldsymbol{\sigma}^2 E = \theta_{Em}^2 \boldsymbol{\sigma}^2 E_k + E_m^2 \boldsymbol{\sigma}^2 \theta_E. \tag{9}$$

When extreme action effects are caused by two stochastically independent variable actions, a failure of members may occur not only in the case of their coincidence but also when the value of one out of two effects is extreme. Therefore, three stochastically dependent safety margins should be considered as follows:

$$Z_{1k} = R_k - E_{1k}, k = 1, 2, ..., n_1, \tag{10}$$

$$Z_{2k} = R_k - E_{2k}, k = 1, 2, ..., n_2, \tag{11}$$

$$Z_{3k} = R_k - E_{12k} = R_{ck} - E_{1k} - E_{2k}, k = 1, 2, ..., n_{12}, \tag{12}$$

where n_{12} is the number of sequence cuts.

The durations of extreme floor and climate actions are: d_q = 1–14 days for merchant and 1–3 days for other buildings, d_s = 14–28 days and d_w = 8–12 hours. Renewal rates of annual extreme actions are equal to λ = 1/year. Therefore, the recurrence number of two joint extreme actions

during the design working life of structures, t_n in years, may be calculated by the formulae:

$$n_{12} = t_n(d_1 + d_2)\lambda_1\lambda_2 \tag{13}$$

where $\lambda_1 = \lambda_2 = 1/t_\lambda$ are the renewal rates of extreme loads (Lukoševičienė and Kudzys 2009).

2.3 *Instantaneous and time-dependent survival probabilities of particular members*

The instantaneous survival probability of particular members at k-th extreme situation, assuming that they were safe at the situations 1,2,…,k–1, may be expressed as:

$$P(S_k) = P(Z_k > 0) = P\{R_k - E_k > 0\},\ k = \overline{1,n} \tag{14}$$

The values of instantaneous survival probability of particular members may be calculated using analytical, numerical integration and Monte Carlo simulation methods. The resistance R_k and single extreme action effect E_k may be treated in the design of structural safety of ductile particular members as statistically independent variables of their random safety margins. Therefore, the instantaneous survival probability of deteriorating members can be expressed by convolution integral as:

$$P(S_k) = \int_0^\infty f_{R_k}(x) F_{E_k}(x)dx \tag{15}$$

where $f_{R_k}(x)$ is the density function of resistance of a member and $F_{E_k}(x)$ is the cumulative distribution function of its extreme action effect.

The computer program (Lukoševičienė and Kudzys, 2009) was written in the Matlab environment and adapted to predictions of time-dependent instantaneous survival probabilities of ductile autosystems of the reinforced concrete or steel members. So, the time-dependent survival probability of particular member as stochastic autosystem with n elements may be defined as follows:

$$P_{as}(S) = P(S_1) \times \prod_{k=2}^{n} \left(P(S_k) \times \left\{ 1 + \rho_{k|f}^{x_k} \left[\frac{1}{P(S_k)} - 1 \right] \right\} \right) \tag{16}$$

where n is the number of extreme situations;

$$\rho_{k|f}^{x_k} = \left(\frac{1}{k-1} \sum_{i=1}^{(k-1)} \rho_{ki} \right)^{x_k} \tag{17}$$

is the bounded conventional correlation factor of a quadratic matrix between safety margins of system elements as a member of conventional correlation vector written in the form:

$$\boldsymbol{\rho} = \left[1, \rho_{2|1}^{x_2}, \ldots, \rho_{k|1\ldots(k-1)}^{x_k} \right] \tag{18}$$

When the vector $\boldsymbol{\rho} = 0$ or $\boldsymbol{\rho} = 1$, the proposed Eqs. (16), (22) and (23) give accurate solution.

Basic correlation coefficients between system elements may be calculated by the equation:

$$\rho_{ki} = \rho(Z_k, Z_i) = \frac{Cov(Z_k, Z_i)}{\boldsymbol{\sigma} Z_k \cdot \boldsymbol{\sigma} Z_i} \tag{19}$$

where $Cov(Z_k, Z_i)$ and $\boldsymbol{\sigma} Z_k$, $\boldsymbol{\sigma} Z_i$ are covariance and standard deviations of safety margins Z_k and Z_i calculated by Eq. (5).

The bounded index of a conventional correlation factor may be expressed as:

$$x_k \approx P(S_1) \times \left[(4.5 + 4\rho_k)/(1 - 0.98\rho_k) \right]^{\nu_k} \tag{20}$$

where its index

$$\nu_k = \frac{\sum_{i=2}^{k} P(S_k)}{(k-1) \times (k + 2\beta_k^2 - 15\beta_k + 30)^{1/2}} \tag{21}$$

helps us evaluate an effect of survival probabilities of system elements $P(S_k) = \Phi(\beta_k)$ on the bounded index by Eq. (16) when a reliability index of k-th element is equal to β_k.

The relation between bounded correlation factor and correlation coefficient for systems consist of four and ten elements are presented in Figure 3.

2.4 *Technical service life prediction*

The technical service life as the lifetime at preset target reliability index of deteriorating members is the period for which it can actually perform, according to the service requirements based on an intended purpose, without major repairs. In any case, the technical service life, t_t, of members comes to an end before the beginning of concrete spalling or steel cracking process at an attack phase (Lukoševičienė and Kudzys, 2009). The design service life of structures is their working life used in the design process taking into consideration its probable dispersion since it is a time-dependent random quality. The design service life should ensure the required level of safety with respect to target service life (Poukhonto, 2003). Target service life of buildings and structures is specified by the client or owner in accordance with general rules (EN 1990, 2000; ISO 2394, 1998). The requirements for the technical service life

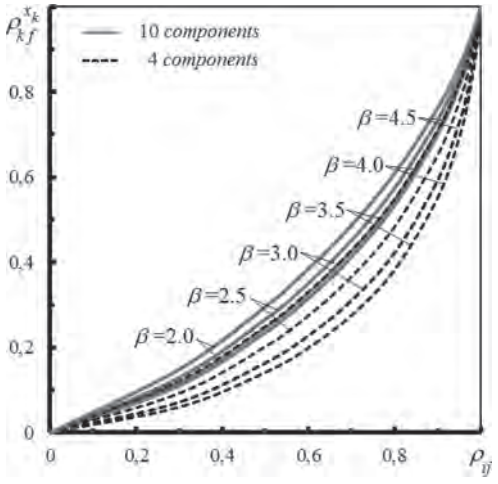

Figure 3. The bounded correlation factor versus basic correlation coefficient.

depending on the level under consideration, may be specified for structural integrity of the building, load carrying capacity and strength of the materials. Most of these requirements have been included in codes and standards (Trbojevic, 2009).

The durability prediction of structures should be considered for beams, columns, slabs, piles, joints and other structural members as auto systems representing their multicriteria failure mode due to various action effects and responses of particular members. Illustrations of series, series-parallel and parallel system are shown in Figure 4. For example, continuous beams are characterised using stochastically dependent conventional elements in series-parallel connections (Figure 4 (c)). Due to system redundancy, according to the research, limit state in any one normal section 1 or 2 of beams does not mean their failure. Besides, the failure of beams in any oblique section 3 implies the failure of auto system.

According to concepts of transformed conditional probabilities, the total survival probabilities of structural members (beams, columns, plates, trusses) as series, series-parallel and parallel systems may be expressed:

$$P_{ss}(S) \approx P(S_1)\times\prod_{k=2}^{m}\left(P(S_k)\times\left\{1+\rho_{k|f}^{x_k}\left[\frac{1}{P(S_k)}-1\right]\right\}\right) \quad (22)$$

$$P_{ps}(S) \approx 1-P(F_1)\times\prod_{k=2}^{m}\left(P(F_k)\times\left\{1+\rho_{k|f}^{x_k}\left[\frac{1}{P(F_k)}-1\right]\right\}\right) \quad (23)$$

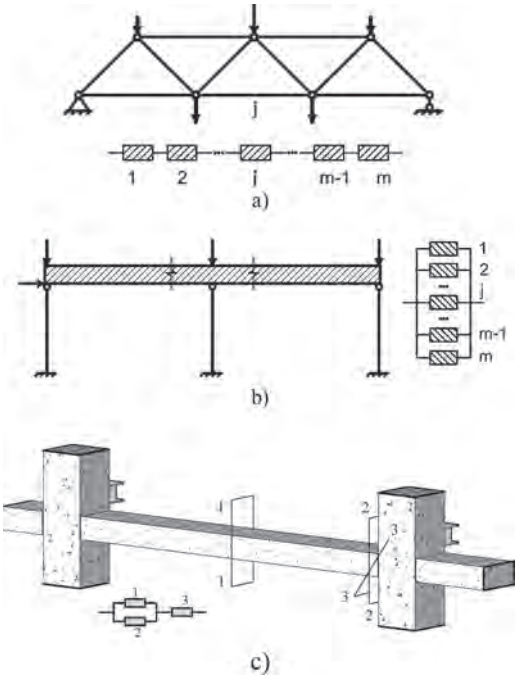

Figure 4. Illustrations of series (a), series-parallel (c) and parallel (b) systems.

$P(S_k)$ from Eq. (22) and $P(F_k)$ from Eq. (23) denote the survival and failure probabilities of ductile autosystem $k = 1\ldots m$; where m is the number of random discrete failure modes; $\rho_{k|f}^{x_k}$ is the bounded conventional correlation factor assessed by Eq. (17).

The generalized reliability indices of series and parallel systems are expressed by:

$$\beta_{ss} = \Phi^{-1}\left[P_{ss}(S)\right] \quad (24)$$

$$\beta_{ps} = \Phi^{-1}\left[P_{ps}(S)\right] \quad (25)$$

where $\Phi^{-1}[\bullet]$ is the inverse cumulative distribution function of the standard normal distribution of their survival probabilities $P_{ss}(S)$ by Eq. (22) and $P_{ps}(S)$ by Eq. (23) (Kudzys and Lukoševičienė 2016).

The design documents recommended by the Joint Committee on Structural Safety (JCSS, 2000) are acknowledged as the progressive probabilistic model code in the design of structural members and their systems. The reliability index of structures is related to the consequences of failure classes when the target value is equal to β_t = 3.3–4.3 (EN 1990, 2002; ISO 2394, 1998). Particular elements and members of the structure may be designed on

	carbonization	Chloride ions				
The 20th year	198×10^{-7}	107×10^{-7}	0.93	57×10^{-7} 56.8×10^{-7}	248×10^{-7} 248.2×10^{-7}	Zhong & Zhao (2005) TCPM
The 40th year	0.04847	0.00914	0.95	0.00908 0.00709	0.04853 0.05052	Zhong & Zhao (2005) TCPM
The 60th year	0.4053	0.1335	0.94	0.1334 0.1263	0.4054 0.4125	Zhong & Zhao (2005) TCPM

the same higher or lower reliability index as for the entire structure. The reliability classes may be defined by the reliability index β concept. Three reliability classes RC1, RC2 and RC3 may be associated with the three consequences classes CC1, CC2 and CC3.

The technical service lives as a quantitative durability parameter of deteriorating structural members may be calculated from Eqs. (22) – (23) when t_t its value becomes like to their life cycle t_n. The computation is iterated until the value t_t that corresponds the target probability $P(T \geq t_n) = \Phi(\beta_T)$ (Figure 5).

The value of technical service life, t_t, at preset reliability index can be defined by analytic-graphic approaches.

3 NUMERICAL EXAMPLES

3.1 *The time-dependent structural safety of deteriorating reinforced concrete members*

The time-dependent structural safety of deteriorating reinforced concrete members are investigated Zhong and Zhao (2005). They proposed the algorithm for failure probability analysis. This method, interesting for practical use, helps engineers to determine approximately the probability of a structure with different failure modes. The sufficient accuracy of numerical values by method of TCP in comparison with this algorithm and MCS methods is demonstrated in Table 1.

3.2 *Technical service life prediction of single storey building members*

The procedure of technical service life prediction is applied to the knee-joint of single storey reinforced concrete building (Figure 6).

Their degradation process is caused by concrete carbonation and the function is: $\varphi(t) = 1 - 0.004(t - t_{in})$, where $t_{in} = 12$ years is the initiation period. The values of parameters of additional variables are: $\theta_{Rm} = \theta_{gm} = \theta_{sm} = 1.0$, $\sigma^2\theta_R = \sigma^2\theta_g == \sigma^2\theta_s = 0$.

The values of mean and variance of shear resistances in this period are: $R_{in,m} = 387.6\ kN$, $\sigma^2 R_{in} = \sigma^2 R(t) = (0.128 \cdot 387.6)^2 = 2461.4(kN)^2$.

The values of means and variances of shear forces caused by permanent and snow loads are: $V_{gm} = 77.7\ kN$, $\sigma^2 V_g = (0.10 \cdot 77.7)^2 = 60.4\ (kN)^2$; $V_{sm} = 30.4\ kN$, $\sigma^2 V_s = (0.60 \cdot 30.4)^2 = 332.7\ (kN)^2$.

The time-dependent survival probability $P(T \geq t)$ of deteriorating knee-joints was calculated using the method of transformed conditional

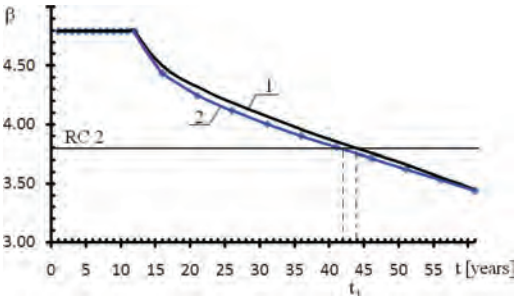

Figure 7. Technical service lives t_1 of knee-joints from the graph of time-dependent reliability indexes by TCPM (1) and numerical integration (2).

probabilities expressed by Eq. (22) and numerical integration methods. The time-dependent drop of reliability indexes $\beta(t) = \Phi^{-1}\left[P\left(T \geq t \right) \right]$ of knee-joints is demonstrated in Figure 7.

According to this Figure 7, the technical service live of considered knee-joints for structures RC2 class are equal about 42 or 44 years using the methods of transformed conditional probabilities (curve *1*) and numerical integration (curve *2*).

The illustrative examples show that the results of system analysis obtained by the proposed TCP method are very close to the probabilistic data computed by exact but sophisticated numerical integration.

4 CONCLUSIONS

The probabilistic technical service life concept related to target reliability indexes of deteriorating particular and structural members helps us to represent their quantitative durability. The probabilistic technical service life of structural members as series, series-parallel and parallel systems may be predicted by analytic-graphic method.

The probability-based analysis and durability prediction of deteriorating members as systems of extreme events may be related to the autosystem concept. The survival and failure probabilities of sustainable series, parallel and series-parallel systems may be calculated using the method of transformed conditional probabilities.

The presented probability-based approaches, design models on durability prediction of structural members may be convenient for many practitioners and can stimulate designers to predict the technical service life of deteriorating structures more actively and effectively.

Reliability quantitative analysis method for mechanical system by using extended fault tree

Tianxiang Yu, Yaxin Liu, Xinchen Zhuang & Bolin Shang
School of Aeronautics, Northwestern Polytechnical University, Xian, China

ABSTRACT: Fault tree analysis is an important method in safety engineering and reliability engineering, which is a top-down method and is able to map the relationship between complex events such as system-level failures and basic events such as component-level failures by creating a logic diagram of the overall system. For the reliability analysis of mechanical systems, it's extremely important to obtain the quantitative relationship between the failure and the design parameters except the logic relationship between the top event and the basic event in the design stage. However, the conventional fault tree analysis is hard to build such relationship. As a result, this paper extends the conventional fault tree by developing a new arborescence under basic events of fault tree. A kind of custom gate is defined within our new method. The custom gate is used to build the quantitative relation between the process variables (force, deformation and other performance feature), which can be used to characterize the basic failure mode, and basic random variables (dimension parameters, material parameters and load parameters, etc.). According to different failure models, the custom gate can be different. Then the limited state function of the basic event can be presented based on physical model. The procedure of this method is demonstrated in this paper, and different reliability models for mechanical system can be represented clearly. A Monte Carlo method involving dependent variables is provided to calculate probability of the top event. An illustrative example of a lock mechanism is presented to demonstrate the method in this work.

1 INTRODUCTION

With the rapid development of aerospace industry, the requirement of high-reliability mechanical system is increasing. The reliability evaluation of mechanical system is of great importance. However, the operation environment for mechanical system is getting more and more complex making reliability assessment of these systems harder.

Although reliability evaluation of electronic products is becoming much maturer based on probability and statistics theories, as well as the failure mechanism, it is still very hard when it comes to the reliability assessment of mechanical systems for the diversity of mechanical components and complexity of the failure mechanism. The conventional reliability assessment based on statistics cannot suit the mechanical system very well, as it is hard to associate the basic random variables (for example the component dimensions and the materials etc.) with the failure modes. As a result, the study of methods based on physical causal mechanisms focuses more on reliability of mechanical systems these years. These method combines probability theory with the physical modes [1–2], for instance, the method of Fault Tree Analysis (FTA).

In fault trees, the logical connections between faults and their causes are represented graphically. FTA is deductive in nature meaning that the analysis starts with a top event (a system failure) and works backwards from the top of the tree towards the leaves of the tree to determine the root causes of the top event [3]. FTA was first put forward in 1961 by Watson [4] of Bell Laboratory and was used in the development of Minuteman Missile. Then it was applied in nuclear industry in 1975 [5]. And in 1977, Lapp and Powers develop a method using computer to create fault trees automatically [6–7]. To overcome some shortcomings of conventional FTA, e.g. in handling the uncertainties, allowing the use of linguistic variables, and integrating human error in failure logic model, the fuzzy FTA [8] was developed. Fuzzy FTA provides a framework where basic notions such as similarity, uncertainty and preference can be modeled effectively. In 1994, Sawyer [9] published his paper on the fuzzy fault tree analysis of mechanical system. Lindhe [10] used fault tree analysis on an integrated level, and a probabilistic risk analysis of a large drinking water system in Sweden was carried out. Mao [11] applied fuzzy fault tree to analysis the automatic water supply system in fire control system. Then, dynamic fault tree (DFT) [12–13] is developed. DFT extend conventional FT by defining additional gates called dynamic gates to model complex interactions such as sequence and functional-dependent failures,

spares and dynamic redundancy management [14]. Yuan [15] applied a quantitative reliability analysis method to warm spare gate based on DFT. Nadjafi [16] investigated the reliability of Emergency Detection System, combining Fuzzy Monte Carlo Simulation and DFT.

Although plenty of work has been done on FTA, the present studies on FTA cannot comprehensively show the failure mechanism of mechanical systems. It is unable to track lowest level items that contributing to the failure modes. The probability statistical information of failure rate for bottom event is usually not sufficient, making the quantity analysis inaccurate. Besides, the correlation between the failure modes and the correlation between their causes are usually ignored. All these correlations make the reliability assessment intractable. Since the conventional fault tree is not accurate enough for complex mechanical system reliability assessment, it is necessary to develop an efficient method.

We improve the conventional FTA method and extend it into a new method. The method presented combines physical model with system reliability theory, and most importantly, can associate the basic variables with failure modes of mechanical systems in a systemic way. As a result, connections between faults and lowest level items are represented. In addition, the correlation of the failure modes can be easily identified with this method, and then correlation analysis can be carried out. Besides, this method is convenient to implement programmatically.

The rest of this paper is organized as follows: In section two, we provide an introduction on the conventional FTA method, and then our extended fault tree method is introduced. In section three, we provide the main process of mechanical system reliability assessment. In section four, we give out an engineering example to demonstrate our method. A brief closure, along with a summary of our future works is provided in section five.

2 FAULT TREE ANALYSIS

In this section, we will firstly give a general description about conventional fault tree on its structure and function. Then we will introduce our new method based on the conventional fault tree.

2.1 *Conventional fault tree*

Fault tree is a common method in system reliability analysis. Conventional fault tree is a kind of graphic method using logic gates to describe the relationship between a system-level failure and basic events such as component-level failures.

A fault tree contains four kinds of elements, which are described as follows:

1. The top event, which is on the root of fault tree, represents the failure of system. In mechanical system, the top event means the failure of the system. For example, the top event in fault tree shown in Figure 1 is "S–Re*l*"
2. The bottom events, which are on the tips of fault tree. The bottom events represent the kind of failure modes that can't be resolved any more. For example, in Figure 1, elements from $g_1 < 0$ to $g_3 < 0$ represent the bottom events.
3. The intermediate events. This kind of events is between the top event and bottom events, and represents the failure modes that can be the consequence of bottom events or other intermediate events. For example, in the fault tree shown in Figure 1, element M_1 is the intermediate event.
4. The logic gates. In fault tree, this kind of elements is used to connect events and describe logical relationship between them. The common used logic gates include AND gate and OR gate. The AND gate means that the event upon it happens if any one of the events below it happens. In another word, the events below AND gate are in series relationship.

The OR gate means that the event upon it happens only when all the events below it happens. In another word, the events below OR gate are in parallel relationship.

Using fault tree, we can estimate the importance degree of each event, and based on the assumption that value of each failure mode is certain, the probability of system failure can be evaluated ultimately.

2.2 *Extended fault tree*

Focusing on the complex characteristics of the failure modes in the mechanism system, we improve and extend the conventional FTA. The new method can be set into two parts: the system calculating tree and the failure mode calculating tree.

The system calculating tree is just the same as conventional fault tree. Each bottom event of system calculating tree is connected to the failure mode calculating tree as its top events.

For the system shown in Figure 1, the diagram of failure mode $g_1 < 0$ calculating tree is shown in Figure 2:

As is shown in Figure 2, the failure mode calculating tree includes four kinds of elements, which will be described in detail as follows:

1. The top node

The top node is put on the top of our new arborescence. This element represents a specific failure mode which is one of the bottom events in system

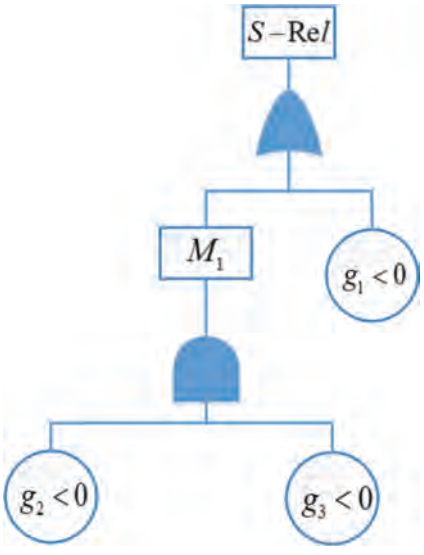

Figure 1. System calculating tree.

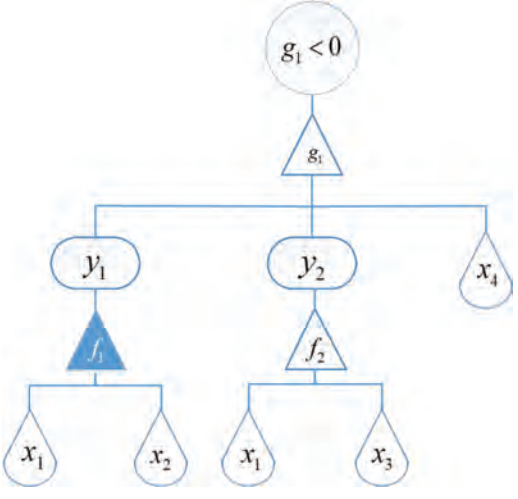

Figure 2. Failure mode calculating tree.

calculating tree. For example, in the failure mode calculating tree shown in Figure 2, the element $g < 0$ is the top node. For convenience of later calculation, we attach the reliability calculation methods to this node. These methods include FOSM, AFOSM, Monte Carlo, etc. As shown in Figure 3, we use a circle to represent the top node.

2. The bottom node

For mechanical system, this kind of elements represents the basic variables. The basic variables can be the geometry size or material of mechanical

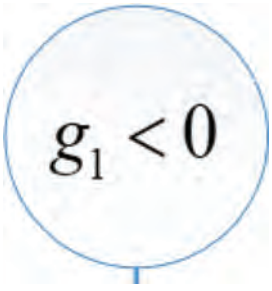

Figure 3. The top node.

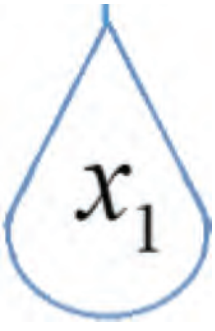

Figure 4. The bottom node.

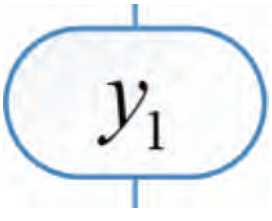

Figure 5. The intermediate node.

parts. In the failure mode calculating tree shown in Figure 2, the elements from x_1 to x_4 are the bottom nodes. Because basic design variables are random in actual engineering, we attach the statistical parameter to these bottom nodes. And in special condition, we will give the probability distribution function (CDF) and probability density function (PDF) of the basic design variables. As show in Figure 4, we use the shape of water drop to represent the bottom nodes.

3. The intermediate node

In Figure 3, the elements y_1 and y_2 are the intermediate nodes. For mechanical system, the intermediate nodes represent the process variables, which depend on the basic design variables. We use the shape in Figure 5 to represent the intermediate node.

4. The custom gate

The failure mode calculating tree is developed to establish connection between a specific failure mode and basic design variables. For this purpose, we put forward a kind of custom gate referring to the function of logic gate in conventional fault tree. We defined that a custom gate should have its input data, output data and a built-in function. The built-in function depends on the physical mechanism of the failure mode.

The custom gate is represented by triangle in the diagram and has different definition in different position.

1. For the connection between basic variables and a specific process variable, we define two kinds of custom gates, the explicit gate and the implicit gate, both of which use basic variables as its input data and process variables as its output data.

When the process variables are obtained by using specific software or algorithm to deal with basic variables, the implicit gate is available and represented by a blue triangle.

The build-in function of an implicit gate can be an instruction to call the proper software or algorithm. For the implicit gate in Figure 2, its build-in function is:

$$y_1 = f_1(x_1, x_2) \tag{1}$$

When there is analytic mathematical model between the process variable and basic variables, the explicit gate is available and represented by a white triangle. The build-in function of explicit gate in Figure 2 is:

$$y_2 = f_2(x_1, x_3) \tag{2}$$

The explicit gate and implicit gate is shown in Figure 6.

2. For the connection between process variables and a specific failure mode, we define a specific gate, the limit sate gate. As shown in Figure 7, this kind of gates use process variables and some basic variables as its input data and output the probability of the failure mode.

This gate contains a limit state equation. The limit state equation is defined by making the value

Figure 6. The implicit gate and explicit gate.

Figure 7. The gate of performance function.

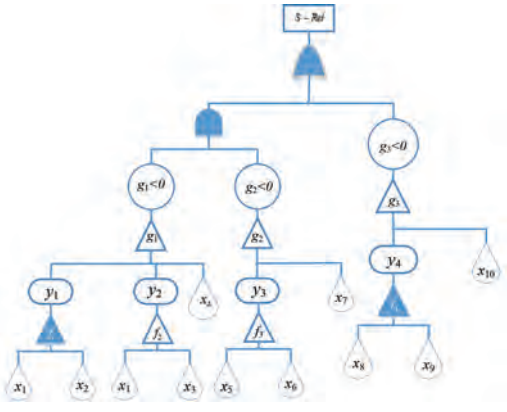

Figure 8. The extended fault tree.

of performance function based on the physical mechanism model of the failure mode equal to zero. For example, the limit state equation in Figure 2 can be expressed as:

$$g_1(y_1, y_2, x_4) = 0 \tag{3}$$

Attaching failure mode calculating tree to the bottom events of system calculating tree, we have our extended fault tree, as is shown in Figure 8.

Based on the extended fault tree described above, we can firstly use failure calculating tree to obtain the probability of each failure mode and then use system calculating tree to obtain the reliability of system.

We can see that there are two main advantages of our extended fault tree compared with the conventional one. First, using our new method, the relationship between basic variables and failure of system can be described in a clear and systematic way. Second, when it comes to a mechanical system with a plenty of complex failure modes, compared with the conventional fault tree, our method can obtain the probability of failure modes more accurately by using implicit gate and explicit gate.

3 PROCESS OF ANALYSIS

The quantitative analysis of the extended fault tree is presented in this section. For a complex mechanical system, in the process of quantitative reliability analysis, the main problem is correlation of the failure modes. To solve the problem of correlation and calculate the reliability of system, a method based on Monte Carlo simulation is provided. The main process is shown in Figure 9.

The process of analysis in detail is as follows:

1. Calculate the minimal cut sets

Cut sets are the unique combinations of failure modes that can cause system failure. Specifically, a cut set is said to be a minimal cut set if, when any basic event is removed from the set, the remaining events collectively are no longer a cut set [17]. The minimal cut sets can be obtained according to the method found by Fussel [18], which is based on the function of logic gates in system calculating tree. For the system shown in Figure 8, there are two minimal cut sets: $\{(g_1 < 0)\}$ and $\{(g_2 < 0),(g_3 < 0)\}$.

Once the minimal cut sets are acquired, then the structure function of system calculating tree can be expressed as:

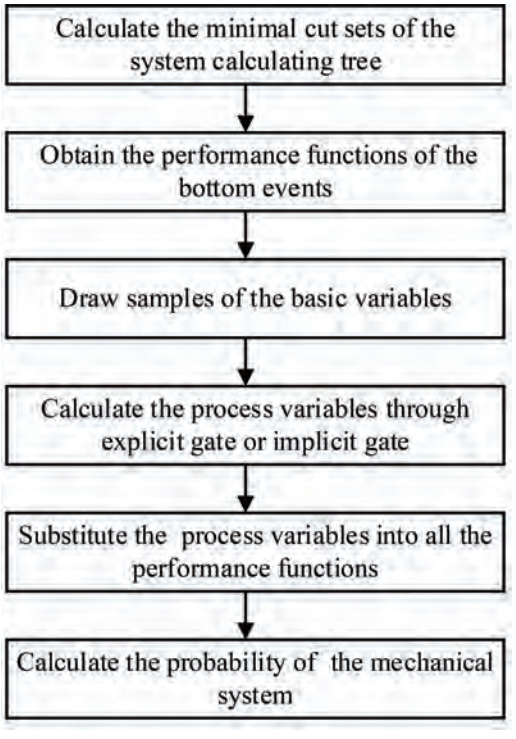

Figure 9. Flowchart of reliability assessment of the mechanical system using Monte Carlo simulation.

$$\Phi(X) = \sum_{j=1}^{N_K} K_j = \sum_{j=1}^{N_K} \prod_{i \in K_j} x_i \tag{4}$$

In Equation (4), N_K is the number of minimal cut sets. K_j represents the *jth* minimal cut, x_i means the *ith* bottom event in the *jth* minimal cut.

$$K_j = \prod_{i \in K_j} x_i \tag{5}$$

As a result, for the system shown in Figure 8, the probability of system failure can be expressed as:

$$P_f = P\{(g_1 < 0) \cup [(g_2 < 0) \cap (g_3 < 0)]\} \tag{6}$$

2. Obtain the performance function of the bottom event

The performance function of the bottom event is obtained by Failure mode calculating tree to associate the bottom nodes or process variables with the bottom event. The common methods used in this process include response surface method (RSM), Kriging method etc.

3. Probability calculation of top event in system calculating tree based on Monte Carlo simulation

The probability of top event in system calculating tree is calculated by

$$\begin{aligned} P(T) = P(K_1 \cup K_2 \cup \cdots \cup K_{N_k}) = \\ \sum_{i=1}^{N_k} P(K_i) - \sum_{i<j=2}^{N_k} P(K_i K_j) + \sum_{i<j<k=3}^{N_k} P(K_i K_j K_k) \\ + \cdots + (-1)^{N_k - 1} P(K_1 K_2 \cdots K_{N_k}) \end{aligned} \tag{7}$$

Considering the correlation between the bottom events and the correlation between minimal cut sets, Equation (7) cannot be solved analytically. Monte Carlo simulation is adopted. Each one of the bottom nodes is considered as a random variable with certain expected values and variances. We draw physical samples from these variables, and calculate the value of process variables by explicit gate or implicit gate. Then probability $P(K_1 K_2 \cdots K_N)$ in Equation (7) is acquired through process variables. At last, the probability of top event can be obtained.

4 CASE STUDY

In this section, we will use our new method to analysis the reliability of a kind of lock mechanism used to control the opening and closing of the aircraft landing gear cabin door.

The mechanism is shown in Figure 10. This system includes six components: a cylinder, a piston, a lock hook, a rocker arm and two connecting rods. There are six revolute joints in the system, which are represented by R0~R5 in Figure 10. The piston is connected to the rocker arm by a spring.

The system has three main failure modes: The start-up failure, the movement failure and the positioning failure.

Each of these failure modes can lead to the failure of system. As a result, the system calculating tree is shown in Figure 11.

In Figure 11, we use $g_1 < 0$ to represent the start-up failure, $g_2 < 0$ to represent the movement failure, $g_3 < 0$ to represent the positioning failure.

The start-up failure occurs when the starting force is smaller than a certain value. As a result, starting force F is considered as the failure index.

The performance function of start-up failure is shown in Equation (8)

$$g_1 = F - [F] \tag{8}$$

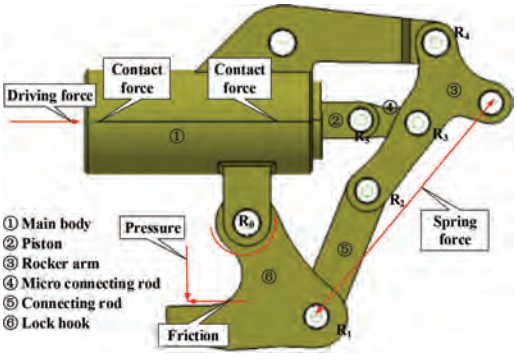

Figure 10. The lock mechanism.

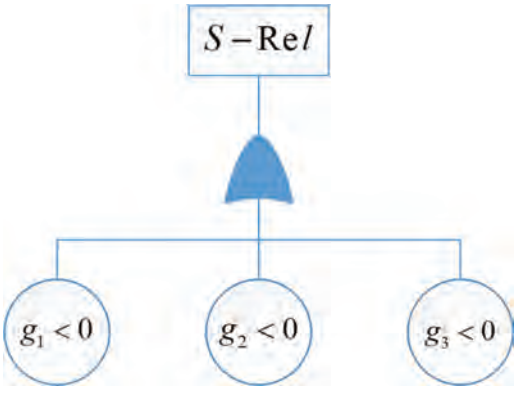

Figure 11. System calculating tree of the lock mechanism.

where F represents the starting force, $[F]$ represents the limit state value of starting force.

The movement failure occurs when time to unlock is shorter than a certain value. As a result, unlocking time is considered as the failure index and the performance function of the movement failure is shown in Equation (9)

$$g_2 = t - [t] \tag{9}$$

where t represents the unlocking time, $[t]$ represent the limit state value of unlocking time.

For both the failure of start-up and movement, there are five influence factors, which are considered as random variables. The distributions of these variables are shown in Table 1.

In Table 1, X_1 represents the elastic coefficient of the spring; X_2 represents the damping coefficient of the spring; X_3 represents the decoupling angle between the lock hook and the lock ring; X_4 represents the maximum contact force between the lock hook and the lock ring; X_5 represents the change rate of driving force attached on piston. There are no explicit functions for the two failure modes. As a result, the implicit functions of these two failure modes are obtained by the dynamics simulation software: LMS Virtual. Lab, as is shown in Figure 12.

As a result, the start-up force and unlocking time can be expressed as follows:

Table 1. The distributions of random variable in the mechanism.

Variables/Unit	Distribution	Mean value	Standard deviation
X_1/(N/m)	Normal	5620	100
X_2/(kg/s)	Normal	478	10
X_3/deg	Normal	46.5	0.5
X_4/N	Normal	4000	400
X_5	normal	14	0.02

Figure 12. Simulation model.

$$F = F(X_1, X_2, X_3, X_4, X_5) \tag{10}$$

$$t = t(X_1, X_2, X_3, X_4, X_5) \tag{11}$$

As a consequence, the failure mode calculating trees of start-up failure and movement failure is shown in Figure 13.

For the positioning failure, to establish the geometric model, we simplify Figure 8 into Figure 14.

Based on the geometric model shown in Figure 9, deflection h is considered as the index of positioning accuracy of the mechanism. The performance function of positioning failure can be expressed as

$$g_3 = h - [h] \tag{12}$$

where h represents the deflection, $[h]$ represents the limit state value of deflection.

According to Figure 12, the deflection h can be written as:

$$h(a,b,f) = a \cdot \sin\left(\frac{\arccos\left(a^2 + f^2 - b^2\right)}{2 \cdot a \cdot f}\right) \tag{13}$$

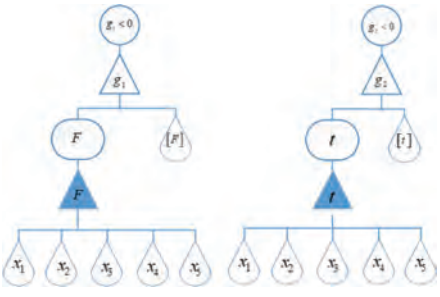

Figure 13. Failure mode calculating trees of start-up failure and movement failure.

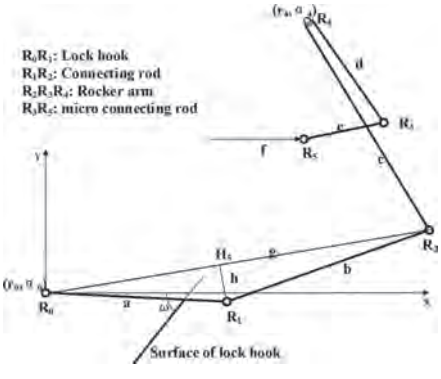

Figure 14. Schematic diagram of the system.

In Equation (13), there are three independent variables: the length of the lock hook represented by a, the length of connecting rod represented by b, the length of piston represented by f. These independent variables are random due to manufacture errors and assembly tolerance. The distributions of their error are shown in Table 2.

Then the failure mode calculating tree of positioning failure is shown in Figure 15.

According to the method mentioned in this paper, the extended fault tree of this lock mechanism is shown in Figure 16.

From Figure 16, it can be concluded that start-up failure and the movement failure are dependent. The positioning failure is independent with the other two failure modes.

There are three minimal cut sets: $\{(g_1 < 0)\}$, $\{(g_2 < 0)\}$ and $\{(g_3 < 0)\}$. According to the process of analysis in Section 3, 1,000,000 samples of the variables (X1, X2, X3, X4, X5, a, b, f) are drawn. Substitute the samples into Equation (10), (11), (13) corresponding the three failure modes. For the three failure modes, failures occur if the values are less than or equal to zero. The probabilities of the three

failure modes are 0.0035, 0.0045 and 0.0082, respectively. The probability of the lock system is 0.0141.

5 CONCLUSIONS

In this paper, a new method of mechanical system reliability quantitative analysis using extended fault tree is introduced. Focusing on the failure modes of mechanism system, we improve and extend the conventional FTA. The new method can be set into two parts: the system calculating tree and the failure mode calculating tree. A kind of custom gate is defined in our new method to associate the basic random variables and the bottom events. A procedure for reliability evaluation of the mechanical system based on the extended fault tree is provided, in which the correlation of the bottom events is considered. A lock mechanism is investigated to demonstrate our method. The result shows that our extended fault tree can effectively be used to assess the reliability of the mechanical system.

In the process of our study, it is found that the correlation exists in mechanical system is extremely complex. As a consequence, in the future, we will focus more on correlation exists among failure modes, and develop a series of software based on our extended fault tree.

Research on kinematic reliability of flapping mechanism for flapping wing flight

Z. Yang & J. Xuan
School of Aeronautics, Northwestern Polytechnical University, Xi'an, Shaanxi, China

ABSTRACT: As the core component, the kinematic reliability of flapping mechanism influences the flight accuracy and efficiency of flapping wing flight directly. The joint clearance caused by wear is the most important factor affecting the kinematic accuracy of the mechanism, which directly affects the control accuracy and flight. This paper analyzes the kinematic reliability of flapping wing mechanism with different clearance of hinges based on the dynamics of mechanisms with clearance. The variation of the flutter angle, flutter angular velocity and angular acceleration of wingtip with different clearance are calculated. The Multiple joints clearance are considered in the flapping wing mechanism. Synchronous accuracy of two wings also be analyzed. Results show the relationships of the flutter angle, flutter angular velocity, angular acceleration and the joints clearance. The results can be used to optimize the flapping mechanism structure parameters.

1 INTRODUCTION

Flapping wing flight (MAV) is a kind of aircraft that imitates the flying creature of nature and relies on flapping wings to generate lift and thrust power simultaneously. It has the unique advantages of high flight efficiency, high maneuverability and compact structure. As the core component, the kinematic reliability of flapping mechanism influences the flight accuracy and efficiency of flapping wing flight directly, such as the kinematic accuracy and synchronism of flapping mechanism. The joint clearance caused by wear is the most important factor affecting the kinematic accuracy of the mechanism, which directly affects the control accuracy and flight. Therefore, the kinematic accuracy and synchronization of flapping wing mechanism with hinge clearance should be investigated.

Tsai (2004) presents an effective method to analyze the transmission performance of linkages. Equivalent kinematical pairs were used to model the motion freedom caused by the joint clearances. The mechanism positions are solved. Ting (2000) analyzes the influence of joint clearance on accuracy of position. Flores (2012, 2012, 2010, 2007) public a series of articles for the mechanism modeling with joint clearance, and also develop algorithm to solve.

Liu (2006, 2007) analyze the force-displacement relationship of spherical joints with clearances based on the Hertz theory.

This paper aims to analyze the kinematic reliability of flapping wing mechanism with different clearance of hinges based on the dynamics of mechanisms with clearance. The flutter angle, flutter angular velocity and angular acceleration of wingtip with different clearance are calculated. The Multiple joints clearance are considered in the flapping wing mechanism. Synchronous accuracy of two wings are also analyzed. The relationships between the flutter angle, flutter angular velocity, angular acceleration and the joint clearance are determined.

2 EVALUATION OF MECHANISM SYNCHRONIZATION

2.1 *Synchronization*

Assuming that: achieving some function needs n mechanisms to conduct the design motions synchronously; the allowable maximum time difference for the mechanisms to finish the motion is ε; t_i is the time that the mechanism i needs to finish the motion. Then the expression for the synchronization requirement of the mechanisms is shown as the following equation:

$$\max(t_i) - \min(t_j) < \varepsilon, (1 \le i, j \le n) \tag{1}$$

If the mechanisms that require motion synchronization are parallel mechanisms, which means the

mechanisms have same design motion and working conditions, then the motion synchronization of the mechanisms can be expressed in another way: the displacement difference of these mechanisms are supposed not to be greater than the prescribed tolerance at the same moment. Assuming that: achieving some function needs n mechanisms to conduct the design motions synchronously; the allowable maximum position difference at the same moment is ε; q_i is the position where the mechanism i is. Then the expression for the synchronization requirement of the mechanisms is shown as the following equation:

$$\max(q_i) - \min(q_j) < \varepsilon, (1 \le i, j \le n) \tag{2}$$

2.2 *The evaluation method of the mechanism synchronization based on the interval estimation*

The traditional probability-based evaluation method of mechanism synchronization can solve the synchronization problems with same probability distribution types and parameters. However, the probability distribution types and parameters are rarely the same in real engineering problems. Therefore, it is better to apply the evaluation method of the mechanism synchronization which is based on the interval estimation.

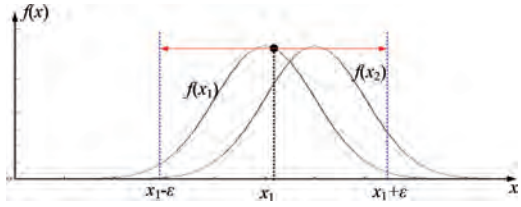

Figure 1. Interval schematic diagram of two mechanism synchronization.

Based on the analysis of two mechanisms, the motion synchronization of three mechanisms can be analyzed. If two mechanisms satisfy the synchronization requirement, then the motion time of the third mechanism must range between $\max(x_1,x_2) - \varepsilon$ and $\min(x_1,x_2) + \varepsilon$. If $x_1 > x_2$, the range of x_3 is $[x_1 - \varepsilon, x_2 + \varepsilon]$; if $x_1 < x_2$, the range of x_3 is $[x_2 - \varepsilon, x_1 + \varepsilon]$. The time interval of synchronization is shown in Fig. 2 and the synchronization probability can be expressed as the following formula:

$$R_{\text{syn}} = \int_0^{\infty} f_1(x_1)\left[\int_{x_1-\varepsilon}^{x_1} f_2(x_2)\left[\int_{x_1-\varepsilon}^{x_2+\varepsilon} f_3(x_3)\mathrm{d}x_3\right]\mathrm{d}x_2\right]\mathrm{d}x_1 + \int_0^{\infty} f_1(x_1)\left[\int_{x_1}^{x_1+\varepsilon} f_2(x_2)\left[\int_{x_2-\varepsilon}^{x_1+\varepsilon} f_3(x_3)\mathrm{d}x_3\right]\mathrm{d}x_2\right]\mathrm{d}x_1 \tag{4}$$

Accordingly, the formula of the synchronization probability of n mechanisms can be deduced:

$$R_{\text{syn}} = \int_0^{\infty} f_1(x_1)\left[\int_{x_1-\varepsilon}^{x_1+\varepsilon} f_2(x_2)\left[\int_{\max(x_1,x_2)-\varepsilon}^{\min(x_1,x_2)+\varepsilon} f_3(x_3)\ldots\int_{\max(x_1,x_2,\ldots,x_{n-1})-\varepsilon}^{\min(x_1,x_2,\ldots,x_{n-1})+\varepsilon} f_n(x_n)\mathrm{d}x_n\ldots\mathrm{d}x_3\right]\mathrm{d}x_2\right]\mathrm{d}x_1 \tag{5}$$

For a system with n mechanisms, the motion times of the mechanisms, which are expressed as x_i ($i = 1,\ldots,n$), are random variables. Besides, the probability density function of x_i is set as $f_i(x_i)$, $i = 1,\ldots,n$.

The allowable maximum time difference for the mechanisms to finish the motion is ε. For any two mechanisms in the system, this requirement can be transformed as a probability requirement: $P\{|x_i - x_j| \le \varepsilon\}$.

For the two mechanisms, once the motion time of one of the mechanism x_1 is determined, then the motion time of the second mechanism should range in $[x_1 - \varepsilon, x_1 + \varepsilon]$ to satisfy the synchronization requirement. As shown in Fig. 1, the probability for the two mechanisms' synchronization can be expressed as the following formula:

$$R = \int_0^{\infty} f_1(x_1)\left[\int_{x_1-\varepsilon}^{x_1+\varepsilon} f_2(x_2)\mathrm{d}x_2\right]\mathrm{d}x_1 \tag{3}$$

As can be seen in Formula (5), the synchronization probability of n mechanisms can be expressed by n-ple integrals. In the n-ple integrals, the upper and lower limits of the outermost layer variable x_1 is the range of the system's motion time, normally as $[0,\infty)$, while the upper and lower limits of every inner layer variable is determined according to the number size of the outer layer variables.

The inner layer integral cannot be solved directly, as its upper and lower limits is determined according to the number size of the outer layer variables. Therefore, the interval method is used to transform the non-deterministic upper and lower limits to deterministic upper and lower limits for the inner layer integral, then the Formula (5) can be solved.

As can be seen in the above analysis, when two mechanisms are considered, there is one independ-

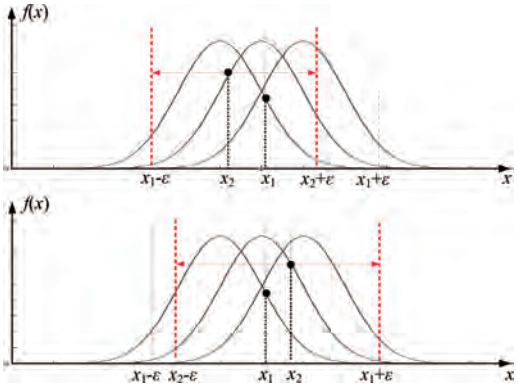

Figure 2. Interval schematic diagram of three mechanism synchronization.

Table 1. The relationship of mechanisms number n and independent integral interval number N.

Number of mechanism	2	3	4	5	…	n
x_{i-1} number of positon	1	2	3	4	…	n–1
Number of Independent interval	1	2	6	24	…	(n–1)!

ent integral interval; when three mechanisms are considered, there are two independent integral intervals; when four mechanisms are considered, there are six independent integral intervals; when n mechanisms are considered, the integral interval of every variable is determined by the number size of all variable before it. Therefore, for a system with n mechanisms, there are $N = (n - 1)!$ independent integral intervals. The relationship of mechanisms number n and independent integral interval number N is listed in Table 1.

From the above analysis, it can be seen that the synchronization probability of n mechanisms can be expressed as the sum of $(n - 1)!$ n-ple integrals. As the $(n - 1)!$ integrals are independent with each other, the synchronization probability of n mechanisms can be deduced:

$$R_n = \sum_{i=1}^{(n-1)!} R_{n,i} \tag{6}$$

For most of the probability distributions, though their probability density functions are elementary functions, their integrals are not elementary functions. Therefore, numerical methods are needed to calculate the synchronization probability of mechanisms, which mainly include numerical integration methods and Monte Carlo Method.

1. Solving the n-ple integrals by Numerical Integration Method

If the n-ple integrals cannot be expressed by elementary functions, then the Newton-Leibniz Equation is not able to solve the integrals. Therefore, the integral equation is transformed to the limit equation:

$$I = \int_a^b f(x)\mathrm{d}x = \lim_{h\to 0} f(\xi_i)h_i \tag{7}$$

In Formula (7), $h_i = x_i - x_{i-1}, x_{i-1} \le \xi_i \le x_i, a \le x_0 < x_1 < \ldots < x_n \le b$. Then an approximation method can be used as shown in the formula:

$$I = \int_a^b f(x)\mathrm{d}x \approx \sum_{i=0}^{n} A_i f(x_i) = I_n \tag{8}$$

In the above formula, $\{x_i\}_{i=0}^n$ are integral nodes, and $\{A_i\}_{i=0}^n$ are the multiplier parameters.

The frequently-used numerical integral methods are: interpolated quadrature formula, complex quadrature formula, Romberg quadrature formula and Gauss quadrature formula.

The n-ple integral can be solved by repeatedly solving the single integral using the above methods.

2. Solving the n-ple integrals by Monte Carlo Method

Assuming that D is a region in the n-dimensional space R_n, $f(x) \in D \subset R_n \to R$, the n-ple integrals on the region D can be expressed as:

$$I = \int_D f(p)\mathrm{d}p \tag{9}$$

where, I can be regarded as the result expectation of the region's measure multiplying function f on the region D. The fundamental Monte Carlo Method is to find a hypercube (with known measure M_c) which contains region D, generate n sample points which obey the uniform distribution in the hypercube, and counting the number of sample points in the region D. Assuming that there is m out n sample points in the regions D, then the measure of region D is approximated as:

$$M_D \approx \frac{mM_c}{n} \tag{10}$$

The expectation of the function f:

$$\bar{f} \approx \frac{1}{m}\sum_{i\in D} f(p_i) \tag{11}$$

2.3 *The analysis of mechanism synchronization*

For the system with n mechanisms, the motion time of every mechanism is random variable and expressed as x_i, $i = 1, \ldots, n$ respectively. The total load

of the system is random variable is also a random variable and expressed as z. As the motion time of mechanism i is related to several influence factors, such as mechanism parameters, working loads and environment conditions, assume that the function of the motion time and the influence factors is:

$$x_i = f(\mathrm{y}_{i1}, \mathrm{y}_{i2}, \cdots \mathrm{y}_{im}, \alpha_i \cdot \mathrm{z}) \tag{12}$$

In the function, $\mathrm{y}_{i1}, \mathrm{y}_{i2}, \cdots \mathrm{y}_{im}$ are m random variables that influence the motion time of the mechanism i, α_i is the load weight of the load on mechanism i to the total load and it is related to the mechanism parameters:

$$\alpha_1 + \alpha_2 + \cdots + \alpha_n = 1 \tag{13}$$

The synchronization requirement of two mechanisms can be expressed as:

$$\max_{\substack{0<i,j<n \\ i \neq j}} (|\mathrm{x}_i - \mathrm{x}_j|) \leq \varepsilon \tag{14}$$

As for the synchronization evaluation of two mechanisms, Coupla function $\mathrm{C}_\theta(u,v)$ can be used, in which θ is the correlation parameter of two mechanisms. The Coupla function can be obtained by sample fitting, and the synchronization probability can be expressed as:

$$R = \int_0^\infty f_1(x_1) \left[\int_{x_1-\varepsilon}^{x_1+\varepsilon} \frac{\partial^2 C_\theta(u,v)}{\partial u \partial v} f_2(x_2) \mathrm{d}x_2 \right] \mathrm{d}x_1 \tag{15}$$

As for the synchronization evaluation of three mechanisms or more, firstly use the sample fitting to obtain the Coupla function, then obtain the joint probability density function $f(x_1, x_2, \ldots x_n)$ via the edge probability density function $f(x_i)$, then the synchronization probability of multi mechanisms can be figured out combined with interval evaluation method.

For the system in which the mechanisms are not independent, as the motion times are correlated with each other and the correlation can hardly be illustrated in mathematical forms, so it is very difficult to obtain the synchronization probability using only mathematical methods. For these non-independent cases, the method combined dynamic simulation and sampling calculation is widely used to obtain the synchronization probability of the mechanisms in the system.

3 SYNCHRONISM ANALYSIS OF FLAPPING MECHANISM

3.1 *Flapping mechanism*

The structure of flapping wing is shown as Fig. 3. The principle of flapping mechanism is shown as

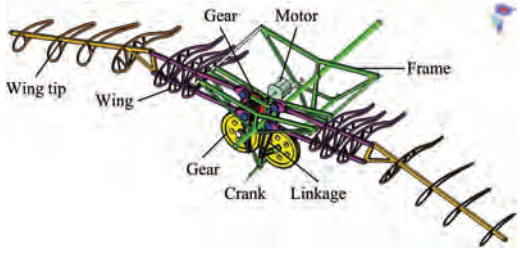

Figure 3. The structure of flapping wing.

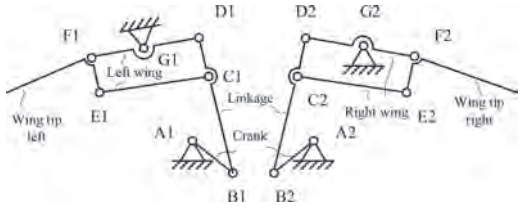

Figure 4. The principle of flapping mechanism.

Table 2. Dimension of revolute joint with clearance.

Revolute joint	Diameter of shaft	Diameter of sleeve
B_1	3	2.6
C_1	12	11.2
D_1	12	11.2
E_1	5.5	5

Fig. 4. The crank drive mechanism to maintain uniform rotation, and drive the wing tip under flutter through the connecting rod.

3.2 *Dynamic simulation of flapping wing mechanism*

LMS Virtual Lab is used to construct dynamic model. For the kinematic pair with joint clearance, combing spherical contact with plane pair to substitute the rotation pair, dimension of revolute joint with clearance are shown as Table 2. The variation of wingtip angle, angular velocity and angular acceleration with time can be calculated. The results are shown as Fig. 5 to Fig. 9.

We can conclude from those figures, the variations of wingtip angle with joint clearance are obvious, especially at the limit position; the variations of wingtip angle velocity with joint clearance are bigger, fluctuate around ideal position; the variations of wingtip angle velocity with joint clearance are extreme, the wingtip is under extreme shock load.

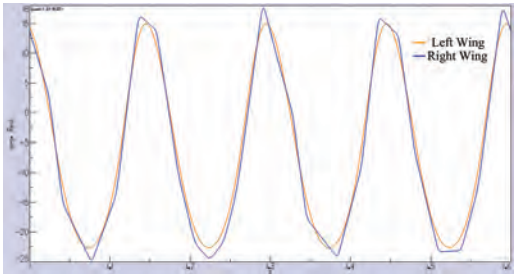

Figure 5. The variation of wingtip angle with time.

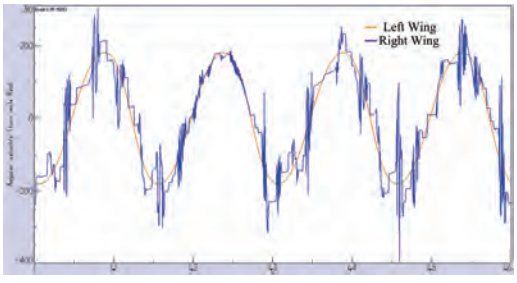

Figure 6. The variation of wingtip angular velocity with time.

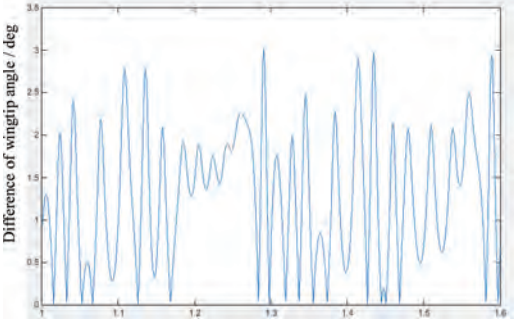

Figure 7. The variation of wingtip angular acceleration with time.

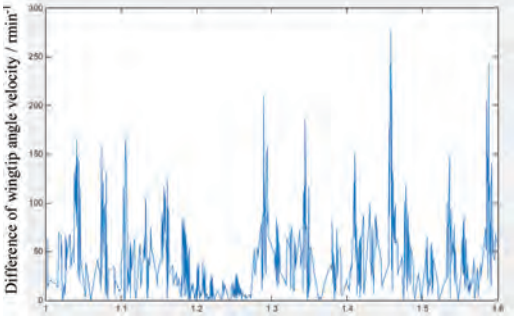

Figure 8. The velocity difference of left and right wing tip with time.

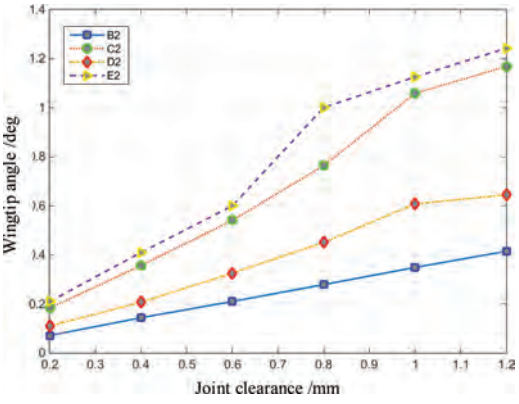

Figure 9. The difference of left and right wingtip angle with time and clearance position.

3.3 *Influence of clearance on motion synchronism*

To analyze the variation of wingtip angle with joint clearance, the joints clearance of B2, C2, D2, E2 are setup from 0.2 mm to 1.2 mm, the difference between left and right wingtips are calculate. The results are shown as Fig. 9.

From the Fig. 9, as the clearance increased, the difference of left and right wingtip is increased. The influence of value of revolute clearance E2 is biggest, and the influence of value of revolute clearance B2 is smallest.

4 CONCLUSIONS

This paper aims to analyze the kinematic reliability of flapping wing mechanism with different joint clearance based on the dynamics of mechanisms with clearance. The results can be used to optimize the flapping mechanism structure parameters. The conclusions as follows.

- The variations of wingtip angle with joint clearance are obviously, especially at the limit position; the variations of wingtip angle velocity with joint clearance are large, fluctuate around ideal position; the variations of wingtip angle velocity with joint clearance are extremely large, the wingtip is under extremely shock load.
- As the clearance increased, the difference of left and right wingtip is increased. The influence of value of revolute clearance E2 is largest, and the influence of value of revolute clearance B2 is smallest.

ABSTRACT: In the last fifteen years the subset sampling method has often been used in reliability problems as a tool for calculating small probabilities. This method is extrapolating from an initial Monte Carlo estimate for the probability content ofa failure domain found by a suitable higher level of the original limit state function. Then iteratively conditional probabilities are estimated for failures domains decreasing to the original failure domain. Here is explained why this concept is very problematic.

1 INTRODUCTION

A basic problem of structural reliability is the calculation of failure probabilities given by *n*-dimensional integrals in the following form

$$P = \int_{g(x)<0} f(x)\, dx \tag{1}$$

Here $f(x)$ is an n-dimensional PDF (probability density function) of a random vector X and $g(x)$ is the LSF (limit state function) giving the failure condition. During the development of structural reliability methods it was found to be favorable to transform the random vector X into a standard normal random vector U with independents components. So the problem was then in this standardized form:

$$P = (2\pi)^{-n/2} \int_{g(u)<0} \exp\left(-\frac{|u|^2}{2}\right) du \tag{2}$$

Such transformations into the standard normal space for random vectors with independent components have been described first by Rackwitz & Fiessler (1977). For random vectors with dependent components the Rosenblatt-transformation is proposed to obtain a transformation but with the exception of the example given in Hohenbichler & Rackwitz (1981) no applications of this transformation concept are known to the author. A practically applicable method seems to be the Nataf-transformation described in Der Kiureghian & Liu (1986).

A newer method for the calculation of failure probabilities is the subset simulation concept. It will be outlined here that there is an intrinsic flaw in it.

2 GLOBAL AND LOCAL EXTREMA

Shortly a few basic facts about local and global extrema are outlined here before proceeding. Let be given a function $f : D \to \mathrm{R}$. A local minimum (maximum) is a point $x_0 \in D$ such that there exists a neighborhood u of x_0 that for all $x \in U \cap D$ one has always

$$f(x) \geq f(x_0) \left(\text{resp.}\ f(x) \leq f(x_0)\right) \tag{3}$$

In a similar way a global minimum (maximum) for this function is defined as a point $x_1 \in D$ such that for all $x \in D$ always

$$f(x) \geq f(x_0) \left(\text{resp.}\ f(x) \leq f(x_0)\right) \tag{4}$$

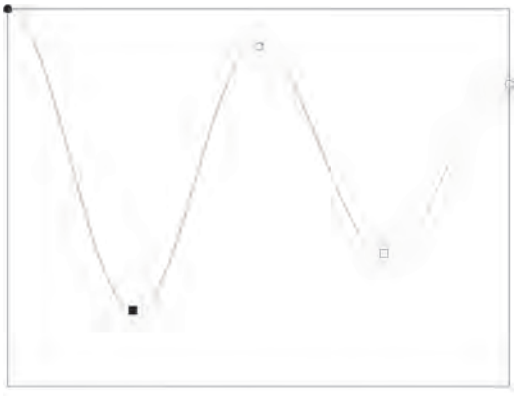
The first is a local property of the function, it depends only on its behavior in any arbitrary small neighborhood of the point. The second is global, one has to know the values of the function over the whole domain of definition. Therefore methods to find local extrema are plentiful and described in all textbooks about numerical analysis, whereas in these textbooks the problem of finding global extrema is covered only in a marginal way (see for e.g. Nocedal & Wright (1999)).

In handling optimization problems it is important to be aware if one searches a global or a local extremum. Mostly a global should be found. But this is often done by using methods for determining local extrema and then in some way a conclusion is made that the obtained local extremum is also a global.

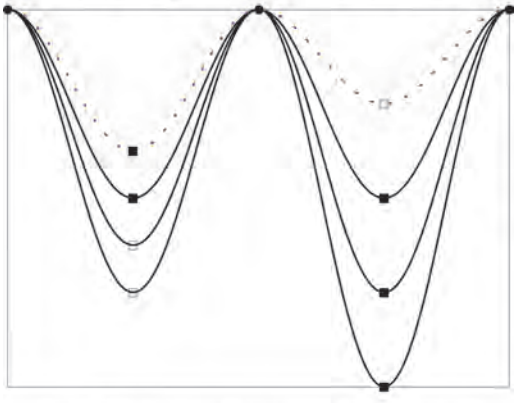
The most usual naïve way for this is to start a local minimum search several times from random starting points and record all obtained local minimum. The

smallest of these can then be considered a global one with some confidence, if enough runs have been made.

In finding global extrema a common misunderstanding is that if one has a function depending on a parameter in a continuous way that then with a continuous change of it also the positions of the global extrema move continuously. But in fact these points jump also in non-pathological cases. In Figure 1(a) for a simple one-dimensional example the difference between local and global extrema is shown. In Figure 1(b) the global minima for a function depending on a parameter are shown, the lower ones by solid curves and the upmost function is shown by a dotted curve. For the three lower functions global minima are on the left side, forthe



(a) Local and global extrema of a function



(b) The global minima of a function depending on a parameter

Figure 1. Global and local extrema of functions: minima are shown by squares, maxima by circles, filled symbols are global extrema.

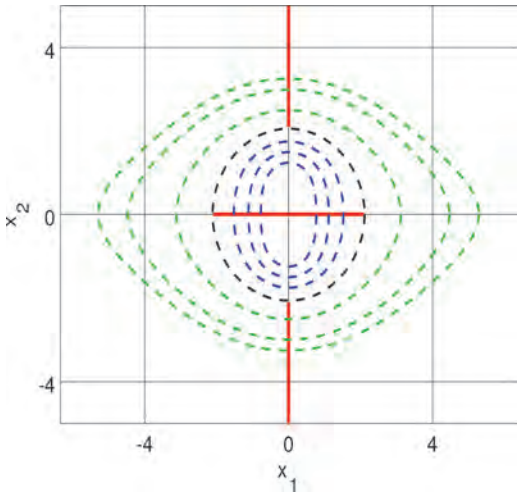


Figure 2. Constrained minimal distance points for the function given in equation (5).

two upper global minima are on the right side of the figure. The second function from above has two minima. The upmost function, denoted by a dotted curve, has its global minimum on the left side of the figure. This shows that the position of a global minimum of a function depending on a parameter does not necessarily vary continuously if the parameter is varied continuously.

Also in global optimization under constraints the minimum points tend to jump if the problem is non-trivial. This will be shown in the following simple example. Let be given a LSF defined by

$$g(u_1,u_2) = \beta - u_1^2 - \frac{u_1^2+u_2^2}{b^2}u_2^2 = \beta - u_1^2 - \frac{\left(u_1^2u_2^2+u_2^4\right)}{b^2} \tag{5}$$

In Figure 2 the positions of the global minima of $|u|$ under the constraint $g(u)=c$ are on the red line segments. Reaching the black circle they jump. In Zhigljavsky & žilinskas (2008) the problem of distinguishing between a local and a global maximum is explained in detail in the first chapter. This is one of the main problems in global optimization. Failing to understand this and accepting local extrema asglobal ones might lead to erroneous results.

3 ASYMPTOTIC ANALYSIS AND FAILURE PROBABILITIES

With concepts of asymptotic analysis one can get asymptotic approximation for failure probabilities. Here only an extremly shortened version is given,

for more details see Breitung (1994). This concept considers the failure probability as a function of the distance of the failure probability to the origin β, defined by

$$\beta = \min_{g(u)\le 0} |u| \tag{6}$$

For smooth LSF's β is the distance of one or more points on the limit state surface $\{g(u)=0\}$ to the origin. If the failure domain F is imbedded into a family of expanding surfaces one has asymptotically

$$\mathrm{P}(F) \approx \Phi(-\beta) \prod_{i=1}^{n-1} (1-\beta\kappa_i)^{-1/2} \tag{7}$$

with the κ_i the main curvatures of the limit state surface at the point u_0, called design point. In the case of several such points their contributions will be added. So looking at the example in Figure 3 the curvatures at the two points are needed for the asymptotic approximation. Does one need the curvatures? Not necessarily. The lemma of Hohenbichler (Breitung (1994), p. 53) says that an approximation can be obtained also if one can calculate the probability content of the neighborhoods of the design points. So one has Figure 4

$$\mathrm{P}(F) \approx \mathrm{P}(A_1) + \mathrm{P}(A_2) \tag{8}$$

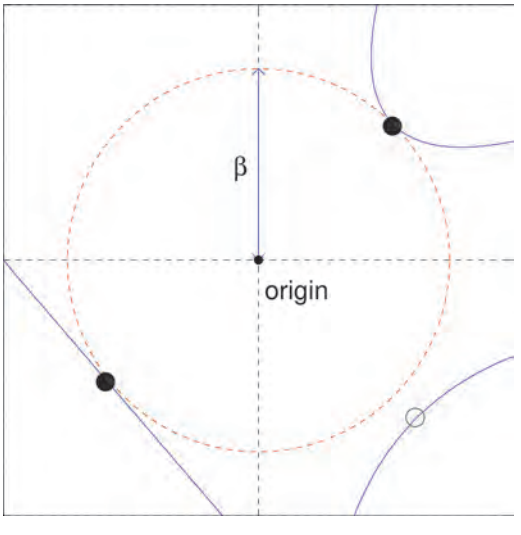

Figure 3. Asymptotic approximation with curvatures.

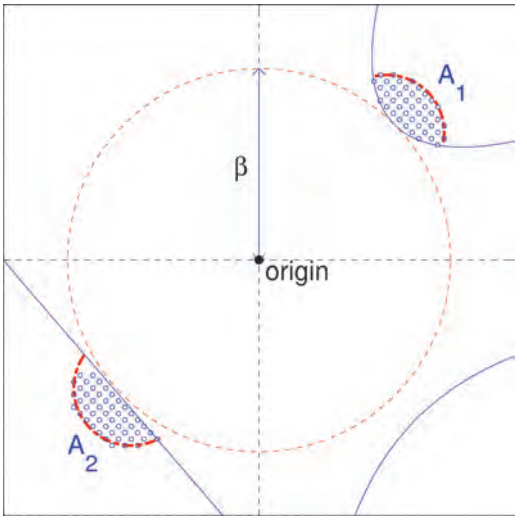

Figure 4. Asymptotic approximation calculating the probability content of the neighborhoods.

4 THE SUBSET SIMULATION CONCEPT

The subset simulation algorithm is a variant of Monte Carlo methods; it tries to avoid the large number of data points which are needed in standard Monte Carlo by using instead of it an iterative procedure. It can be subsumed under the generic term of stochastic optimization procedures.

While importance sampling methods try to improve the efficiency of Monte Carlo by identifying regions with high probability content and moving more date points there, SuS starts from an enlarged failure domain whose design points are much nearer to the origin and then moves step by step towards the original failure domain. These regions are defined here by domains in the form $F_i = \{g(u) < a_i\}$ with the a_i's being positive and $a_i \to 0$. The basic thought of the method (see (Au & Beck 2001) and (Au & Wang 2014)) is now to write the failure probability $P(F)$ as a product of conditional probabilities

$$\begin{aligned} \mathrm{P}(F_n) &= \mathrm{P}(F_1 \mid F_0)\mathrm{P}(F_2 \mid F_1)\ldots\mathrm{P}(F_n \mid F_{n-1}) \\ &= \prod_{k=0}^{n-1} \mathrm{P}(F_{k+1} \mid F_k) \end{aligned} \tag{9}$$

Here $\mathbb{R}^n = F_0 \supset F_1 \supset F_2 \supset \ldots \supset F_n = F$. In Figure 5 such a standard case is shown, the design points for the various LSF's are shown by black squares. Since the respective (suitably chosen) conditional probabilities are relatively large compared with the failure probability P(F) which has to be estimated, such an access to the problem has the advantage that these conditional probabilities can

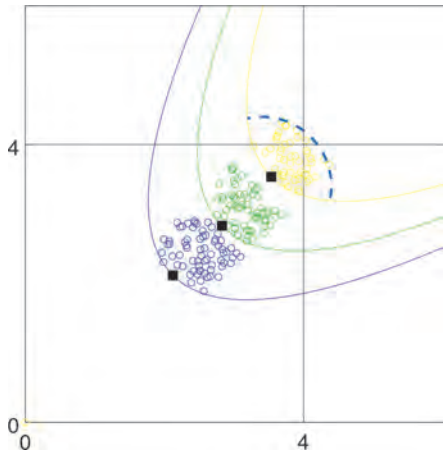

Figure 5. Typical SuS example.

be estimated more efficiently with much smaller sample sizes. The details how these samples are produced with Monte Carlo Markov chains can be found in the references given above. SuS can be seen as a stochastic continuation method (this concept is explained in Allgower & Georg (2003)). Such methods try to extrapolate from a point x which solves an equation system $F(x, \tau)$ for a given values of the parameter τ to find solutions for other values of τ.

5 SUBSET SIMULATION AND STOCHASTIC MINIMIZATION

It seems not to be quite clear how to classify this SuS in mathematics, it uses MCMC as a tool, but MCMC is not the objective. The goal of the approach is to find an estimator $\hat{p}$ for the unknown probability $p = \mathrm{P}(F_n)$. Now in a Bayesian setting estimation procedures are mostly based on using a loss function and then determining the estimator as a minimizer ofthe expected value of the loss function. This is outlined in Box & Tiao (1973), appendix A5.6, p. 308. For a loss function $L(.)$ then the estimator $\hat{\theta}$ for a parameter θ is chosen such that

$$IE\Big(L\big(\hat{\theta} - \theta\big)\Big) \to \min \tag{10}$$

Therefore a parameter estimation always is transformed into a minimization problem. Since there is a stochastic component, it is a stochastic minimization and since one wants the best estimator, it is a global stochastic minimization (see e.g. Spall (2004)).

In SuS the chosen loss function is the squared coefficient of variation for the estimator $\widehat{\mathrm{P}(F_n)} = \hat{p}$

$$IE\left[\left(\frac{\hat{p} - p}{p} \right)^2 \right] \to \min \tag{11}$$

Under the assumption of unbiasedness and independence of the estimators $\hat{p}_i = \widehat{\mathrm{P}(F_i \mid F_{i-1})}$ of this can be approximated by

$$IE\left[\left(\frac{\hat{p} - p}{p} \right)^2 \right] \approx \sum_i IE\left[\left(\frac{\widehat{p_i} - p_i}{p_i} \right)^2 \right] \tag{12}$$

Then the approximative optimal estimator is given by choosing for the $\hat{p}_i$'s the value of the empirical conditional distribution function at the points c_i, since these are unbiased minimal variance estimators for the p_i's (see e.g. Lehmann & Casella (1998)). This shows that the estimation in SuS is a minimization procedure. And the goal is clearly to find an estimator which achieves the global minimum value for the estimation error in equation (12).

6 EXAMPLES

All the examples with the exception of the last one were calculated with the SuS algorithm given in Li & Cao (2016). For the last example the algorithm given in Uribe (2016) was used, since it records the seeds. As parameters were taken 500 samples per step, an acceptance probability of 0.1 and a chain length of ten. This setup was used in Au & Wang (2014) for estimates of the context of two-dimensional domains. The design points are marked by red circles and the SuS data points by green points.

The focus here is on the geometric structure of the failure domains and their design points, on purpose the different probability estimates which can be computed are excluded. Only two-dimensional cases are considered, since only for them it is possible to produce informative diagrams showing the behavior of the algorithm.

The claim of SuS proponents is that the method is much more general than FORM/SORM and makes no use of design point concepts. But this should mean that for such simple two-dimensional cases, where it is essential to find the design points for getting useful estimates of the reliability index and/or the failure probability, also the SuS approach should give *a fortiori* good results.

In the examples cases are shown where the data points of the SuS algorithm move not to the design point but to points further away from the origin

than the design point leading to an overestimation of the reliability index and an underestimation of the failure probability. In Breitung (2016) and Breitung (2017) similar examples were studied.

6.1 *Basic example*

A simple example will show the misunderstanding in the SuS algorithm about global and local minimization. Let be given two LSF's g_1 and g_2 and together with them define a third g as minimum of both:

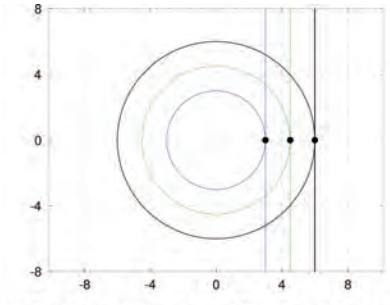
$$\begin{aligned} g_1(u_1,u_2) &= 6-\frac{u_1}{6} \\ g_2(u_1,u_2) &= 5+u_1, \\ g(u_1,u_2) &= \min(g_1,g_2) \end{aligned} \tag{13}$$

Consider now two reliability problems. In the first the failure domain is given by

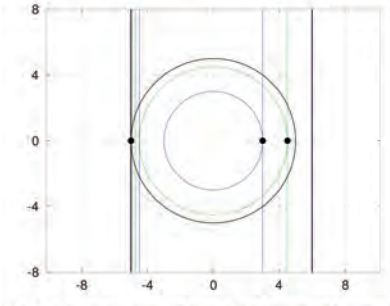
$$F_1 = \{g_1(u_1,u_2) < 0\} \tag{14}$$

In the second the failure domain F is given by

$$F = \{g(u_1,u_2) < 0\} \tag{15}$$

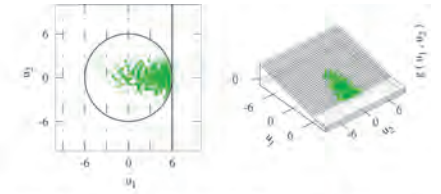


(a) The design points (black filled circles) for the LSF's $g_1(u_1,u_2) = 0.5, 0.25, 0$

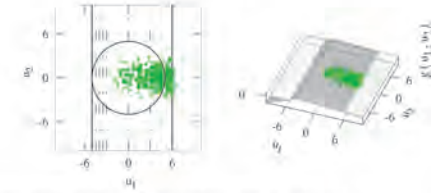


(b) The design points (black filled circles) for the LSF's $g(u_1,u_2) = 0.5, 0.25, 0$

Figure 6. The design points for the LSF's g_1 and g.



(a) SuS algorithm for the LSF g_1, a) solid line contour $g_1 = 0$, dash-dotted lines further contours for $g_1 > 0$, b) graph of g_1; green dots show SuS data points



(b) SuS algorithm for the LSF g, a) contour line $g = 0$, b) graph of g; green dots show SuS data points

Figure 7. SuS for the LSF's g_1 and g.

In both cases it is a series system which fails if at least one of the two functions is less than zero. The LSF's are shown in Figure 7. The SuS algorithm works correctly in the first case, see Figure 7a, but fails for the second, see Figure 7b.

6.2 *Invariance*

An important reason that the Hasofer-Lind index was adopted as a measure for reliability is its invariance under reformulations or reparametrizations of the underlying reliability problem (see Hasofer & Lind (1974)). Also the convergence proofs for the beta point search algorithms do not depend on the specific form of the LSF. But clearly one has to start the search algorithm from different points to obtain all global minimal distance points, i.e. design points. Consider now a series system consisting of two independent components, so failure occurs if at least one fails. The first component fails if $u_1 > 5$ and the second component if $u_2 < -4$. Now, this limit state surface can be the zero set of different LSF's. For example, one has

$$g(u_1,u_2) = \min\begin{cases} 5-u_1 \\ 4+u_2 \end{cases} \tag{16}$$

Here both LSF's are linear, with SuS one obtains as expected an estimate for the asymptotic failure probability approximation $\widehat{P(F)} \approx \Phi(-4) \approx 3.17 \cdot 10^{-5}$. The performance of the SuS method is shown in Figure 8.

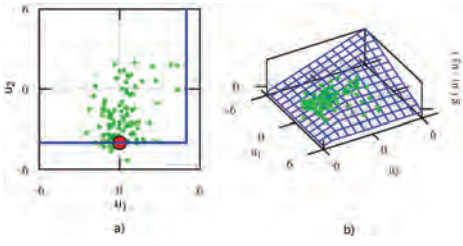


Figure 8. Series system defined by LSF in equation (16).

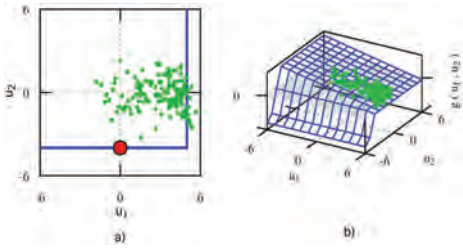

Figure 9. Series system defined by LSF in equation (18).

Assume now that the LSF for the second random variable is given not by a linear but by a logistic function in the form:

$$g_2^*(u_2) = \frac{1}{1+exp\,(-2(u_2+4))} - 0.5 \tag{17}$$

Then the LSF $g^*(u_1,u_2)$ given by

$$g^*(u_1,u_2) = \min\begin{cases} 5-u_1 \\ \dfrac{1}{1+exp\,(-2(u_2+4))} - 0.5 \end{cases} \tag{18}$$

defines the same limit surface as before, but the shape of the LSF is different and the contour lines of these functions are different in the safe and unsafe domain, both LSF's have only the contour of zero level set in common. Here, with the LSF defined in equation 18, the points in SuS converge towards the point (5,0) and one gets as probability estimate a value of $\Phi(-5) \approx 2.87 \cdot 10^{-7}$ whereas the true failure probability is approximately equal to $\Phi(-4) \approx 3.17 \cdot 10^{-5}$ as shown in Figure 9. So, here the different forms of the LSF's influence the result of the method. The reason is that the structure of the LSF in the neighborhood of the origin is different from its form near the limit state surface.

The same limit state surface can be described by a plethora of different LSF's. Their specific forms will influence the behavior of the SuS algorithm. Especially for more complicated LSF's for series or parallel systems it might be useful to clear inasmuch this can create convergence problems or lead to incorrect results. Certainly there will be cases where the result will not depend on the changing structures of the LSF's, but as the example above shows, it would be overoptimistic to assume that this is generally so.

The same limit state surface can be described by a plethora of different LSF's. Their specific forms will influence the behavior of the SuS algorithm. Especially for more complicated LSF's for series or parallel systems it might be useful to clear inasmuch this can create convergence problems or lead to incorrect results. Certainly there will be cases where the result will not depend on the changing structures of the LSF's, but as the example above shows, it would be overoptimistic to assume that this is generally so.

6.3 *Several design points*

Let the LSF be

$$g_\beta(u_1,u_2) = \frac{\beta^2}{2} - |u_1 \cdot u_2|. \tag{19}$$

Due to the symmetry of the LSF there are four beta points. In a FORM/SORM analysis one obtains using the results found in the following asymptotic approximation one has for the failure probability

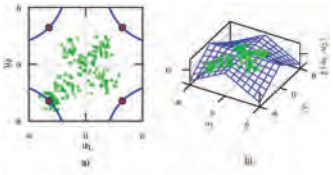
$$P(g_\beta(u_1,u_2) < 0) \sim 2\sqrt{2} \cdot \Phi(-\beta), \beta \to \infty. \tag{20}$$

Here clearly in a SORM analysis the beta point search algorithms have to be started several times to find all beta points.

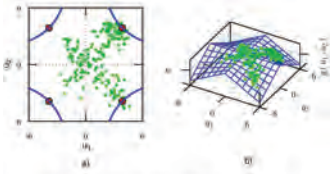
If this problem is examined now with SuS the possible outcomes of runs are shown in Figure 10. In fifty runs of SuS in one case only one beta point was detected, in 11 two, in 29 three and only in nine cases all four were found. This might lead to a systematic underestimation of the failure probability when not all beta points are found. If now several runs are combined, there will still be a bias, the failure probability will be underestimated. It is unclear to the author how to get a good estimator of the failure probability here without making some sort of geometric analysis similar to FORM/SORM. Also in the FORM/SORM approach the search algorithm for design points can end in local minimum distance points. But this is well known and by running the search from many different starting points one can expect to find all relevant design points (see e.g. Ditlevsen & Madsen (1996), section 5.2 and Melchers & Beck (2018), section 4.3.7).

6.4 *Stationarity of seeds*

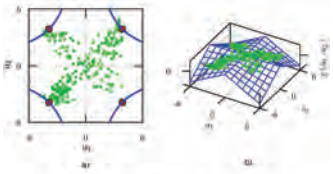
A recurring claim in the SuS literature is that the seeds for the next step which lie in the failure domain F_i already have a stationary distribution over this



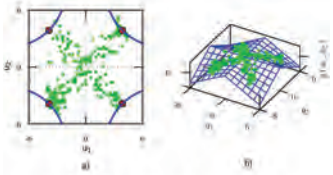
(a) SuS detects one design point



(b) SuS detects two design points



(c) SuS detects three design points



(d) SuS detects four design points

Figure 10. SuS for the LSF $g(u_1,u_2)=15-|u_1\cdot u_2|$.

domain, i.e. perfect sampling. This is true only for the first step, in all further steps the seeds do not have this stationary distribution. This was discussed in Botev & Kroese (2012), section 7 and in remark 4.4.3 in Botev (2009), but it seems that these findings remained unnoticed. The claim is true only for the first step in the algorithm where the seeds are coming from a Monte Carlo sample. This can be shown using theorem 2.4.1, p. 24 in Arnold et al. (2008). As explained in Geyer (2011) for proving that a MCMC produces exactly stationary data points, the random mechanism creating those must be studied.

Here a simple argument is given that the seeds in higher steps do not have this stationary distribution. Consider the simple case that F_i is a semi infinite interval $[b_i,\infty)$. An explanation that this cannot be correct is the fact that in one Markov chain generated with the MCMC algorithm proposed there, the next point can be the same point as before if the point found by the iteration algorithm is rejected. So the probability that the smallest seed on the interval F_i is equal to the left limit point b_i of the interval is larger than zero. But for a stationary distribution it is zero.

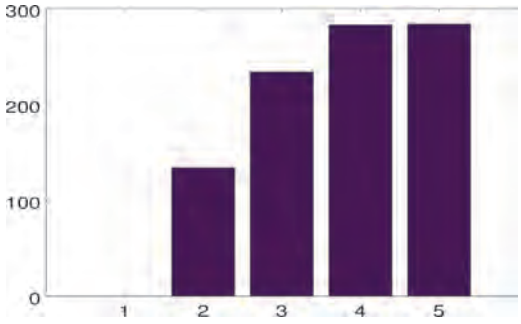


Figure 11. Occurence of seeds with distance zero from the lower end point.

To demonstrate this for the problem with $g(u)=5-u$ one thousand runs SuS runs were made with 500 points per step and an acceptance probability of 0.1 and 10 samples per chain. In the following Figure 11 it is recorded how often thesmallest seed had distance zero from the next lower order statistic. For the first step this never happens, but from the second step it happens quite often. This contradicts the claim that the seeds have a stationary distribution over $F_i=[c_i,\infty)$ for $i>1$. Important here is to note that if the distributions were stationary, a double would occur with probability zero, so even one such event happening during a numerical simulation makes the claim of stationarity invalid. The fact that for different SuS implementations and points in steps the number might be lower does not change the conclusions; since it is a qualitative not a quantitative statement. If at least one such point appears in a numerical simulation the claim of stationarity is disproved.

7 PROBLEM STRUCTURE AND SUS

Another important point which is problematic in SuS is the ignoring of the problem structure. This is advertised as a special feature. For example in Zuev et al. (2012) it is written:

> *Subset Simulation provides an efficient stochastic simulation algorithm for computing failure probabilities for general reliability problems without using any specific information about the dynamic system other than an inputoutput model. This independence of a systems inherent properties makes Subset Simulation potentially useful for applications in different areas of science and engineering where the notion of "failure" has its own specific meaning,…*

Contrasting this opinion there is the following quote from Monahan (2011) p. 394:

> *For MCMC, an extremely naive user can generate a lot of output without even under- standing the problem. The lack of discipline of learning about the problem that other methods require can lead to unfounded optimism and confidence in the results.*

8 CONCLUSIONS

The subset simulation approach to structural reliability analysis ignores the problem how to distinguish between local and global constrained mimimum distance points on the limit state surface. It finds minimum points without checking if there are other minimum points which give a smaller value. Certainly this analysis is restricted to cases where design points exist, but also for these cases SuS should give correct results. This problem of local minima is known in FORM/SORM methods and is avoided by running design point searches from different starting points. Therefore there is a considerable danger of obtaining erroneous results, since SuS ignores the possibility of finding only local minima instead of global. This misunderstanding of the basic problem can be seen in all papers about SuS as far as the author knows, it is always assumed that there is no need to ascertain that the found solution is not based on a local minimum. But this is the essential problem of global minimization to avoid local minima and to escape from them towards global minima.

It is obvious that similar problems will appear for examples in higher dimensions. The simple examples here were chosen, because they allow an illustration of the behavior of the method in a graphical way, which is not possible in higher dimensions. Maybe each of these primitive examples can be solved by adding to SuS some specific adhockeries for the example, but in this way the principal problem of avoiding local extrema is not addressed. And this has to be resolved for SuS to be accepted as a meaningful reliability method furthermore.

Two-dimensional approach towards a probabilistic model of fatigue cracking of an industrial pipeline

M. Zieja
Air Force Institute of Technology, Warsaw, Poland

M. Jasztal, S. Stępień & M. Ważny
Military University of Technology, Warsaw, Poland

ABSTRACT: The subject addressed in this paper concerns the constantly developing methods of determining the fatigue strength of industrial pipelines. The description of semi-elliptical crack propagation proposed in the paper applies a deterministic model based on a modified Paris' formula, which became the basis for developing a probabilistic model, being the subject of this publication. Based on a differential equation, a Fokker-Plank parabolic partial equation was derived, which describes a crack development in a probabilistic sense, at the same time taking into account deterministic model relationships. A solution of the equation is a two-dimensional normal distribution of crack propagations. A manner of estimating the distribution parameters is also stated. Having a distribution of probability with known parameters, in the case of an assumed probability of exceeding the permissible crack length, the fatigue life of model elements cut-out from industrial pipelines was estimated.

1 INTRODUCTION

Forecasting the propagation of fatigue cracks in elements of industrial pipelines is an important and still not fully addressed issue, which is of fundamental significance due to severe outcomes of a potential damage. The subject approached in this paper concerns the constantly developing methods of determining the fatigue strength of such objects (Mazur 2002, Song et al. 2002, Śnieżek & Goss 2006, Śnieżek et al. 2007, Śnieżek & Stępień 2007). Current solutions in this field consider the growth of surface cracks, outgoing from free edges of the body and propagate along the pipeline surface, as well as into the material, towards the pipe wall thickness (Boukharouba & Pluyinage 1999, Kim & Hwang 1997, Song et al. 2002, Śnieżek & Stępień 2007, Śnieżek et al. 2006). The occurring randomness of the load, material properties, geometry, etc., prompts many scientists to apply probabilistic crack propagation models (Ahammed 1997 & 1998, Ahammed & Melchers 1997, Caleyo 2002, Kocańda et al. 1999). However, some of them (Baranowski & Małachowski 2015, Kocańda et al. 1999, Śnieżek & Stępień 2007, Śnieżek et al. 2006, Tomaszek et al. 2008), when applying a probabilistic description of a crack growth dynamics, take into account the relationships of a deterministic model, which physically reflects the aspects of fatigue crack growth. Therefore, the description of semi-elliptical crack propagation suggested in the paper, which includes a probabilistic model based on a deterministic model published by the authors (Zieja et al. 2017). A physical description of a crack growth utilizes a modified Paris' formula, taking into account two mutually dependent crack direction, i.e., along the small and large ellipses. The development of the model was based on experimental tests on overhead industrial pipelines after thirty years of operation (made from 1H18 N9T steel), as well as sections of new pipelines, prior to handing them over to operation (made from 1.4541 steel). Samples for fatigue tests were cut out from these pipelines and then subjected to flat (non-zero-pulsating) bending at different value of stress amplitudes. An analysis of many variants of mutual interconnection of cracking velocity in both directions, provided a surprising conformity of the results of interconnection between quotients of cracking velocity in both direction and the quotient of crack length (for different samples and load values) (Zieja et al. 2017). The conducted analysis indicates that in the case of surface length of the crack, it is possible to apply the classic Paris' formula, whereas in the case of cracking towards the depth, the correction factor had to be applied. Next, fatigue life calculations were conducted based on the proposed modifications variants of the Paris' formula, with the obtained fatigue lives being similar, and at the same time "safer" in

relation to the actual fatigue life obtained during fatigue tests. It confirmed the possibility of utilizing the presented variants of the deterministic model. The deterministic model developed in the paper (Zieja et al. 2017) became the base for developing the probabilistic model, which is the main subject of this article.

2 BASIC ASSUMPTIONS OF THE PROBABILISTIC MODEL

In order to describe fatigue cracking in the general case of a random load, an equation proposed by prof. Henryk Tomaszek was used (Kocańda et al. 1999, Śnieżek & Stępień 2007, Tomaszek et al. 2008):

$$\begin{aligned}&\frac{\partial U(a,c,t)}{\partial t} = -C(a,c)U(a,c,t) - \\ &-\frac{\partial b_1(a,c)U(a,c,t)}{\partial a} - \frac{\partial b_2(a,c)U(a,c,t)}{\partial c} + \\ &+\frac{\partial^2 \mu(a,c)U(a,c,t)}{\partial a \partial c} + \frac{1}{2}\frac{\partial^2 d_1(a,c)U(a,c,t)}{\partial a^2} + \\ &+\frac{1}{2}\frac{\partial^2 d_2(a,c)U(a,c,t)}{\partial c^2}\end{aligned} \tag{1}$$

where $U(a,c,t)$ = a function of length c and depth a densities of cracks at a time of t; $C(a,c)$ = a factor characterizing the possibility of a catastrophic crack event, when the crack depth is a, and length is c; $d_1(a,c)$ and $d_2(a,c)$ = mean squares of crack increment in relevant directions, in adopted units of time; $b_1(a,c)$ and $b_2(a,c)$ = mean values of crack increment in relevant directions, in adopted units of time; and $\mu(a,c)$ = correlation moment in an assumed unit of time:

$$\mu(a,c) = r\sqrt{d_1(a,c)}\sqrt{d_2(a,c)},$$

where as r is a crack length and depth correlation factor.

Further analysis of the equation (1) is a difficult issue, since it lacks an analytical solution. However, by adopting certain assumptions, it is possible to simplify the above equation. The assumptions for the probabilistic model have the following form:

a. there are such lengths of fatigue cracks (in both, mutually perpendicular directions) that within a certain interval (or for a given number of load cycles), the probability of a catastrophic element crack is equal to zero;
b. in the deterministic approach, the velocities of fatigue cracking are often defined by appropriately modified Paris' formulas (Zieja et al. 2017);
c. load cycles with a duration of Δt may not appear in a continuous manner, but rather randomly, with an intensity of λ i.e. $\lambda \Delta t \leq 1$.

The following differential equation describing a two-dimensional crack growth in the probabilistic sense, may be formed under these assumptions:

$$U_{a,c,t+\Delta t} = (1-\lambda\,\Delta t)U_{a,c,t} + \lambda\,\Delta t\,U_{a-\Delta a,c-\Delta c,t} \tag{2}$$

where $U_{a,c,t}$ = a probability that at a time t, the crack length is c, and the depth is a; Δa and Δc = crack increments into and along the surface of a material, over a time interval of Δt; and λ = load cycle appearance intensity.

3 THE DETERMINATION OF CRACK LENGTH DISTRIBUTION PROBABILITY

From the equation (2), after a transition to functional notation, we obtain:

$$\begin{aligned}&U(a,c,t+\Delta t) = (1-\lambda\Delta t)U(a,c,t) + \\ &+\lambda\Delta t\,U(a-\Delta a, c-\Delta c, t)\end{aligned} \tag{3}$$

where $U(a,c,t)$ = crack length density function.

Expanding the equation terms into a Taylor series and taking into account, for t, the terms of expansion to the first derivative, and for a and c, the terms of expansion to the second derivatives, the following was obtained:

$$\begin{aligned}&U(a,c,t+\Delta t) = U(a,c,t) + \frac{\partial U(a,c,t)}{\partial t}\,\Delta t \\ &U(a-\Delta a, c-\Delta c, t) = U(a,c,t) - \frac{\partial U(a,c,t)}{\partial c}\,\Delta c - \\ &-\frac{\partial U(a,c,t)}{\partial c}\,\Delta c + \frac{1}{2}\frac{\partial^2 U(a,c,t)}{\partial a^2}\,\Delta a^2 + \\ &+\frac{1}{2}\frac{\partial^2 U(a,c,t)}{\partial c^2}\,\Delta c^2 + \frac{\partial^2 U(a,c,t)}{\partial a \partial c}\Delta a \Delta c.\end{aligned} \tag{4}$$

The equation (2), after conversions, will assume the following form:

$$\begin{aligned}&\frac{\partial U(a,c,t)}{\partial t} = -\lambda\frac{\partial U(a,c,t)}{\partial a}\Delta a - \lambda\frac{\partial U(a,c,t)}{\partial c}\Delta c + \\ &+\frac{1}{2}\lambda\frac{\partial^2 U(a,c,t)}{\partial a^2}\Delta a^2 + \frac{1}{2}\lambda\frac{\partial^2 U(a,c,t)}{\partial c^2}\Delta c^2 + \\ &+\lambda\frac{\partial^2 U(a,c,t)}{\partial a \partial c}\Delta a \Delta c\end{aligned} \tag{5}$$

The Δa and Δc increments should be determined as time functions from the relevant relationships of a deterministic model, presented in a previous

paper (Zieja et al. 2017). For known increments, we can write:

$$\frac{\partial U(a,c,t)}{\partial t} = -b_1(t)\frac{\partial U(a,c,t)}{\partial a} - b_2(t)\frac{\partial U(a,c,t)}{\partial c} + \\ + \frac{1}{2}d_1(t)\frac{\partial^2 U(a,c,t)}{\partial a^2} + \frac{1}{2}d_2(t)\frac{\partial^2 U(a,c,t)}{\partial c^2} + \\ + \mu(t)\frac{\partial^2 U(a,c,t)}{\partial a \partial c} \tag{6}$$

where $b_1(t) = \lambda \Delta a(t)$; $b_2(t) = \lambda \Delta c(t)$; $d_1(t) = \lambda \Delta a^2(t)$; $d_2(t) = \lambda \Delta c^2(t)$; and $\mu(t) = \lambda \Delta a(t) \Delta c(t)$.

Whereby, the dot over the variables means a derivative after time. The solution of the equation (6) has the following form:

$$U(a,c,t) = \frac{1}{2\pi}\frac{1}{\sqrt{d_1(t)d_2(t)}} \times \\ \times \frac{1}{\sqrt{1-r^2}} e^{-\frac{1}{2(1-r^2)}\left[\frac{(a-b_1(t))^2}{d_1(t)} - 2r\frac{(a-b_1(t))(c-b_2(t))}{\sqrt{d_1(t)d_2(t)}} + \frac{(c-b_2(t))^2}{d_2(t)}\right]} \tag{7}$$

where $b_1(t) = \int_0^t \lambda\, \Delta a(w)\, dw$; $b_2(t) = \int_0^t \lambda\, \Delta c(w)\, dw$;

$d_1(t) = \int_0^t \lambda\, \Delta a^2(w)\, dw$; $d_2(t) = \int_0^t \lambda\, \Delta c^2(w)\, dw$;

$\mu(t) = \int_0^t \lambda\, \Delta a(w) \Delta c(w)\, dw$; and $r = \frac{\mu(t)}{\sqrt{d_1(t)d_2(t)}}$.

4 THE DETERMINATION OF CRACK LENGTH DISTRIBUTION PARAMETERS

Defining the parameters of presented distributions requires the determination of the increments of length "c" and depth "a" of a crack, within one load cycle. For this purpose, we shall utilize the relationships in the previously developed deterministic model (Zieja et al. 2017). Based on the relationships (8), (9), (10) describing the cracking velocity in three variants, and taking into account the solutions of the deterministic models shown below, the determination of required crack length and depth increments was attempted.

The 1st variant—common is only the exponent m of the Paris' formula for both cracking directions:

$$V_a = \frac{da}{dN} = C_a \Delta K_a^m = C_a \left(M_{ka} \Delta\sigma \sqrt{\pi a}\right)^m \\ V_c = \frac{dc}{dN} = C_c \Delta K_c^m = C_c \left(M_{kc} \Delta\sigma \sqrt{\pi c}\right)^m \tag{8}$$

where a = crack depth; c = half the length of a surface crack; ΔK_a = the range of the stress intensity factor for crack depth a; ΔK_c = the range of the stress intensity factor for surface length c; N = number of load cycles; $\Delta\sigma$ = stress range; C_a, C_c, m = Paris formula factors; M_{ka} and M_{kc} = correction factors, taking into account the finiteness of element dimensions, determined for the crack length c and depth a, respectively.

The 2nd variant—correction of the stress intensity factor with a c/a quotient, for the velocity in the direction of the crack depth:

$$V_a = \frac{da}{dN} = C_a \Delta K_a^m = C_a \left(M_{ka} \frac{c}{a} \Delta\sigma \sqrt{\pi a}\right)^m \\ V_c = \frac{dc}{dN} = C_c \Delta K_c^m = C_c \left(M_{kc} \Delta\sigma \sqrt{\pi c}\right)^m. \tag{9}$$

The 3rd variant—correction of the stress intensity factor with a square of the c/a quotient, for the velocity in the direction of the crack depth:

$$V_a = \frac{da}{dN} = C_a \Delta K_a^m = C_a \left(M_{ka} \left(\frac{c}{a}\right)^2 \Delta\sigma \sqrt{\pi a}\right)^m \\ V_c = \frac{dc}{dN} = C_c \Delta K_c^m = C_c \left(M_{kc} \Delta\sigma \sqrt{\pi c}\right)^m. \tag{10}$$

The below notations include the probability P_{th} of an event in which a stress range $\Delta\sigma$ exceeds the threshold value and a crack grows. Moreover, it was assumed that $N = \lambda t$ and additional factors were introduced:

$$\alpha_a = C_a M_{ka}^m P_{th} \Delta\sigma^m \pi^{\frac{m}{2}} \\ \alpha_c = C_c M_{kc}^m P_{th} \Delta\sigma^m \pi^{\frac{m}{2}}. \tag{11}$$

Below you can find the determined two-dimensional crack length and depth increments. The solutions were presented in two variants: for the values of the exponent $m = 2$ and $m \neq 2$ (conducting calculations for specific values of the exponent is only dictated by limitation of the mathematical apparatus and does not have physical justification).

For $m = 2$:

Variant 1:

$$\Delta a = a_0 \alpha_a e^{\alpha_a \lambda t} \\ \Delta c = c_0 \alpha_c e^{\alpha_c \lambda t}; \tag{12}$$

Variant 2:

$$\Delta a = \frac{\alpha_a c_0^2 e^{2\alpha_c \lambda t}}{\sqrt{\frac{\alpha_a}{\alpha_c} c_0^2 \left(e^{2\alpha_c \lambda t} - 1\right) + a_0^2}}; \\ \Delta c = c_0 \alpha_c e^{\alpha_c \lambda t} \tag{13}$$

Variant 3:

$$\Delta a = \frac{\alpha_a c_0^4 e^{4\alpha_c \lambda t}}{\left[\frac{\alpha_a}{\alpha_c} c_0^4 \left(e^{4\alpha_c \lambda t} - 1\right) + a_0^4\right]^{\frac{3}{4}}}.$$
$$\Delta c = c_0 \alpha_c e^{\alpha_c \lambda t}. \tag{14}$$

For $m \neq 2$:
Variant 1:

$$\Delta a = \alpha_a \left(\frac{2-m}{2} \alpha_a \lambda t + a_0^{\frac{2-m}{2}}\right)^{\frac{m}{2-m}}$$
$$\Delta c = \alpha_c \left(\frac{2-m}{2} \alpha_c \lambda t + c_0^{\frac{2-m}{2}}\right)^{\frac{m}{2-m}}; \tag{15}$$

Variant 2:

$$\Delta a = \frac{\alpha_a \left(\frac{2-m}{2} \alpha_c \lambda t + c_0^{\frac{2-m}{2}}\right)^{\frac{2m}{2-m}}}{\left\{\frac{\alpha_a}{\alpha_c}\left[\frac{2-m}{2} \alpha_c \lambda t + c_0^{\frac{2-m}{2}}\right]^{\frac{2+m}{2-m}} + a_0^{\frac{2+m}{2}} - \frac{\alpha_a}{\alpha_c} c_0^{\frac{2+m}{2}}\right\}^{\frac{m}{2+m}}}$$
$$\Delta c = \alpha_c \left(\frac{2-m}{2} \alpha_c \lambda t + c_0^{\frac{2-m}{2}}\right)^{\frac{m}{2-m}}; \tag{16}$$

Variant 3:

$$\Delta a = \frac{\alpha_a \left(\frac{2-m}{2} \alpha_c \lambda t + c_0^{\frac{2-m}{2}}\right)^{\frac{4m}{2-m}}}{\left\{\frac{\alpha_a}{\alpha_c}\left[\frac{2-m}{2} \alpha_c \lambda t + c_0^{\frac{2-m}{2}}\right]^{\frac{2+3m}{2-m}} + a_0^{\frac{3m+2}{2}} - \frac{\alpha_a}{\alpha_c} c_0^{\frac{2+3m}{2}}\right\}^{\frac{3m}{3m+2}}}$$
$$\Delta c = \alpha_c \left(\frac{2-m}{2} \alpha_c \lambda t + c_0^{\frac{2-m}{2}}\right)^{\frac{m}{2-m}}. \tag{17}$$

Next, the parameters of relevant probability distributions were determined. It required the calculation of integrals present in the formula (7). The results obtained for the considered calculation variants are presented below.

For $m = 2$:
Variant 1:

$$b_1(t) = a_0 e^{\alpha_a \lambda t};$$
$$b_2(t) = c_0 e^{\alpha_c \lambda t};$$
$$d_1(t) = \frac{1}{2} a_0^2 \alpha_a e^{2\alpha_a \lambda t};$$
$$d_2(t) = \frac{1}{2} c_0^2 \alpha_c e^{2\alpha_c \lambda t}; \tag{18}$$

Variant 2:

$$b_1(t) = \sqrt{\frac{\alpha_a}{\alpha_c} c_0^2 \left(e^{2\alpha_c \lambda t} - 1\right) + a_0^2};$$
$$b_2(t) = c_0 e^{\alpha_c \lambda t};$$
$$d_1(t) = \frac{\alpha_c}{2}\left[\frac{\alpha_a}{\alpha_c} c_0^2 \left(e^{2\alpha_c \lambda t} - 1\right) + a_0^2 + \left(\frac{\alpha_a}{\alpha_c} c_0^2 - a_0^2\right) \ln\left[\frac{\alpha_a}{\alpha_c} c_0^2 \left(e^{2\alpha_c \lambda t} - 1\right) + a_0^2\right]\right]$$
$$d_2(t) = \frac{1}{2} c_0^2 \alpha_c e^{2\alpha_c \lambda t} \tag{19}$$

Variant 3:

$$b_1(t) = \sqrt[4]{\frac{\alpha_a}{\alpha_c} c_0^4 \left(e^{4\alpha_c \lambda t} - 1\right) + a_0^4};$$
$$b_2(t) = c_0 e^{\alpha_c \lambda t};$$
$$d_1(t) = \frac{\alpha_c}{2}\left[\sqrt{\frac{\alpha_a}{\alpha_c} c_0^4 \left(e^{4\alpha_c \lambda t} - 1\right) + a_0^4} - \frac{\left(\frac{\alpha_a}{\alpha_c} c_0^4 - a_0^4\right)}{\sqrt{\frac{\alpha_a}{\alpha_c} c_0^4 \left(e^{4\alpha_c \lambda t} - 1\right) + a_0^4}}\right];$$
$$d_2(t) = \frac{1}{2} c_0^2 \alpha_c e^{2\alpha_c \lambda t}; \tag{20}$$

For $m \neq 2$:
Variant 1:

$$b_1(t) = \left[\frac{2-m}{2} \alpha_a \lambda t + a_0^{\frac{2-m}{2}}\right]^{\frac{2}{2-m}};$$
$$b_2(t) = \left[\frac{2-m}{2} \alpha_c \lambda t + c_0^{\frac{2-m}{2}}\right]^{\frac{2}{2-m}};$$
$$d_1(t) = \frac{2\alpha_a}{2+m}\left[\frac{2-m}{2} \alpha_a \lambda t + a_0^{\frac{2-m}{2}}\right]^{\frac{2+m}{2-m}};$$
$$d_2(t) = \frac{2\alpha_c}{2+m}\left[\frac{2-m}{2} \alpha_c \lambda t + c_0^{\frac{2-m}{2}}\right]^{\frac{2+m}{2-m}}; \tag{21}$$

Variant 2:

$$b_1(t)=\left\{\frac{\alpha_a}{\alpha_c}\left[\frac{2-m}{2}\alpha_c\lambda t+c_0^{\frac{2-m}{2}}\right]^{\frac{2+m}{2-m}}+a_0^{\frac{2+m}{2}}-\frac{\alpha_a}{\alpha_c}c_0^{\frac{2+m}{2}}\right\}^{\frac{2}{2+m}};$$

$$b_2(t)=\left[\frac{2-m}{2}\alpha_c\lambda t+c_0^{\frac{2-m}{2}}\right]^{\frac{2}{2-m}};$$

$$d_1(t)=\frac{2}{2+m}\alpha_a^{\frac{4}{2+m}}\alpha_c^{\frac{m-2}{2+m}}\left[\frac{2-m}{2}\alpha_c\lambda t+c_0^{\frac{2-m}{2}}\right]^{\frac{2+m}{2-m}};$$

$$d_2(t)=\frac{2\alpha_c}{2+m}\left[\frac{2-m}{2}\alpha_c\lambda t+c_0^{\frac{2-m}{2}}\right]^{\frac{2+m}{2-m}};\tag{22}$$

Variant 3:

$$b_1(t)=\left[\frac{\alpha_a}{\alpha_c}\left[\frac{2-m}{2}\alpha_c\lambda t+c_0^{\frac{2-m}{2}}\right]^{\frac{2+3m}{2-m}}+a_0^{\frac{3m+2}{2}}-\frac{\alpha_a}{\alpha_c}c_0^{\frac{2+3m}{2}}\right]^{\frac{2}{3m+2}};$$

$$b_2(t)=\left[\frac{2-m}{2}\alpha_c\lambda t+c_0^{\frac{2-m}{2}}\right]^{\frac{2}{2-m}};$$

$$d_1(t)=\frac{2}{2+m}\alpha_a^{\frac{4}{3m+2}}\alpha_c^{\frac{3m-2}{3m+2}}\left[\frac{2-m}{2}\alpha_c\lambda t+c_0^{\frac{2-m}{2}}\right]^{\frac{2+m}{2-m}};$$

$$d_2(t)=\frac{2\alpha_c}{2+m}\left[\frac{2-m}{2}\alpha_c\lambda t+c_0^{\frac{2-m}{2}}\right]^{\frac{2+m}{2-m}}.\tag{23}$$

Determining the variant $d_1(t)$ for any value of the exponent m, in the 2nd and 3rd variants of the model required the determination of integral values, with their analytical calculation significantly difficult. It was decided to simplify the integrands through omitting the constants, with their value (especially for large t) has a little impact on the calculation results. In addition, such a simplification will increase the variance, which translates to a more conservative estimation of the fatigue life. As a result of the conducted calculations, expressions were obtained (18÷23), which define the expected value and crack length and depth variance for individually considered calculation variants.

5 ESTIMATING THE FACTORS OCCURRING IN EXPRESSIONS DEFINING DISTRIBUTION PARAMETERS

In order to present distribution parameters in an explicit form, it is necessary to estimate the value of coefficients α_a, α_c, m and a correlation coefficient r. The actual crack growth during operation depends on many factors of a random character, e.g. the course of a random load. Determining an element fatigue life in the probabilistic approach requires the knowledge of the crack growth, covering a full probabilistic characteristic of the crack propagation, therefore, providing information on random cracking factors. Let it be a general notation, in the following form:

$$\begin{matrix}\left[(a_0,t_0),(a_1,t_1),(a_2,t_2),...,(a_n,t_n)\right]\\ \left[(c_0,t_0),(c_1,t_1),(c_2,t_2),...,(c_n,t_n)\right].\end{matrix}\tag{24}$$

Based on experimental data concerning crack growth (24), the values of required factors should be estimated. The value of the m coefficient was decided to be determined according to the commonly adopted manner in a deterministic system, from a relationship binding the velocity of a crack over the surface of material V_c with the value of the stress intensity coefficient. Whilst, the values of the remaining coefficients were determined based on a method with the biggest credibility. Due to the fact that the method is commonly known, its description was omitted. The form of the obtained distribution parameters coefficient estimation results is presented below.

The correlation coefficient relationship for the adopted experimental data has the following form:

$$r^*=\frac{\frac{1}{n}\sum_{k=0}^{n-1}\frac{\left[(a_{k+1}-a_k)-b_1^*(\lambda t_{k+1}-\lambda t_k)\right]\times\left[(c_{k+1}-c_k)-b_2^*(\lambda t_{k+1}-\lambda t_k)\right]}{\lambda t_{k+1}-\lambda t_k}}{\sqrt{d_1^*}\sqrt{d_2^*}},\tag{25}$$

where:

$$b_1^*=\frac{a_n}{\lambda t_n};$$

$$b_2^*=\frac{c_n}{\lambda t_n};$$

$$d_1^*=\delta_1^2=\frac{1}{n}\sum_{k=0}^{n-1}\frac{\left((a_{k+1}-a_k)-b_1^*(\lambda t_{k+1}-\lambda t_k)\right)^2}{\lambda t_{k+1}-\lambda t_k};$$

$$d_2^*=\delta_2^2=\frac{1}{n}\sum_{k=0}^{n-1}\frac{\left((c_{k+1}-c_k)-b_2^*(\lambda t_{k+1}-\lambda t_k)\right)^2}{\lambda t_{k+1}-\lambda t_k}.$$

The expressions used to estimate factors α_a, α_c have the following form:

For $m = 2$:

Variant 1:

$$\alpha_a = \frac{1}{\lambda t_n} \ln \frac{a_n}{a_0}; \quad \alpha_c = \frac{1}{\lambda t_n} \ln \frac{c_n}{c_0}; \tag{26}$$

Variant 2:

$$\alpha_a = \frac{1}{\lambda t_n} \frac{a_n^2 - a_0^2}{c_n^2 - c_0^2} \ln \frac{c_n}{c_0}; \quad \alpha_c = \frac{1}{\lambda t_n} \ln \frac{c_n}{c_0}; \tag{27}$$

Variant 3:

$$\alpha_a = \frac{1}{\lambda t_n} \frac{a_n^4 - a_0^4}{c_n^4 - c_0^4} \ln \frac{c_n}{c_0}; \quad \alpha_c = \frac{1}{\lambda t_n} \ln \frac{c_n}{c_0}. \tag{28}$$

For $m \neq 2$:

Variant 1:

$$\alpha_a = \frac{1}{\lambda t_n} \frac{2}{m-2} \left(\frac{1}{a_0^{\frac{m-2}{2}}} - \frac{1}{a_n^{\frac{m-2}{2}}} \right); \quad \alpha_c = \frac{1}{\lambda t_n} \frac{2}{m-2} \left(\frac{1}{c_0^{\frac{m-2}{2}}} - \frac{1}{c_n^{\frac{m-2}{2}}} \right); \tag{29}$$

Variant 2:

$$\alpha_a = \frac{1}{\lambda t_n} \frac{2}{m-2} \left(\frac{1}{c_0^{\frac{m-2}{2}}} - \frac{1}{c_n^{\frac{m-2}{2}}} \right) \frac{a_n^{\frac{2+m}{2}} - a_0^{\frac{2+m}{2}}}{c_n^{\frac{2+m}{2}} - c_0^{\frac{2+m}{2}}}; \quad \alpha_c = \frac{1}{\lambda t_n} \frac{2}{m-2} \left(\frac{1}{c_0^{\frac{m-2}{2}}} - \frac{1}{c_n^{\frac{m-2}{2}}} \right); \tag{30}$$

Variant 3:

$$\alpha_a = \frac{1}{\lambda t_n} \frac{2}{m-2} \left(\frac{1}{c_0^{\frac{m-2}{2}}} - \frac{1}{c_n^{\frac{m-2}{2}}} \right) \frac{a_n^{\frac{3m+2}{2}} - a_0^{\frac{3m+2}{2}}}{c_n^{\frac{3m+2}{2}} - c_0^{\frac{3m+2}{2}}}; \quad \alpha_c = \frac{1}{\lambda t_n} \frac{2}{m-2} \left(\frac{1}{c_0^{\frac{m-2}{2}}} - \frac{1}{c_n^{\frac{m-2}{2}}} \right). \tag{31}$$

6 FATIGUE LIFE ESTIMATION METHOD

Using the developed form of the crack length distribution with known parameters, it is possible to determine the probability of not exceeding the permissible crack lengths $R(t)$:

$$R(t) = P\left(a \le a_d, c \le c_d, t\right) = \int_{-\infty}^{a_d} \int_{-\infty}^{c_d} U(a,c,t)\, da\, dc. \tag{32}$$

According to the assumptions of the probabilistic model, the permissible crack lengths a_d and c_d should be determined in such a manner, so that the risk of immediate element destruction is sufficiently low. Mutual interconnection of both cracking directions hinders the calculations associated with a two-dimensional normal distribution. The information about linking random variables of the crack length is provided by the correlation coefficient value. In the case of a correlation coefficient value, estimated acc. to the previous equation (25), the coordinate system should be converted so that the correlation coefficient for the converted random variables was equal to zero. The coordinates are converted according to the relationship:

$$\begin{aligned} a' &= a\cos\alpha + c\sin\alpha \\ c' &= -a\sin\alpha + c\cos\alpha, \end{aligned} \tag{33}$$

where the angle α is determined from the formula:

$$tg2\alpha = \frac{2r^* \sqrt{d_1^*} \sqrt{d_2^*}}{d_1^* - d_2^*}. \tag{34}$$

With such a conversion, the modified crack lengths a' and c' are independent random variables for each determined t. The distribution parameters should also be converted according to the above rule:

$$\begin{aligned} b_1'(t) &= b_1(t)\cos\alpha + b_2(t)\sin\alpha; \\ b_2'(t) &= -b_1(t)\sin\alpha + b_2(t)\cos\alpha; \\ d_1'(t) &= \left(\sqrt{d_1(t)}\cos\alpha + \sqrt{d_2(t)}\sin\alpha\right)^2; \\ d_2'(t) &= \left(-\sqrt{d_1(t)}\sin\alpha + \sqrt{d_2(t)}\cos\alpha\right)^2. \end{aligned} \tag{35}$$

In the new coordinate system, the relationship (32) shall assume the following form:

$$\begin{aligned} R(t) &= P\left(a \le a_d, c \le c_d, t\right) = \\ &= P_1\left(a' \le a_d', t\right) \cdot P_2\left(c' \le c_d', t\right), \end{aligned} \tag{36}$$

where: $P_1\left(a' \le a_d', t\right)$ and $P_2\left(c' \le c_d', t\right)$ are determined from one-dimensional normal

distribution. Using normal distribution tables requires additional standardization of random variables. Assuming that $R(t) \leq R_0$, where: R_0 is the minimum permissible probability of not exceeding the permissible crack lengths a_d and c_d, for which an element's fatigue life may be determined. At the same time, probability $1 - R_0$ will be the probability of exceeding permissible operational durations.

7 CALCULATION EXAMPLE

The example shall utilize the data from experimental tests presented in papers (Śnieżek & Stępień 2007, Zieja et al. 2017). The sample designations assumed in the aforementioned elaborations were kept. As per the previously presented assumptions for three variants of the model, calculations of factors present in expressions for crack length distribution parameters were made, and their results are shown in Table 1 below.

Having the values of calculated coefficient (as per the previously presented procedure), the estimation of the fatigue life for individual samples was commenced. It was decided to present the obtained results in groups concerning a given material and a given loading manner. For all samples, a minimum probability of not exceeding the permissible crack parameters $R_0 = 0{,}9$ was assumed.

For Group I samples cut out from a new pipeline, prior to including the operation, made from 1.4541 steel (acc. to EN 10088-3), subject to flat non-zero-pulsating bending with a frequency of 20 Hz (cycle asymmetry coefficient R = 0) with subsequent stress nominal amplitude values given in Table 2. Permissible crack lengths in individual directions: $a_d = 3$ mm; $c_d = 9$ mm.

For Group II samples cut out from a pipeline after 30 years of operation, made from 1H18N9T steel (acc. to PN-71/H-86020), subject to flat non-zero-pulsating bending with a frequency of 20 Hz (cycle asymmetry coefficient R = 0) with subsequent stress nominal amplitude values given in table 4. Permissible crack lengths in individual directions: $a_d = 3$ mm; $c_d = 9$ mm.

The obtained fatigue life calculation results, based on the three developed model variants are similar to the actual life, obtained during fatigue tests of bent samples. At the same time, in the second and third calculation variant, "safe" fatigue lives were achieved in comparison to the actual life, however less conservative from the point of

view of preventive forecasting of fatigue life, in comparison to the fatigue life results for the first variant. It confirms the earlier remarks regarding the possibility of applying the probabilistic model to estimate fatigue life.

8 CONCLUSIONS

The probabilistic description of semi-elliptic crack propagations proposed in the paper utilizes a previously developed deterministic model (Zieja et al. 2017), based on the modified Paris' formula. On the basis of the differential equation, the Fokker-Plank parabolic partial equation, which describes a crack development in a probabilistic sense, was derived, at the same time taking into account the deterministic model relationships. A solution of the equation is a two-dimensional normal distribution of crack propagations. A manner of estimating the distribution parameters is also stated. Having the distribution of probability with known parameters, in the case of an assumed risk of exceeding the permissible crack length, the fatigue life of model elements cut-out from industrial pipelines was estimated.

The conducted analyses took into account the interconnection of cracking directions, which is the main advantage of the two-dimensional model. The forecast fatigue life depends on two permissible crack lengths. Taking into account the critical conditions allows to ensure a higher safety level in relation to a single condition.

Experimental tests regarding the fatigue life of model elements with a propagating semi-elliptical crack, enabled to provide the calculation model with necessary data, describing the development character of the considered two-dimensional cracks. The forecast and recorded during the experimental tests fatigue lives of samples show satisfying compliance. However, the fatigue lives forecast on the basis of developed mathematical models are lower than in the case of the experimental ones, hence, "safe" and, in addition, less conservative than the results obtained on the basis of a deterministic model and presented in the paper (Zieja et al. 2017).

Environmental contours for design of ice-capable vessels

Wei Chai, Bernt J. Leira & Chana Sinsabvarodom
Department of Marine Technology, Norwegian University of Science and Technology, Trondheim, Norway

ABSTRACT: The environmental contour method is an established method for design of ships and marine structures. In this method, environmental contours for a given return period are developed in order to identify the environmental conditions which are associated with the most critical structural responses, and then the long-term extreme response for the same return period can be effectively estimated based on the response statistics of the most critical (short-term) responses. In this work, the environmental contour method is described for design of ice-capable vessels in Arctic regions. In particular, for vessels sailing in Arctic regions, the most dangerous condition is associated with ice ridges. Based on the probability distributions of key parameters of the first-year ice ridges which determine the ice ridge loads, the environmental contours are developed. The effects of the correlation between different environmental variables are discussed. A simple case is proposed to illustrate application of the environmental contour method for design of ice-capable vessels.

1 INTRODUCTION

For ships and marine structures subjected to environmental loads, such as wind, wave and ice forces, etc., evaluation of the extreme response over their specific lifetime is necessary and important at the design stage. The full long-term analysis which accounts for the structural response from each short-term environmental condition and the occurrence rate of each short-term condition is recognized as the most reliable and accurate approach. However, such long-term analysis is time consuming, especially for large and complex systems (Leira, 2008).

In order to improve the computational efficiency, the long-term analysis can be simplified either by reducing the computation cost of short-term analysis (Chai et al., 2016) or by developing approximate method that requires a lower number of short-term analysis, such as the IFORM (inverse first order reliability method) (Giske et al., 2017) and the environmental contour method (Haver and Winterstein, 2009).

The environmental contour method offers a simplified and fast way to estimate the long-term extreme response and has been widely used for design of ships and marine structures at the early design stage (Li et al., 2016, DNV, 2010, Baarholm et al., 2010). An environmental contour is the locus of all environmental parameters correspond to a given annual exceedance probability along which extreme responses with the corresponding return period should lie. Traditionally, establishment of such environmental contour for a given return period is based on the IFORM and the joint distribution of the environmental parameters.

The main advantage for the environmental contour method lies in the fact that the structural response is uncoupled from the description of the environmental variables. As a result, the long-term extreme response for a given return period can be approximately estimated on the basis of response statistics associated with the most critical short-term environmental conditions along the environmental contour, which corresponds to a given return period. Therefore, in this method, short-term analyses are performed only for a few conditions on the environmental contour and then numerical simulations or experiments are performed in order to identify the most critical short-term response for further application (Winterstein et al., 1993).

In this work, the concept of environmental contour is applied for design of ice-capable vessels operating in Arctic regions. For ships sailing in sea ice areas without icebergs, ice ridges are assumed to pose a major threat to the vessel since they determine and govern the design loads for the vessel (Høyland, 2014). Key parameters of the ice ridge which determine the main loads of the ship-ice ridge interaction process are identified at first. Then, probabilistic models are applied to describe the distributions of these key parameters in order to develop the environmental contours.

The procedure of extreme response prediction based on the environmental contour method is simply described in this work. Finally, a simple case is given to illustrate the development of a

desired environmental contour used for design of ice-capable vessels.

2 ENVIROMENTAL CONTOUR METHOD

In this section, construction of the environmental contour for a given return period and application of the environmental contour method are presented. Assume that for the N-year return period, the corresponding failure probability of the structure response is given as P_f. As for the traditional IFORM to generate the environmental contour with a N-year return period, a n-dimensional (n is the dimensionality of the environment parameter vector) hypersphere with radius β_F is first created in the U space, with the value of β_F being given as (Haver and Winterstein, 2009):

$$\beta_F = \Phi^{-1}(1 - P_f) \tag{1}$$

where Φ represents the cumulative density function of the standard normal distribution.

Then, the n-dimensional hypersphere is transformed into the physical parameter space by consideration of the joint distribution of the environmental parameters in order to get the environmental contour. Figure 1 presents an example of an environmental contour in the physical parameter space.

After establishment of the environmental contour with the N-year return period, a limited set of design conditions, i.e. short-term environmental conditions, are selected on the environmental contour (e.g. see Figure 1). Time consuming numerical calculations (or expensive experiments) for structural responses are only needed for these selected environmental conditions. The most critical short-term response is identified in order to estimate the long-term extreme response with the N-year return period. The main process of applying the environmental contour method for long-term extreme response approximation is presented in Figure 2.

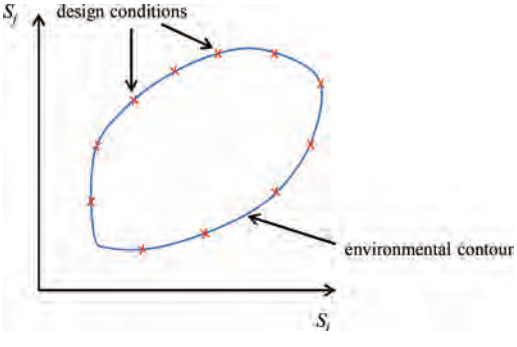

Figure 1. Environmental contour in the physical parameter space and selected environmental design conditions.

3 FIRST-YEAR ICE RIDGE

A ridge is a line or wall of broken ice features forced by pressure or shear. When first formed, an ice ridge is simply a pile of unconsolidated ice blocks. Then, these blocks may become to some extent consolidated by refreezing processes and form the ice ridge. Figure 1 illustrates a typical ice ridge, which consists of two parts: the sail and the keel. The sail part is above the water and has pores filled with air and snow. The keel is the underwater part and can be further separated into an upper completely frozen layer called the consolidated layer, which is always thicker than the surrounding level ice and a lower unconsolidated part that has loose blocks partially refrozen together with water trapped between the blocks (ISO, 2010).

Generally, ice ridges are subdivided into first-year versus older ice ridges. During its first winter and summer, an ice ridge is called a first-year ice ridge (e.g. Figure 3). The consolidation process in the keel part progresses with time and the keel part is closed to fully consolidated if the ridge has survived one summer's melt. Ridges that survive one or more summers are referred to as old ice ridges.

In this work, first-year ice ridges are considered for design of ice-capable vessels. For one thing, the ice conditions along the commercial Arctic shipping routes, such as the Northern Sea Route, are mostly first-year and few ice appears in summer seasons. For another, fewer studies have been made on old ice ridges than the first-year ice ridges and studies for the mechanical and physical properties of the multi-year ice ridges are very limit.

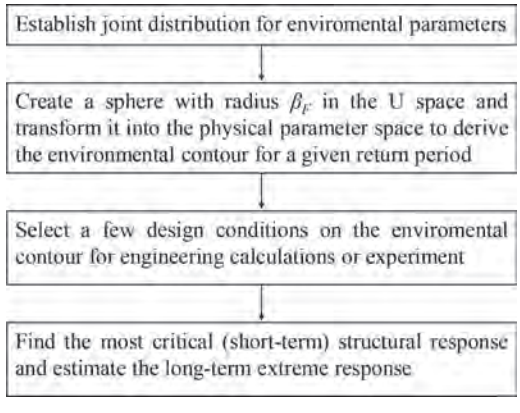

Figure 2. Flowchart of the environmental contour method used for approximate the long-term extreme response.

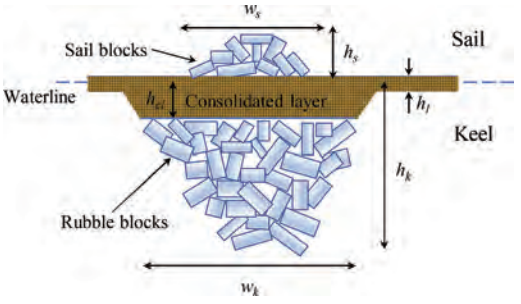

Figure 3. First-year ice ridge with some key parameters: sail draft h_s, sail width ws, consolidated layer thickness h_{cl}, surrounding level ice thickness h_l, keel draft h_k and keel width w_k.

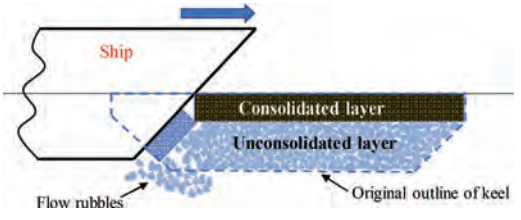

Figure 4. Illustration of ship interacting with a typical first-year ice ridge.

For the scenario of an ice-capable ship interacting with a first-year ice ridge, the ship structure can be simplified as a downward sloping structure. The effects of ridge sail can be neglected since the volume of the sail is small compared to that of the keel part (ISO, 2010). Former studies on a ridge failure against a confederation bridge, whose piers are designed as (slope) ice-breaking cones, have shown that failure of the consolidated layer is the dominant term in determining the keel loads due to the ice ridge interaction with the slope structure. Also, there is no correlation between the keel depth, h_k, and the keel loads. Based on former studies for first-year ice ridge interacting with slope structures, the ship-ice ridge interaction process is illustrated in Figure 4. Flow rubbles from the unconsolidated layer would be cleared by the local water current. The action due to the consolidated layer part can be approximated as level ice with an equal thickness that interacts with the vessel and the mechanical properties of the consolidated layer are assumed to be close to those of level ice. Therefore, the ship-ridge interaction process is further simplified as a ship-level ice interaction event for the purpose of preliminary design.

The ship-level ice interaction process is initiated by a localized crushing of the ice edge and then the contact area between the ship and the ice sheet as well as the crushing force both increase when the ship is advancing and penetrating the ice features. The ice sheet eventually deflects and the bending stresses imply a flexural failure at a certain distance from the crushing region (Jordaan, 2001). Therefore, the ice thickness, the crushing strength and the flexural strength of the (equivalent) level ice are considered as the key parameters for determining the loads due to ship-ice ridge interaction process at the early design stage.

4 PROBABILISTIC MODELS

In this section, probabilistic models are applied in order to describe the distributions of the abovementioned key parameters which determines the loads due to ship-ice ridge interaction. These key parameter are believed to be dependent on geographical location and season, etc. In this work, the first-year ice ridges in the Barents Sea are considered since many field experiments have been performed in this area by relevant Norwegian and Russian research institutes.

The average thickness of the consolidated layer, based on measurements which are collected by mechanical drilling, can be described by a Gamma distribution (Strub-Klein and Sudom, 2012):

$$f(h_{cl}) = \frac{1}{\Gamma(k)\theta^k} h_{cl}^{k-1} \exp\left(-\frac{h_{cl}}{\theta}\right) \tag{2}$$

where k and θ are the shape and scale parameters for the Gamma distribution, respectively. Based on the experimental data, these two values are determined to be 2.97 and 0.54.

The fitted and sample probability density function of the consolidated layer thickness are plotted in Figure 5. However, sample data for the flexural

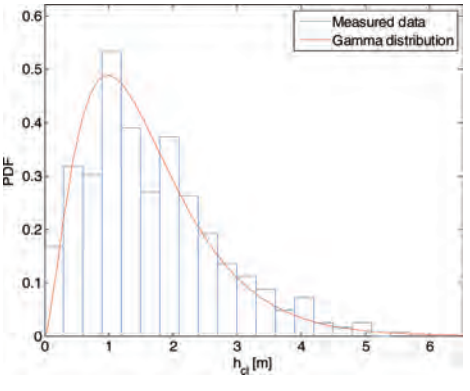

Figure 5. Probability distribution for the consolidated layer thickness h_{cl}.

strength σ_f and the crushing strength σ_c of the consolidated layer is very limited. The mechanical properties of the surrounding level sea ice can serve as effective alternatives (Timco et al., 2000). On the basis of the experimental data for the flexural strength of the level ice in the Barents Sea, the marginal PDF (probability density function) of the flexural strength is described by a two-parameter Weibull distribution (Krupina and Kubyshkin, 2007):

$$f(\sigma_f) = \frac{\beta}{\alpha}\left(\frac{\sigma_f}{\alpha}\right)^{\beta-1}\exp\left(\left(\frac{\sigma_f}{\alpha}\right)^{\beta}\right) \tag{3}$$

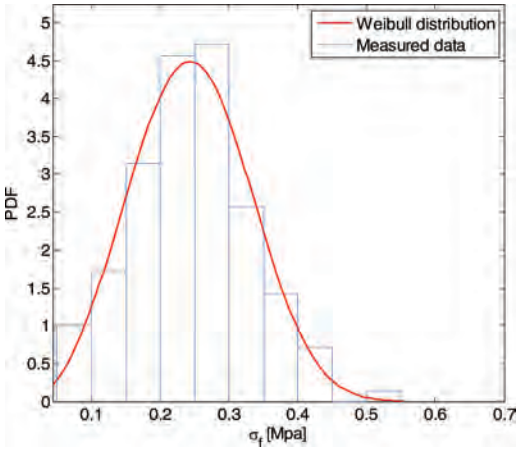

Figure 6. Probability distribution for the flexural strength σ_f.

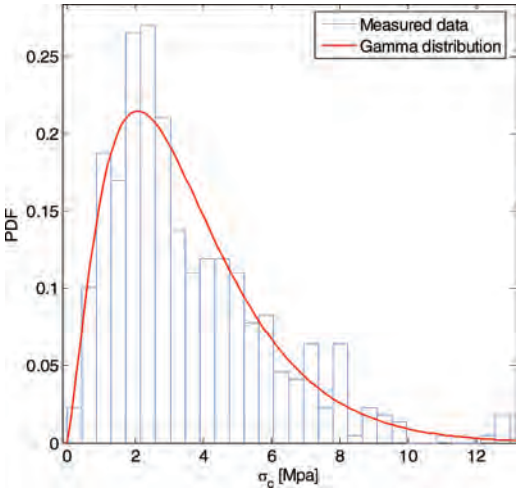

Figure 7. Probability distribution for the crushing strength σ_c.

where the scale parameter $\alpha = 0.274$ and the shape parameter $\beta = 3.167$ are obtained from actual data. The marginal PDF and the empirical histogram of the flexural strength are presented in Figure 6.

Full-scale measurements have been performed to collect the data of the crushing (or compressive) strength of the level ice in the Barents Sea. The distribution of the crushing strength for the vertically loaded samples can be described by the Gamma distribution given in equation (1) with a shape parameter of 2.5 and a scale parameter of 1.40 (Strub-Klein, 2017). The marginal PDF of the of the crushing strength and the corresponding empirical histogram based on experimental data are shown in Figure 7.

5 ENVIROMENTAL CONTOUR

Assume that the desired ice-capable ship mainly sails and operates in the Barents Sea with an annual voyage length of 5000 km in ice ridge fields. The ice ridge density is 2/km along the route. Therefore, for a 50-year return period, the failure probability P_f is determined as:

$$P_f = 1/(50 \cdot 5000 \cdot 2) \tag{4}$$

Correspondingly, the radius of the sphere in the U space, β_F is equal to 4.611 according to equation (1).

Transformation of the sphere in the U space into the environmental contour in the physical parameter space is generally based on the inverse Rosenblatt transformation (DNV, 2010). However, in order to perform such a transformation, the joint distribution of the environmental parameters as described by the conditional modeling approach is required. This necessitates a great amount of sampled data. Due to the limitation of experimental data for the first-year ice ridge statistics, only the marginal PDFs of the abovementioned key parameters can be obtained. Nevertheless, the joint distribution of the environmental parameters with consideration of the correlations between these environmental variables can be approximated by the Nataf distribution model (Silva-González et al., 2013). Then, the environmental contours can be obtained by the Nataf transformation.

Let the variables S_1, S_2 and S_3 represent the consolidated layer thickness, the flexural strength and the crushing strength, respectively. The symbols ρ_{12}, ρ_{13} and ρ_{23} denote the correlation coefficients between these variables. The Nataf transformation model is given as:

$$F_{S_1}(s_1) = \Phi(u_1) \tag{5}$$

$$F_{S_2}(s_2) = \Phi(u_2\sqrt{1-\rho_{12}'^2} + \rho_{12}'\Phi^{-1}(F_{S_1}(s_1))) \tag{6}$$

$$\begin{aligned} F_{S_3}(s_3) = \Phi(&\frac{u_3}{\sqrt{1-\rho_{12}'^2}}\sqrt{1-\rho_{12}'^2-\rho_{13}'^2-\rho_{23}'^2+2\rho_{12}'\rho_{13}'\rho_{23}'} \\ &+\frac{1}{1-\rho_{12}'^2}(\rho_{13}'-\rho_{12}'\rho_{23}')\Phi^{-1}(F_{S_1}(s_1)) \\ &+\frac{1}{1-\rho_{12}'^2}(\rho_{23}'-\rho_{12}'\rho_{13}')\Phi^{-1}(F_{S_2}(s_2))) \end{aligned} \tag{7}$$

where U_1, U_2 and U_3 represent independent standard normal variables and their values can be obtained based on the following equation:

$$\sum_{i=1}^{3} u_i^2 = \beta_F^2 \tag{8}$$

The coefficients ρ_{ij}' ($i, j = 1, 2, 3$; $i \neq j$) are the corresponding (equivalent) correlation coefficients used in the Nataf transformation and their relationship with ρ_{ij} can be approximated by a semi-empirical equation, which is given as:

$$\rho_{ij}' = \xi \cdot \rho_{ij} \tag{9}$$

where relevant description for determining the function ξ can be found in Ref. (Liu and Der Kiureghian, 1986).

There exist few previous studies on the correlation between these three key parameters for sea ice material. For simplicity, we assume that the correlation coefficients ρ_{ij} ($i, j = 1, 2, 3$; $i \neq j$) are equal to 0.5. Correspondingly, the 50-year contour surface for the three key parameters is obtained by the Nataf model described by equations (5)–(9) and it is plotted in Figure 8.

The correlation coefficients in this simple case are chosen somewhat arbitrarily due to a imitated amount of information in the literature. Therefore, the influence of the correlation coefficient on the shape of the environmental contour is studied in a parametric way. For simplicity, a two-dimensional contour line on the contour surface is selected for this sensitive study. The consolidated layer is fixed as its mean value 1.59 m, and the corresponding two-dimensional contour lines for different values of the correlation coefficient between the flexural strength and the crushing strength are plotted in Figure 9. In addition, for the sensitive study, ρ_{12} and ρ_{13} are kept at a fixed value equal to 0.5.

It is seen in Figure 9 that the variation of the correlation coefficient has a quite important effect on the shapes of the contour lines. The maximum values of the flexural strength and the crushing strength on the contour line do not change with the correlation coefficient. However, the critical

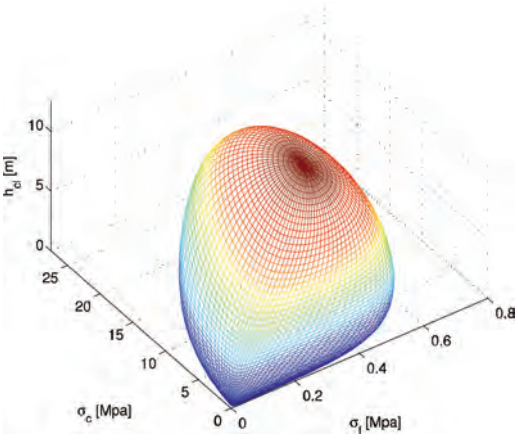

Figure 8. The 50-year contour surface for the consolidated layer thickness, flexural strength and crushing strength.

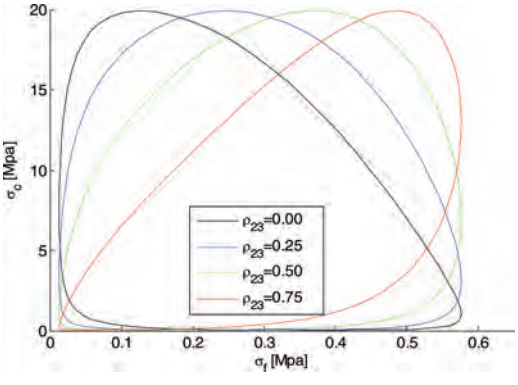

Figure 9. Influence of the correlation coefficient on the two-dimensional contour lines.

region with large values of the flexural strength and crushing strength becomes narrow as the correlation coefficients increase. Narrower critical region implies that large values of the flexural strength are more easily (or more possibility) to be accompanied by large values of the crushing strength, which would cause serious structural response. Therefore, the correlation coefficients has significant influence on the extreme response for the ice-capable vessel sailing in the ice ridge field.

6 CONCLUSIONS

In this work, the environmental contour method was proposed for design of ice-capable vessels sailing in areas with ice ridges. Environmental

contours for the key parameters of the first-year ice ridge have been established by applying the Nataf model.

Based on the abovementioned simple case, it is found that variation of the correlation coefficients between the environmental parameters has a very important influence on the shapes of the environment contour as well as on the extreme response of the vessel. Therefore, a reliable numerical model is important in order to investigate this influence.

Furthermore, better knowledge for the correlations between these key parameters, either provided by experiments or numerical simulations, will promote the development of reliability-based design of ice-capable vessels in Arctic regions.

Partial factors for fatigue loads in the Eurocode system for road bridge design

S.B. Hashemi, J. Maljaars & H.H. Snijder
Department of the Built Environment, Eindhoven University of Technology, Eindhoven, The Netherlands

ABSTRACT: In the Eurocode system, for fatigue design of bridges, the recommended partial factor for fatigue traffic loads is set to 1. In this paper, the adequacy of this approach is investigated by performing a reliability analysis on two types of welded joint in a main girder of a steel motorway bridge. For this purpose, a weigh in motion measurement dataset belonging to a main Dutch motorway has been compared with the fatigue load model 4 of Eurocode EN 1991-2 with respect to the stress spectrum and the fatigue damage of two structural steel details. Several structural schemes have been considered to study the effect of the shape and length of the influence line. The distributions of the stochastic variables such as dynamic amplification, accuracy of the structural model, and future traffic trends have been estimated or taken from literature. Partial factors for fatigue loads have then been calibrated in such a way that the target reliability is obtained. The influence of each stochastic variable on partial factors has been studied by derivation of the sensitivity factors. The results show that a considerably higher fatigue partial factor is required for fatigue loads on road bridges than the value of 1 currently recommended in EN 1991-2.

1 INTRODUCTION

Most of the parameters governing the load effects on a structure as well as the structure's response are uncertain in nature. To avoid the complexity of dealing with these random variables, standards such as Eurocode provide a deterministic model for structural design wherein characteristic values are provided for the load and the resistance and these values need to be corrected by partial factors to arrive at the design values, the latter giving the desired reliability level. In the other word, partial factors are introduced to link the deterministic models used for practical design to the required reliability level. The general equation for design of a structural component according to the Eurocode standard (EN1990, 2002) is;

$$\frac{R_c}{\gamma_M} - \gamma_F \times E_c \geq 0 \quad \rightarrow \quad R_d \geq E_d \tag{1}$$

where R_c and R_d are the characteristic and design values of the material resistance respectively, E_c and E_d are the characteristic and design values of the load effect, γ_M is the partial factor for the resistance and γ_F is the partial factor for the load effect. In the Eurocode system for fatigue design of bridges (EN1991-2, 2003) (EN1993-1-9, 2005), a partial factor larger than 1 is recommended only on the resistance side of the limit state (γ_{Mf}) and the partial factor on the load side (γ_{Ff}) is recommended as 1. The factor γ_{Mf} depends on the choice of fatigue assessment method as well as the consequences of failure. For the safe-life fatigue assessment method and a structure with high consequence of failure, γ_{Mf} is recommended as 1.35. In this paper, the adequacy of these partial factors is investigated in a probabilistic approach where all influential random variables are attempted to be modelled as close to reality as possible. For this purpose, several structural schemes are defined and for each one of them, two structural details are designed to meet the Eurocode's safety requirements. Subsequently, the reliability of each designed case at the end of service life (100 years) is evaluated by the probabilistic approach and is compared with the safety requirement of the Eurocode (EN1990, 2002). Partial factors are calibrated in such a way that the deterministic design with partial factors arrives at the target reliability level.

2 METHODS

To consider the effects of the shape and length of the influence lines on the reliability analysis outcomes, four different structural schemes (Figure 1) with three different span lengths (L = 5 m, 20 m and 100 m) are considered. These are the same structural schemes which have been used for calibration of fatigue load models in Eurocode. Furthermore, two common structural details in

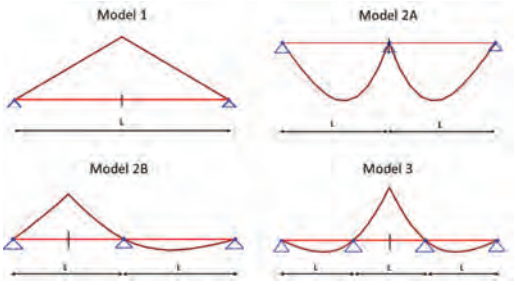

Figure 1. Structural schemes used in the analyses.

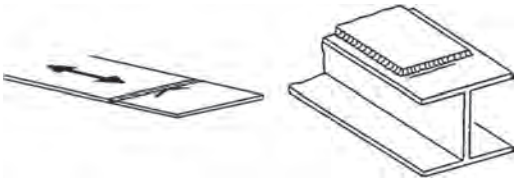

Figure 2. Left: Transverse butt welded joint (Category 80), Right: Cover plate (Category 50).

bridges, transverse butt weld joint and cover plate (Figure 2), are chosen to study the effect of the different S-N curves on the partial factors.

2.1 *Deterministic approach*

The first step in the reliability analysis is to design a structure for fatigue according to the Eurocode system. For this purpose, the fatigue load model 4 (FLM4) for road bridges has been applied on the selected structural scheme (influence line) and for a fictitious cross section (section modulus) the characteristic stress spectrum will be obtained by using the rain flow cycle counting method. FLM4 is selected for this purpose because it is the most accurate fatigue load model in the Eurocodes. It consists of a set of five heavy vehicles, each having a certain axle configuration, load distribution and fraction of the total traffic volume. These are pulled over the influence line, resulting in a stress history. A rain flow counting procedure subsequently provides the characteristic stress spectrum, which is multiplied by a partial factor γ_{Ff} so as to arrive at the design stress spectrum. The design stress spectrum is to be compared to the fatigue resistance. However, because the recommended value of γ_{Ff} is set equal to 1, the characteristic and design spectra are the same. The cumulative stress spectrum obtained for the structural scheme 3 with span length of 100 m is shown with solid black curve in Figure 3.

The fatigue resistance is a term referring to the capability of a specific structural detail to withstand the repetitive loads. This feature can be studied by laboratory tests and be presented by the so called S-N curve. The number of the load cycles (N) that the detail can resist under repetitive loading with stress range $\Delta\sigma$ is recorded during the experiment and the S-N curve is the curve fitting these points. In Eurocode (EN1993-1-9, 2005), this curve is tri-linear in log-log scale and can be presented by the following equation;

$$\log(N) = \log(a_i) - m_i \log(\Delta\sigma) \tag{2}$$

where a – the N-axis-intercept – and m – the negative inverse slope – are properties depending on the detail type and the index i indicates two different branches of the trilinear curve. The first line (i = 1) descends with $m_1 = 3$ until the point known as the constant amplitude (CA) fatigue limit (CAFL) which is defined at $N = 5 \cdot 10^6$ cycles. To consider the effect of the variable amplitude (VA) loading, the second line (i = 2) is extended from the CAFL with $m_2 = 5$ until the fatigue cut-off limit at $N = 10^8$ cycles. Damage below this cut-off value is ignored. The characteristic values of a_1 and a_2 can be calculated using (EN1993-1-9, 2005) for each detail type.

The characteristic S-N curves are divided by γ_{Mf} to obtain the design curves. These S-N curves are shown in blue in Figure 3 for the cover plate.

Having the design stress spectrum and design S-N curves, the fatigue damage (D) can be calculated using the Palmgren Miner damage accumulation rule (Miner, 1945). According to this rule, all stress cycles cause proportional fatigue damage which is linearly additive:

$$D_n = \sum_i d_i = \sum_i n_i / N_i \tag{3}$$

where D_n is the damage due to $n = \sum_i n_i$ cycles, d_i is the damage caused by all stress cycles n_i in the design stress spectrum that have the same range $\Delta\sigma_i$ and N_i is the number of cycles to failure for

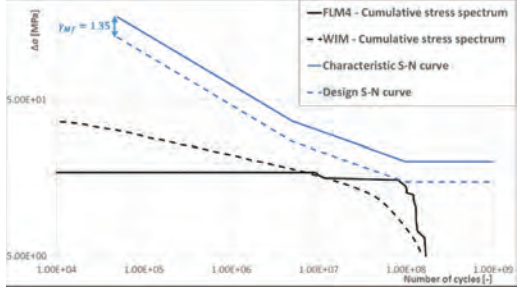

Figure 3. Deterministic cumulative stress spectra and S-N curves for cover plate.

that same stress range obtained from the S-N relation in equation (2).

For the structures designed by Eurocode's regulations, D_n should be equal to or smaller than 1 at the end of life. By adjusting the section modulus in such a way that D_n is equal to 1, a structure is obtained that just meets the requirement for fatigue.

In the next step, to simulate the reality more accurately, a Weigh In Motion (WIM) data set belonging to a main Dutch highway (A16) is used instead of FLM4. WIM is a traffic measurement system which is able to record the speed, the number of axles, the axle loads and the axle distance of a passing vehicle as well as the distance between consecutive vehicles. In the considered WIM dataset, these traffic properties are recorded for a traffic flow in one direction and for the duration of one month. Thus, to simulate the traffic flow for the structure's entire service life of 100 years, the recorded number of $2 \cdot 10^5$ heavy vehicles should be multiplied by 1200 if trends are absent. The analysis is proceeded by applying the measured traffic on the previously adjusted influence line for each structural scheme and detail. This resembles the situation when a bridge is designed following Eurocode system and is loaded by actual traffic. The stress spectra for actual traffic are calculated as explained for FLM4 and in this paper are referred to as 'WIM' spectra. The WIM cumulative stress range spectrum for the case of structural scheme 3 with span length of 100 m is shown with dashed black curve in Figure 3. The stress range spectrum of both load models are indicated in Figure 3 for the structural scheme 3 and span length of 100 m.

2.1.2 *Probabilistic approach*

There are several sources of uncertainty on the load side such as dynamic amplification factor (DAF), trend amplification factor (t) and load effect model uncertainty (B). On the material resistance side, uncertainties can be considered by scatter of the fatigue test data. In the following, these random variables are described in more detail.

A DAF should be introduced to compensate for the absence of the dynamic vehicle-bridge interaction in the WIM database. Theoretical studies to determine the DAF are usually aimed at the ultimate limit state and give an exaggerated effect for a fatigue assessment. In practice, this factor can therefore be calculated as the ratio between the maximum stress recorded at the crossing of a test vehicle with high speed (e.g. 80 km/h) and with low speed (e.g. 20 km/h). Based on the strain gauge measurements carried out on some Dutch motorway bridges, DAF in this study is assumed to be distributed according to Table 1. However, there is room for improvement of this distribution by collecting more measurement data.

The trend amplification factor takes into account possible change in load over time. The design life of important bridges is usually 100 years and in that period vehicle's number and weight can change significantly. Clearly, there is a large uncertainty in estimating trends and nevertheless, it should be estimated based on either the assumptions or extrapolation of very limited available data. The Dutch standard for assessment of existing structures (NEN8701, 2011) suggests an increase of 20% on axle loads in 100 years, i.e. a linear trend in time with an average annual increase of 0.2% with respect to the design year (Figure 4). An uncertainty over this trend increasing with time with a standard deviation of 0.05 after 100 years is assumed. The linear trend is approximately equivalent to an average increase of 10% in axle loads over the entire life with a standard deviation of 9%. The annual loads are thus multiplied by factor (t) which is statistically distributed as

Table 1. Distribution of random variables.

Variable		Distribution	*mean*	STD
DAF	Dynamic amplification factor	Log-normal	1	0.05

*a_1 and a_2 are fully correlated.

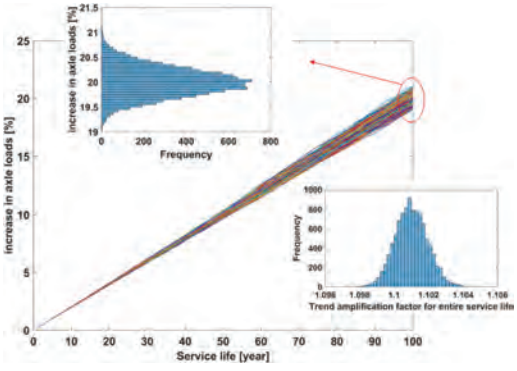

Figure 4. Trend amplification factor distribution.

shown in Figure 4 and is presented in Table 1. A possible change in number of vehicles is not considered. Background of this assumption is that the considered highway—containing 3 lanes per traffic direction—is believed to have reached is maximum capacity. A higher number of vehicles is expected to result into significant traffic jam and thus no larger number of passing vehicles.

Section 2.1.1 demonstrates that an influence line is required to determine the stress ranges. In practice, such an influence line is subtracted from a structural model of the bridge. The model may contain approximations and errors, so this influence line might be different from reality. The uncertainty related to this issue is known as the load effect model uncertainty. By comparing the calculated influence line with the influence line derived from the measurement, this uncertainty can be evaluated. In this study, the JCSS (JCSS, 2001) recommendation is used for the distribution of the load effect model uncertainty (Table 1).

The fatigue resistance is known for its significant scatter. This is mainly due to the uncontrollable differences in test samples. For simplicity, the slopes of the fitted lines m_1 and m_2 are assumed to be constant and the scatter is presented by the random variables a_i in Equation (2). EN 1993-1-9 includes the characteristic lines having 95% probability of survival and the scatter is not mentioned. Therefore, in this research, the standard deviations of the logarithm of $a_i (Log(a)_{STD,i})$ are taken from the British standard (BS7608, 2014). Starting with the characteristic values a_1 and a_2 from Eurocode (EN1993-1-9, 2005), their mean values can be obtained as;

$$Log(a)_{mean,i} = Log(a)_{characteristic,i} + 1.645 Log(a)_{STD,i} \quad (4)$$

Having the distribution parameters for all random variables, reliability analysis can be performed to evaluate the safety status of the designed details at the end of the service life. Figure 5 shows the WIM cumulative stress spectrum and its lower (5% fraction) and upper (95% fraction) bounds for the structural scheme 3 with span length of 100 m as well as the mean S-N curve and S-N curves with 5% and 95% probability of survival for a cover plate detail including all random variables introduced above.

2.2 *Reliability analysis*

The limit state function is defined as;

$$g(\boldsymbol{X}) = D_{cr} - D_n(\boldsymbol{X}) \quad (5)$$

where the random variable D_{cr} is the critical damage, D_n is the fatigue damage at the end of life and $\mathbf{X}$ is the vector of all previously mentioned random variables. D_{cr} follows a lognormal distribution with parameters according to Table 1 (JCSS, 2001). Failure can be defined as the situation wherein $g(\boldsymbol{X}) < 0$. Therefore, probability of failure is defined as;

$$P_f = P\left[g(\boldsymbol{X}) < 0 \right] = \int_{g(x)<0} f_x(\boldsymbol{X})\, dx \quad (6)$$

where $f_x(\boldsymbol{X})$ is the multivariable probability density function of $\mathbf{X}$. First Order Reliability Method (FORM) is used to approximate the integral in equation (6). FORM, developed by (Hasofer & Lind, 1974) is based on the idea that in the standard normal space, the reliability index, β, is the shortest distance from origin to the limit state surface $g(\boldsymbol{U}) = 0$, where $\mathbf{U}$ is the vector of normalized random variables. The point $\mathbf{u}^*$ on the limit state surface which has the shortest distance to the origin is known as the design point or the most probable failure point. Finding the design point is an iterative process and once calculated, the reliability index is

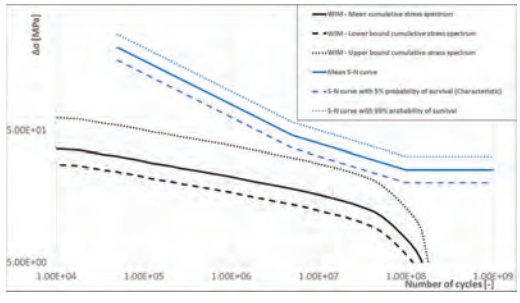

Figure 5. Probabilistic cumulative stress spectra and S-N curves for cover plate including all random variables.

obtained. Another direct outcome of the FORM is the sensitivity factor of each random variable, α_i, which is a measure for the relative importance of the standard deviation of the ith random variable to the reliability index. It can be calculated as;

$$\alpha_i = -u_i^* / \beta \tag{7}$$

Sensitivity factors are used for derivation of partial factors according to the following equation;

$$\gamma_{fi} = \frac{\left[1 - \alpha_i \beta_t STD(E_i)\right] \times mean(E_i)}{characteristic(E_i)} \tag{8}$$

where β_t is the target reliability index (Section 2.1.4), E_i is the ith random variable and γ_{fi} is the required partial factor for E_i.

Fatigue design factor (FDF) is defined as the multiplication of partial factors of resistance and load effect random variables;

$$FDF = \prod_i \gamma_{Mfi} \times \prod_j \gamma_{Ffj} = \gamma_{Mf} \times \gamma_{Ff} \tag{9}$$

The accuracy of FORM is checked by a Crude Monte Carlo (CMC) simulation with $4 \cdot 10^6$ number of samples. In this method, the probability of failure can be calculated as the ratio of the number of failure cases $\left(g(X) < 0\right)$ over the total number of CMC samples. Having the probability of failure, the reliability index can be calculated as;

$$\beta = -\Phi^{-1}\left(P_f\right) \tag{10}$$

where $\Phi^{-1}(.)$ is the inverse cumulative normal distribution function.

2.3 *Target reliability index*

Target reliability index (β_t) is the answer to the question "What level of safety is sufficient?". Several factors play a role in this answer, including the consequence of failure in terms of both loss of human life and economical aspects, the required cost for improving safety, the structure's planned service life and the type of considered limit state. In Eurocode, β_t for fatigue limit state is ranging between the target values of the reliability indices for the ultimate and serviceability limit states. For the structures such as bridges which can be categorized into the consequence class 3 (EN1990, 2002), with details having large consequences of failure and that are designed according to the safe life concept, the target reliability index for fatigue is set equal to the ultimate limit state value of 4.3.

3 RESULTS AND DISCUSSIONS

Having in mind that the results of this study are widely dependent on the assigned distributions of the random variables, the reliability indices at the end of life for both cover plate and transverse butt welded joint and for the all structural schemes are shown in Figure 6. For all considered cases, the reliability index is lower than the target value when applying the recommended values of partial factors. In addition, it can be observed that the value of β depends on the shape and length of the influence line. This is caused by the approximations and simplifications in the fatigue load model FLM4. Furthermore, it can be observed that the cover plate results in slightly higher reliability at the end of life than the transverse butt weld joint, due to the differences in scatter of the fatigue resistance (Table 1).

The corresponding fatigue design factors for each detail and structural scheme and under the WIM spectra (structure designed with characteristic FLM4 and loaded by WIM measured traffic) are shown in Figure 7.

For the span length of 100 m and especially for Model 2A, the values of FDF are much higher than the value resulting from the recommended

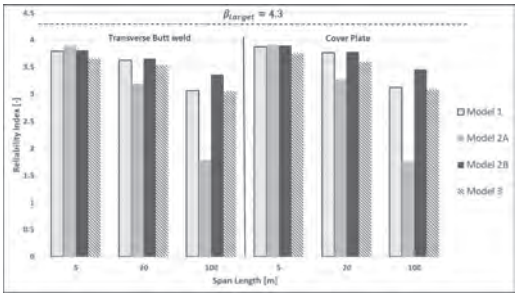

Figure 6. Reliability indices at the end of life.

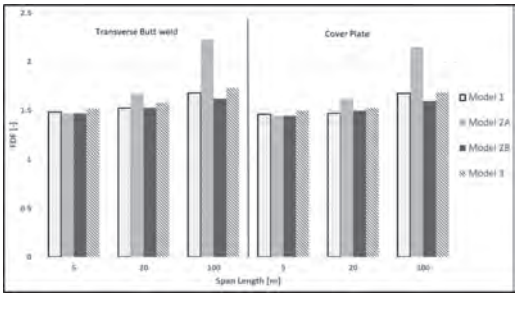

Figure 7. Required fatigue design factors to reach the target reliability index at the end of service life.

partial factors and these are not in line with the other values. The reason is the deficiency of FLM4 to simulate the real traffic flow for the bridges with very long span. In the Dutch national annex to EN 1991-2 (EN1991-2/NB, 2011), this flaw is fixed by introducing a second heavy vehicle on the bridge in 20% of the number of heavy vehicle crossings for continuous positive or negative influence lengths larger than 60 m. The center to center distance between these two vehicles is set as 50 m.

Repeating the reliability analysis with FLM4a according to the Dutch NA, the values of FDF for the span length of 100 m are reduced to the values presented in Figure 8. These values can still be as high as 1.92 for model 2 A but usually fatigue is not the dominant failure mode at location of the intermediate support of a two span bridge. This example—and the still significant differences between the various structural schemes—demonstrate the necessity of updating the fatigue load models in the Eurocode.

Now that the FDF is determined, the next step is to distribute this over γ_{Mf} and γ_{Ff}. A direct determination of the partial factors based on the FORM sensitivity factors is problematic, because:

- for fatigue the three-branch S-N curve uncertainty is related to the number of cycles and not to the stress range, and;
- the entire stress range spectrum influences the reliability instead of a single stress value. As demonstrated in Figure 3, the shape of the stress range spectrum of FLM4 is not in agreement with that of the WIM data.

For this reason, an intermediate step is taken where the section modulus is determined using the S-N curve as resistance model and the WIM database as load model. In this case, the uncertainty on the load side is captured in the multiplication of the DAF, t and B. This results in a single multiplication factor for the stress spectrum and hence

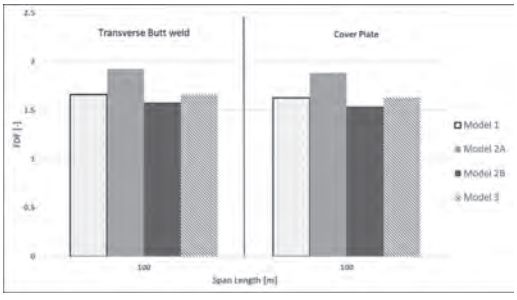

Figure 8. Required FDF after modification of FLM according to the Dutch national annex.

Table 2. Sensitivity factors of random variables.

Variable	DAF	t	B	$Log_{10}(a_1)$	$Log_{10}(a_2)$	D_{cr}
α	–0.268	–0.0044	–0.534	0.0739	0.728	0.329
$\sum \alpha^2$	0.357			0.643		
γ_{Ffi}*	1.06	1.1	1.23			

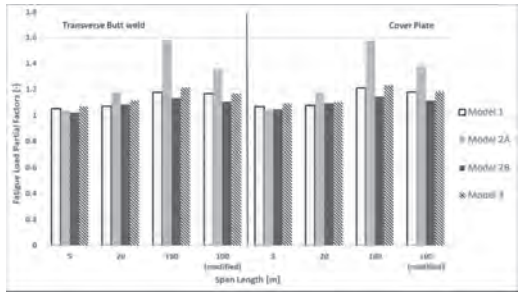

Figure 9. Fatigue load partial factors.

enables the determination of a modified partial factor for the load side, γ_{Ff}*, via the influence factors α_t, α_{DAF} and α_B. Note that γ_{Ff}*, considers the uncertainties related to the load side but not the inaccuracy of FLM 4 to represent the WIM measurement. The same analysis gives the modified fatigue design factor FDF* and the partial factor on the resistance side can now be determined as γ_{Mf} = FDF*/γ_{Ff}*. Finally, the partial factor on the load side including the difference between the actual WIM data and the FLM4 model is determined with the FDF of the original analysis of Figures 7 and 8, via γ_{Ff} = FDF/γ_{Mf}.

As expected, the factors FDF*, α_t, α_{DAF}, α_B and γ_{Mf} are almost independent on the structural models—variation of less than 2%. This demonstrates the consistency of the approach.

Table 2 presents the sensitivity factors of all random variables as well as γ_{Ffi}* values for the transverse butt welded joint located on model 2B with span length of 20 m.

For the case of transverse Butt welded joint, the value calculated for γ_{Mf} is 1.42 (i.e. 5% higher than Eurocode's recommendation) and for the case of cover plate it is equal to 1.37 (1.8% higher than Eurocode's recommendation). The calculated values of γ_{Ff} are presented in Figure 9. It can be observed that for all considered cases, γ_{Ff} has a value larger than Eurocode's recommended value of 1. Considering all studied structural schemes with all assigned span lengths and for both structural details, γ_{Ff} takes the average value of 1.16 with standard deviation of 0.13.

4 CONCLUSION

In this paper the necessity of increasing the values of partial factors for fatigue traffic load models in Eurocode to design a steel bridge with the safe-life assessment approach has been studied. For this purpose, two different structural details located in twelve structural schemes have been designed to meet the Eurocode's fatigue safety requirements. After studying the random variables which influence the fatigue limit state and assigning a distribution to each one of them, each designed detail has been loaded by measured traffic and reliability analysis has been performed to evaluate the safety status of the detail at the end of its life. It has been observed that in all cases, the reliability index is lower than the minimum acceptable value set by the standard. The reliability depends on the structural detail as well as the shape and length of influence line. The study has been proceeded by calculating the values of the partial factors that are needed to reach the standard's target reliability level. The calculated fatigue resistance partial factors are 1.37 and 1.42 for the two steel details considered and these values are slightly higher than the recommended factor of 1.35 in the Eurocodes. The main finding of this study is that the value of fatigue load partial factor recommended by the Eurocodes is too low for fatigue load model FLM4. For all studied structural schemes and for both chosen details, the required load partial factors γ_{Ff} are higher than the factor 1 as recommended by the Eurocodes. The factor γ_{Ff} strongly depends on the shape and length of influence lines and varied between 1.02 and 1.58 for the considered systems.

The values presented should not be considered as 'the truth' because they are subjected to the choices of the distributions of load related variables. Nonetheless, it is clear that the recommended partial factor of 1 in the current Eurocodes is too small and the large differences in the calculated factors demonstrate the necessity of improving the fatigue load models in the Eurocode.

A sensitivity analysis to study the effect of the most influential load related random variables on the partial factors is another outcome of this study. It has been found that load effect model uncertainty has a large impact on the results, followed by the load trend amplification factor. Dynamic amplification factor has a lower influence than the other variables. Based on this analysis, future studies can be planned to evaluate the distribution parameters of these random variables.

Reliability analysis in the presence of Aleatory uncertainty

L.G. Crespo, S.P. Kenny & D.P. Giesy
Dynamic Systems and Control Branch, NASA Langley Research Center, Hampton, Virginia, USA

ABSTRACT: This paper proposes a method for characterizing a system's response given data. This response might prescribe the failure domain needed to assess the reliability of such a system. We focus on the case in which not all uncertain parameters affecting the response are observable and the measurements are corrupted by noise. In this setting, the system response is not given by a function but instead by a random process. In this paper we use a staircase random predictor model to characterize such a process. Consequently, the resulting failure probability is not a scalar but a random variable. This variable accounts for the aleatory contributions of the model-form uncertainty and the measurement noise affecting the system's response. Furthermore, we propose a framework that enables trading off the system's performance, measured by the extension of an acceptable range of operating conditions, against the system's reliability, measured by an admissible range of failure probabilities. The risk incurred by such a practice is ignoring a (small) percentage of the predicted worst-case system responses. These ideas are illustrated by performing the reliability analysis of an aeroelastic structure subject to flutter instability. Furthermore, this paper puts forth a means to quantify the error resulting from having a dataset of limited size when performing the above analysis.

1 INTRODUCTION

Metamodeling (Simpson, Peplinski, Koch, & Allen 2001) refers to the process of creating a mathematical representation of a phenomenon based on input-output data. This paper uses a metamodeling technique for constructing computational models describing the distribution of a continuous output variable. These models are called *Random Predictor Models* (RPMs) because the predicted output corresponding to any given input is a random variable. One common example of an RPM is a Gaussian Process (GP) model (Rasmussen & Williams 2006). In contrast to GP models, which only lead unimodal and symmetric responses, we focus on RPMs having a bounded support set and prescribed values for the first four moments. The manipulation of these functions enables the generation of predictors that accurately describe possibly skewed and multimodal responses typical of many physical phenomena.

This paper extends the developments on RPMs made by the authors to account for sampling error in the moment estimates. As an application, we use RPMs for the reliability and risk analysis of a flexible structure. To make the paper self-contained, essential concepts are presented. Supplemental information is available at (Crespo, Giesy, & Kenny 2017a).

2 PROBLEM STATEMENT

A DGM is postulated to act on a vector of input variables, $x \in \mathbb{R}^{n_x}$, to produce an output, $y \in \mathbb{R}^{n_y}$. In this article the focus will be on the single-output ($n_y = 1$) multi-input ($n_x \geq 1$) case. The dependency of the output on the input is arbitrary. This covers the case in which y is a function of x with all components of x available (so there is only one output value for each available input), the case in which y is a function of x but not all components of x are available (so there might be infinitely many outputs for each measured input, and the case in which y is an arbitrary random process of x. Assume that N Independent and Identically Distributed (IID) input-output pairs are obtained from a stationary DGM, and denote by $\mathbb{D} = \left\{x^{(i)}, y^{(i)}\right\}$, for $i = 1, \quad N$ the corresponding data sequence. The main objective of a predictor model is to generate a computational representation of a DGM based on the data in $\mathbb{D}$. Two types of predictors will be used hereafter. An Interval Predictor Model (IPM) yields a bounded interval of output values at any value of the input. The desired IPM is a narrow interval wherein unobserved data will fall with high probability. Conversely, a Random Predictor Model (RPM) yields a random variable at any value of the input. The desired RPM accurately describes the distribution governing the DGM.

3 PRELIMINARIES

Consider the continuous random variable z with support set $\Delta_z = [z_L, z_U]$ Probability Density Function (PDF) $f_z : \Delta_z \subset \mathbb{R} \to \mathbb{R}^+$, and Cumulative Distribution Function (CDF) $F_z : \Delta_z \to [0,1]$. Denote by m_r the r-th central moment of z, which is defined as

$$m_r = \int_{\Delta_z} (z-\mu)^r f_z(z)\, dz, r = 0,1,2,\ldots \tag{1}$$

where μ is the expected value of z. Note that $m_0 = 1$, $m_1 = 0$, m_2 is the variance, m_3 is the third-order central moment, and m_4 is the fourth-order central moment. Where reference is made to the r-th moment of a random variable, we assume that the corresponding integral in (1) converges for that distribution.

The random variables of interest will be constrained to have a bounded support set and given values for μ, m_2, m_3, and m_4. The bounded support constraint is $\Delta_z \subseteq \Omega_z$, where $\Omega_z = [\underline{z}, \overline{z}]$ with $\overline{z} \geq \underline{z}$ given, whereas the moment constraints are given by (1). The parameters of these constraints will be grouped into the variable $\theta_z \in \mathbb{R}^6$ given by

$$\theta_z = [\underline{z}, \overline{z}, \mu, m_2, m_3, m_4]. \tag{2}$$

Any random variable z having a support set contained by $[\underline{z}, \overline{z}]$ with moments μ, m_2, m_3, and m_4 must satisfy the feasibility conditions $g(\theta_z) \leq 0$ given in (Crespo, Giesy, & Kenny 2017b). The realizations of θ satisfying these conditions constitute the θ-feasible domain, Θ, defined as

$$\Theta = \{\theta : g(\theta) \leq 0\}. \tag{3}$$

A member of Θ will be called θ-feasible. Determining membership in Θ is a distribution-free assessment applicable to possibly infinitely many random variables satisfying the desired constraints.

A particular class of random variables that can realize most of Θ is proposed in (Crespo, Giesy, & Kenny 2017b). This class is called *Staircase* because the PDF of its members is piecewise constant over bins of equal width. Staircase variables, are calculated by solving the convex optimization program

$$\min_{\ell \geq 0} \{ J(\theta, n_b) : A(\theta, n_b)\ell = b(\theta), \theta \in \Theta \}, \tag{4}$$

where J is the cost function used for optimization, n_b is the number of bins partitioning Ω_z, $\ell \in \mathbb{R}^{n_b}$ are the values of the PDF at the bin centers, and $A\ell = b$ are moment matching constraints. Staircase variables enable modeling complex phenomena efficiently. Staircase variables will be denoted as

$$z \sim S_z(\theta_z, n_b, J). \tag{5}$$

When the cost is chosen to be the entropy, E, we obtain a maximal entropy staircase variable. The points $\theta \in \Theta$ for which a staircase variable with n_b bins exists constitutes the staircase feasible domain, $\mathcal{S}(n_b)$. As expected, $\mathcal{S}(n_b) \subset \Theta$. Supplemental information is available at (Crespo, Giesy, & Kenny 2017b).

3.1 *Staircase estimation*

This section focuses on the estimation of the hyperparameter θ_z of a staircase variable S_z from the samples $z^{(1)}, \ldots z^{(N)}$. Expert opinion should be used to prescribe n_b and the bound to the support Ω_z. Whereas Ω_z must[1] contain $\dot{\Delta} = [\min\{z^{(j)}\}, \max\{z^{(j)}\}]$, the moments μ, m_2, m_3, and m_4 can be chosen to be the sampling moments $\dot{\mu}, \dot{m}_2, \dot{m}_3$ and $\dot{m}_4$. The developments that follow account for the error incurred by using these estimates.

Lets first focus on the error incurred by using $\Omega_z \supset \dot{\Delta}$. Finite values of N often make $\dot{\Delta}$ a subset of the support set Δ. Scenario optimization (Campi & Garatti 2008) enables bounding the probability of the tails of the PDF of z extending beyond $\dot{\Delta}$. In particular,

$$\mathbb{P}\left[z \notin \dot{\Delta} \right] = \kappa q^\top \ell \leq \hat{\epsilon}, \tag{6}$$

where

$$\hat{\epsilon} = 1 - e^{\log(\beta)/(N-1)}, \tag{7}$$

β is the confidence parameter, and $q \in \mathbb{R}^{n_b}$ is:

$$q_i = \begin{cases} 1 & \text{if } (z_i, z_{i+1}] \subset \Omega_z \setminus \dot{\Delta}, \\ 0 & \text{if } (z_i, z_{i+1}] \subset \dot{\Delta}, \\ \dfrac{min\{z^{(j)}\} - z_i}{z_{i+1} - z_i} & \text{if } z_i \leq \min\{z^{(j)}\} \leq z_{i+1}, \\ \dfrac{z_{i+1} - max\{z^{(j)}\}}{z_{i+1} - z_i} & \text{otherwise.} \end{cases}$$

Equation (6) ensures that the staircase variable conforms to the tails probability bound from convex scenario theory.

We now focus on the error in the sample moments. This error, fully prescribed by the corresponding sampling distributions, can be quantified

[1] Sampling estimates will be denoted with a dot-superscript.

by using bootstrapping techniques. Alternatively, an asymptotic approximation to the sampling distribution, grounded in the central limit theorem, can be used instead. Such a distribution is given by the normal variables

$$\begin{aligned}
\mu &\sim \mathcal{N}_{\mu}\left(\dot{\mu}, \sqrt{\frac{\dot{m}_2}{N}}\right), \\
m_2 &\sim \mathcal{N}_{m_2}\left(\dot{m}_2, \sqrt{\frac{\dot{m}_4 - \dot{m}_2^2}{N}}\right), \\
m_3 &\sim \mathcal{N}_{m_3}\left(\dot{m}_3, \sqrt{\frac{t_1}{N}}\right), \\
m_4 &\sim \mathcal{N}_{m_4}\left(\dot{m}_4, \sqrt{\frac{t_2}{N}}\right),
\end{aligned} \tag{8}$$

conditional on $\theta \in \Theta$, where $\dot{m}_k$ for k = 5,6,7,8 are the sample fifth, sixth, seventh and eighth central-order moments and $t_1 = \dot{m}_6 - \dot{m}_3^2 - 6\dot{m}_4\dot{m}_2 + 9\dot{m}_2^3$, $t_2 = \dot{m}_8 - \dot{m}_4^2 - 8\dot{m}_5\dot{m}_3 + 16\dot{m}_2\dot{m}_3^2$. These expressions correspond to an arbitrarily distributed variable z for a sufficiently large value of N (Kendall & Stuart 1969). For small values of N, bootstrapping techniques often yield a more accurate approximation.

To account for sampling error in the calculation of a staircase variable, the moment matching constraints are replaced by the polynomial inequality constraints

$$\underline{\mu} \le \mu(\ell) \le \bar{\mu}, \tag{9}$$

$$\underline{m}_2 \le m_2(\ell) \le \bar{m}_2, \tag{10}$$

$$\underline{m}_3 \le m_3(\ell) \le \bar{m}_3, \tag{11}$$

$$\underline{m}_4 \le m_4(\ell) \le \bar{m}_4, \tag{12}$$

where $\mu(\ell) = r_2\ell, m_2(\ell) = r_3\ell - \mu^2, m_3(\ell) = r_4\ell - \mu^3 - 3\mu m_2$ and $m_4(\ell) = r_5\ell - 4\mu m_3 - 6\mu^2 m_2 - \mu^4$ are the moments realized by the staircase variable, r_i is the i-th row vector of A in (4), and the moment bounds are the $1 - \alpha$ confidence intervals corresponding to the sampling distributions, e.g., $\dot{\mu} - 1.96\sqrt{\dot{m}_2/N} \le \mu(\ell) \le \dot{\mu} + 1.96\sqrt{\dot{m}_2/N}$ for a 95% confidence interval. Note that the box of moments defined by (9–12) might not be fully contained in Θ.

Sampling error can be accounted for by solving for a maximal entropy staircase variable constrained by Equations (6), and (9–12). The resulting staircase variable will not account for the manner in which the sampling distribution allocates probability within the box of moments. This consideration can be taken into account by using a likelihood-dependent cost, such as

$$J(\ell) = -E(\ell) - \log\{L(\ell)\}, \tag{13}$$

where $L = \mathcal{N}_{\mu(\ell)}\mathcal{N}_{m_2(\ell)}\mathcal{N}_{m_3(\ell)}\mathcal{N}_{m_4(\ell)}$ is the likelihood function corresponding to the sampling distribution.

In summary, staircase variables provide (i) the ability to represent a wide range of density shapes, (ii) the ability to represent most of the feasible space Θ, (iii) the ability to account for the effects of having a limited number of observations, and (iv) the low-computational cost required to efficiently perform various uncertainty quantification tasks.

4 PREDICTOR MODELS

4.1 *Interval predictor models*

This section presents a means to calculate the support set of an RPM. This will be carried out by finding a baseline IPM using the same data sequence $\mathbb{D}$ that will be used to construct the RPM.

An IPM assigns to each instance vector $x \in X \subseteq \mathbb{R}^{n_x}$ a corresponding outcome interval in $Y \subseteq \mathbb{R}$. That is, an IPM is a set-valued map, $I_y : x \to I_y(x) \subseteq Y$, where $I_y(x)$ is the prediction interval. Depending on context, the term IPM will refer to either the function I_y or its graph $\{(x,y) : x \in X, y \in I_y(x)\}$ in $X \times Y$. A nonparametric IPM is given by

$$I_y(x) = \left\{\left[\underline{y}(x), \bar{y}(x)\right], \bar{y}(x) \ge \underline{y}(x)\right\}. \tag{14}$$

where the functions $\underline{y}(x)$ and $\bar{y}(x)$ are the lower and upper boundaries of the IPM respectively. A parametric IPM is obtained by associating to each $x \in X$ the set of outputs y that result from evaluating the function $y = M(x,p)$ at all values of p in the set P, so

$$I_y(x,P) = \{y = M(x,p), p \in P\}. \tag{15}$$

Attention will be limited to the case in which the output depends linearly on p and arbitrarily on x, so $y = p^T\varphi(x)$, where $\varphi(x) \in \mathbb{R}^{n_p}$ is an arbitrary basis. Several IPM types can be calculated within this framework. In thispaper we use the technique used in (Crespo, Kenny, & Giesy 2016).

Example 1: Next we use an analytically described DGM of which we have full knowledge. Figure 1 shows the corresponding one percentiles. Note that the support set, moments and modality of the DGM are strongly nonlinear functions of the input. The high concentration of percentile lines at the edge of the support indicates a bimodal structure. N = 1000 IID observations were drawn from the DGM

to form the data sequence $\mathbb{D}$. This data, shown in Figure 1, was then used to construct an IPM with $n_p = 20$ terms and a Gaussian basis structure. That is, $\varphi_i(x) = e^{-(x-u_i)^2/v_i}$, where $u_i \in \mathbb{R}$ is a center and $v_i \in \mathbb{R}$ is a length-scale parameter, for $i = 1, \ldots, n_p$. Centers are uniformly distributed over $X = [-\pi, \pi]$, whereas the length scale parameters are made all equal to $\pi/5$. Figure 1 also shows the resulting IPM. Notice that the IPM tightly encloses all the data as intended. An IPM will be used to describe the support of the DGM, whereas RPMs, introduced next, will be used to characterize its distribution.

4.2 *Random predictor models*

An RPM is a mapping that assigns to each input vector $x \in X$ a corresponding random variable $R_y(x)$. A non-parametric RPM is the random variable-valued map given by

$$R_y(x) = \left\{ f_{y(x)}(y(x)), y(x) \in \Delta_y(x) \right\}, \tag{16}$$

where $f_{y(x)}$ is the PDF of y at $x \in X$ having the support set $\Delta_y(x) = \left[\underline{y}(x), \bar{y}(x) \right] \subseteq Y$. By contrast, a parametric RPM is obtained by associating to each $x \in X$ the set of outputs y corresponding to all values of p described by a random vector with joint PDF $f_p(p)$ supported in Δ_p, so

$$R_y(x, f_p) = \left\{ y = M(x, p), p \sim f_p(p), p \in \Delta_p \right\}. \tag{17}$$

The RPMs used below assume a staircase structure. As such, they require prescribing an input-dependent hyper-parameter $h(x) = [n_b(x), \theta_{y(x)}]$ for all $x \in X$. Hereafter we will assume that $n_b(x)$ is a fixed constant, and focus on the prescription of $\theta_{y(x)}$. Define as

$$\tilde{\theta}_{y(x)} = \left[\tilde{\underline{y}}(x), \tilde{\bar{y}}(x), \tilde{\mu}_{y(x)}, \tilde{m}_{2,y(x)}, \tilde{m}_{3,y(x)}, \tilde{m}_{4,y(x)} \right],$$

a set of target functions prescribed according to the data, and by $\theta_{y(x)}$ the set functions realized by an RPM. An RPM that accurately represent the DGM must make $\theta_{y(x)}$ close to $\tilde{\theta}_{y(x)}$. The strategy for prescribing $\theta_{y(x)}$ according to the data sequence $\mathbb{D}$ presented in (Crespo, Giesy, & Kenny 2017b) will be used here. $\tilde{\theta}_{y(x)}$ is based on a weighted average of values $y^{(i)}$ for $x^{(i)}$ close to x.

A non-parametric RPMs with a staircase structure can be readily calculated from the target functions $\tilde{\theta}_{y(x)}$ by making the prediction at any input value $x \in X$ realize the corresponding target. Once a set of staircase-feasible target functions $\tilde{\theta}_{y(x)}$ is obtained, the RPM $S_{y(x)}\left(\tilde{\theta}_{y(x)}, n_b, J\right)$ can be readily evaluated at any value of the input. The resulting RPM will conform to the target regardless of the choice of J.

Example 2: Next we use the data sequence of the DGM in Example 1 to derive an RPM. Figure 2 shows the functions in $\theta_{y(x)}$ corresponding to the DGM (solid lines) along with the target functions $\tilde{\theta}_{y(x)}$ (dashed lines). Note that the target functions approximate the DGM well in spite of only using N = 1000 observations. The difference between the two sets of functions is caused by the limited amount of data available and by using neighboring data to calculate $\tilde{\theta}_{y(x)}$. The targets $\tilde{\theta}_{y(x)}$ in Figure 2 were used to build the RPM $S_{y(x)}\left(\tilde{\theta}_{y(x)}, 500, E\right)$. This RPM is staircase-feasible throughout X. This was also the case for values of n_b as small as 100. The plot at the top of Figure 3 shows the 1-percentiles of this RPM. This figure was generated by calculating staircase

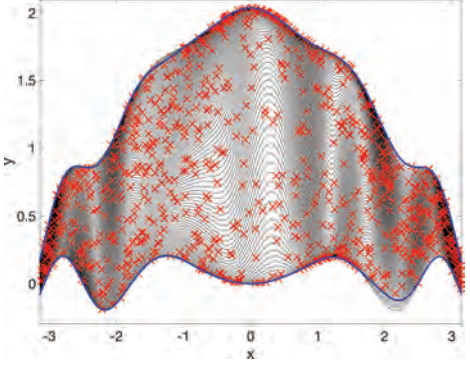

Figure 1. One-percentiles of the DGM (black lines), N = 1000 observations (red ×), and IPM limits (blue lines).

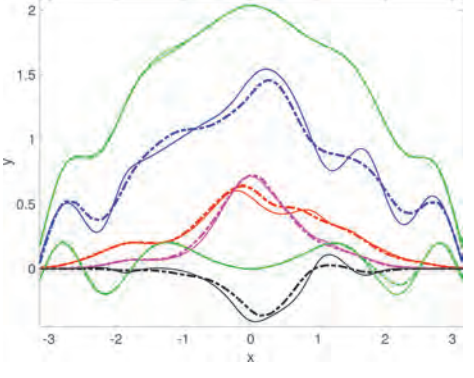

Figure 2. Support set (green), mean (blue), variance (red), third-order- (black), and fourth-order-central moment (magenta) functions corresponding to the DGM (solid) and to the target (dashed-dotted).

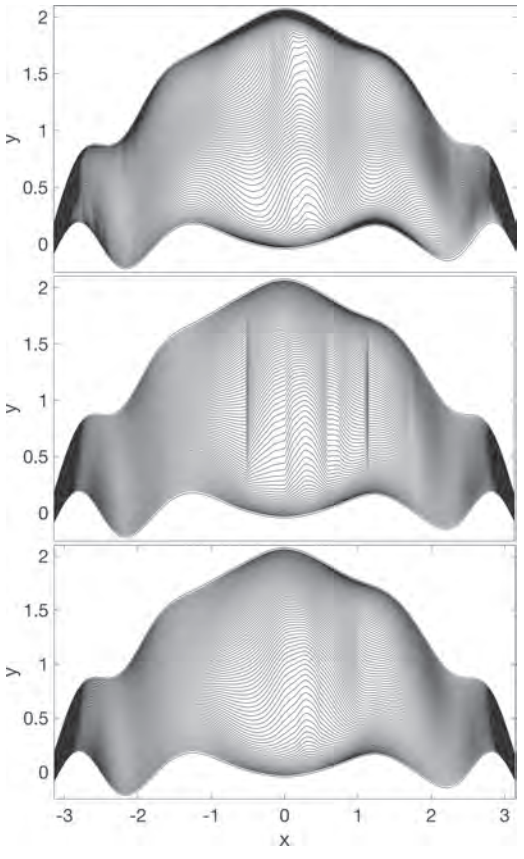

Figure 3. Moment-matching RPM (top), moment-bounded RPM of maximal entropy (middle), and moment-bounded RPM (bottom) based on Equation (13).

variables over a uniform grid of input values in X, sampling them, smoothing the corresponding empirical CDF using a Gaussian kernel (Silverman 1986), and grouping the points belonging to the same percentile line. The moment functions attained by the RPM are indistinguishable from the targets shown in Figure 2. The comparison between the DGM, shown in Figure 1, and the moment-matching RPM indicates excellent agreement despite only using $N = 1000$ data points. Note that RPM describes well the bimodal structure of the DGM by replicating the regions where probability is highly concentrated, i.e., the regions in the upper and lower limit of the support where many percentile lines coalesce. Furthermore the skewness of the probability mass in the interior of the support set follows the same oscillatory patterns present in the DGM.

Example 3: Next we study the effects of the sampling error on the empirical target $\tilde{\theta}_{y(x)}$, and on the resulting staircase RPM. The observations prescribing the target functions at x are weighted according to their separation from such a point (Crespo, Giesy, & Kenny 2017a). The weight is the greatest when the datum is at x, and it approaches zero as its separation from x increases. For the functions shown in Figure 2, the number of observations having a non-negligible weight ranges from 110 to 261. To quantify the sparsity of the dataset we define the equivalent number of observations, n_e, as

$$n_e(x) = \sum_{i=1}^{N} w\left(x^{(i)}, x\right). \tag{18}$$

The effects of the sparsity in the data will be quantified using the developments in Section 3.1. In particular, we will generate a maximal entropy RPM satisfying the constraints (6) and (9–12) for $N = n_e(x)$. The value of n_e is inversely proportional to the size of the box of moments. For this data sequence, the value of n_e ranges between 47.15 and 112. This indicates that the dataset is sparse. In contrast to the RPM at the top of Figure 3, the resulting RPM will not match moments estimated from the data but instead, it will realize moment functions bounded by their sample uncertainty. As such, we will refer to this RPM as a moment-bounded RPM. Figure 4 shows the 95% confidence intervals of the four moment functions. Note that the range of these intervals exhibits oscillations, reaching their largest spread near $x = 0$. These regions contain the moments realized by staircase variables comprising the moment-bounded RPM, which are shown as solid lines. The first three

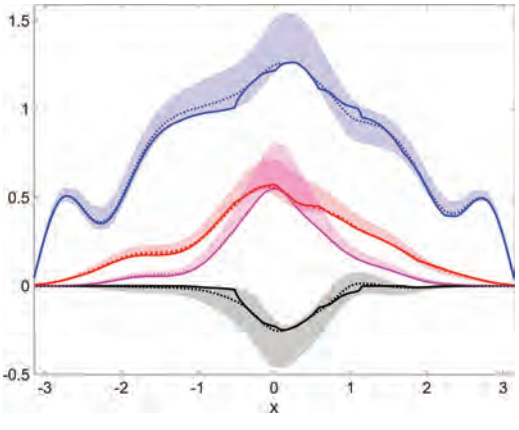

Figure 4. Optimal mean (blue), variance (red), third-order- (black), and fourth-order-central moments (magenta) corresponding to a moment-bounded RPM using maximal entropy (solid lines), Equation (13) (dotted lines), and corresponding sampling error ranges (shaded regions).

moments vary in the interior of their confidence intervals whereas the fourth moment stays on the lower limit. All but the fourth moment function take on values that vary within the intervals. The uncertainty in the sample moments increases the expected entropy $\mathbb{E}_x[E]$ of the RPM from –0.3642 to 0.7484.

Figure 3 shows the moment-matching RPM as well as moment-bounded RPMs of maximal entropy. Note that the most prominent features of the process, such as the peaks at the boundaries of the support set and the patterns of the lines in its interior, have faded in the latter predictor. Furthermore, note that the derivative discontinuities in the moment functions of Figure 4 yield derivative discontinuities in the percentile lines. Such discontinuities can be eliminated by using a Kernel smoother or by using another cost function. Alternatively, we can calculate a moment-bounded RPM having the cost function in Equation (13). The corresponding moment functions are shown as dotted lines in Figure 4. In contrast to the moments for the maximal entropy formulation, the new moments have continuous derivatives throughout X. The resulting RPM, shown at the bottom of Figure 3, exhibits smooth percentile lines. This is achieved at the expense of a minor entropy reduction to $\mathbb{E}_x[E] = 0.73$. As n_e increases, the width of the confidence intervals reduces making moment-bounded RPMs converge to the moment-matching RPM. The PDF-matching or the maximum-likelihood staircase formulations are preferable when n_e is sufficiently large.

Example 4: Next we consider the reliability analysis (Rackwitz 2001) of an airfoil subject to aeroelastic flutter (Mahler, Touze, Doare, Habib, & Kerschen 2017). During flutter the pitch and plunge dynamics are coupled yielding a self-sustaining limit cycle oscillation that might compromise the structural integrity of an aircraft. The onset of flutter depends on the free stream airflow speed v, as well as inertial, geometrical, and material properties of the wing. These parameters include the plunge and pitch stiffnesses, the aerodynamic lift, the location of the center of mass, and the location of the elastic axis. In this context, a reliability analysis seeks to quantify the probability of flutter instability (i.e., probability of failure) given probabilistic prescriptions for the parameters.

The objectives of this example are two-fold. First, we use RPMs to characterize the system response. Measurement error and model-form uncertainty make the data and the response aleatory, thereby justifying such a modeling choice. A deterministic response model along with a probabilistic description of the parametric uncertainty would enable the calculation of the failure probability. However, when the response is intrinsically aleatory, the failure probability can only be determined to lie within a range of values. We then explore the reduction in the range of failure probabilities resulting from ignoring a (small) percentage of the responses predicted by the RPM.

The stability of the system is evaluated by calculating the damping coefficient, y (i.e., the output in the context of this paper) of the time response to a given flow speed. As in (Canor, Caracoglia, & Denoel 2015), damping is related to the real part of the eigenvalues of a linear dynamic model. Non-negative values of y denote an unstable system, whereas negatives values correspond to a stable system. Hence, the failure domain is defined as

$$\mathcal{F} = \{x : y(x \mid v) \geq 0\}. \tag{19}$$

The measured output y depends on measurement errors, as well as epistemic and aleatory uncertainties. In this example we will divide the uncertain parameters into two groups. The primary group consists of measurable parameters having a strong influence on the output (e.g., stiffnesses), whereas the secondary group consist of parameters that are either weakly important, unmeasurable, or unknown to the analyst (e.g., measurement error, unsteady aerodynamics, etc.). In this study the primary group of parameters constitute the input x. Note that variations in the secondary parameters make $y(x)$ aleatory. Hence, in contrast to a standard reliability analysis for which a parametric model explicitly prescribes the dependency of the limit state on the uncertain parameters (Sun, Wang, Rui, & Tong 2017), the limit state we are aiming to identify will not be a deterministic function of all the parameters, but instead a random process depending on the primary parameters. This implies that the failure probability will range on an interval whose spread depends upon the manner in which the RPM describing $y(x)$ crosses zero (failure boundary).

For simplicity in the analysis, x will be assumed to be a single non-dimensional parameter describing the ratio of the pitch and plunge stiffnesses. Independent input-output pairs $\mathbb{D} = \{x_i, y_i\}$ for $i = 1, \quad N$, were obtained by simulating the flutter dynamics of N = 2500 individual airfoils. The randomness in the output stems from variability of not only x but also of the secondary aerodynamic and structural parameters affecting y. It is expected that such parameters mostly vary within 10% of their nominal value.

Figure 5 shows the input-output data for the free stream airflow speeds v = 0.75, v = 0.79, v = 0.83, v = 0.87, v = 0.91, v = 0.95. Each chosen airfoil was evaluated at these speeds. Note that the number of data points falling into the failure domain $y \geq 0$

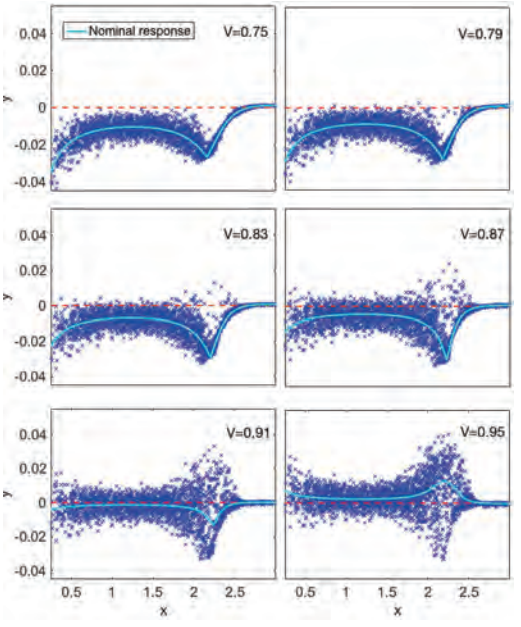

Figure 5. Nominal system response (solid line), and $N = 2500$ observations (blue ×) for several airflow speeds.

increases with v. In all cases, however, the $y = 0$ manifold is crossed by the nominal response near $x = 2.8$. The response of a calibrated deterministic model, to be referred to as a nominal response, is shown as a solid curve. Whereas the nominal system for all but the greatest speed crosses into the instability region at $x = 2.8$, somewhere in $v \in [0.91, 0.95]$ the curve flips to the opposite side of $y = 0$ (see the bottom plots in Figure 5). Reliability analyses using the nominal responses as the limit states will yield an abrupt discontinuity in the failure probability at that speed. This sudden change in the response is caused by a bifurcation. The manner by which the system transitions into instability (e.g, the region in x becoming unstable first) cannot be inferred from studying the nominal system.

The data for all 6 speeds was processed and the resulting moment functions were calculated. Figure 6 shows these functions and their corresponding uncertainty ranges. Note the high sensitivity of the functions to v. For instance, the variance varies considerably throughout x converging to a small value when x is large. Furthermore, the third-order central moment at $x = 2.15$ goes from being practically zero to being large, first positive and then negative. Features like these, driven by the dynamics of the system, can not be accurately described by a GP model. These functions were then used to calculate a maximal entropy RPM with $n_b = 300$ bins. Figure 7 shows

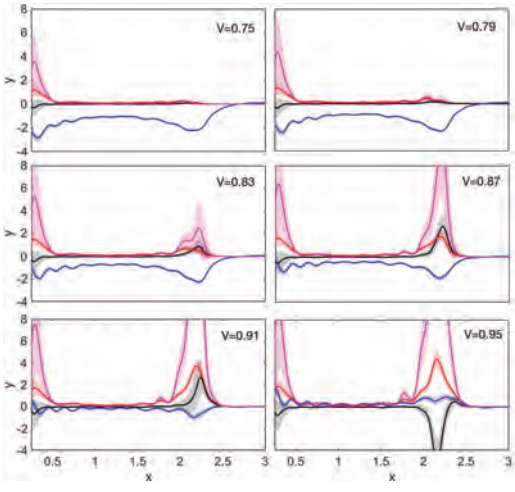

Figure 6. Mean (blue), second- (red), third-(black), and fourth-order (magenta) central moments along with their sampling error ranges (shaded areas).

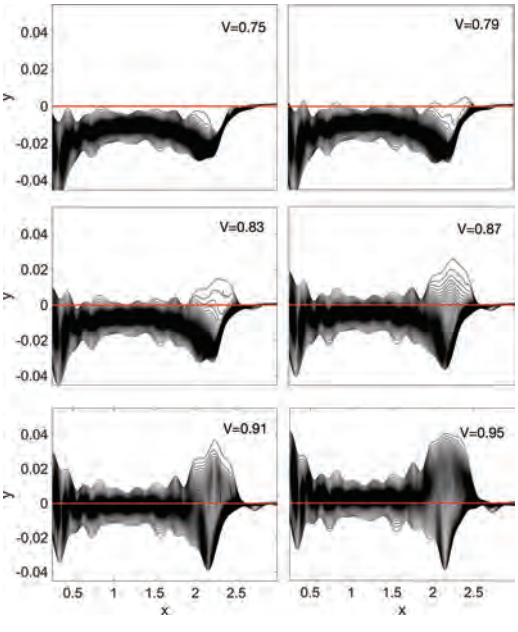

Figure 7. RPMs for several airflow speeds.

the one-percentile curves for the resulting RPMs. The excursion of individual percentiles into the instability region prescribes the severity (i.e., what is the failure probability for a fixed value of x and v) and the manner (i.e., which x region transitions to instability first) by which flutter occurs.

The crossing $y(x \mid v) = 0$ occurs over a range of x values. Let's formalize this notion by defining the τ-percentile of the RPM as

$$y_\tau(x \mid v) = F^{-1}_{y(x|v)}(\tau/100), \tag{20}$$

where $F_{y(x|v)}$ is the distribution of the RPM for speed v, and $\tau \in [0,100]$ is the percentile of interest. Hence, $y_{100}(x \mid v)$ is the upper limit of the RPM and $y_0(x \mid v)$ is the lower limit.

The failure domain associated with the τ-percentile at airspeed v is $\mathcal{F}_\tau = \{x : y_\tau(x \mid v) > 0\}$, whereas the corresponding failure probability is

$$\mathbb{P}[\mathcal{F}_\tau] = \int_{\mathcal{F}_\tau} f_x(x)\,dx, \tag{21}$$

where $f_x(x)$ is the PDF of x. $f_x(x)$ can be prescribed according to the available data or to expert opinion[2]. Modeling the response as an RPM yields the failure probability range

$$r(v) = \left[\ \mathbb{P}[\mathcal{F}_0], \mathbb{P}[\mathcal{F}_{100}]\ \right]. \tag{22}$$

This range can be readily computed for any $f_x(x)$. For instance, if x is a Beta random variable with hyper-parameters 3 and 3 and support [0, 3], we obtain $r(0.75) = [0.0040, 0.0187]$, $r(0.77) = [0.0059, 0.8814]$, $r(0.79) = [0.0024, 0.9948]$. These ranges account for all predicted outputs regardless of their likelihood. The upper limit of some of these ranges is distressingly close to one. However, it is possible that a very small portion of the predicted responses is responsible for most of the spread in the failure probability range. At this point the analyst might want to contemplate the following questions: If we are willing to ignore some of the worst predicted outputs what will be the corresponding reduction in the failure probability range? How large should be such a reduction (if any) to justify taking such a risk? By worst-case outputs we mean those leading to the largest decrease in the upper limit of the failure probability range. In this context, the risk, to be denoted as $\zeta \in [0,100]$, is the percentage of the worst-case predicted responses the analyst is willing to neglect. The analyst might be willing to accept a small risk providing that the corresponding reduction in the failure probability is sufficiently large. This will be the case when the limits of $r(v)$ are prescribed by extreme, low-probability events occurring at the long tail of a distribution. For a given ζ, the failure probability range is given by

$$r(v,\zeta) = \left[\ \mathbb{P}[\mathcal{F}_0], \mathbb{P}[\mathcal{F}_{100-\zeta}]\ \right]. \tag{23}$$

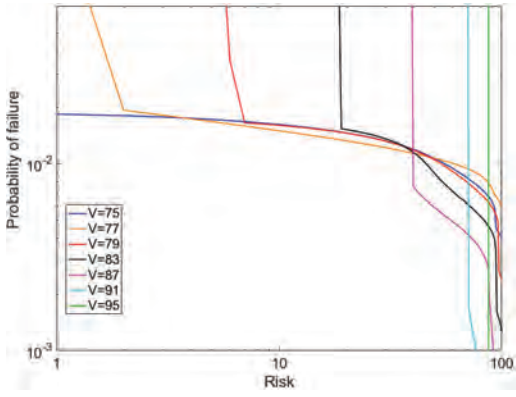

Figure 8. Failure probability vs. risk for several airflow speeds.

Figure 8 shows $\mathbb{P}[\mathcal{F}_{100-\zeta}]$ as a function of the risk ζ for several airflow speeds. This figure enables making informed risk-based decisions regarding the reliability assessment of the system. For instance, the range of failure probabilities corresponding to a zero risk for $v = 0.77$ is $r(0.77, 0) = [0.0059, 0.8814]$. These two values correspond to the points on the $v = 0.77$ curve for which the risk is 100 (smallest failure probability) and zero (largest failure probability). This level of risk implies that all predicted outcomes are accounted for. If the analyst is willing to ignore the worst 2 percent of the outputs, Figure 8 leads to $r(0.77, 2) = [0.0059, 0.0193]$. These two values correspond to the points on the $v = 0.77$ curve for which the risk is 100 (smallest failure probability) and 2 (largest failure probability). Therefore, a risk of 2 percent decreases the largest failure probability by 0.8621. This illustrates that a small percentage of the predicted responses is responsible for most of the spread in the range of failure probabilities, and that a risk averse approach might yield an overly conservative prediction. Whereas the zero-risk interval contains *all* predicted responses, the small-risk interval contains *most* of the responses more tightly. This information enables the analyst to avoid making overly conservative assessments driven by extreme low-probability events rarely seen in practice.

[2]If the realizations of x in $\mathbb{D}$ were controlled to ensure a good coverage of the response function over the domain of interest X, they should not be used to prescribe a naturally occurring $f_x(x)$, e.g., variations resulting from a manufacturing process.

5 CONCLUSIONS

This paper illustrates the use of staircase RPMs by applying them to the reliability analysis of an aeroelastic structure. The ability of the staircase variables to describe skewed and multimodal responses over an input-dependent interval makes them well suited for structural dynamics and controls applications. We consider the case in which the predictor is designed to match sample moments exactly (a setting applicable to large datasets), as well as the case in which the predictor accounts for the uncertainty in those estimates (a setting applicable to sparse datasets). The versatility and low computational cost of the proposed framework makes it appropriate for a wide range of applications in science and engineering.

Israel Electrical Corporation

ABSTRACT: In reliability engineering, load–sharing is typically associated with a system in parallel configuration. Examples include bridge support structures, electric power supply systems, multiprocessor computing systems, etc. We consider a reliability maximization problem for a high–voltage commutation device, wherein the total voltage across the device is shared by the components in series configuration. Here, the increase of the number of load–sharing components increases component–level reliability (as the voltage load per component reduces) but may decrease system–level reliability (due to the increased number of components in series). We review optimal solutions for the proportional hazard and accelerated life models with the underlying exponential & Weibull distributions and elaborate on the log–linear, power, and Eyring laws used in the life–load models.

1 INTRODUCTION

A load–sharing system is typically associated with a system in parallel configuration. In their renowned text on System Reliability Theory, Rausand and Hoyland (2009) write "Consider a parallel system with two identical components. The components share a common load." Another famous text by Kapur and Lamberson (1977) also treats load–sharing systems exclusively as parallel systems.

Examples of parallel load–sharing systems include but are not limited to: civil engineering [e.g., structures (Chen & Lui 2005)], materials engineering [e.g., composites with fiber bundles (Phoenix & Tierney 1983)] power engineering [e.g., distributed generation systems (Marwalli & Keyhani 2004)], computer/network engineering [multiprocessor computing systems (Eager et al. 1986)]. Load–sharing system are also often discussed in the context of (still parallel) systems with k–out–of–n configuration, e.g., Huang & Xu (2010) and Amari & Bergman (2008).

In many applications of electrical and power engineering, namely in high voltage power equipment, one often runs into problem of switching high voltages by solid–state devices, where the system voltage (10–100 kV) well exceeds the operating voltages of individual switching components (1–3 kV). One of the commonly practiced ways to increase the voltage capability of high voltage switching devices is to put single switching components in a series configuration. Shown in Figure 1 is a high voltage thyristor switch (Gurevich & Krivtsov 1991), wherein the total switching voltage is shared by the serially connected thyristors.

In this case, the increase of the number of thyristors increases thyristor–level reliability (as the voltage load per thyristor reduces) but may decrease system–level reliability (due to the increased number of components in series). Clearly, the system reliability function in this case should have a maximum associated with an optimal number of thyristors in series.

We derived (Krivtsov et al. 2017) optimal solutions to the two popular life–load models: the

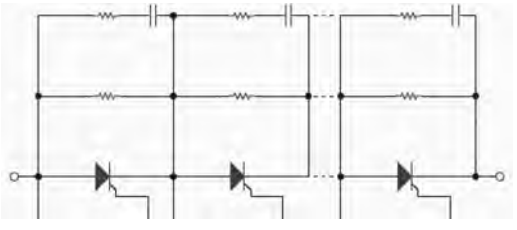

Figure 1. A serial load–sharing system, wherein total commutating voltage is shared by the serially connected SCRs (thyristors).

proportional hazard and the accelerated failure time with the underlying exponential and Weibull distributions. In this paper, we elaborate on the log–linear, power and Eyring laws used in the aforementioned life–load models.

2 PRELIMINARIES

Let $h(t;L)$ be the load–dependent failure rate of a component. Two commonly used models relating failure time to a load level are: the Proportional Hazard Model (PHM) and the Accelerated Failure Time Model (AFTM).

2.1 *Proportional hazard model*

Under the PHM, we have:

$$h(t;L) = \psi(L)\cdot h(t;L_0) = \psi(L)\cdot h_0(t), \tag{1}$$

where $h_0(t)$ is the baseline failure rate and $\psi(L_0)=1$.

The commonly used model for $\psi(L)$ is the log–linear (exponential) law: $\psi(L)=\exp(\alpha_0+\alpha_1 L)$. In fact, the exponential term can be replaced by any known positive, non–decreasing function. For example, for the log–linear law:

$$\psi(L)=\exp(\alpha_0+\alpha_1 L)=\delta\cdot\exp(\alpha_1 L) \tag{2}$$

For the power law:

$$\psi(L) = \delta\cdot L^{\alpha} \tag{3}$$

For the linear law:

$$\psi(L) = c+\alpha L \tag{4}$$

For the Eyring law:

$$\psi(L)=L^{-1}\exp(\alpha_0+\alpha_1/L) \tag{5}$$

The baseline failure rate can follow any time–varying function. Further, for the cumulative hazard and the reliability functions, we have:

$$H(t;L) = \psi(L)\cdot H_0(t) \tag{6}$$

$$R(t;L)=\exp\{-H(t;L)\}=[R_0(t)]^{\psi(L)} \tag{7}$$

2.2 *Accelerated failure time model*

Under this model, the effect of the load is multiplicative in time. The reliability function is expressed as:

$$R(t;L) = R_0(t\cdot\phi(L)) \tag{8}$$

where $R_0(.)$ is the reliability function at the baseline load. Function $\phi(L)$ represents the acceleration factor at load L. Without loss of generality, we can assume that $\phi(L_0)=1$. When there is only one type of load, commonly used forms of $\phi(L)$ include the power law:

$$\phi(L) = \delta\cdot L^{\alpha} \tag{9}$$

the log–linear law:

$$\phi(L) = \delta\cdot\exp(\alpha L) \tag{10}$$

and the Eyring law:

$$\phi(L)=L^{-1}\exp(\alpha_0+\alpha_1/L) \tag{11}$$

Finally, for the hazard functions we have:

$$H(t;L) = H_0(t\cdot\phi(L)) \tag{12}$$

$$h(t;L) = \phi(L)\cdot h_0(t\cdot\phi(L)) \tag{13}$$

It must be noted that if the baseline distribution is Weibull (or Exponential) and the multiplicative factor (acceleration factor) follows the power law, then the AFTM and PHM coincide. However, in general, there is no direct duality between the models.

2.3 *System reliability under series load–sharing*

Consider a load–sharing series system with n components. The total load on the system is $L_T \equiv V$. The load is equally distributed between the components. Hence, the load on each component is:

$$L \equiv \frac{L_T}{n} = \frac{V}{n} \tag{14}$$

and the system's reliability is:

$$R_s(t;V,n)=[R(t;V/n)]^n \tag{15}$$

Note that for fixed t, function $R(t;V/n)$ is an *increasing* function in n. However, function R^n is a *decreasing* function in n. Hence, there is an optimal value of n that maximizes the system reliability.

Alternatively, one can consider a logarithmic function of system reliability:

$$\ln R_s(t;V,n) = \mathrm{n}\cdot\ln R(t;V/n) \tag{16}$$

The right hand side of the above equation has two product terms. The first term increases with n and the second term decreases with n. Further, it implies that

$$H_s(t;V,n) = n \cdot H(t;V/n) \tag{17}$$

To maximize the system reliability, we need to minimize the corresponding cumulative hazard function. Again, it has two product terms. The first term increases with the number of components and the second term decreases with the number. Hence, there exist an optimal value that minimizes the cumulative hazard function and maximizes the system reliability.

3 OPTIMAL NUMBER OF COMPONENTS IN A SERIES LOAD–SHARING SYSTEM

3.1 *Load–sharing under PHM*

The system reliability in this case is:

$$\begin{aligned} R_s(t;V,n) &= \left[R(t;L) \right]^n \equiv \left[R\left(t;\frac{V}{n} \right) \right]^n \\ &= \left[\left[R_0(t) \right]^{\psi(V/n)} \right]^n = \left[R_0(t) \right]^{n\cdot\psi(V/n)} \end{aligned} \tag{18}$$

It follows that for fixed t, $R_0(t)$ is also fixed. Hence, for fixed t, to maximize the system reliability, we need to minimize $g(n) \equiv n \cdot \psi(V/n)$. Thus, the optimal n is independent of the form of the underlying failure time distribution $R_0(t)$ and is also independent of mission time t.

Under the log–linear law, we have:

$$\psi(L) = \exp(\alpha_0 + \alpha_1 L) = \delta \cdot \exp(\alpha_1 L) \tag{19}$$

For notational simplicity, hereafter we'll use α in the place of α_1. Hence,

$$\psi(L) \equiv \psi(V/n) = \delta \cdot \exp(\alpha \cdot V/n) \tag{20}$$

$$g(n) \equiv n \cdot \psi\left(\frac{V}{n} \right) = n\delta \cdot \exp(\alpha \cdot V/n) \tag{21}$$

The minimum of $g(n)$ can be obtained as

$$\begin{aligned} &\frac{d}{dn} g(n) \equiv \delta \cdot \exp\left(\alpha \cdot \frac{V}{n} \right) + n\delta.\exp\left(\alpha \cdot \frac{V}{n} \right)\left(-\frac{\alpha V}{n^2} \right) \\ &\frac{d}{dn} g(n) = 0 \Rightarrow n = \alpha \cdot V \end{aligned} \tag{22}$$

Thus, the optimal n that maximizes system reliability is

$$n = \|\alpha \cdot V\| \tag{23}$$

where ||.|| is the *nearest integer function.*

Figure 2 shows system–level reliability as a function of the number of the load–sharing components in series (with $\delta = 1$, $\alpha = 2$ and $V = 3$) for various values of component reliability. As expected, the optimal number does not depend on the latter.

It can be shown that for a PHM in the power law form, depending on model parameters, the optimal n will be either 1 or ∞. The linear law has a similar behavior. In both cases, the cost function can be used as regularization.

3.2 *Series load–sharing under AFTM*

The system reliability in this case is:

$$\begin{aligned} R_s(t;V,n) &= \left[R(t;L) \right]^n \\ &\equiv \left[R_0\left(t \cdot \phi(L) \right) \right]^n = \left[\exp\left\{ -H_0\left(t \cdot \phi(L) \right) \right\} \right]^n \end{aligned} \tag{24}$$

$$\begin{aligned} &R_s(t;V,n) \\ &= \exp\left\{ -n \cdot H_0\left(t.\phi(L) \right) \right\} = \exp\left\{ -H_s(t;V,n) \right\} \end{aligned} \tag{25}$$

where

$$H_s(t;V,n) = n \cdot H_0\left(t \cdot \phi(L) \right) \tag{26}$$

From the equation above, it follows that a) maximizing the system reliability is equivalent to minimizing the cumulative hazard function and b) unlike the PHM, the optimal value *does*

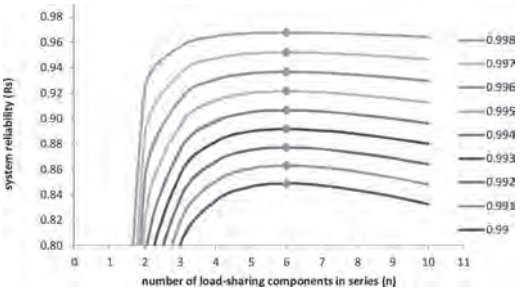

Figure 2. System–level reliability as a function of the number of the load–sharing components in series (with $\delta = 1$, $\alpha = 2$ and $V = 3$) for various values of component reliability. Optimal n is marked with the asterisk.

depends on the form of the underlying failure time distribution.

3.2.1 *AFTM with power law and the underlying exponential distribution*

For the exponential distribution, we have:

$$H_0(t) = \lambda t \tag{27}$$

Hence,

$$H_s(t;V,n) = n \cdot \lambda t \cdot \phi(L) = n \cdot \lambda t \cdot \phi(V/n) \tag{28}$$

In this case, maximizing the system reliability is equivalent to minimizing $g(n) \equiv n\phi(V/n)$. The optimal n is independent of the mission time or even the baseline hazard function.

Now, for the power law:

$$\phi(L) = \delta \cdot L^{\alpha} \tag{29}$$

and

$$g(n) = n\phi\left(\frac{V}{n}\right) = n\delta\left(\frac{V}{n}\right)^{\alpha} \tag{30}$$

Similar to the PHM with the power law, depending on model parameters, the optimal n will again be either 1 or ∞. The cost function can be used to regularize this case.

3.2.2 *AFTM with log–linear law and the underlying exponential distribution*

For the log–linear law:

$$\phi(L) = \delta \cdot \exp(\alpha L) \tag{31}$$

and

$$g(n) = n\phi\left(\frac{V}{n}\right) = n\delta \cdot \exp\left(\alpha \cdot \frac{V}{n}\right) \tag{32}$$

Note that the functional form of $g(n)$ is the same as in the PHM model with the log–linear law. Thus, the optimal n that maximizes system reliability is

$$n = \|\alpha \cdot V\| \tag{33}$$

3.2.3 *AFTM with Eyring law and the underlying exponential distribution*

$$\phi(L) = L^{-1}\exp(\alpha_0 + \alpha_1 / L) \tag{34}$$

and

$$g(n) = n\phi\left(\frac{V}{n}\right) = \frac{n^2}{V}\exp\left(\alpha_0 + \alpha_1 \frac{n}{V}\right) \tag{35}$$

The minimum of $g(n)$ is $\arg\left(\frac{d}{dn}g(n) = 0\right)$.

Let $X(n) \equiv \exp(\alpha_0 + \alpha_1 \frac{n}{V})$. Then with $\frac{d}{dn}g(n) \equiv \frac{X(n)}{V}(2n + \alpha_1)$, it becomes easy to show that the optimal n that maximizes system reliability is

$$n = \left\| -\frac{1}{2} \right\| \tag{36}$$

3.2.4 *AFTM with power law and the underlying Weibull distribution*

For the Weibull distribution, we have:

$$H_0(t) = \left(\frac{t}{\eta}\right)^{\beta} \tag{37}$$

Hence,

$$H_s(t;V,n) = n \cdot \left(\frac{t}{\eta}\right)^{\beta} \cdot \left[\phi(V/n)\right]^{\beta} \tag{38}$$

From the equation above, it follows that a) maximizing the system reliability is equivalent to minimizing $g(n) \equiv n \cdot [\phi(V/n)]^{\beta}$, and b) the optimal value of n is independent of the mission time and the scale parameter of the Weibull distribution.

For the power law:

$$\phi(L) = \delta \cdot L^{\alpha} \tag{39}$$

and

$$g(n) \equiv n\left[\phi\left(\frac{V}{n}\right)\right]^{\beta} = n\left[\delta \cdot \left(\frac{V}{n}\right)^{\alpha}\right]^{\beta} \tag{40}$$

Again, depending on model parameters, the optimal n will again be either 1 or ∞. The cost function can be used to regularize this case.

3.2.5 *AFTM with log–linear law and the underlying weibull distribution*

For the log–linear law:

$$\phi(L) = \delta \cdot \exp(\alpha L) \tag{41}$$

and

$$g(n) \equiv n\left[\phi\left(\frac{V}{n}\right)\right]^{\beta} = n \cdot \delta^{\beta} \cdot \exp\{\alpha\beta V/n\} \tag{42}$$

Hence,

$$\frac{d}{dn}g(n) = 0 \Rightarrow n = \alpha \cdot \beta \cdot V \tag{43}$$

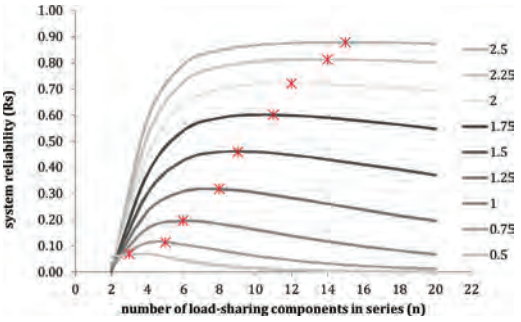

Figure 3. System–level reliability as a function of the number of the load–sharing components in series (with $\alpha = 2$ and $V = 3$) for various values of Weibull shape parameter with the scale parameter of $\eta = 1$ and mission time $t = 0.1$. Optimal n is marked with the asterisk.

Thus, the optimal n that maximizes the system reliability is:

$$n = \|\alpha \cdot \beta \cdot V\| \tag{44}$$

Figure 3 shows system–level reliability as a function of the number of the load–sharing components in series (with $\alpha = 2$ and $V = 3$) for various values of Weibull shape parameter with the scale parameter of $\eta = 1$ and mission time $t = 0.1$.

An evidential network-based method for common-cause failure analysis under uncertainty

S. Qiu & Henry X.G. Ming
School of Mechanical Engineering, Shanghai Jiao Tong University, Shanghai, China
Shanghai Key Laboratory of Advanced Manufacturing Environment, Shanghai, China

Y. Hou
INSA Centre Val de Loire, Bourges, France

ABSTRACT: In an engineering system, multiple components may fail simultaneously due to a shared cause or Common Cause (CC). This kind of failure is referred to as a Common-Cause Failure (CCF), and it contributes greatly to the system unreliability. Due to the insufficiency of historical data and system complexities, uncertainty is an inevitable problem in system reliability analysis. This paper proposes a Valuation-Based System (VBS) method to incorporate CCFs explicitly in system reliability analysis considering parametric uncertainty (related to reliability data of components) and model uncertainty (related to the system structure). The method can model different kinds of uncertainties, have no limitation on the type of failure distributions of system components, and allow the relationship between CCs being s-independent, s-dependent or mutually exclusive.

1 INTRODUCTION

Systems can be subject to Common-cause Failures (CCFs), where multiple components fail or malfunction simultaneously due to a shared cause or Common Cause (CC). For example, redundancy technique is often used to improve the system reliability, but it also has negative effects on the system reliability because identical components may fail simultaneously due to a CC. The presence of CCF makes the system be more prone to fail. Therefore, it is important to take into account the contributions of CCFs in system reliability analysis. There are two types of CCFs existing in engineering systems: external CCFs that are caused by external factors such as extreme weather and human errors, and internal CCFs that caused by propagated failures within the system such as the functional dependencies or physical dependencies between components (Misra 2008, Xing & Levitin 2013). In this paper, only external CCFs are taken into account.

CCFs have received considerable attention in system reliability analysis (Vaurio 2003, Misra 2008). Xing et al. (2007) summarized the limitations of existing CCF models, including being concerned with a specific system structure (Xie, Zhou, & Wang 2005), being applicable only to exponential time-to-failure distributions (Anderson & Agarwal 1992), having combinatorial explosion problems (Dai, Xie, Poh, & Ng 2004), limiting components belonging to at most one single Common-Cause Group (CCG) (Vaurio 1998), having a single CC (Amari, Dugan, & Misra 1999), defining CC as being s-independent or mutually exclusive (Vaurio 2003). Motivated by the limitations of existing methods, Xing *et al.* (Xing, Meshkat, & Donohue 2007, Xing 2008, Xing, Shrestha, Meshkat, & Wang 2009) proposed a Fault Tree (FT)-based Efficient Decomposition and Aggregation (EDA) approach which decomposes an original reliability problem with CCFs into a number of reduced reliability problems without considering the effect of CCFs using the Total Probability Theorem. However, in the EDA approach, models of some reduced reliability problems share common sub-models, and these sub-models are stored and evaluated several times. To improve the efficiency of the EDA approach, Mo and Xing (2013) extended the EDA approach by proposing an enhanced Decision Diagram-based (DD-based) method in which a single compact DD is generated to model all reduced reliability problems sharing their isomorphic sub-DDs.

Uncertainty analysis is challenging in reliability and risk analysis of complex systems (Qiu et al. 2014, Qiu et al. 2015, Qiu et al. 2018). Different kinds of uncertainties present in reliability studies because of many reasons, such as the randomness in phenomena and the insufficiency of data. As summarized in Pate-Cornell (1996), uncertainty is usually clas-

sified into two types: aleatory uncertainty and epistemic uncertainty. Aleatory uncertainty is due to the inherent variation in physical systems. It is also called irreducible uncertainty because it cannot be reduced. Epistemic uncertainty arises from the lack of knowledge. It is also called reducible uncertainty because it can be reduced by acquiring knowledge. Reliability parameters of components generally come from statistics, experiments, expert's opinions, similar components, etc. Therefore, uncertainties related reliability parameters of components may be aleatory or epistemic. In the previous CCF studies, only aleatory parametric uncertainty quantified by probability is taken into account. When it is difficult to measure the probabilities of CCs accurately, parametric models such as beta-factor model, binomial failure rate model, have been widely used to quantitatively analyze CCFs (Misra 2008). However, except the aleatory uncertainty coming from the randomness, there may exist epistemic uncertainty coming from the insufficiency of data and information in real systems. Because the probability cannot distinguish aleatory and epistemic uncertainties, probabilistic methods are not appropriate to analyze CCFs when there are aleatory and epistemic uncertainties. Therefore, non-probabilistic methods need to be developed for the CCF analysis considering aleatory and epistemic uncertainties.

Our proposed non-probabilistic method is based on Valuation-Based System (VBS). VBS was first introduced by Shenoy (1989) as a framework for representation of and reasoning with knowledge under uncertainty. Different types of uncertainties can be modeled and quantified in the framework of VBS using different uncertainty theories, including probability theory, imprecise probability theory, belief functions theory, possibility theory, etc. The proposed VBS method is suitable to analyze CCFs considering both of aleatory and epistemic uncertainties, have no limitations on the type of failure distributions of system components and allow the relationship between CCs being s-independent, s-dependent, or mutually exclusive. In the proposed VBS method, n CCs are modeled as n basic events and their three kinds of relationships are also considered in the model.

The structure of this paper is organized as follows. Section 2 presents the basic notions of the VBS. Section 3 presents an illustrative computer system. Section 4 presents the proposed VBS method and applies it to the illustrative example. Section 5 gives some conclusions and perspectives.

2 VALUATION-BASED SYSTEM

Shenoy (1989) introduced VBS as a framework for representation of and reasoning with knowledge under uncertainty. This framework belongs to the family of graphical models. In a VBS, a set of variables and a set of valuations affected to the subsets of the variables are used to represent knowledge. Reasoning with this knowledge means to find the marginals of the joint valuation for the variables of interest using two operators called combination and marginalization. VBS can represent different types of uncertainties in different domains including probabilities, basic probability assignments (bpas), possibility values, etc. The detailed definitions and features of VBS in reliability analysis based are discussed as follows (Qiu et al. 2017, Qiu et al. 2017).

2.1 *Basic probability assignments (bpas)*

A reliability analysis problem can be modeled using a finite set of variables that represent the components and system states. For a variable X, the frame of discernment Ω_X denotes the set of all the possible values that X can take. The mapping $m^{\Omega_X}: 2^{\Omega_X} \to [0,1]$ is called bpa if $\forall A \in 2^{\Omega_X}, \sum_{A \subseteq \Omega_X} m^{\Omega_X}(A) = 1$.

The set A can be an event or a subset of events. Indeed, a bpa m^{Ω_X} is assigned to each subset of 2^{Ω_X} such that $m^{\Omega_X}(A)$ represents the subjective probability assigned to the information which exactly supports A.

The lower bound of the probability over a set A on Ω_X represents the sum of all bpas of subsets that imply A. It is computed as follows (Shafer 1976)

$$\underline{P}(A) = \sum_{B|B \subseteq A} m^{\Omega_X}(B) \quad A, B \subseteq \Omega_X \tag{1}$$

The upper bound of the probability over A on Ω_X is defined as the total amount of bpas of subsets that are consistent with A. It is computed as follows

$$\overline{P}(A) = \sum_{B|B \cap A \neq \varnothing} m^{\Omega_X}(B) \quad A, B \subseteq \Omega_X \tag{2}$$

The following example explains the meaning of m, $\underline{P}$ and $\overline{P}$. Suppose that variables X and Y represent the states of Component 1 and Component 2. These variables may have two qualitative values: failed or working. The frames of discernment Ω_X and Ω_Y of X and Y are given by $\Omega_X = \Omega_Y = \{F, W\}$.

An expert assigns bpas to the two values of X as follows: $m_1^{\Omega_X}(\{W\}) = 0.7, m_1^{\Omega_X}(\{W, F\}) = 0.2, m_1^{\Omega_X}(\{F\}) = 0.1$. The expert assigns also bpas to the two states of Y as follows: $m_2^{\Omega_Y}(\{W\}) = 0.6, m_2^{\Omega_Y}(\{W, F\}) = 0.4$.

According to Eq.1 and Eq. 2, the probability of the event A: "*Component 1 is in the working state*", is included in

$[\underline{P}(A), \overline{P}(A)] = [m_1^{\Omega_X}(W), m_1^{\Omega_X}(\{W\}) + m_1^{\Omega_X}(\{W,F\})]$ = [0.7,0.9]. The value 0.7 represents all the information that implies the event A, whereas the value 0.9 represents all the information that is consistent with the event A according to the expert. The length of the interval $\overline{P}(A) - P(A) = 0.2$ represents the imprecision about A.

2.2 *Joint basic probability assignments*

Let X and Y be two variables defined on frames Ω_X and Ω_Y. Let $\Omega_X \times \Omega_Y$ be the cartesian product of Ω_X and Ω_Y. A bpa $m^{\Omega_X \times \Omega_Y}$ defined on $\Omega_X \times \Omega_Y$ is called a joint bpa, and can be seen as an uncertain relation between variables X and Y. To evaluate the VBS, joints bpas defined on the cartesian product of variables are used to show the degree (or strength) of the relationship between variables.

We retake the same example, and we aim to evaluate the probability of the event: "The system composed of components 1 and 2 is in the working state" which is represented by a variable S. The variable S may have two qualitative values: failed or working, and its frame of discernment is given by $\Omega_S = \{W,F\}$. The variable S depends on the variables X (state of Component 1) and Y (state of Component 2). This relationship will be represented by a joint bpa m_3. The expert gives the following joint bpa m_3 in order to define the degree of relationships between the variables:

$$\begin{cases} m_3^{\Omega_X \times \Omega_Y \times \Omega_S}(\{(W_1,W_2,W_S),(F_1,F_2,F_S)\}) = 0.75 \\ m_3^{\Omega_X \times \Omega_Y \times \Omega_S}(\{F_1,W_2,W_S),(W_1,F_2,W_S)\}) = 0.2 \\ m_3^{\Omega_X \times \Omega_Y \times \Omega_S}(\{\Omega_X \times \Omega_Y \times \Omega_S\}) = 0.05 \end{cases}$$

Fig. 1 represents the VBS of the example. As we can see, we have three nodes which represent the variables X, Y and S. We have also three bpas: m_1, m_2, and m_3 which respectively represent the bpas assigned to X, Y, and the relationship between X, Y and S.

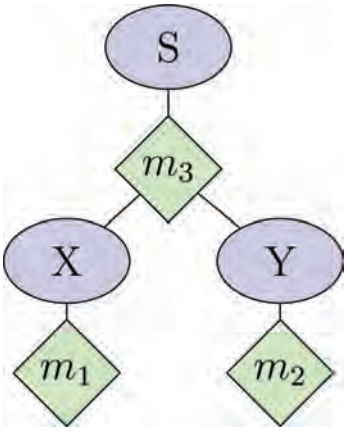

Figure 1. VBS example.

2.3 *Inference in VBS*

After constructing the VBS and assigning the bpas of events (variables) and joints bpas of relationship between events (variables), we have to use inference in order to obtain the probability of the variable of interest. Making inference means to find marginals for the variables of interest using combination and marginalization operators.

The combination operation of two bpas $m_i^{\Omega_X}$ and $m_j^{\Omega_Y}$ respectively defined on Ω_X and Ω_Y is performed as follows (Smets & Kennes 1994)

$$m_{i \oplus j}^{\Omega_X \times \Omega_Y}(H) = \frac{\sum_{A \cap B = H, \forall A,B \subseteq \Omega_X \times \Omega_Y} m_i^{\Omega_X \times \Omega_Y}(A)\, m_j^{\Omega_X \times ga_Y}(B)}{1 - \sum_{A \cap B = \varnothing, \forall A,B \subseteq \Omega_X \times \Omega_Y} m_i^{\Omega_X \times \Omega_Y}(A)\, m_j^{\Omega_X \times \Omega_Y}(B)} \quad (3)$$

Note that in order to combine two bpas respectively defined on Ω_X and Ω_Y, they must be defined on the same frame of discernment $\Omega_X \times \Omega_Y$. The operation which allows one to extend a bpa m^{Ω_X} defined on Ω_X to $\Omega_X \times \Omega_Y$ is called the vacuous extension and defined as follows

$$m^{\Omega_X \uparrow (\Omega_X \times \Omega_Y)}(B) = \begin{cases} m^{\Omega_X}(A) & \text{if } B = A \times \Omega_Y, \forall\ A \subseteq \Omega_X \\ 0 & \text{otherwise.} \end{cases} \quad (4)$$

On the other hand, the marginalization operator is used to focus the information contained by a valuation onto a smaller domain. Indeed, the marginal (or projection) of the bpa $m^{\Omega_X \times \Omega_Y}$ on the frame Ω_X is defined by

$$m^{(\Omega_X \times \Omega_Y)\downarrow \Omega_X}(A) = \sum_{B \subseteq \Omega_X \times \Omega_Y / Proj(B \downarrow \Omega_X) = A} m^{\Omega_X \times \Omega_Y}(B), \forall A \subseteq \Omega_X \quad (5)$$

where $Proj(B \downarrow \Omega_x) = \{x \in \Omega_x / \exists y \in \Omega_y, (x,y) \in B\}$.

To summarize, for a variable of interest Z that depends on two other variables X and Y, $(\oplus m)^{\downarrow \Omega_Z}$ is computed by marginalizing (projection) on Ω_Z the joint valuation $\oplus m$ obtained by the combination of the bpas $m^{\Omega_X}, m^{\Omega_Y}$, and the joint bpa $m^{\Omega_X \times \Omega_Y \times \Omega_Z}$.

We retake the same example in order to compute the upper and lower probabilities of the event: "the system composed of components 1 and 2 is in the working state". We first combine the bpas $m_1^{\Omega_X}, m_2^{\Omega_Y}$, and the joint bpa $m_3^{\Omega_X \times \Omega_Y \times \Omega_S}$

using Eq. 4 (After vacuous extension of each bpa using Eq. 5). Then, we marginalize the obtained bpa $(m_1 \oplus m_2 \oplus m_3)^{\Omega_X \times \Omega_Y \times \Omega_S}$ on the frame Ω_S using Eq. 6. Finally, using Eqs. 1 and 2, we obtain upper and lower probabilities of the event "the system composed of components 1 and 2 is in the working state" from the bpa $m_3^{(\Omega_X \times \Omega_Y \times \Omega_S)\downarrow \Omega_S}$ as follows: $\left[\underline{P}(W_S), \overline{P}(W_S) \right] = \left[0.9,1 \right]$.

3 AN ILLUSTRATIVE EXAMPLE

Here we use an example of a computer system subject to CCFs proposed by Mo and Xing (2013). This system consists of three processors (P_1, P_2, and P_3), two buses (B_1 and B_2), and three memory units (M_1, M_2, and M_3). It works if at least two of the three processors, at least one of the two buses, and at least one of the three memory units work. Fig. 2 shows the reliability block diagram of the example computer system.

Two CCs are supposed to affect the components in the example computer system. CC_1 affects processor P_1 and memory unit M_1. CC_2 affects processor P_1, bus B_2 and memory unit M_2. Thus, the two CCGs are $CCG_1 = \{P_1, M_1\}$ and $CCG_2 = \{P_1, B_2, M_2\}$. There are three kinds of relationships between CC_1 and CC_2: s-independent, s-dependent, or mutually exclusive.

Assume that all components and the system are binary, and their frames of discernment are $\Omega = \{0,1\}$ where '0' denotes failed state and '1' denotes working state. The frame of discernment of CCs is $\Omega_{CC_i} = \{0_i, 1_i\}$ where '0_i' denotes the non-occurrence of CC_i and '1_i' denotes the occurrence of CC_i.

Probabilities used in this example are given as follows (Mo & Xing 2013):

- Failure probabilities of components: $q_{P_1} = q_{P_2} = q_{P_3} = 0.002$, $q_{B_1} = q_{B_2} = 0.001$, $q_{M_1} = q_{M_2} = q_{M_3} = 0.003$. Reliabilities of components are hereinafter denoted by p.
- Occurrence probabilities of CCs: $\Pr\{CC_1\} = 0.001$ and $\Pr\{CC_2\} = 0.0015$.
- If CCs are s-dependent, the conditional occurrence probabilities are $\Pr\{CC_2 \mid CC_1\} = 0.0025$ and $\Pr\{CC_2 \mid \leftarrow CC_1\} = 0.0015$.

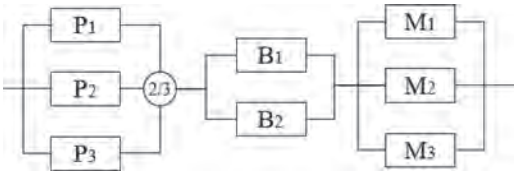

Figure 2. Reliability block diagram of the example computer system.

4 PROPOSED VBS METHOD

This section presents the explicit VBS method to incorporate CCFs considering only aleatory uncertainty represented by probability, and applies it to the example computer system given in Section 3.

4.1 *Proposed method*

The proposed VBS method contains the following five steps:

Step 1: Develop the VBS model of the studied system. Each CC is modeled by a basic event, and the relationship between CCs is modeled by a basic event.

Step 2: Establish the truth table that represents the relationship between CCs and transform the truth table into a bpa. There are three kinds of relationships between CCs: s-independent, s-dependent, or mutually exclusive. In this work, n CCs occurring s-dependently means that CC_i depends on CC_{i-1}. A variable R is used to describe the three kinds of relationships. Its frame of discernment is $\Omega_R = \{1_R, 2_R, 3_R\}$, where '$1_R$' denotes s-independent, '2_R' denotes s-dependent, and '3_R' denotes mutually exclusive. The occurrence of CCs is influenced by their relationship, e.g., if n CCs are mutually exclusive, no CCs can occur simultaneously. Table 1 is the truth table for CCs under different relationships with the corresponding conditional probabilities.

Step 3: Establish truth tables that represent the relationships between CCs and their affecting components, and transform truth tables into bpas. A component in the system may be affected by several CCs. For example, if a component x is affected by $CC_l, CC_{l+1}, \ldots, CC_k$, Table 2 is the truth table representing the relation between x and these CCs.

Step 4: Establish truth tables that represent the relationships between components, subsystems, the system, and transform truth tables into bpas. For example, for a system consisting of n components in parallel, its truth table is shown in Table 3.

Step 5: Declare bpas for leaf nodes according to their reliabilities, calculate the joint bpa and marginalize it over the frame of *System*.

4.2 *Illustrative example*

In this subsection, the proposed VBS method is used to model and evaluate the reliability of the example computer system.

Step 1: Fig. 3 shows the valuation network of the example computer system in the proposed VBS

Table 1. Truth table for CCs under different relationships.

0_{x_1}	⋯	$0_{x_{n-1}}$	1_{x_n}	1_S	**1**
0_{x_1}	⋯	$1_{x_{n-1}}$	0_{x_n}	1_S	**1**
0_{x_1}	⋯	$1_{x_{n-1}}$	1_{x_n}	1_S	**1**
⋮	⋮	⋮	⋮	⋮	⋮
1_{x_1}	⋯	$1_{x_{n-1}}$	1_{x_n}	1_S	**1**

method. 15 variables and 14 bpas are used to model the example computer system. Two CCs and the relationship between CCs are modeled separately as basic events.

Step 2: The relationship between two CCs can be s-independent, s-dependent, or mutually exclusive. Table 4 is the truth table for CCs under different relationships with the corresponding conditional probabilities.

The truth table in Table 4 is transformed into the following bpa $m_{13}^{\Omega_R\Omega_{CC1}\Omega_{CC2}}$:

$$m_{13}\left(\{1_R,0_1,0_2\},\{2_R,0_1,0_2\},\{3_R,0_1,0_2\}\right)=0.9975$$
$$m_{13}\left(\{1_R,0_1,1_2\},\{2_R,0_1,1_2\},\{3_R,0_1,1_2\}\right)=0.0014985$$
$$m_{13}\left(\{1_R,0_1,0_2\},\{2_R,0_1,0_2\},\{3_R,0_1,1_2\}\right)=0.0000015,$$
$$m_{13}\left(\{1_R,1_1,0_2\},\{2_R,1_1,0_2\},\{3_R,1_1,0_2\}\right)=0.0009975$$
$$m_{13}\left(\{1_R,1_1,0_2\},\{2_R,1_1,1_2\},\{3_R,1_1,0_2\}\right)=0.000001$$
$$m_{13}\left(\{1_R,1_1,1_2\},\{2_R,1_1,1_2\},\{3_R,1_1,0_2\}\right)=0.0000015$$

Step 3: P_1 is affected by CC_1 and CC_2. Table 5 shows the truth table representing the relationship between P_1 and two CCs.

The truth table in Table 5 is transformed into the following bpa $m_5^{\Omega_{CC1}\Omega_{CC2}\Omega_{P_1}}$:

$$m_5(\{0_1,0_2,1_{P_1}\},\{0_1,1_2,0_{P_1}\},\{1_1,0_2,0_{P_1}\},\{1_1,1_2,0_{P_1}\})=0.998$$
$$m_5(\{0_1,0_2,0_{P_1}\},\{0_1,1_2,0_{P_1}\},\{1_1,0_2,0_{P_1}\},\{1_1,1_2,0_{P_1}\})=0.002$$

The same for $B_2(m_9)$, $M_1(m_{10})$ and $M_2(m_{11})$.

Step 4: The relationships between components, subsystems and the system depend on the system structure. For example, the processor subsystem works if at least two out of the three

Table 4. Truth table for two CCs under different relationships.

R	CC_1	CC_2	$\Pr\{CC_1 \,\&\, CC_2 \mid R\}$
1_R	0_1	0_2	$\Pr\{-CC_1\}\Pr\{-CC_2\} = 0.9975015$
1_R	0_1	1_2	$\Pr\{-CC_1\}\Pr\{CC_2\} = 0.0014985$
1_R	1_1	0_2	$\Pr\{CC_1\}\Pr\{-CC_2\} = 0.0009985$
1_R	1_1	1_2	$\Pr\{CC_1\}\Pr\{CC_2\} = 0.0000015$
2_R	0_1	0_2	$\Pr\{-CC_1\}\Pr\{-CC_2 \mid -CC_1\} = 0.9975015$
2_R	0_1	1_2	$\Pr\{-CC_1\}\Pr\{CC_2 \mid -CC_1\} = 0.0014985$
2_R	1_1	0_2	$\Pr\{CC_1\}\Pr\{-CC_2 \mid CC_1\} = 0.0009975$
2_R	1_1	1_2	$\Pr\{CC_1\}\Pr\{CC_2 \mid CC_1\} = 0.0000025$
3_R	0_1	0_2	$1 - \Pr\{CC_1\} - \Pr\{CC_2\} = 0.9975$
3_R	0_1	1_2	$\Pr\{CC_2\} = 0.0015$
3_R	1_1	0_2	$\Pr\{CC_1\} = 0.001$

Table 5. Truth table of the relationship between P_1 and CCs.

CC_1	CC_2	P_1	$\Pr\{P_1 \mid CC_1 \,\&\, CC_2\}$
0_1	0_2	1_{P_1}	$p_{P_1} = 0.998$
0_1	0_2	0_{P_1}	$q_{P_1} = 0.002$
0_1	1_2	0_{P_1}	**1**
1_1	0_2	0_{P_1}	**1**
1_1	1_2	0_{P_1}	**1**

Table 6. Truth table of the processor subsystem.

P_1	P_2	P_3	P	$\Pr\{P \mid P_1 \,\&\, P_2 \,\&\, P_3\}$
0_{P_1}	0_{P_2}	0_{P_3}	0_P	**1**
0_{P_1}	0_{P_2}	1_{P_3}	0_P	**1**
0_{P_1}	1_{P_2}	0_{P_3}	0_P	**1**
0_{P_1}	1_{P_2}	1_{P_3}	1_P	**1**
1_{P_1}	0_{P_2}	0_{P_3}	0_P	**1**
1_{P_1}	0_{P_2}	1_{P_3}	1_P	**1**
1_{P_1}	1_{P_2}	0_{P_3}	1_P	**1**
1_{P_1}	1_{P_2}	1_{P_3}	1_P	**1**

processors work, thus the truth table of the processor subsystem is given in Table 6.

The truth table in Table 6 is transformed into the following bpa $m_2^{\Omega_{P_1}\Omega_{P_2}\Omega_{P_3}\Omega_P}$:

$$m_2(\{0_{P_1},0_{P_2},0_{P_3},0_P\},\{0_{P_1},0_{P_2},1_{P_3},0_P\},\{0_{P_1},1_{P_2},0_{P_3},0_P\},\{0_{P_1},1_{P_2},1_{P_3},1_P\},\{1_{P_1},0_{P_2},0_{P_3},0_P\},\{1_{P_1},0_{P_2},1_{P_3},1_P\},\{1_{P_1},1_{P_2},0_{P_3},1_P\},\{1_{P_1},1_{P_2},1_{P_3},1_P\}) = 1$$

The same for the bus subsystem (m_3), the memory subsystem (m_4), and the entire system (m_1).

Step 5: m_6, m_7, m_8, m_{12} represent the knowledge about the states of P_2, P_3, B_1, M_3. According to their failure probabilities, we have

$$m_6^{\Omega_{P_2}}(\{0_{P_2}\}) = m_7^{\Omega_{P_3}}(\{0_{P_3}\}) = 0.002$$
$$m_6^{\Omega_{P_2}}(\{1_{P_2}\}) = m_7^{\Omega_{P_3}}(\{1_{P_3}\}) = 0.998$$
$$m_8^{\Omega_{B_1}}(\{0_{B_1}\}) = 0.001 \quad m_8^{\Omega_{B_1}}(\{1_{B_1}\}) = 0.999$$
$$m_{12}^{\Omega_{M_3}}(\{0_{M_3}\}) = 0.003 \quad m_{12}^{\Omega_{M_3}}(\{1_{M_3}\}) = 0.997$$

m_{14} represent the knowledge about the relationship of CCs. There are three kinds of relationship between CCs:

- $m_{14}^{\Omega_R}(\{1_R\}) = 1$ if CCs are s-independent;
- $m_{14}^{\Omega_R}(\{2_R\}) = 1$ if CCs are s-dependent;
- $m_{14}^{\Omega_R}(\{3_R\}) = 1$ if CCs are mutually exclusive.

The system reliability is computed by $(m_1^{\Omega_P\Omega_B\Omega_M\Omega_S} \otimes m_2^{\Omega_{P_1}\Omega_{P_2}\Omega_{P_3}\Omega_P} \otimes \ldots \otimes m_{13}^{\Omega_R\Omega_{CC1}\Omega_{CC2}} \otimes m_{14}^{\Omega_R})^{\downarrow\Omega_S}$. If CCs are s-independent, the obtained system unreliability is 2.44843e-05. If CCs are s-dependent, the obtained system unreliability is 2.44883e-05. If CCs are mutually exclusive, the obtained system unreliability is 2.44859e-05.

The obtained results are different from the results in Mo and Xing (2013), because the conditional probabilities $\Pr\{Systemfailure \mid CCE_i\}$ in the compared paper are incorrect.

The proposed explicit VBS method is more efficient than the explicit FT-based methods Vaurio 2003, Wang, Xing, & Levitin 2014). In the explicit FT-based methods, if there are n CCs in which CC_i affects m_i components, then $\sum_{i=1}^{n} m_i$ basic events and logical gates are needed to model CCs in the expanded FT models. In the proposed explicit VBS method, only n basic events are needed to model CCs. And as explained in Wang et al. (2014), the explicit FT-based method is only applicable to systems subject to s-independent CCs, whereas the proposed explicit VBS method is applicable to systems subject to s-independent, s-dependent, or mutually exclusive CCs by introducing a variable representing the relationship between CCs.

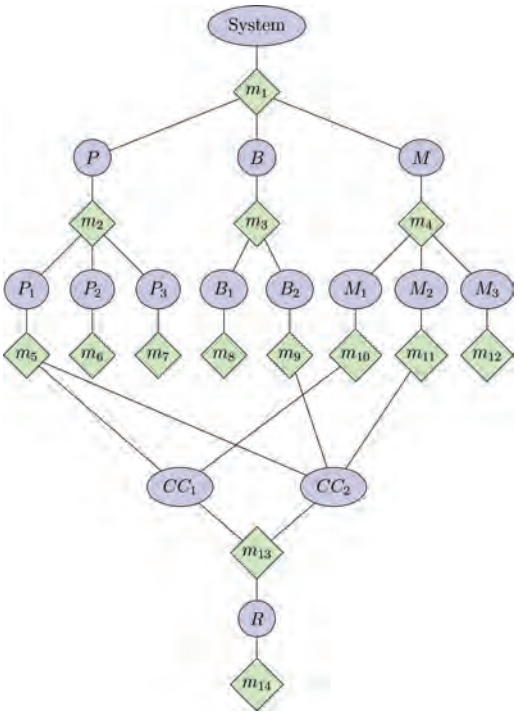

Figure 3. Valuation network of the example computer system subject to CCFs in the proposed VBS method.

Table 7. Truth table of the processor subsystem under model epistemic uncertainty.

P_1	P_2	P_3	P	$\Pr\{P\|P_1 \,\&\, P_2 \,\&\, P_3\}$

1_{P_1}	1_{P_2}	0_{P_3}	1_P	**1**
1_{P_1}	1_{P_2}	1_{P_3}	1_P	**1**

4.3 *Epistemic model uncertainty*

This subsection takes the epistemic model uncertainty into account. Epistemic model uncertainty means that the analyst cannot give the precise system structure due to the lack of knowledge or information. For example, in the example computer system, the analyst has difficulty in judging the structure of the processor subsystem due to the lack of relative knowledge. He/she cannot judge whether it is a parallel system or a 2-out-of-3: G system (the subsystem works if and only if at least two out of the three processors work). The epistemic uncertainty of the analyst can be described by the truth table in Table 7. Items in bold represent the epistemic model uncertainty.

The truth table in Table 7 is transformed into the following joint bpa $m_2^{\Omega_{P_1}\Omega_{P_2}\Omega_{P_3}\Omega_P}$:

$$m_2\Big(\{0_{P_1},0_{P_2},0_{P_3},0_P\},\{0_{P_1},0_{P_2},1_{P_3},0_P\},\{0_{P_1},0_{P_2},1_{P_3},1_P\},\{0_{P_1},1_{P_2},0_{P_3},0_P\},\{0_{P_1},1_{P_2},0_{P_3},1_P\},\{0_{P_1},1_{P_2},1_{P_3},1_P\},\{1_{P_1},0_{P_2},0_{P_3},0_P\},\{1_{P_1},0_{P_2},0_{P_3},1_P\},\{1_{P_1},0_{P_2},1_{P_3},1_P\},\{1_{P_1},1_{P_2},0_{P_3},1_P\},\{1_{P_1},1_{P_2},1_{P_3},1_P\}\Big)=1$$

All other bpas remain unchanged. The proposed VBS method is applied to model and evaluate the system unreliability under this epistemic model uncertainty. Finally, the system unreliability obtained by the VBS method is [2.57036e-06,2.44843e-05].

5 CONCLUSION

In this paper, a VBS method is proposed to analyze CCFs considering aleatory and epistemic uncertainties. In the proposed VBS method, n CCs are modeled as n basic events and their three kinds of relationships are also considered in the model. Our proposed VBS method is suitable to analyze CCFs considering both of aleatory and epistemic uncertainties, have no limitations on the type of failure distributions of system components and allow the relationship between CCs being s-independent, s-dependent, or mutually exclusive. In the future, the proposed VBS approach will be extended to analyze the Belief CCF which means that the occurrence of a CC may result in failures of different components with different degrees of belief.

A mathematical model for preliminary reliability and maintainability allocation

Z. Vintr & K. Hasilová
University of Defence in Brno, Czech Republic

M. Vintr
Independent Reliability Consultant, Brno, Czech Republic

ABSTRACT: The article deals with a simple way to allocate reliability and maintainability requirements which enables us to specify single system parts requirements preliminarily in early phases of system development and design. The method might be used for the system made of subsystems arranged into a serial structure when a failure of any subsystem leads to a whole system fault. For the whole system, however, there are no separately set requirements for its reliability and maintainability level, but overall it is necessary to achieve a certain level of availability. The method is based on a rational presumption that the requirements for a single subsystems reliability and maintainability level should be determined so that the subsystems in which a higher failure occurrence might be expected could have stricter maintainability level requirements than the systems with a higher reliability level. The suggested method is illustrated through a practical example.

1 INTRODUCTION

From a dependability point of view, a decisive property of numerous technical systems is their availability defined as the ability to be in a state to perform as required. What is really important then is not the system reliability or maintainability level itself, but their mutual combination expressed by availability.

Availability is of major importance in the systems used in non-stop operation (manufacturing technology, electric power generation and distribution, etc.), or they are involved in relatively long missions and their interruption is undesirable (means of transport, weapon systems, etc.). During designing a complex weapon system, there was a requirement specified for its availability level, and while forming the system conception, the allocation of single subsystems reliability and maintainability was already required.

The performed allocation was expected to be only preliminary and the results were to serve as a part of input information to decide about the conceptual solution of the whole system and all its subsystems. Therefore, it was required that the method should be easy to apply and provide only general information about single subsystems. Based on the overall requirement for the whole system availability level, the aim of the method was to determine general requirements for a single subsystems reliability and maintainability level. The method was also expected to be easy and fast to apply since during a development and design process a number of possible system conceptions are assumed to be formulated, therefore the method should enable us to assess quickly their advantages and disadvantages also from the dependability point of view.

In the available literature there are different methods and procedures dealing with the allocation of availability requirements. A certain part of these methods is based on the application of differently defined importance coefficients (Jigar et al. 2016; Barabady & Kumar 2007), or they use purposefully selected weighted parameters (Chang et al. 2009; Hagmark & Virtanen 2006). Also a generic algorithm and its modifications which enable a multi-criteria decision process to be made, are used when allocating availability requirements (Elegbede & Adjallah 2003; Huang et al. 2009; Oliveto 1999). The multi-criteria approach is also applied by other methods (Chiang & Chen 2007; Mohamed et al. 2002), which, when allocating the requirements, observe whether certain optimizing aims are fulfilled, e.g. minimization of system ownership costs (Kumar et al. 2007). There are also the methods based on the application of fuzzy sets in combination with a hierarchy process (Wang et al. 2012), for example, or in the form of intuitionistic fuzzy optimization (Song et al. 2015).

All the introduced approaches are based on the assumption that relatively accurate information about the system design and functions is available. In view of this fact, the possibilities of using these methods and procedures during the period of designing a basic system conception are very limited since in this phase of system development and design all necessary information has not been available yet.

Another problem is that the methods are relatively complex and their practical application is by no means trivial and might be time consuming if it is carried out for a bigger amount of system arrangement versions.

In view of these facts, we have suggested a simple method of availability requirements allocation which enables us to specify very quickly the requirements for single subsystems reliability and maintainability with only limited input information about the system design.

The requirements allocation performed with the use of the suggested method is only general and its results serve as the basis for evaluating different conceptions of the suggested system and selecting the best version.

After the system conception is clarified, it is necessary during the system development and design to perform repeated allocation of availability requirements using sophisticated allocation methods which will result in achieving final requirements for single subsystems and their components reliability and maintainability.

2 SOLUTION ASSUMPTIONS

Solution assumptions result from the above mentioned mission and the nature of the system for whose development and design the allocation method was suggested. The analysed system is characterized by the following properties:

- The considered system consists of n inter-independent subsystems (from a reliability point of view).
- All subsystems are arranged into a serial structure (from a reliability point of view).
- The failure of any subsystem results in the fault of all the system and its operation is interrupted. At any moment only one subsystem can be in a fault state.
- The system gets into an available state after the restoration of a relevant subsystem.
- Possible administrative, logistic and technical delays are not considered.
- Times between failures and times to restoration have exponential distributions.

The inherent availability of the system characterized this way might be expressed by the following formula:

$$A = \frac{MTBF}{MTBF + MTTR} = \frac{\mu}{\lambda + \mu} \tag{1}$$

where $MTBF$ is Mean Operating Time Between Failures, $MTTR$ is Mean Time to Restoration, λ is Failure Rate and μ is Repair Rate, and then the following formulas apply:

$$\lambda = \frac{1}{MTBF} \tag{2}$$

$$\mu = \frac{1}{MTTR} \tag{3}$$

For a mutual relation between the failure rate of a whole system and the failure rates of single systems for the system defined above the following formula applies (Vintr & Holub 2001):

$$\lambda = \sum_{i=1}^{i=n} \lambda_i \tag{4}$$

where λ_i is failure rate of the i-th subsystem and n is the total number of subsystems. Also the relation between repair rate μ of a whole system and repair rates of single subsystems can be expressed in a similar way. If the failure rate of single subsystems is known, the formula for a given system might be expressed in the following manner (Vintr & Holub 2001):

$$\mu = \frac{\sum_{i=1}^{i=n} \lambda_i}{\sum_{i=1}^{i=n} \frac{\lambda_i}{\mu_i}} \tag{5}$$

where μ_i is Repair Rate of the i-th subsystem.

The final equation characterizing the relation between whole system availability and the measures of single subsystems reliability and maintainability can be obtained by substituting from the equations (4) and (5) to the equation (1):

$$A = \frac{1}{1 + \sum_{i=1}^{i=n} \frac{\lambda_i}{\mu_i}} \tag{6}$$

This equation might also be transformed and then it can express the dependence of the whole system availability A on the level of single subsystems availability A_i (Vintr & Holub 2001):

$$A = \frac{1}{1 - n + \sum_{i=1}^{i=n} A_i^{-1}} \tag{7}$$

3 BASIC ALLOCATION PRINCIPLE

The nature of the solved task required that within the allocation not only the requirements for single systems availability would be specified, but also the requirements for each subsystem reliability and maintainability level would be determined. These requirements made the task solution rather complicated since at the time of preliminary allocating the requirements only general systems conception and general information about functions to be carried out by the system were known.

This information provides at least a general idea of the position and the task of each subsystem and its presumed design complexity. When it comes to the maintainability of single systems, however, it is very difficult to draw any conclusions from this information. In order to overcome this obstacle, a general principle expressing the required relation between a reliability and maintainability subsystems level has been formulated.

This principle is based on a rational requirement that the subsystems with a lower reliability level (more frequent failure occurrence might be expected) should have a higher maintainability level (they will be repaired more often) than the subsystems with a higher reliability level (they will be repaired less often). Generally, this principle says that the mean time to recovery as a subsystem maintainability measure should be directly proportional to the mean operating time between failures as a subsystem reliability measure. When applying this principle, the following should apply:

$$\frac{MTTR_i}{MTBF_i} = \frac{\lambda_i}{\mu_i} = s \tag{8}$$

where s is a required ratio between $MTTR$ and $MTBF$ in all subsystems.

After adapting the equation (6) with the use of the relation expressed by the equation (8), we obtain the following formula:

$$A = \frac{1}{1+ns} \tag{9}$$

After adapting the introduced equation, we get the formula which enables us to calculate the ratio s when knowing a required system availability level A and the number of subsystems n:

$$s = \frac{1-A}{nA} \tag{10}$$

4 ALLOCATION PROCEDURE

The initial step of the whole process is the expert determination of the requirements for a whole system reliability level in the form of a specific value $MTBF$, or a failure rate λ. This is based on the nature of the suggested system, the way of its application, and the evaluation of the consequences of a possible operation interruption caused by a failure. Also the information about the behaviour of similar systems can be used.

The next step is to introduce the weight factor which represents the ratio between single subsystems failure rate and the required failure rate of the whole system:

$$\omega_i = \frac{\lambda_i}{\lambda} \tag{11}$$

By substituting from the equation (11) to the equation (4) we then obtain basic condition which has to be fulfilled by the sum of single weight factors:

$$\sum_{i=1}^{i=n} \omega_i = 1 \tag{12}$$

Next, the weight factors have to fulfil the following condition:

$$\omega_i \geq \frac{\lambda_{i(\min)}}{\lambda} \tag{13}$$

where $\lambda_{i(\min)}$ represents a maximum acceptable requirement for a subsystem reliability level. This requirement is again determined by an expert decision and enables the subsystem reliability requirements to be rationally performable with respect to the used technologies. In fact, the maximum acceptable requirement for system reliability has to be determined so that $n\lambda_{i(\min)} < \lambda$ applies.

The introduced method requires that in the next step the weight factors for all subsystems are to be determined using an expert decision. However, the weight factors have to fulfil the requirements resulting from the equations (12) and (13), therefore this is a rather difficult task. In order to make it simple, a method of subsystems point aided estimation has been used (Vintr & Holub 2001).

When applying this method, to each subsystem a point value $a_i \in [1; a_{i(\max)}]$ is allocated. This point value characterizes a required system reliability level. The higher the required subsystem reliability level when compared with other subsystems, the higher the point value allocated to the system. The range of the used point scale, or the maximum point value $a_{i(\max)}$, is determined so that it could enable single subsystems requirements to be finely differentiated.

For the transformation of the determined point values into the weight factors value, the following equation is used:

$$\omega_i = a_i\, k + q \tag{14}$$

where real numbers k and q are linear transformation coefficients. Using this formula ensures that the determined weight factors will fulfil the conditions expressed by the equations (12) and (13). If the formula (14) is to be applied practically, it is necessary to determine the values of coefficients k and q.

With respect to the relation between the point evaluation of a relevant subsystem and its reliability level described above, the following equation must apply:

$$\omega_{i(\min)} = a_{i(\max)}\, k + q \tag{15}$$

With respect to the formula (11), this equation might be further adapted as follows:

$$\frac{\lambda_{i(\min)}}{\lambda} = a_{i(\max)}\, k + q \tag{16}$$

If we substitute into the equation (12) for ω_i the expression from the equation (14) and modify it appropriately, we get the following equation:

$$k \sum_{i=1}^{i=n} a_i + n\, q = 1 \tag{17}$$

The equations (16) and (17) form a system of two equations of two unknown variables, and after solving them, we can determine the values of coefficients k and q:

$$k = \frac{n\, \lambda_{i(\min)} - \lambda}{\lambda \left(a_{i(\max)}\, n - \sum_{i=1}^{i=n} a_i \right)} \tag{18}$$

$$q = \frac{\lambda\, a_{i(\max)} - \lambda_{i(\min)} \sum_{i=1}^{i=n} a_i}{\lambda \left(a_{i(\max)}\, n - \sum_{i=1}^{i=n} a_i \right)} \tag{19}$$

The resulting relation for determining the weight factor might be obtained by substituting the coefficients expressed this way into the equation (14):

$$\omega_i = \frac{a_i\, (n\, \lambda_{i(\min)} - \lambda) + \lambda\, a_{i(\max)} - \lambda_{i(\min)} \sum_{i=1}^{i=n} a_i}{\lambda \left(a_{i(\max)}\, n - \sum_{i=1}^{i=n} a_i \right)} \tag{20}$$

When knowing the weight factor, it is possible to determine both the requirement for each subsystem reliability level:

$$\lambda_i = \omega_i\, \lambda \tag{21}$$

and also the maintainability level requirement, using the equations (8) and (10):

$$\mu_i = \lambda_i \frac{n\, A}{(1 - A)} \tag{22}$$

5 EXAMPLE OF THE METHOD APPLICATION

The practical application of the suggested method will be demonstrated by the following example. It is required that the preliminary allocation of reliability and maintainability requirements for the system consisting of eight subsystems is to be performed. The system fulfils the initial prerequisites for the application of this method (see Chapter 2).

For the whole system, the $A = 0.997$ level availability is required and the required failure rate was determined as $\lambda = 2.5 \cdot 10^{-4}$. The maximum acceptable reliability level for single subsystems was determined in the form of a minimum acceptable value of subsystem failure rate $\lambda_{i(\min)} = 1.25 \cdot 10^{-5}$.

In the system, a point evaluation of a required single subsystems reliability level was performed when applying the point scale $a_i \in [1; 10]$. The results of the point evaluation are put in Table 1. Coefficients k and q have been calculated using the equations (18) and (19) and the following results have been obtained $k = -0.01875$ and $q = 0.2375$.

The requirements for the single subsystems reliability and maintainability level were determined on the basis of the point evaluation using the equations (20), (21) and (22). The results of the performed calculations are also put in Table 1.

Table 1. Results of calculation.

Subsystem number i	Point value a_i	Weight factor ω_i	Failure rate λ_i	Repair rate μ_i
1	1	2.19E–01	5.47E–05	1.45E–01
2	10	5.00E–02	1.25E–05	3.32E–02
3	7	1.06E–01	2.66E–05	7.06E–02
4	8	8.75E–02	2.19E–05	5.82E–02
5	6	1.25E–01	3.13E–05	8.31E–02
6	5	1.44E–01	3.59E–05	9.55E–02
7	2	2.00E–01	5.00E–05	1.33E–01
8	9	6.88E–02	1.72E–05	4.57E–02

6 CONCLUSIONS

The suggested method enables us to perform relatively simple preliminary allocation of reliability and maintainability requirements with very limited information about the analysed system. Therefore, the application of this method is suitable mainly at early stages of the system development and design when different system conceptions are taken into consideration. In this situation the method enables us to specify very quickly general requirements for single subsystems reliability and maintainability and provides inputs used for evaluating different conceptions of the suggested system and selecting the most appropriate variant.

All the allocation model can be easily made in any spreadsheet processor enabling us to evaluate very easily how the change of allocation input parameters influences the results.

A drawback of this method is that most of the input parameters have to be determined using an expert decision, and the expert's knowledge and his experience level inevitably influence the results of the performed allocation. Therefore, when determining allocation input parameters, it is advisable not to involve an individual, but a group of experienced experts.

In conclusion it is necessary to emphasize that the suggested allocation method is by its nature only preliminary and if we are to clarify the systems conception, it is necessary during its development and design to perform repeated availability requirements allocation using sophisticated allocation methods.

Methodology for the preparation of accelerated reliability testing of electronic components in combat vehicles

X.P. Cu
Faculty of Military Technology, University of Defence, Czech Republic

H.A. Bui
Department of Foreign Languages, University of Fire Fighting and Prevention in Hanoi, Vietnam

ABSTRACT: Accelerated Reliability Testing (ART) consists of tests designed to determine the reliability information of a product such as failure intensity, failure probability or survival, or time to failure of a particular product. ART is divided into three phases: preparation phase, implementation phase, evaluation phase. This paper describes the methodology for the preparation of ART of electronic components used in combat vehicles. Before ART is performed, it is extremely important to do test planning including sample selection, test condition selection, ART method selection, determination of stresses level and test duration, etc. The successful design of an ART requires good knowledge of the intended use condition, environmental impact profile, operation and design of the product. Electronic components in combat vehicles often operate in harsh environments and they are generally expected to be subject to higher levels of stress than common commercial electronic components.

1 INTRODUCTION

Reliability is ability to perform as required, without failure, for a given time interval, under given conditions. The time interval duration can be expressed in units appropriate to the item concerned, e.g. calendar time, operating cycles, distance run, etc., and the units should always be clearly stated. Given conditions include aspects that affect reliability, such as: mode of operation, stress levels, environmental conditions, and maintenance (IEC 60050-192). Because of the reliability of a system or a device is mainly dependent on the reliability of its components, the evaluation of the reliability of the components is very important to understand the reliable life of the overall systems and devices.

Reliability of electronic component is estimated by using the standard handbook, statistical analysis of operation & maintenance data or performing reliability testing experiments (Varde 2010). In general, the use of standard handbooks, like MIL-HDBK-217 approach, has some inherent limitations as it does not allow simulations with projected component load profiles; relatively large uncertainties that are associated with various parameters and hence, in the final results; no provisions to assess the root cause of component failure; it is not effective in predicting the reliability of new components or new design of conventional components, etc. Hence, another approach to determine the reliability of electronic components should be using accelerated test methods.

Accelerated test is testing in which the stress level, or rate of stress application, exceeds that occurring under specified operational conditions, to reduce the duration required to produce a stress. The object of the methods is to either identify potential design weakness or provide information on item dependability or to achieve necessary reliability/availability improvement, all within a compressed or accelerated period of time response (IEC 62506).

Accelerated testing methods help investigate the reliability of electronic components as regards certain dominant failure mechanisms under normal operating conditions, provide details about the various degradation mechanisms and thereby improved understanding of the root cause of the failure (Varde 2010).

Accelerated tests are commonly used in the automotive and electrotechnical industries to assess or demonstrate component and system reliability, to detect failure modes which may occur during the life of product, to compare different manufacturers, etc. For military purposes, accelerated tests are possible to apply for the electronic components in combat vehicles.

Common reasons for failure in electronic components are environmental contaminants and conditions, such as temperature, thermal cycles,

humidity and other failures deriving (e.g. vibration, ripple voltage, and overvoltage). Based on the cumulative damage model, expected test information, and assumptions about product usage, accelerated test methods can be divided into three types (IEC 62506):

- Qualitative accelerated tests (type A);
- Quantitative accelerated tests (type B);
- Quantitative time and event compressed tests (type C).

Qualitative accelerated tests (type A) are used primarily to identify failures and failure modes without attempting to make any predictions as to the product's life under use conditions (Reliasoft Corporation 2001). Commonly used qualitative testing models are HALT (Highly accelerated limit tests), HAST (Highly accelerated stress test), HASS/HASA (Highly accelerated stress screening/audit). Qualitative tests are performed with the specimens subjected to a single severe level of stress, to multiple stresses, or to a time-varying stress (e.g., stress cycling, cold to hot, etc.). The results of the tests are then used to increase the margin of strength of the design. Moreover, they provide valuable information such as the types and levels of stresses to employ during a subsequent quantitative test.

Quantitative accelerated tests (type B) are designed to quantify the life characteristics of the product component or system under using conditions, and thereby provide reliability information (Reliasoft Corporation 2001). The purpose of quantitative accelerated testing is to estimate one or more reliability information such as failure intensity, failure probability or survival, or time to failure. It can also be used to assist in the performance of risk assessments or design comparisons.

Quantitative time compressed tests (type C1) are achieved by excluding the "shutdown time" i.e. by focusing the test just on the switch-on time. However, only focusing on the operating time can ignore damage during downtime. Quantitative event compressed tests (type C2) are used to repeat events with greater intensity than the product usage in practice. With this type of testing, some negative consequences can be created by using continuous stress, in some way causes failures that do not occur under normal conditions.

Accelerated testing type A is used in product design phase (new electronic component development, modernization of existing components applying new technologies). Accelerated testing type B and C is used to quantify the reliability parameters of the electronic components, thereby minimizing the lack of reliability information of electronic components used in combat vehicles.

This paper presents the process of designing a quantitative accelerated test applied to electronic components in combat vehicles.

2 ELECTRONIC COMPONENT IN MODERN COMBAT VEHICLES

Today's modern combat vehicles achieve the parameters of the major military characteristics (tactical-technical parameters) through a high proportion of electronic components with digital control. The digitization of military technologies is one of the key requirements of individual armaments, newly purchased combat vehicles, or weapon systems. These electronic components contribute significantly to the achievement of the reliability of vehicles. In-vehicle electronic systems can be divided into control systems, protection systems and information systems (Chloupka 2012). Electronic control systems control mechanical, hydraulic, and other functions (e.g. fuel injection, steering, braking). In modern combat vehicles, engine, transmission, active suspension and brake systems, are controlled by electronic control unit (ECU).

Protection systems work with digital and analog information, and they do not directly connect to control links, for example, diagnostic system, navigation system, security and detection systems. Data collected by protection systems will be shared with other systems, or directly trigger protective elements. The function of these systems is controlled by the control algorithm.

Information systems work with data unrelated to control links. The crew can track and share information from the different vehicles that are aggregated and displayed on the display (e.g., displaying the vehicle's own position on a map). The crew also can distribute information to defined systems in combat vehicle (weapon systems, protection systems) and then can make decisions in combat activities.

Electronic components in-vehicle electronic systems are generally expected to be subject to higher levels of stress than commercial electronic components, mainly temperature, vibrations, shocks, voltage, dustiness and humidity. The basic requirements for electronic components in combat vehicles are shown in Table 1.

Electronic components act in the same way no matter whether for military or civilian purposes; therefore, the standardized procedures of accelerated tests have been already available for commercial electronic components, they can be applied or modified for use on electronic components of combat vehicles (Vintr et al. 2013).

Table 1. The basic requirements for electronic components in combat vehicles.

Parameter	Value
MTTF	15 years
Power supply	18 V to 33 V
Ambient Operating Temperature	–40°C to 70°C
Storage temperature	–40°C to 80°C
Vibration	10 G, 40 to 500 Hz
Mechanical shock	500 G, 0.2 ms to 2 ms
Repeated mechanical shock	20 G, 1 ms to 15 ms
Relative humidity	98% at 25°C
Chemical resistance	1 mg/m^3
Dust resistance	2 g/m^3
Impulse voltage resistance	70 V/3 ms

3 MODELS FOR ACCELERATED RELIABILITY TESTING

These are the models of stress during the life of a product when the damage after a unit of test time is appropriately accelerated by increasing the stress level. The underlying assumption when using any of these models is that the components operating under normal conditions experience the same failure mechanism as those occurring at the accelerated stress conditions. It is assumed that the time-scale transformation or acceleration factor is constant and hence implies linear acceleration (Chaluvadi 2008).

3.1 *Arrhenius model*

Temperature is commonly used as an environmental stress for testing of electronic devices. This is generally modeled using the Arrhenius reaction rate, which is used for constant temperature stresses and is based on the assumption that absolute temperature is due to the emergence of certain mechanisms of failure. The Arrhenius reaction rate equation is given by (IEC 62506):

$$R(T) = Ae^{-\frac{E_a}{k_B T}} \tag{1}$$

where $R(T)$ is the speed of reaction; A is a constant (which is not a function of temperature); E_a is the activation energy (eV); k_B is the Boltzman's constant, $k_B = 8{,}617385.10^{-5}$ (eV/K); T is the absolute temperature (K). The Arrhenius life-stress relationship is given by:

$$L(T) = Ce^{\frac{D}{T}} \tag{2}$$

The relationship is linearized by taking the natural logarithm of both sides in the Arrhenius equation or:

$$\ln[L(T)] = \frac{D}{T} + \ln(C) \tag{3}$$

where $L(T)$ represents a quantifiable life measure such as *MTTF*, characteristic life, etc.; $\ln(C)$ is the intercept of the line; D is the slope of the line ($= E_a/k_B$).

Since the Arrhenius is a physics-based model derived for temperature dependence, it is used for temperature accelerated tests. For the same reason, temperature values must be in absolute units (Kelvin), even though the Arrhenius equation is unitless.

Acceleration factor is the ratio of the stress response rate of the test specimen under the accelerated conditions, to the stress response rate under specified operational conditions.

$$A_{F\_Arr} = \frac{R(T_{Test})}{R(T_{Use})} = \frac{Ce^{-\frac{E_a}{k_B T_{Test}}}}{Ce^{-\frac{E_a}{k_B T_{Use}}}} = e^{\frac{E_a}{k_B}\left(\frac{1}{T_{Use}} - \frac{1}{T_{Test}}\right)} \tag{4}$$

where T_{Use} and T_{Test} are use temperature and test temperature. Arrhenius model is applied to a plurality of statistical distributions in reliability analysis. Its applicability is determined by conditions where exposure to thermal stress is expected by a constant temperature. The model is not applicable for damage caused by low temperature. For such types of damage, it is recommended that a failed test be performed to determine a specific model.

3.2 *Eyring model*

This model is most often used when thermal stress (temperature) is the acceleration variable, which is similar to the Arrhenius model. However, the Eyring model is also used for stress variables other such as humidity. The relationship is given by (IEC 62506):

$$L(S_E) = \frac{1}{S_E} e^{-\left(A - \frac{B}{S_E}\right)} \tag{5}$$

where $L(S_E)$ represents a quantifiable life measure, such as *MTTF*, characteristic life, median life, etc.; S_E is the stress level (temperature values are in absolute units Kelvin). A and B are model parameters to be determined by the test or approximated by the literature values. The acceleration factor in this model is:

$$A_{F\_E} = \frac{L(S_{E\_Test})}{L(S_{E\_Use})} = \frac{S_{E\_Use}}{S_{E\_Test}} e^{B\left(\frac{1}{S_{E\_Use}} - \frac{1}{S_{E\_Test}}\right)} \quad (6)$$

where S_{E_Use} and S_{E_Test} are the use stress level and accelerated stress level.

The Eyring model can be used for all types of mathematical probability distributions that are normally used in reliability analysis. Mathematical levels of reliability can be determined for individual parameters or functions based on appropriate statistics.

3.3 *Inverse Power Law (IPL) model*

This model is commonly used to test electronic devices when the stress is dynamic stresses such as shock, vibration or climatic stresses such as temperature cycles, temperature changes, humidity. The relationship is given by (IEC 62506):

$$L(S) = \frac{1}{CS^n} \quad (7)$$

where: $L(S)$ represents a quantifiable life measure, such as *MTTF*, characteristic life, etc.; S is the stress; C is the model parameters to be determined; n is the model parameter dependent on the behavior of the stress to be determined.

The parameter n in the inverse power relationship is a measure of the effect of the stress on the life. As the absolute value of n increases, the greater the effect of the stress. Negative values of n indicate an increasing life with increasing stress. An absolute value of n approaching zero indicates small effect of the stress on the life, with no effect (constant life with stress) when $n = 0$.

The IPL appears as a straight line when plotted on a log-log paper. The equation of the line is given by:

$$\ln[L(S)] = -nL(S) - \ln(C) \quad (8)$$

For the IPL relationship, the acceleration factor is given by:

$$A_{F\_IPL} = \frac{L(S_{Use})}{L(S_{Test})} = \frac{\frac{1}{CS_{Use}^n}}{\frac{1}{CS_{Test}^n}} = \left(\frac{S_{Test}}{S_{Use}}\right)^n \quad (9)$$

where S_{Use} and S_{Test} are the use stress level and accelerated stress level.

3.4 *Coffin-Manson model*

This model is used to test electronic devices when the stress is a thermal cycle. The failure mechanism is thermal cracking. The equation of the model is (Cui 2005):

$$N = \frac{C}{\Delta T^{\gamma}} \quad (10)$$

where $\Delta T = T_{\max} - T_{\min}$ is the temperature range; $T_{\max}$ is the high extreme temperature; $T_{\min}$ is low extreme temperature; N is the number of cycles to failure; C and γ are properties of the material and test setup. The acceleration factor is given by:

$$A_{F\_CM} = \left(\frac{\Delta T_{test}}{\Delta T_{use}}\right)^{\gamma} \quad (11)$$

where ΔT_{use}, ΔT_{test} are temperature range under normal operation and temperature range under test operation.

4 DESIGN OF ACCELERATED TEST OF ELECTRONIC COMPONENTS

Before performing tests, it is fundamental to plan and determine the characteristic of the sample and the stress-scheme (De Carlo et al. 2014). Planning activities are performed respecting the specifications, the budget and the time constraints. The purpose of ART is to provide objective and reproducible data on the reliability of the object. This requires that the test conditions described in the test plan and the methods used to process the test results are as reproducible as possible and that the test samples used are representative. The steps for designing the ART of electronic components in combat vehicles are presented below.

- Select electronic components in combat vehicles;
- Determine operating conditions of electronic components;
- Decide stress types, levels and numbers;
- Decide sample numbers;
- Calculate acceleration factors and test duration.

4.1 *Electronic components selection in combat vehicles*

If electronic components have not been identified before, based on the results of the analysis below, it is possible to identify representative electronic component for the implementation of ART.

- Analyze overview about each electronic component used in the combat vehicle;
- Analyze the importance of electronic components for the overall functions of the combat vehicle;

- Analyze tactical and technical data of individual electronic components, design, technological level of electronic components (processor technology, processor boards, and displays);
- Analyze the location of electronic components in combat vehicles;
- Specify the applicability of the results obtained by the accelerated test to other similar electronic components.
- Analyze the reliability data of an electronic component specified by the manufacturer, or it may be routed for the purpose of an accelerated test.

4.2 *Operating conditions of electronic components*

The conditions for performing the ART are typically determined on the basis of normal operation of the combat vehicles. Modern combat vehicles have the diagnostic system that archives the operating time for selected components, allowing for the setting of accelerated test parameters. Military equipment is often used as follows (Vintr et al. 2013):

- Free state, during which the electronic components are switched off – up to 90% of operating life time;
- Operating state, during which the electronic components are switched on – up to 10% of operating life time.

4.3 *Stress types, level and number*

In the automotive and electrotechnical industries, when performing accelerated tests, the most commonly used stresses are temperature, temperature cycling, humidity, vibrations/shocks, voltage (overvoltage/low voltage) or combination of these stresses. The different types of stress have different effects on the load of the electronic component and its failure rate, which is reflected in the value of acceleration factor and accelerated test time. By combining different types of stress during an accelerated test, it is possible to achieve higher overall acceleration factor, which means a substantial shortening of cumulative test time. Accordingly, it is necessary to understand the behavior of electronic components with different types of stress by performing tests on statistical samples. In general, procedures designed for commercial electronic components can also be applied to electronic components of combat vehicles. However, it must be remembered that military elements do not behave similarly to commercial electronic components. For this reason, it is also necessary to analyze the accelerated test procedure of commercial electronic component before it is applied to electronic components of combat vehicles.

When performing the ART of electronic components in combat vehicles, there are four types of stress should be focused, namely temperature cycling, temperature, humidity and vibration. The temperature is the basic stress of electronic components. It is sometimes said that temperature is the enemy of reliability of all electronic components. Whether they are used for commercial or military, these components are stressed by the environmental temperature when turned off and the operating temperature when turned on. The temperature cycling which particularly stresses on the solder joints of the electronic components results in a total failure of the electronic components (for example breaking of solder joints, loss of conductive contact, and deformation of the processor plate). The basic factors that affect the failure rate of electronic components by temperature cycling are:

- Type of solder is used and its properties;
- Temperature rise in electronic components;
- Minimum temperature difference (e.g., on/off).

During the switch off state the electronic components of combat vehicles are stressed by ambient temperature. Depending on the season of the year, the idle state does not have a profound effect on an average annual temperature.

During the operation of military equipment, the electronic components are switched on and by their function they generate their own heat. After switch of the equipment it reaches its operating temperature. The resulting temperature of an electronic part depends then on the ambient temperature at which the electronic part is switched on. In order to find out the operating temperatures of electronic parts placed in combat vehicles, an experiment has to be performed.

When determining temperature cycling, it is necessary to find out the time and the number of the switch on/off of electronic components during operation. Modern combat vehicles with electronic components are able to record and archive the time of switch on/off including an hour, a day and a year.

For other stresses such as humidity and vibration, the stress level is also based on the operating conditions and operating environment of combat vehicles. Then, the experiments are performed with selected military electronic components. Based on this information, it is possible to specify the types of stresses or combinations which have a major influence on the reliability or the failure rate of the electronic components. The determination of stress level in test depends on operating limits of electronic components and technical parameters of test equipment such as temperature range, temperature rate of change, humidity range.

The required information for the test calculation is shown in Table 2.

4.4 *The number of samples in test*

The goal of ART affects the determination of sample numbers, the extent of accelerated test, types of damages, possibilities of failure diagnosing, the method of failure resolution.

In qualitative accelerated tests (type A), the sample selection range is determined by the number of stresses and the number of failures detected. For example, in the classic HALT, it requires one sample for low temperature, one for high temperature, one for vibration, one for temperature cycles and one for the combined test by temperature cycles and vibrations; therefore, total is 5 samples. In order to account for more than one failure mode, it is recommended to use another 2 to 5 samples, so the recommended total selection range is 7 to 10 objects (IEC 62506).

In quantitative accelerated tests (type B and C), the number of samples is determined mainly by estimating the constant failure rate or time to failure. A typical selection range for accelerated testing is 77 samples for 1000 h (JESD 47G). In the case of exponential distribution, standards for test plans such as IEC 61123 and IEC 61124 can be used. For a test using Weibull's distribution, at least 5 to 10 failures are expected. Because Weibull's test is often stopped, when one-third of the objects under test fails, the selection range is 15 to 30 objects (IEC 62506).

Table 2. Operating conditions and types of stresses.

Parameter	Symbol	Value (unit)
Operation time		
Switch on	t_{on}	h
Switch off	t_{off}	h
Temperature		
Switch on	T_{on}	K
Switch off	T_{off}	K
Test temperature	T_{test}	K
Temperature change	ΔT_{use}	K
Temperature change in test	ΔT_{test}	K
Total number of cycles	N_{use}	
Speed of temperature change	ξ_{use}	K/min
Speed of temperature change in test	ξ_{test}	K/min
Vibration	W_{use}	m/s^2
Vibration in test	W_{test}	m/s^2
Relative humidity	RH_{use}	%
Humidity in test	RH_{test}	%
Required lifetime	t_0	h
Required reliability	$R_0(t_0)$	
Activation energy	E_a	eV

4.5 *Acceleration factor and test duration*

4.5.1 *Temperature*

When stress is temperature, it is possible to use the Arrhenius reaction model or the Eyring model to calculate the acceleration factor. The Eyring model contains constants A and B, and for military electronic elements, it has to be determined by other tests. To determine them, extensive experiments are needed (on a statistically significant number of electronic components). For products of medium complexity, precision acceleration tests may become problematic because of the different components and materials have different values of constants B; therefore, the accelerated tests of electronic components often use the Arrhenius reaction model. According to the standard GS 95003-1-2010 prescribed in vehicle electrical and electronic components using the Arrhenius reaction model. When using the Arrhenius reaction model is necessary to set the value of activation energy E_a, which directly affects the magnitude of the acceleration factor. The values of activation energy with different standards are shown in Table 3. Figure 1 shows the effect of activation energy E_a on the acceleration factor.

The acceleration factor is given by Arrhenius reaction model:

$$A_T = e^{\frac{E_a}{k_B}\left(\frac{1}{T_{on}}-\frac{1}{T_{test}}\right)} \tag{12}$$

The time with the temperature at switch off state is normalized to the temperature at switch on state:

$$t_{on\_N} = t_{on} + t_{off} e^{-\frac{E_a}{k_B}\left(\frac{1}{T_{off}}-\frac{1}{T_{on}}\right)} \tag{13}$$

The test duration of the ART is:

$$t_{T\_test} = k\frac{t_{on\_N}}{A_T} = k t_{on\_N} e^{-\frac{E_a}{k_B}\left(\frac{1}{T_{on}}-\frac{1}{T_{test}}\right)} \tag{14}$$

Table 3. The values of activation energy (Chloupka 2012).

Electronic components	MIL217F (1996)	RDF (1996)	MIL217 plus (1996)	FIDES (2009)
Bipolar logic	0.4 eV	0.4 eV	0.8 eV	0.7 eV
CMOS logic	0.35 eV	0.3 eV	0.8 eV	0.7 eV
BICmos logic	0.5 eV	0.4	0.8 eV	0.7 eV
Linear	0.65 eV		0.8 eV	0.7 eV
Memories	0.6 eV		0.8 eV	0.7 eV
VHSIC	0.4 eV		0.8 eV	0.7 eV

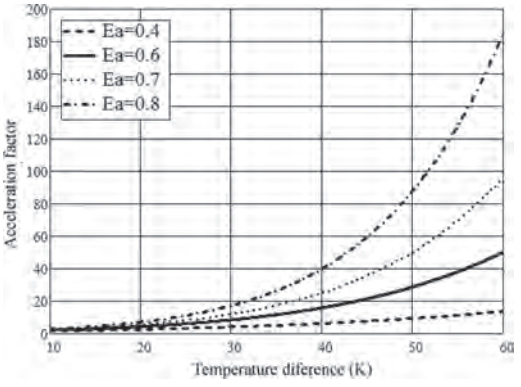

Figure 1. Acceleration factor with different values E_a.

where k is the multiplier of the actual duration of the stress, is determined from the graph in the standard IEC 62506.

4.5.2 *Temperature cycling*
The acceleration factor is given by Coffin-Manson model:

$$A_{TC} = \left(\frac{\Delta T_{use}}{\Delta T_{test}}\right)^{-n} \left(\frac{\xi_{use}}{\xi_{test}}\right)^{-1/3} \tag{15}$$

where n is the temperature cycle exponent (n typical value is around 2).

Number of cycles in test is given by:

$$N_{test} = k\frac{N_{use}}{A_{TC}} = kN_{use}\left(\frac{\Delta T_{use}}{\Delta T_{test}}\right)^{n} \left(\frac{\xi_{use}}{\xi_{test}}\right)^{1/3} \tag{16}$$

Figure 2 shows the schematic of temperature cycle profile. The temperature cycle profile can be characterized by: High extreme temperature (T_{max}), low extreme temperature (T_{min}), temperature change (ΔT), Ramp rates and dwell times at extreme temperatures (Cui 2005). The test duration of a temperature cycle is:

$$t_{TC} = 2\frac{\Delta T_{test}}{60\xi_{test}} + \frac{t_{T\_test}}{N_{test}} + t_{T\_low} \tag{17}$$

where t_{T_low} is dwell time at the lower temperature extreme.

4.5.3 *Humidity*
During the humidity test, the acceleration is achieved by increasing the relative humidity during the test as well as by increasing the test temperature above the expected values during use.

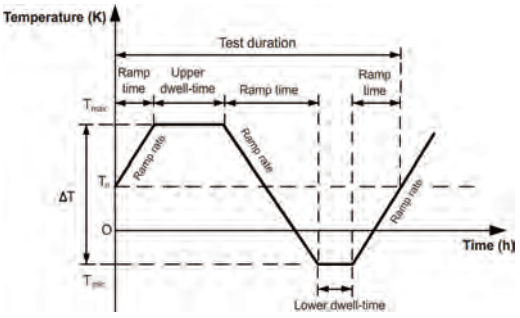

Figure 2. Schematic of temperature cycle profile.

Thermal acceleration is the same as the temperature exposure test for the full equivalent time using the t_{on_N} for the switching temperature. The acceleration factor for the humidity test is given by Hallberg-Peck model:

$$A_{RH} = \left(\frac{RH_{use}}{RH_{test}}\right)^{-h} e^{\frac{E_a}{k_B}\left(\frac{1}{T_{on}} - \frac{1}{T_{RH}}\right)} \tag{18}$$

where T_{RH} is temperature with humidity test, h is the exponent for the acceleration factor caused by humidity according to IPL model.

The test duration of exposure in humidity is given by:

$$t_{RH\_test} = k\frac{t_{on\_N}}{A_{RH}} = kt_{on\_N}\left(\frac{RH_{use}}{RH_{test}}\right)^{h} e^{-\frac{E_a}{k_B}\left(\frac{1}{T_{on}} - \frac{1}{T_{RH}}\right)} \tag{19}$$

4.5.4 *Vibration*
With stress is vibration, it is possible to use the IPL model to calculate the acceleration factor.

$$A_W = \left(\frac{W_{use}}{W_{test}}\right)^{-w} \tag{20}$$

where w is the exponent for the acceleration factor caused by vibration according to IPL model. In the absence of the test-specific constant, it is usually assumed that $w = 4$.

The test duration is given by:

$$t_{W\_test} = k\frac{t_{W\_use}}{A_W} = kt_{W\_use}\left(\frac{W_{use}}{W_{test}}\right)^{w} \tag{21}$$

where t_{W_use} is operation time in vibration test. Typically, for electronic components in automo-

Table 4. Calculation results for ART.

Stress Test: Temperature Acceleration Model: Arrhenius						
T_{on} [K]	T_{off} [K]	t_{on} [h]	t_{off} [h]	T_{test} [K]	A_T [–]	t_{T_test} [h]
Stress Test: Temperature cycling Acceleration Model: Coffin Manson

tive, one hour of non-accelerated vibration test is estimated with distance traveled approximately 1600 km; therefore, $t_{W\_use} = D/1600$ (h), where D is total distance traveled in kilometer of automotive.

4.5.5 *Combined stresses*

To determine the overall acceleration factor, it will be assumed that temperature cycles and vibration cause the same failure mode while temperature and humidity cause another failure mode. The overall acceleration factor is given by:

$$A = \frac{A_{TC}A_W + A_T A_{RH}}{4} \tag{22}$$

Then the total test duration is:

$$t_{test} = -\frac{t_0}{\ln(R_0(t_0))A} \tag{23}$$

The calculation results for ART of electronic components are shown in the Table 4.

5 CONCLUSIONS

This article presents the steps for designing a quantitative ART of electronic components in combat vehicles. Commonly used stress types for electronics components are temperature, temperature cycling, vibration, humidity or combination of stresses. However, in practice, it is necessary to analyze the type of electronic components, operating conditions, operating environments, and capabilities of the existing test equipment to select the type of characteristic stress for the failure mode of electronic components. The ART method of electronic components provided in the commercial industry can be applied for electronic components in combat vehicles after the detailed analysis. The next step is conducting the ART and evaluate the results under actual operating conditions.

Approximation method for reliability of one-unit repairable system with time redundancy

Xiaoyue Wu & Haiyue Yu
School of Systems Engineering, National University of Defense Technology, Changsha, China

ABSTRACT: For some engineering repairable systems like the spaceflight Telemetry, Tracking and Control (TTC) system, mission can be executed within a given time interval and been regarded as successful so long as the system remains in operational state for a minimum length of time. Thus, such system has time redundancy in mission execution and higher mission reliability. This paper presents a discrete approximation method to numerically calculate the mission reliability of such kind of system with one repairable unit and binary states. The time window is divided into a number of time slices and then the mission reliability of the system is derived by solving two groups of recursive discrete time equations. All these equations are established by decomposing the corresponding random event into a number of disjoint events at discrete time points with reduced time lengths. A numerical example is provided for a one unit system. The results of the example are compared with those previously obtained by other solution methods. It was shown that the proposed methods are computationally efficient, and the approximated missionreliability converges to the analytical results when the width of the divided time slices decreases.

1 INTRODUCTION

In engineering practice, there are systems that have time redundancy in mission execution. Specifically, such system needs to work continuously for a minimum length of time to accomplish prescribed critical missions within a given time interval (called time window). A typical example of such system is the space flight Telemetry, Tracking and Control (TT&C) system that provide services such as orbit tracking, remote control and data transmission to spacecrafts during their fly over the ground stations (Wu 2014, Guest 2013). Sometimes, the TT&C service requires only a short time duration within the time window when the spacecraft fly over, so time redundancy exists in such cases.

Although many research works have been done on mission reliability of systems, not enough attention has been given to mission reliability of system with time redundancy. Many existing works are on phased-mission system(PMS) which accomplishes missions in consecutive phases and requires that the system must keep in operational state for all the time duration of the mission phase (Xing & Amari 2008). The existing methods for mission reliability generally includes analytical methods, and simulation methods. Models based on Boolean algebra, Binary Decision Diagrams (BDD), fault trees, and Continuous Time Markov Chains (CTMC) are among the most commonly used analytical methods (Kim & Park 1994, Xing & Amari 2008). To avoid the strict restriction on the modeling assumptions and computational complexity, simulation models like Petri nets, Monte Carlo can provide alternative options (Wu & Wu 2015, Wu & Hillston 2016), but may have precision and computation time issues.

To evaluate the mission reliability of such kinds of systems, the effect of time redundancy should be taken into consideration to avoid underestimating the mission reliability. For repairable one-unit systems, Wu presented a model by decomposing the mission success event into a number of disjoint events, and gave general formulas for its computation (Wu 2014). Later, for semi-Markov systems with multiple units, Wu and Hillston gave an analytical approach based on matrix integral equations for mission reliability evaluation (Wu & Hillston 2015). The integral matrix equations are numerically computed by time discretization approximation. However, both of these analytical methods involving complicated integral expressions and numerical computations. Monte Carlo methods have also been applied for reliability evaluation of such systems (Wu & Guo 2017, Wu & Hillston 2016). The main purpose of this paper is to present a new analytical approach for evaluating mission reliability of repairable one-unit systems with time redundancy. As the first step for mission reliability evaluation, we divided the time window into a number of time slices, and then build recursive equations for numerical computation. Thus, it is different from our previous approaches in the

order of discretizationas we do time discretization firstly and then build reliability evaluation model afterwards.The new approach is expected to be more effective and more computationally efficient.

2 MISSION RELIABILITY MODEL

2.1 *Basic assumptions*

In this paper, we make the following assumptions:

- the system has one unit that is repairable and has two states: operational state (or up state) and failure state (or down state).
- the time to failure and repair time both follow exponential distribution.
- the unit after repair is "as good as new".
- the system is required to accomplish its mission within the time window $[0,T]$.
- the mission is successfully accomplished if the system can keep in up state continuously for time duration no less than T_d.

2.2 *Equations for mission reliability*

Let the interval $[0,T]$ be divided into N intervals as follows.

$$0 =< w_0 < w_1 < \cdots < w_{n-1} < w_N = T \tag{1}$$

where

$$\begin{aligned} w_i &= i\delta, \quad i = 1,\cdots,N \\ \delta &= T / N \end{aligned} \tag{2}$$

Let

$$d = \min_i |T_d - i\delta| \tag{3}$$

Assume that the time to failure of the system W and the repair time Z follow exponential distribution with failure rate λ, and repair rate μ respectively, namely $W \sim Exp(\lambda), Z \sim Exp(\mu)$.

Now we introduce the following notations

P_{ud}^k: the probability that the system starts from up state and remains in up state continuously until at time w_k enters into down state.

P_{du}^k: the probability that the system starts from down state and remains in down state continuously until at time w_k enters into up state.

$P_u(n,d)$: the probability that the system has an operational span not less than T_d within time interval $[0,T_n]$, and the system starts at up state.

$P_d(n,d)$: the probability that the system has an operational span not less than T_d within time interval $[0, T_n]$, and the system starts at down state.

Thinking from renewal points of view, we obtain the following equations

$$P_u(n,d) = \sum_{k=d}^{\infty} P_{ud}^k + \sum_{k=1}^{d-1} P_{ud}^k \cdot P_d(n-k,d) \tag{4}$$

$$P_d(n,d) = \sum_{k=1}^{n-d} P_{du}^k \cdot P_u(n-k,d) \tag{5}$$

Obviously, the boundary conditions are

$$P_u(n,d) = 0 \quad n < d \tag{6}$$

$$P_d(n,d) = 0 \quad n \le d \tag{7}$$

The mission reliability can be obtained by calculating $P_u(N,d)$, which is the probability that the system starts in up state and has at least a continuous time duration T_d of operational state during time interval $[0,T], T = \delta N$.

2.3 *Probabilities of sojourn time*

For implementing the previously established model, it is necessary to give methods for calculating the sojourn time probabilities corresponding to different starting states of the system.

Since both the working time and repair time of the system follows exponential distribution, we can describe the behavior of the system with a binary state continuous time Markov chain (CTMC) model.

By the CTMC theory (Ross 2010), for $k > 0$, we have

$$\begin{aligned} P_{ud}^k &= exp(-\lambda w_k)\left(1 - exp(-\lambda\delta)\right) \\ &= exp(-\lambda k\delta)\left(1 - exp(-\lambda\delta)\right) \end{aligned} \tag{8}$$

$$\begin{aligned} P_{du}^k &= exp(-\mu w_k)\left(1 - exp(-\mu\delta)\right) \\ &= exp(-\mu k\delta)\left(1 - exp(-\mu\delta)\right) \end{aligned} \tag{9}$$

3 ALGORITHM FOR SOLVING EQUATIONS

3.1 *Recursive equations*

For brevity, we define the following notations:

$$G_n = P_u(n,d) \tag{10}$$

$$F_n = P_d(n,d) \tag{11}$$

$$A_k = P_{ud}^k \tag{12}$$

$$B_k = P_{du}^k \tag{13}$$

$$C = \sum_{k=d}^{\infty} A_k = exp(-\lambda w_d) = exp(-\lambda d\delta) \tag{14}$$

Then, the equations (4) and (5) can be rewritten as

$$G_n = C + \sum_{k=1}^{d-1} A_k \cdot F_{n-k} \tag{15}$$

$$F_n = \sum_{k=1}^{n-d} B_k G_{n-k} \tag{16}$$

The associated boundary conditions are

$$G_n = 0 \quad n < d \tag{17}$$

$$F_n = 0 \quad n \le d \tag{18}$$

which make equations (15),(16) more specific

$$G_n = C + \sum_{k=1}^{M(n,d)} A_k \cdot F_{n-k} \tag{19}$$

$$F_n = \sum_{k=1}^{n-d} B_k G_{n-k} \tag{20}$$

where $M(n,d) = \min\{d-1, n-d\}$.

Thus, we obtain recursive equations for find the mission reliability $G_N = P_u(N,d)$.

3.2 *Solution procedure*

Based on the previous results, the mission reliability of the system can be solved with the following computational procedure.

Step 1 : Initialization

Set N, δ, d.

Set $G_n^{old} = 0, F_n^{old} = 0, \quad n = 0, \cdots, N$.

Step 2 : Calculate C, and $A_k, B_k, k = 1, \cdots, N$.

Step 3 : from $n = 1$ to $n = N$, calculate

$$G_n^{new} = C + \sum_{k=1}^{M(n,d)} A_k \cdot F_{n-k}^{old} \tag{21}$$

$$F_n^{new} = \sum_{k=1}^{n-d} B_k G_{n-k}^{old} \tag{22}$$

Step 4 : if the difference between G^{new} and G^{old} is small enough, then stop. The value of G_N^{new} will be the mission reliability.

Otherwise, set $G^{old} \leftarrow G^{new}$, $F^{old} \leftarrow F^{new}$, go back to Step 3.

4 NUMERICAL EXAMPLE

To verify the proposed model and the solution algorithm, we use an example of one-unit system (Wu 2014), the time to failure and repair time of the unit are both of exponential distributions. The failure rate and repair rate of the unit are $\lambda = 1/60$ and $\mu = 1/10$ respectively. The system is required to work continuously for $T_d = 60$ within the given time interval [0, T], $T = 100$. For this example, the mission reliability obtained by other methods is 0.533, including analytical and simulation methods (Wu 2014, Wu & Hillston 2015).

Table 1. Mission reliability for different N.

N	$R = G_N$	N	$R = G_N$
100	0.5093	2000	0.5322
200	0.5208	2500	0.5324
500	0.5283	3000	0.5326
800	0.5302	3500	0.5327
1000	0.5308	4000	0.5328
1200	0.5313	4500	0.5329
1500	0.5317	5000	0.5329

Table 2. Mission reliability after different iterations.

Iteration	3	5	8	10	15
$R = G_N$	0.5100	0.5313	0.5328	0.5329	0.5329

The proposed method is used to solve the mission reliability. To study the approximation precision of the time discretization, different value of N for the fixed time window [0, T] is used to compute the mission reliability. The results are shown in Table 1.

In order to see the convergence performance of our recursive algorithm for solving equations (19) and (20), the mission reliability calculated after different number of iterations are provided in Table 2, where the number of discretization is set as $N = 4500$.

From Table 2, we can see that our algorithm has fast convergence speed. After about 8 iterations of the recursive equations, the value of the mission reliability sufficiently approaches the analytical result 0.533.

By comparison of the mission reliability results in the two tables, we can find that the number of discretization of time window has more influence on the precision of the obtained results. When the length of time slice becomes about 1/50 of the length of the time window, it can be expected that the obtained mission reliability reach satisfied precision.

5 CONCLUSIONS

For one-unit repairable systems with time redundancy that requires only a minimum length of operational time within a time window for its mission

success, we present an analytical approximation approach to calculate the mission reliability. Based on the system behaviors at discrete time points, the recursive equations for mission reliability are established for different system starting states and remaining time durations. Moreover, an iterative numerical computation procedure is presented for obtaining the system mission reliability. This approach is different from our previous approach by making time discretization before building the recursive equations. Results of numerical example shows that the proposed method provides an efficient way for mission reliability evaluation of systems with time redundancy. As future research work, we will try to extend the model and algorithm to more complicated cases.

ABSTRACT: In this paper, a new reliability analysis method for complex mechanical system which contains hybrid uncertainties is proposed. The hybrid uncertainties containing randomness and intervals are considered in the limit-state function of reliability. Middle Point Limit-State (MPLS) model is first proposed for calculating the reliability index of hybrid uncertainties, and this model could make the index interval smaller and accurate. For complex mechanical systems, system hierarchy technique is used in reliability modeling, and composite limit-state function is then obtained to calculate the system reliability. By constructing the optimization model of the composite limit-state function, the reliability index interval can be obtained, and artificial bee colony algorithm is employed to solving these optimization models. The reliability index interval obtained through the method proposed by this paper could be more precise comparing to existing techniques. The reliability indexes containing the interval and MPLS index may be a more useful analysis tool to assess the mechanical systems reliability with hybrid uncertainties. A numerical case is carried out to illustrate this method and an engineering case of the satellite driving system is used as a typical complex mechanical system to demonstrate the analysis method proposed in this paper.

1 INTRODUCTION

The complexity of modern mechanical system generally emerges in two sides: first, the system structure and its components are complex, mechanical systems are typical multi-level systems, and there are many elements in every level. Second, the uncertain information of mechanical system is complex. Depending on the amounts of the statistic information, some variables or parameters have sufficient statistical information and they are probabilistic variables; some other variables lack enough statistical information, so they could only be given upper and lower values of interval.

While dealing with the hybrid uncertainties of interval and probability, some researches have been emerged in the structure reliability analysis field. Techniques as: transforming the interval uncertainties to random uncertainties, then calculating the reliability with classical random reliability theory such as First Order Reliability Method (FORM), Second Order Reliability Method (SORM) (Hurtado et al 2012, Hurtado 2013); assuming the interval variables obey uniform distribution in the interval range, and the non-probabilistic reliability index is used to estimate the reliability of structures (Jiang et al. 2013, Wang et al 2010, Qiu et al. 2008). These methods are based on the assumption that the interval variables obey random distributions. This assumption has neglected the objective fact that interval variables have no enough information but only the upper and lower boundaries. In order to overcome the above deficient, some other techniques like tow-step method has been developed for the hybrid uncertainties structural system (Jiang et al. 2011, Du 2007, Guo et al. 2009), this technique is not suitable for the system reliability analysis, the main problem is the interval extension because of the Interval Arithmetic Method (IAM). With the complexity of the mathematic process, the range of the output interval will become too large to accept. Interval-truncation approach (Lu et al. 2002, Zhao et al. 2008) is developed to reduce interval extension, and it could make sense in simple interval arithmetic equations, but is not suitable for the complex problems, especially for complex mechanical systems. Other epistemic uncertainty theory such as fuzzy possibility (Singh et al. 2008) and dempster-shafer evidence theory (Flage et al. 2011, Zio et al. 2012) could also deal with the interval uncertainty, but these theories are suitable for specific uncertainty structure as fuzzy set, basic belief assignment. The uncertainty measures such as possibility, belief and plausibility are used for reliability assessment.

This paper aims to develop an efficient and relative accurate reliability analysis method for complex mechanical system with hybrid uncertainties.

A Middle Point Limit-State (MPLS) model is first introduced in this paper to deal with the hybrid uncertainties of interval and probability, and the composite limit-state function and optimization model for complex mechanical system reliability analysis are also proposed by this paper. First the system reliability model is built with the hierarchy model of the system, and then the composite limit-state function of the system is obtained according to different levels and logic gates of the hierarch systems. The optimization model for calculating the system reliability index is constructed and Artificial Bee Colony (ABC) algorithm is employed to solve it. The optimization model method has been used in the fuzzy industrial system analysis (Fales 2010, Harish et al. 2012, Sharma et al. 2009, Garg et al. 2013). The main contribution of this method is that the Optimization Model Based Method (OMM) instead of IAM, is used to calculate the system reliability, and the final results of reliability interval will be more precise. It should be noted that the mechanical systems in the paper are considered with two states and the basic logic gates "AND" and "OR" are used.

The remainder of this paper is organized as follows. Random distribution with interval parameters are employed to quantify the uncertainty, and the MPLS model is introduced for this case in section 2; section 3 are reliability model establishment of complex mechanical system; section 4 demonstrates the reliability analysis method based on the optimization model and ABC algorithm; a numerical case and an engineering case are carried out in section 5 to demonstrate this method. Finally, a conclusion is given in section 6.

2 MIDDLE POINT LIMIT-STATE MODEL FOR HYBRID UNCERTAINTIES

Define the limit-state function Z of mechanical system as follows:

$$Z = g(\boldsymbol{X}, \boldsymbol{Y}) \tag{1}$$

where $\boldsymbol{X} = \{x_1, x_2, \cdots, x_n\}$ are random variables, $\boldsymbol{Y} = \{y_1, y_2, \cdots, y_m\}$ are interval variables, and the upper and lower boundary values of $\boldsymbol{Y}$ are given:

$$\boldsymbol{Y} = [\boldsymbol{Y}_{\min}, \boldsymbol{Y}_{\max}] \tag{2}$$

The mean value and deviation of $\boldsymbol{Y}$ are defined as:

$$\boldsymbol{Y}_{\mathrm{m}} = \frac{\boldsymbol{Y}_{\min} + \boldsymbol{Y}_{\max}}{2} \tag{3}$$

$$\boldsymbol{Y}_{\mathrm{r}} = \frac{\boldsymbol{Y}_{\max} - \boldsymbol{Y}_{\min}}{2} \tag{4}$$

Because of the interval variables $\boldsymbol{Y}$, the limit-state function Z is an area composed of two surfaces in the probabilistic space. It is shown as in Figure 1.

For reliability analysis of the hybrid uncertainty limit-state function Z, this paper constructs a "middle point limit-state (MPLS)" model to calculate the reliability index β. In the MPLS model, a new limit-state function is constructed when all the interval variables are chosen as the middle point in the interval ranges. And this limit-state function is defined as:

$$Z_{\mathrm{m}} = g(\boldsymbol{X}, \boldsymbol{Y}_{\mathrm{m}}) = 0 \tag{5}$$

When using the FORM or SORM, The equation (1) could be rewritten as:

$$Z = g(\boldsymbol{X}, \boldsymbol{Y}) = \mathrm{g}(\mathrm{T}(\boldsymbol{U}, \boldsymbol{Y})) = G(\boldsymbol{U}, \boldsymbol{Y}) \tag{6}$$

where $\boldsymbol{U} = \{u_1, u_2, \cdots, u_n\}$ is the standard normal variables transferred from $\boldsymbol{X}$.

The reliability index β^{m} of the Z_{m} can be obtained by solving the follow optimization model:

$$\begin{cases} \beta^{m} = \min\limits_{U} \|\boldsymbol{U}\| \\ s.t. \quad G(\boldsymbol{U}, \boldsymbol{Y}_{\mathrm{m}}) = 0 \end{cases} \tag{7}$$

For reliability index interval $\beta^{\mathrm{I}} = [\beta^{\min}, \beta^{\max}]$, the following two optimization problems can be solved.

$$\begin{cases} \beta^{\min} = \min\limits_{U} \|\boldsymbol{U}\| \\ s.t. \quad \min\limits_{Y} G(\boldsymbol{U}, \boldsymbol{Y}) = 0 \end{cases} \tag{8}$$

and:

$$\begin{cases} \beta^{\max} = \min\limits_{U} \|\boldsymbol{U}\| \\ s.t. \quad \max\limits_{Y} G(\boldsymbol{U}, \boldsymbol{Y}) = 0 \end{cases} \tag{9}$$

The redefinition of reliability index interval β^{I}. Through the above work, three reliability indexes

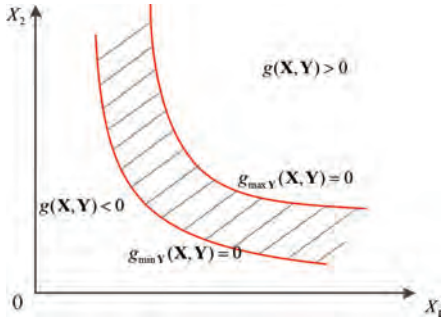

Figure 1. State space of performance function including interval variables.

$\beta^{\min}, \beta^{\max}$ and β^{m} is obtained, then the reliability index interval β^{I} of Z can be defined according to the following cases:

case 1:

If $\beta^{\min} \geq \beta^{m}$, then $\beta^{I} = [\beta^{m}, \beta^{\max}]$.

case 2:

If $\beta^{\max} \leq \beta^{m}$, then $\beta^{I} = [\beta^{\min}, \beta^{m}]$.

case 3:

If $\beta^{\min} < \beta^{m} < \beta^{\max}$, then $\beta^{I} = [\beta^{\min}, \beta^{\max}]$, and β^{m} is an accessory reliability index. The final reliability index is defined as:

$$\beta = \begin{cases} \beta^{I} \\ \beta^{m} \end{cases} \tag{10}$$

The reliability is:

$$R = \begin{cases} R^{I} = \Phi(\beta^{I}) \\ R^{m} = \Phi(\beta^{m}) \end{cases} \tag{11}$$

3 COMPOSITE LIMIT-STATE FUNCTION METHOD FOR MECHANICAL SYSTEM RELIABILITY ANALYSIS

3.1 *Hierarchy model of mechanical system*

For complex mechanical system, the reliability analysis is full of challenge because of the complexity both in structure and uncertainty information, especially when the amount of its elements is too large. Due to this reason, system hierarchy technique is an efficiency way for complex mechanical reliability analysis.

The system hierarchy method is as shown in Figure 3. In this method, the mechanical system is divided into different levels according to its structure and components. Generally, the top level is the system and the bottom level contains the variables and parameters of basic elements. Middle levels are sub-systems or parts of the mechanical system. Different levels are jointed by the logic gates.

In the hierarchy model of the system reliability, logical operations of the gates in the hierarchy model are appointed as follows.

For the "AND" logical gate, the reliability is:

$$R_{\text{AND}} = \prod_{i} R_i \tag{12}$$

For the "OR" logical gate, the reliability is:

$$R_{\text{OR}} = 1 - \prod_{i} (1 - R_i) \tag{13}$$

It should be noted that all the components or failure modes are independent with each other.

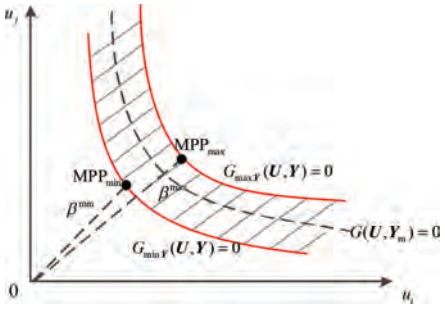

Figure 2. Reliability index of hybrid uncertainty.

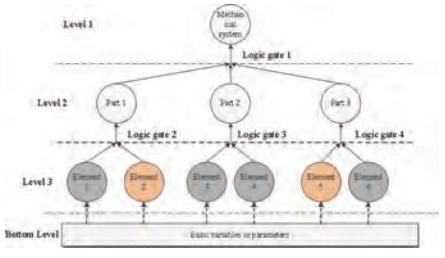

Figure 3. The hierarchy model of mechanical system.

3.2 *Composite limit-state function and calculation of system reliability*

In section 3.1, the complex mechanical system is modeled by different levels and logic gates according the system hierarchy method. Then this section proposes the construction of the composite limit-state function and how to calculate the system reliability. The Figure 3 is used to illustrate this method. Through this figure, we could see that the bottom levels are the basic variables and parameters, and the variables are both probabilistic and interval in this paper. Then every element in level 3 could have the limit-state functions based on its failure modes and variables, and these limit-state functions are defined as:

$$\boldsymbol{Z}_{\text{level3}} = \left\{ Z^{1}_{level3}, Z^{2}_{level3}, \cdots, Z^{6}_{level3} \right\} \tag{14}$$

$$Z^{i}_{level3} = g\left(\boldsymbol{X}_i, \boldsymbol{Y}_i\right) \tag{15}$$

The index Z^{i}_{level3} represents limit-state of the ith element in level 3. The indexes $\boldsymbol{X}_i$ and $\boldsymbol{Y}_i$ represent the probabilistic variables and interval variables of the ith element.

For level 2, the limit-state function of the part 1, part 2 and part 3 could be obtained based on the index $\boldsymbol{Z}_{\text{level3}}$ and the logic gate. And these limit-state functions are:

$$\boldsymbol{Z}_{\text{level2}} = \left\{ Z^1_{level2}, Z^2_{level2}, Z^3_{level2} \right\} \tag{16}$$

$$Z^1_{level2} = L\left(Z^1_{level3}, Z^2_{level3} \right) \tag{17}$$

In which $L(\bullet)$ is a logic function. For level 1, the limit-state function of the mechanical system could be obtained through the index $\boldsymbol{Z}_{\text{level2}}$ and the logic gate 1, and the limit-state function is as:

$$Z_{sys} = L\left(Z^1_{level1}, Z^2_{level2}, Z^2_{level3} \right) \tag{18}$$

and Z_{sys} is defined as the composite limit-state function of the mechanical system. However, the composite limit-state function is not suitable for using directly, especially for the large systems with too much variables, and the limit-state function in this paper are considered as the hybrid uncertainty limit-state function. So this paper employs the reliability index instead of the limit-state function. According to MPLS in section 2, every limit-state function of element in the level 3 could get a reliability index interval β^{I} and R^{I}, then, the reliability of the composite limit-state function Z_{sys} could be defined as:

$$R^{\text{I}}_{sys} = L\left(R^{\text{I}}_1, R^{\text{I}}_2, \cdots, R^{\text{I}}_i \right) \tag{19}$$

where the function principle of L is the same as the equation (19).

After calculation, the index R^{I}_{sys} is also an interval and defining it as:

$$R^{\text{I}}_{sys} = \left[R^{\min}_{sys}, R^{\max}_{sys} \right] \tag{20}$$

where $R^{\min}_{sys}$ and $R^{\max}_{sys}$ are the lower and upper boundary of the interval respectively.

4 RELIABILITY ANALYSIS OF COMPLEX MECHANICAL SYSTEM

4.1 *Optimization models for calculating the reliability*

For the reliability computation of R^{I}_{sys}, the optimization model based method (OMM) is utilized instead of the interval arithmetical method (IAM). The boundary values of R^{I}_{sys} in equation (20) could be obtained by solving the optimization problems as follows:

For $R^{\min}_{sys}$

$$\begin{aligned} &\text{Minimize} && g\left(R^{\text{I}}_1, R^{\text{I}}_2, \cdots, R^{\text{I}}_i \right) \\ &\text{Subject to} && R^{\min}_i \le R^{\text{I}}_i \le R^{\max}_i \end{aligned}$$

For $R^{\max}_{sys}$

$$\begin{aligned} &\text{Maximize} && g\left(R^{\text{I}}_1, R^{\text{I}}_2, \cdots, R^{\text{I}}_i \right) \\ &\text{Subject to} && R^{\min}_i \le R^{\text{I}}_i \le R^{\max}_i \end{aligned}$$

According to (Garg & Sharma 2012), the smaller of the interval range, the more meaningful of the system reliability decision. For the complex mechanical system, the optimization model is obviously a high nonlinear problem, thus a high efficient optimization algorithm is needed here. Artificial bee colony (ABC) algorithm is proved to be an effective algorithm (Peng et al. 2013), and this paper will use it to calculate the optimization models to get the system reliability.

The whole steps of the reliability analysis method proposed in this paper are as follows:

Step 1: analyze the structure and components of the mechanical system, build the reliability model with system hierarchy technique;

Step 2: identify the bottom elements of the system, collect and extract the uncertainty information of these elements;

Step 3: build the reliability limit-state functions of these elements, if it is implicit problem, the RSM is needed. Then the composite limit-state function of the system is identified;

Step 4: calculate the reliability index interval β^{I} and R^{I} of the elements based on the MPLS method proposed in the section 2, and then construction the optimization model for solving the boundary of the R^{I}_{sys} of the composite limit-state function Z_{sys};

Step 5: optimize the model with ABC algorithm, the mechanical system reliability index R^{I}_{sys} and R^{m}_{sys} are obtained.

Artificial Bee Colony (ABC) algorithm was proposed by Karaboga for optimizing numerical problems (Karaboga 2007, 2008). The algorithm simulates the intelligent foraging behavior of honeybee swarms. It is a very simple, robust and population based stochastic optimization algorithm.

5 CASE STUDY

5.1 *The numerical case*

Assume the hierarchy model of a mechanical system as shown in Figure 4, after system hierarchy, there are 5 levels in the mechanical system S, the bottom level is the basic variables. There are 9 elements in the level 4, and all these elements are considered with hybrid uncertainties. Their basic variables and limit-state function are given. The 5 logic gates G_1~G_5 are as follows: G_1, G_2 and G_4 are "OR" gates, G_3 and G_5 are "AND" gates. Now we calculate reliability index of S with the method proposed in this paper.

Denote the reliability performance functions of the bottom elements E_1~E_9 as follows:

$$\begin{cases} g(\boldsymbol{X},\boldsymbol{Y})_{E_1} = x_1 \cdot y_1 / x_3^2 - 0.8\, x_2 / y_1 \\ g(\boldsymbol{X},\boldsymbol{Y})_{E_2} = 567 \cdot x_4 \cdot x_5 - 0.5 y_2^2 \\ g(\boldsymbol{X},\boldsymbol{Y})_{E_3} = x_6 \cdot x_7^2 + \sqrt{2} / x_7 - y_3 \\ g(\boldsymbol{X},\boldsymbol{Y})_{E_4} = x_8 - \sqrt{300 x_9^2 + 1.92 y_4^2} \\ g(\boldsymbol{X},\boldsymbol{Y})_{E_5} = \exp\left[0.4(y_5 + 2) + 5.02\right] \\ \quad - \exp\left[0.3 y_6 + 500\right] - 200 x_{10} x_{11}^2 \\ g(\boldsymbol{X},\boldsymbol{Y})_{E_6} \\ \quad = y_7 - 6 x_{11} \cdot y_8 / (x_{12}^2 \cdot x_{13}) - 6 x_{11} \cdot y_9 / (x_{12} \cdot x_{13}^2) \\ g(\boldsymbol{X},\boldsymbol{Y})_{E_7} \\ \quad = x_{14}^3 \cdot y_{10} \cdot y_{11} / x_{15} + \sqrt{2} x_{15}^2 / \sqrt{y_{10}} - 326 \\ g(\boldsymbol{X},\boldsymbol{Y})_{E_8} \\ \quad = 0.01 - (48 x_{16} + 32) / (18 x_{17} + 3) \cdot y_{12} / (y_{13} y_{14}) \\ g(\boldsymbol{X},\boldsymbol{Y})_{E_9} = \sqrt{x_{18}} \cdot x_{19} / y_{15} - x_{20} / y_{16} \end{cases} \tag{21}$$

The uncertainties of all variables are as shown in Table 1 and Table 2. Based on the MPLS model proposed in this paper, the reliability index β_i. of the bottom elements of the system could be obtained, and the results are listed in Table 3.

Construction of the composite limit-state function of the system S. According to the system structure and its logic gates, the composite limit-state function can be obtained as:

$$\begin{cases} G_{sys}(\boldsymbol{X},\boldsymbol{Y}) = L_{\mathrm{OR}}(\mathrm{g}_{M_1}, \mathrm{g}_{M_2}) \\ \mathrm{g}_{M_1} = L_{\mathrm{OR}}\left(g_{E_1} \sim g_{E_4}\right) \\ \mathrm{g}_{M_2} = L_{\mathrm{AND}}\left(\mathrm{g}_{M_3}, \mathrm{g}_{M_4}\right) \\ \mathrm{g}_{M_3} = L_{\mathrm{OR}}\left(g_{E_5}, g_{E_6}\right) \\ \mathrm{g}_{M_3} = L_{\mathrm{AND}}\left(g_{E_7}, g_{E_8}, g_{E_9}\right) \end{cases} \tag{22}$$

where L is the function according to the logic operation (12) and (13). Similarly, the system reliability R_S^{I} could be obtained according the equation (23)

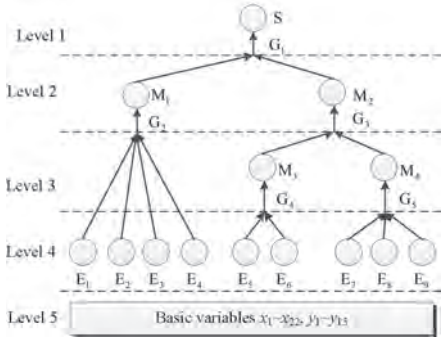

Figure 4. Hierarchal model of the system S.

$$\begin{aligned} R_{sys} &= R_1 \cdot R_2 \cdot R_3 \cdot R_4 \\ &\cdot \left[1 - (1 - R_5 \cdot R_6) \cdot (1 - R_7) \cdot (1 - R_8) \cdot (1 - R_9)\right] \end{aligned} \tag{23}$$

The system reliability R_{sys}^{m} is calculated directly according to equation (23), it is: $R_{sys}^{\mathrm{m}} = 0.94960402$.

The lower boundary value of the system reliability R_{sys}^{I} is

$$\begin{aligned} &\text{minimize} && R_{sys} \\ &\text{subject to} && R_{E_i} \in \left[R_{E_i}\right] \end{aligned}$$

The upper boundary value of the system reliability R_S^{I} is

$$\begin{aligned} &\text{maximize} && R_{sys} \\ &\text{subject to} && R_{E_i} \in \left[R_{E_i}\right] \end{aligned}$$

The ABC is used to optimize the above models, it has been implemented in Matlab (MathWorks) and the program has been run on a T6400@2GHz Intel Core (TM) 2 Duo processor with 2 GB of Random Access Memory (RAM). The selected values of all the parameters for ABC are given as:

Colony size (CS) = 20 × number of subunits.
Limit for scout = (CS × D)/2, where D is dimension (number of variables)
Number of generation = 500.

The termination criterion has been set to a maximum number of generations of order of relative error equal to 10^{-6}, whichever is achieved first.

The results of the ABC algorithm are: 0.93429182 (the lower boundary) and 0.96392416 (the upper boundary). The optimization process is as shown in Figure 5 and Figure 6.

6 RESULTS AND DISCUSSION

According to the reliability analysis method proposed in this paper, when all variables are the mean values, the reliability of system is $R_{sys}^{\mathrm{m}} = 0.94960402$. The index R_{sys}^{I} is as follows: if using IAM directly, the reliability interval R_{sys}^{I} is [0.91771156, 0.96653623], if using OMM, the reliability interval R_{sys}^{I} with ABC algorithm is [0.93429182, 0.96392416]. Comparing to the IAM result, the interval range obtained through the OMM is smaller, especially is the lower boundary of the interval. The lower boundary value is reduced about 0.01658026. The upper boundary value is almost the same with the IAM result, which is reduced about 2.61207e-3. This is because the reliability interval of all the bottom elements are smaller

Table 1. Uncertain information of random variables.

Variables	Distribution	Mean	Variance	Variables	Distribution	Mean	Variance
x_1	Normal	26	0.1	x_{11}	Normal	1000	100
x_2	Normal	3.2	0.05	x_{12}	Normal	100	15
x_3	Weibull	7.2	0.07	x_{13}	Lognormal	200	20
x_4	Lognormal	0.6	0.131	x_{14}	Weibull	10	0.1
x_5	Lognormal	2.18	0.03	x_{15}	Normal	4	0.085
x_6	Normal	2.2	0.01	x_{16}	Extreme I	0.3	0.003
x_7	Normal	12.5	0.1	x_{17}	Lognormal	0.1	0.001
x_8	Extreme I	48	3	x_{18}	Normal	152	0.01
x_9	Normal	1.0	0.16	x_{19}	Normal	60	0.085
x_{10}	Weibull	1.0	0.001	x_{20}	Normal	1.6	0.02

Table 2. Uncertain information of interval variables.

Variables	Upper boundary	Lower boundary	Variables	Upper boundary	Lower boundary
y_1	3	2.8	y_9	27	23
y_2	33.78	31.72	y_{10}	4.6	4.2

E_9	2.8845,3.2076	3.0313

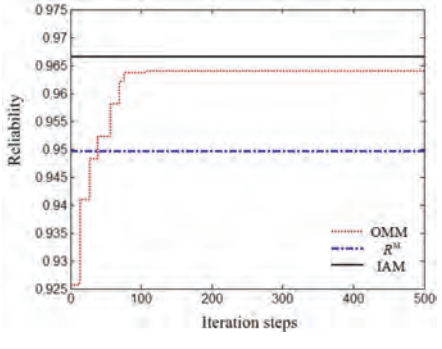

Figure 5. Optimization process of the upper boundary.

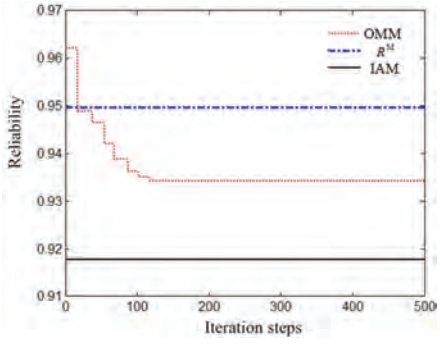

Figure 6. Optimization process of lower boundary.

than 1. It also could be seen that the interval reduction in this case is not obvious in this case, this can be explain that the system is not complex enough.

The spread width to the index R_{sys}^{m} is as follows: through IAM, the left spread width is 0.03189246, and the right spread width is 0.01693221. Through OMM, the left spread width is 0.0153122, and the right spread width is 0.01432014. Suppose the index R_{sys}^{m} is the most sensitivity point in the interval of the index R_{sys}^{I}, then interval obtained by OMM is more sensitive than the result obtained by IAM.

In order to illustrate the advantages of the ABC algorithm, other intelligence optimization algorithms as particle swarm optimization (PSO) algorithm and genetic algorithm (GA) are also used for these same optimization models. The results are listed in Table 4. It shows that ABC algorithm and PSO algorithm could get almost the same results. The results demonstrate that ABC and the PSO are both good at the global searching ability in the optimization process. But PSO need more steps (177) than ABC (102) to convergence to a stable solve. The GA convergences very quickly (only 77 steps), but the optimization results is much rougher than the ABC and PSO.

6.1 *Engineering case*

A satellite driving system is composed of a stepper motor, a harmony reducer, a photoelectric encoder and a microswitch. The CAD model of the satellite driving system is as shown in Figure 7. After structure analysis, the hierarchy model of the driving system as shown in Figure 8. The event in top level is the failure of driving system.

Through the calculation and statistical experiments, in the driving system, the reliability indexes of the bottom elements are shown in Table 5.

Based on the hierarchy model in Figure 9, the system reliability is:

$$R_S = R_{E_1} \cdot R_{E_4} \cdot R_{E_5} \cdot R_{E_6} \cdot R_{E_7} \cdot \left[1-\left(1-R_{E_2}\right)\cdot\left(1-R_{E_3}\right)\right] \cdot R_{E_8} \cdot R_{E_9} \cdot R_{E_{10}} \cdot R_{E_{11}} \tag{24}$$

The upper and lower boundary values of the system reliability could be obtained by solving follow optimization models.

$$\begin{aligned} &\text{minimize/maximize} && R_S \\ &\text{subject to} && R_{E_i} \in \left[R_{E_i}\right] \end{aligned}$$

Based on the data in Table 5, the reliability R_S^{m} could be obtained directly and it is 0.97313495. For R_S^{I}, the result of the OMM is $R^{\mathrm{I}} = [0.9485038, 0.9911342]$ and the result of the IAM is $R^{\mathrm{I}} = [0.9338912, 0.9933270]$. It can be shown that the interval obtained by OMM is obviously smaller than the interval obtained by IAM, it means that the OMM can reduce the interval extension in this problem. Through the Figure 10, we can see that ABC algorithm could maintain in the optima margin stably for a high nonlinear problem. The OMM based on the ABC algorithm could get precise interval result for a complex system, and it is meaningful for the decision making.

The left spread width and right spread width to the Rm is as shown in Table 6. The spread width of the OMM is smaller than the IAM. Compared to the IAM, the left spread width of the OMM reduce about 0.0145918(37.1825%), and the right spread width reduce 0.0021858(10.82878%).

7 CONCLUSION

In this paper, a reliability analysis method is proposed for complex mechanical system. This method overcomes the complexity difficult of uncertain information brought by the completeness difference of the statistic information. The reliability index β^{I} as well as β^{m} of the middle point limit state function is introduced to comprehensively assess of the hybrid uncertainty system reliability. This method could avoid both subjective assumption to interval variables and information waste of random variables.

Composite limit-state function is used to build the reliability model of the complex mechanical system, and it could deal with the complex of large variables and information. Optimization model based technique is employed to solve the system reliability index interval, and advance intelligence ABC algorithm is utilized in the optimization models. This optimization model based method could conquer the difficulties brought by the complexity of the system structure, and also could avoid the interval extension induced by the IAM. Through this method, the higher sensitivity zone of the reliability interval will be achieved; this is very useful and meaningful for reliability estimation and decision making for complex mechanical system.

Common cause failures and cascading failures in technical systems: Similarities, differences and barriers

L. Xie, M.A. Lundteigen & Y.L. Liu
NTNU, Trondheim, Norway

ABSTRACT: Many technical systems continue to increase in size and complexity, with more interactions and interdependencies between components. Dependent failures, such as common cause failures and cascading failures, are becoming important concerns to system reliability. Both failure types may lead to the unavailability of multiple components at the same time or within a short time interval. Although many researchers have studied common cause failures and cascading failures respectively, there is little comparison of the two concepts. This paper investigates the similarities and differences of these two failure groups, with focus on the conditions and nature of initiations and propagation of such failures. Moreover, a comparison is also made about suitable barrier strategies that can either prevent or reduce the consequences of failure. The paper concludes the study with a demonstration of reliability modeling for common cause- and cascading failures.

1 INTRODUCTION

Technical systems, such like railway systems, processing systems in chemical and petroleum plants, and power grids, are becoming increasingly complex. These systems include many physical components, with a huge number of interaction and interdependencies. Sometimes, those failures occurring in multiple components are resulted from the interconnections. We refer to such failures as dependent failures. Within the category of dependent failures, there are two sub-categories that are of specific interest: common cause failures (CCFs) and cascading failures (Rausand and Lundteigen, 2014). In the chemical and process industry, cascading processes are called as domino effects (Abdolhamidzadeh et al., 2010, Abdolhamidzadeh et al., 2009, Landucci et al., 2016).

Past accidents and near misses have shown that dependent failures are one of main threats to a complex system. For example, CCFs are main contributors of failures in safety systems of the oil and gas industry (Smith and Simpson, 2004, Lundteigen and Rausand, 2007). Fires in the chemical and process industry highlight the severe cascading consequences (Landucci et al., 2016, Cozzani and Reniers, 2013). The blackouts in United States, Canada in 2003, and Europe in 2006 are also the examples of cascading failures (Kotzanikolaou et al., 2013, Andersson et al., 2005). Many other infrastructure systems, like water distribution networks, transportation, also often suffer from cascading failures (Lin et al., 2014, Shuang et al., 2014, Ouyang, 2014).

So far, it seems like most attention has directed to CCFs and in specific for safety-critical systems where redundancy is used actively to enhance reliability (Paula et al., 1991, Humphreys and Jenkins, 1991, Lundteigen and Rausand, 2007, IEC61508, 2010, A. Mosleh, 1998). There have been two main strategies suggested for incorporating defenses against CCFs in design. One is to carry out analyses to identify and remove causes, and the other is to introduce measures to reduce the effects of CCFs in case they occur. Suggested methods include cause-defense matrices, common cause analysis, and zonal analysis (Humphreys and Jenkins, 1991, Paula et al., 1991).

The defenses to CCFs are typically identified in design, however, measures in the operational phase are also important (Lundteigen and Rausand, 2007). Even for an excellent system design, there will always remain a risk of CCFs. It is therefore required to include the contribution of CCFs in quantitative analyses used to demonstrate adequate reliability. A high number of models has been introduced for this purpose (Vesely, 1977, Fleming, 1975, Evans et al., 1984, Mosleh and Siu, 1987). The standard beta factor model is perhaps the most widely adopted, due to its simplicity (Fleming, 1975, IEC61508, 2010). The PDS method (Hauge et al., 2015) is an extension of the standard beta factor, where a second parameter is added to account for voting, e.g. 2-out-of-3 and 1-out-of-3.

As for cascading failures, it is of interest to consider efficient means to avoid or reduce the vulnerability of the failures in the system design, and to quantify cascading failures. An important

task in these analyses is to study interdependencies, and many analyzing approaches in literature are based the topology of complex network (Motter and Lai, 2002, Wang, 2012, Albert and Barabási, 2002). One kind of cascading failures are the failures when a heavily load component fails, and its load is redistributed to other components, resulting in loads on that exceed their capacities. State-based approaches, such as Markovian process, approaches based on the Bayesian network models, and Monte Carlo Simulation have been used to analyze cascading failures (Iyer et al., 2009, Calviño et al., 2016, Erp et al., 2017).

In fact, many technical systems can be subject to both CCFs and cascading failures, thus it is important to consider both failure categories in reliability analysis. Unfortunately, very limited attention has been directed comparing the two types of dependent failures, and their corresponding defense strategies. Kotzanikolaou et al. (2013) highlight that CCFs may have cascading effects, but do not go into much detail.

The objective of this paper is therefore to make a comprehensive comparison on the concepts, causes, and mechanisms of the two failures, and provide some suggestions on the analysis and defense strategies. In this paper, we use the term of barrier to denote a specific defense measure.

The rest of the paper is organized as follows: In section 2, we discuss the definitions and interpretations of CCFs and cascading failures. Sections 3 and 4 present the similarities and distinctions of the two failures. In section 5, we clarify the barriers against the two failures. A small example is then employed in section 6, to illustrate that the effects of CCFs and cascading failures. Conclusions and discussions occur in section 7.

2 DEFINITIONS AND INTERPRETATIONS

According to Humphreys and Jenkins (Humphreys and Jenkins, 1991), *dependent failures refer to the failures whose probability cannot be expressed by unconditional probability of the individual event*. Dependencies in a technical system may derive from the sameness of the types of components, exposure from the same environment, the use of shared resources, functionality, the common shocks and the incapability to resist certain hazardous events (Rausand, 2013).

People in different industrial sectors define CCFs in their own ways. Nuclear sector defines it as *two or more component fault states exist at the same time, or with a short interval, because of a shared cause* (Mosleh et al., 1988). The generic standard on design and operation of electric, electronic, and programmable electronic safety-related systems, IEC 61508, defines a CCF as a *failure that is the result of one or more events, causing concurrent failures of two or more separate channels in a multiple channel system, leading to system failure* (IEC61508, 2010). Both definitions emphasize that CCFs involve at least two failures that are due to a shared or common cause.

Cascading failure may be *multiple failures, where initiated by the failure of one component in the system that results in a chain reaction, the so-called domino effect* (Rausand and Øien, 1996). In power systems, cascading failure is referred to *a sequence of dependent failures of individual components that successively weakens the systems* (Baldick et al., 2008). It differs from the definition in infrastructures that limit the cascading failure to the propagation of failures between components (Rinaldi et al., 2001). Generally, we can find some same elements in the definitions that cascading failures are multiple failures initiated by one, and a sequential effect occurs.

From the perspective of failure causes, both CCFs and cascading failures result from some common vulnerabilities of more than one component. These two types of failures are interrelated in some cases (Laprie et al., 2007, Kotzanikolaou et al., 2013). However, they are still two distinctive categories of dependent failures. As Smith and Watson explained, CCFs emphasize that failures are located in 'first in line', which means that the failure are only dependent on the causes, but not on each.

In the following sections, we try to elaborate similarities and difference between the two failures.

3 SIMILARITIES

We categorize the similarities between CCFs and cascading failures into three: *multiplicity*, *timeliness* and *classification of causes*.

3.1 *Multiplicity*

Both CCFs and cascading failures obviously involve more than one components. We are concerned with the *effect of failure* of several components and *functions* for two categories of failures.

3.2 *Timeliness*

For both CCFs and cascading failures, the time from the first failure to the existence of multiple failures is often short. In case of insufficient mitigation measures, the collapse of an entire system may occur very soon. For example, in the Three Mile Island accident caused by CCFs in 1979, the radiation level in the primary coolant water

was around 300 times of the expected level after only 2 hours (Hasani, 2017). The power blackout in India in 2012 due to cascading failures, spread across 22 states within 12 hours and affected more than 620 million people (Russel, 2012).

3.3 *Root causes*

Root causes of both CCFs and cascading failures are the common vulnerability of more than one components in a system. Coupling factors between components can explain why multiple components are destroyed by a common hazardous event, e.g. cold temperature, extreme snowfall or electrical failure. Meanwhile, for cascading failures, couplings also can explain why multiple components are affected by the faults of relevant components. For example, the unavailability of one processing unit increases the workload of another unit.

4 DIFFERENCES

For differences between two types of failures, we categorize them into two: *initiation* and *propagation* of failures, as shown in Table 1. Initiation of failures.

As seen in Table 1, the initiating event of a CCF can be either replicated or occur simultaneously for several components. The effect of CCFs arises from shared causes, may be simultaneous failures or failures with some time apart. A cascading failure always starts with a single preceding component failure, as the effect of an initiating event.

Table 1. Differences between CCFs and cascading failures.

Difference	Characteristics	CCFs	Cascading failures
Initiation	Triggering condition	Shared causes	Conditional on preceding failures
	Occurrence	Simultaneously or during a critical time of interest	Sequence
Propagation	Sequence	First in line	Series
	Consequence	Finite	Possibly infinite
	Pathway	Cause-components	Connected/ dependent components

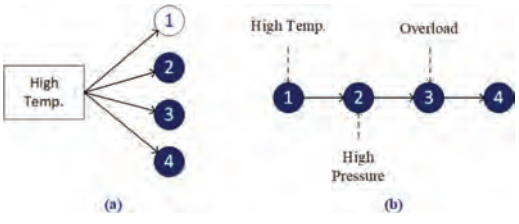

Figure 1. CCF and cascading failures.

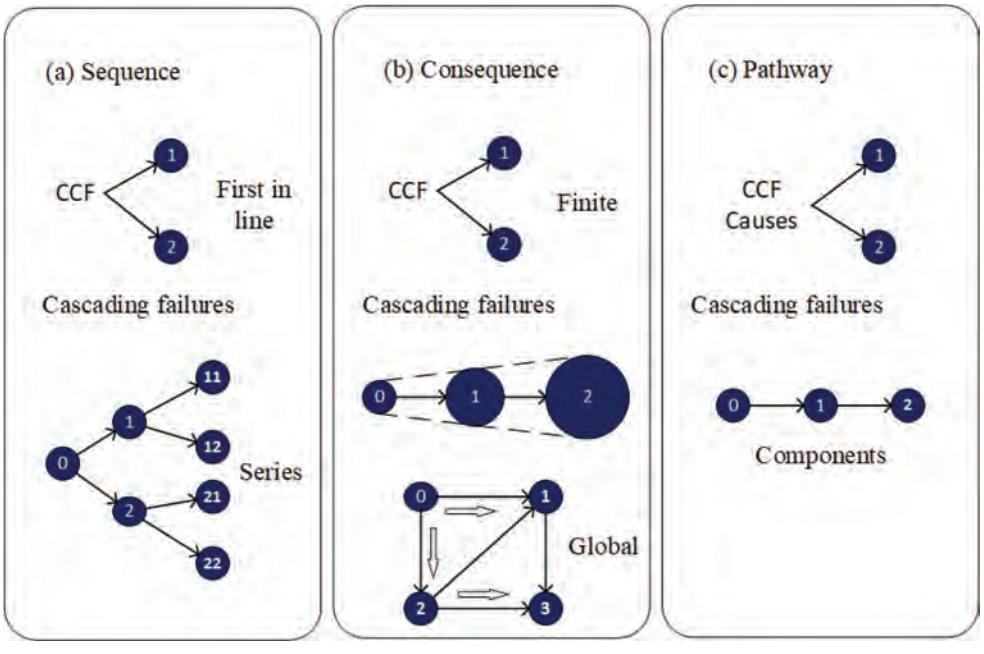

Figure 2. Comparisons of CCFs and cascading failures in terms of impact and effect.

To illustrate these differences, we introduce two small examples, as shown in Figure 1. High temperature is the initiating event of both a CCF and a cascading failure in this case. In Figure 1(a), all the four components expose themselves to high temperature, and so all or some of the components fail simultaneously or in a short interval. However, in the case of a cascading failure of Figure 1(b), only component 1 is exposed to high temperature, and fails due to this initiating event. Then, the failure of component 1 trigger the failures of other components due to diverse reasons. Even in the same cascading sequence, the failure causes can be different for the different components.

4.1 *Propagation of failures*

Propagation of failure means in this context the evolvement of multiple failures, with the initiating event already manifested. Figure 2 illustrates the differences in the propagation of CCFs and cascading failures. CCFs are *first in line* failures that delineate the exclusion of dependent failures from CCF definition (Smith and Watson, 1980), which implies that CCFs are directly linked to the failure causes. On the contrary, the propagation of a cascading failure follows a series of interactions. CCFs are most different from cascading failures in terms of the approaches of propagation. As shown in Figure 2(a), for CCFs, the first in line failure only occurs on component 1 and 2. For the consequence of failure propagation, as shown in Figure 2(b), a cascading failure can escalate and result in worse impacts on the other parts of a system, such as more serious disruptions, overload to neighbors and longer recovery time etc. CCFs highlight a direct cause-effect relationship between the cause and the failed components (Rausand and Lundteigen, 2014), whereas the pathway of cascading failures involve the interactions or dependencies between relevant components, see in Figure 2(c).

5 BARRIERS

Barriers are employed to prevent, control or mitigate undesired events or accident (Sklet, 2006). Sometimes, barriers are also called defenses, protection layers or countermeasures. In general, a barrier function can be realized by many different means, such as by a technical or physical system, human actions and procedural deficiencies.

In the design phase of a system, it is possible to introduce barriers against potential failures, like separation, diversity, quality control, simplicity of design etc. Some of them are effective to reduce the probability of CCFs, and some of them are more functional for protecting the system from cascading failures. Considering the similarities and differences of CCFs and cascading failures, we can categorize barriers into three groups: *barriers against both failures*, *barriers against CCFs* and *barriers against cascading failures*.

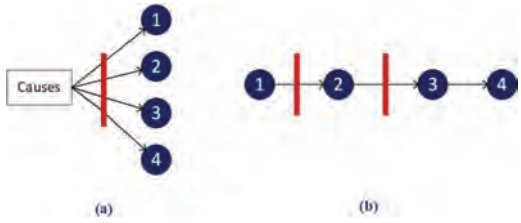

Figure 3. Barriers for CCF and cascading failures.

- Barriers efficient for both failures: Such kind of barriers should be designed in consideration of the similarities of CCFs and cascading failures, such like their root causes and coupling factors. One way of barrier design is therefore to mitigate and reduce the vulnerability to root causes. Simplicity can be regarded as a barrier, for example, to reduce system complexity that is one important source of vulnerability. Another way of barrier design is to decrease the coupling degrees among components. Spatial and temporal separations are examples of decreasing coupling degrees. In practices, we can find that firewalls in a process plant are effective barriers to prevent fire disasters.
- Barriers against CCFs: The effectiveness of such barriers is to isolate failure causes and components, as shown in Figure 3(a). One example is diversity of the design. Diverse components will often have different failure modes, and are therefore less likely to be affected by the common cause. However, diversity is not effective to mitigate cascading failures. When the failure of one component brings higher workload to its neighbors and their failure probabilities, no matter the components are identical or not.
- Barriers against cascading failures: The main purposes of this kind of barriers are to stop or slow down failure propagation, as shown in Figure 3(b). An example for this class of barriers is a process shutdown valve that can isolate related process segments. In case abnormal events have occurred in the upstream facility, the shutdown valve can stop or limit the flow between two facilities, and thereby cease the failure propagation.

In the next section, we will use a small example to illustrate the quantitative analyses for CCFs and cascading failures, and the effects of barriers.

6 CASE STUDY

Suppose a system comprising two parallel components. The effects of failures and corresponding barriers for the two dependent failures are studied separately, as illustrated in Figure 4.

For modeling CCFs, a new *independent* "CCF" event is added in the standard beta model with beta-factor β. The parameter β can be interpreted as the conditional probability that a failure of a channel is in fact a common-cause failure:

$$\beta = \Pr(CCF \,|\, Failure\ of\ channels) \tag{1}$$

With inclusion of CCFs, the total system reliability can be obtain as:

$$R(t) = 2R - R^{(2-\beta)} \tag{2}$$

where $R = 0.8$ and $\beta = 0.1$.

For modeling cascading failures, it is necessary to consider the effects of functional dependency between the two components, and Bayesian network model is an approach we used here. The conditional failure probability is a measure of dependency that differ from the conditional probability β for CCFs. The conditional probability for cascading failures can be defined as:

$$\Pr(Comp.B\ fails \,|\, comp.A\ fails) = \frac{F_D}{F_A} \tag{3}$$

Here, F_A and F_B denote the individual failure probability for component A and B. F_D denotes the failure probability for component A on the condition of component A has failed. The total system reliability with cascading failures can be obtained as:

$$\begin{aligned} R(t) &= 1 - F_A(F_B + F_D - F_B F_D) \\ &= 1 - (1-R)^2 - (1-R)^2 R P_r \end{aligned} \tag{4}$$

where P_r denotes conditional probability between component A and B and is assigned as $0.1 (\Pr = 0.1)$.

As shown in Figure 5, the total system reliability with CCFs becomes 0.946, but it is 0.957 with the effects of cascading failures at that time. This

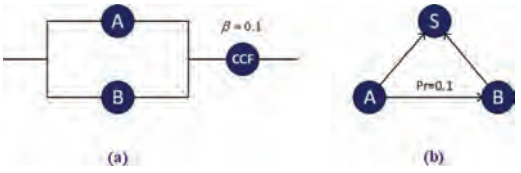

Figure 4. Case study for CCF and cascading failures.

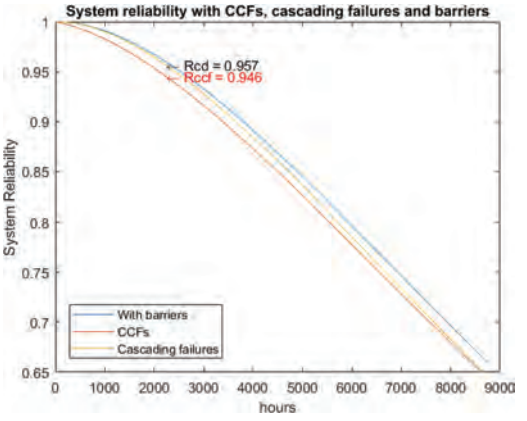

Figure 5. Reliability with cascading failures & CCFs.

implies that CCFs may have more influence on the reliability performance than cascading failures in this case, when using similar assumptions about the probability of having additional failures, when a first failure has occurred.

We now introduce time-dependent probabilities for reliability analysis, and assume that the time to failure is exponentially distributed, with failure rate of 1E-04 per hour for each component. For the system with CCFs, the total system reliability can be obtain as:

$$R(t) = \left[2e^{-(1-\beta)\lambda t} - e^{-2(1-\beta)\lambda t}\right] e^{-\beta\lambda t} \tag{5}$$

For the system with cascading failures, the total system reliability can be obtain as:

$$R(t) = 1 - (1 - e^{-\lambda t})^2 - (1 - e^{-\lambda t})^2 e^{-\lambda t} P_r \tag{6}$$

Figure 5 illustrates calculated system reliability considering the effects of the two failures as a function of time. We can see that, in this case, the two failures seems to have comparable effects on the system reliability.

For CCFs, the function of barriers is to separate shared root causes from the components. The function of the barriers against cascading failures is to prevent propagation of the failures between component A and B. Reliability of the system with barriers is illustrated in the blue line in Figure 5, implying that the system reliability will increase when performing barriers function against the failures.

7 CONCLUSION AND FURTHER WORK

Exploring similarities and difference between CCFs and cascading failures facilitate us to answer

the following questions: 1) why such dependent failures initiate, 2) how dependent failures contribute to disruptions in the systems, and 3) what kind of barriers are needed and how they should be implemented. In this paper, we find that CCFs and cascading failures may have comparable influences on the performance of a simple system. More probabilistic and quantitative analyses are required, to evaluate the impacts of cascading failures in a larger and more complex system (Erp et al., 2017).

Our further work will involve modeling the interdependent systems with cascading failures and CCFs, and developing tools to evaluate reliability for complex systems. It is also of interest to identify different failure modes and perform barrier analysis for both of the failures, which can help to allocate barriers and thereby optimize barrier functions.

Industry 4.0 and complexity: Markov and Petri net based calculation of PFH for designated architectures and beyond

M. Albert
SICK AG, Waldkirch, Germany

M. Dorra
Institute for Occupational Safety and Health of the German Social Accident Insurance (IFA), Sankt Augustin, Germany

ABSTRACT: Industry 4.0 opens up for a new area of industrial automation and challenges established methods for the assurance of safety. Traditionally, the architecture is a major criterion for the determination of safety levels and so-called designated architectures serve as a basis for the calculation of the *PFH* (EN ISO 13849-1, 2015, IEC 62061, 2015). This easy approach is, however, limited to systems which can be directly mapped to the assumptions. For modern, software-intensive systems the extended possibilities for online diagnostics makes this mapping particularly difficult. To make the *PFH* calculation more flexible and transparent, we have derived Markov-based analytic equations for the designated architectures. In this paper, we will sketch our approach for a single-channel system with diagnostics. We compare the result to Petri net simulations, analyze the influence of individual parameters and argue how these models can be extended to more complex systems even beyond the realm of the designated architectures.

1 INTRODUCTION

In machinery the demand for safety and flexibility at the same time has led to the development of a large variety of safety functions. According to the risk associated with particular hazards in the application, these functions are intended to assure an appropriate risk reduction. Accordingly, the integrity of the safety function is typically specified as a Safety Level, e.g. as the "Safety Integrity Level" (SIL) of IEC 61508 (IEC 61508-1, 2010), the SIL claim of IEC 62061 (IEC 62061, 2015), or the Performance level (PL) of ISO 13849-1 (EN ISO 13849-1, 2015).

These standards directly link the achievable safety level to a target probability of dangerous failures. For safety in machinery (usually operated in high demand mode), this is the average frequency of dangerous failures of the safety function *PFH* (IEC 61508-4, 2010, Innal et al. 2010).

Most implementations of safety functions involve electrics and/or electronics but the complete functional chain often also employs pneumatics, hydraulics or mechanics. Irrespective of the technologies, the safety-related reliability in terms of the *PFH* value can be kept sufficiently low by using diagnostics and redundancy. The standards IEC 61508, IEC 62061 and ISO 13849 (IEC 61508-1, 2010, IEC 62061, 2015, EN ISO 13849-1, 2015) governing the functional safety of machinery address a couple of simple and generic system architectures but pursue different ways in evaluating the *PFH* value: IEC 61508 and IEC 62061 by provision of equations for calculation of the *PFH*, ISO 13849-1 by tables. However, the underlying approaches of these standards as well as the assumptions made result in several shortcomings concerning the applicability of these simple approaches to real systems. On the other hand, in all of the standards, stochastic modeling is suggested as a suitable method to determine the *PFH* value of systems which cannot directly be mapped to their dedicated architectures.

Among these methods, Markov models have proven to be a suitable tool for the calculation of safety-related reliability measures (Brissaud & Oliveira 2012, Dutuit et al. 2008).

Unlike numerical methods (stochastic Petri nets, Monte Carlo simulation), they enable the derivation of analytic equations (Dutuit et al. 2008). Their major drawbacks are the limitation to exponentially distributed processes (constant transition rates) and the (exponential) explosion of the state space with the number of elements. These drawbacks make the application to more complex systems with non-exponentially distributed processes and many states difficult (IEC 61508-6, 2010).

In the first part of this paper, we will argue, how the limitation to exponentially distributed processes can be overcome for a single channel system

with diagnostics (1oo1D) without significantly reducing the precision of the results. Subsequently, a very general analytic formula for the calculation of the *PFH* for the 1oo1D systems will be derived.

The second part will show, how the analytic results can be reproduced by Petri net based Monte-Carlo simulations and will argue how the corresponding Petri net can be extended to more complex systems.

2 SINGLE-CHANNEL SYSTEM WITH DIAGNOSTICS

Figure 1 shows the block diagram of the single channel system with diagnostics (1oo1D) considered in this paper.

The functional channel F with the dangerous failure rate λ_{FD} performs the safety function. The diagnostic channel M (monitor) with the dangerous failure rate λ_{MD} tests F with the diagnostic coverage *DC* and the diagnostic rate r_t. With respect to F "dangerous failure" means loss of the safety function whereas with respect to M "dangerous failure" means loss of the diagnostic function which M should execute for F. β is the "common cause factor" as defined by IEC 61508-6, 2010, Annex D. It represents a measure for the susceptibility of F and M to dangerous failures due to the same causes. If a dangerous failure of F is detected, M initiates a safe state. The diagnostic channel M is not tested by any diagnostics. Failures of the diagnostic channel will hence not be detected. The system is subject to regular demands of the safety function that occur at random points in time. r_d represents the mean demand rate. At least one demand occurs per year (high demand mode of operation, see IEC 61508-4, 2010).

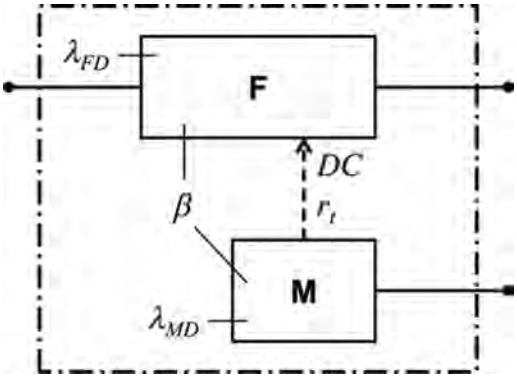

Figure 1. Block diagram of a single channel system with diagnostic channel.

2.1 *State transition model of the single channel system*

Modelling the above-noted features of the 1oo1D systems leads to the state transition model depicted in Figure 2. All system states shaded in light grey are dangerous states because the safety function cannot be executed due to a failure of channel F. A demand on the safety function will lead to a hazardous event if the system is in one of these states.

Assuming time-constant failure rates, the transitions representing those failures are exponentially distributed functions (solid arrows). Testing of F and demand of the safety function are supposed to be uniformly distributed (dashed arrows) which corresponds to a constant frequency of occurrence. These processes are either driven by automatic periodic procedures (especially the tests) or their frequency is estimated (especially the demands). In the latter case the estimation typically comprises an average frequency only and there is no basis for the assumption of any other distribution than the uniform distribution as an adequate representation of regularity. On the contrary the repair process complies with a jump distribution (dotted arrows, labeled with the repair rate r_r). Failures of the functional channel F and of the monitor M due to the same cause ("common cause failures") are associated with the common cause failure rate λ_{CC}. A common cause failure can only occur in the OK state from where it leads directly to the state "F DU, M D".

Since not all of the transitions have exponential distribution functions, this graph does not represent a Markov model.

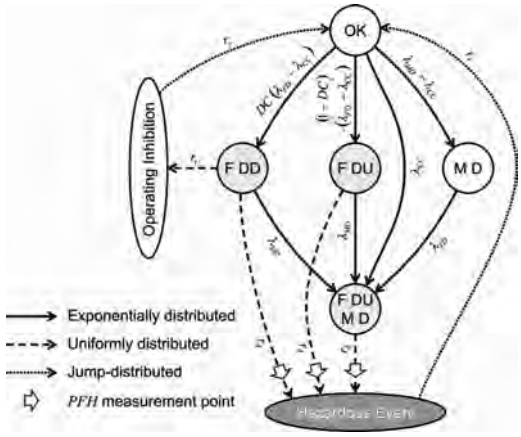

Figure 2. State transition model for the single channel system with diagnostics; "F DD": F failed dangerously detectable, "F DU": F failed dangerously undetectable, "M D": M failed dangerously (unable to detect faults of F).

Applying a demand of the safety function while the system is in one of the dangerous states will result in a "hazardous event". Therefore, according to Figure 2, the *PFH* is made up of the absolute flow (events per time unit) associated with the demand-driven transitions. This is where the *PFH* measurement points are located.

2.2 *Principles for model simplification*

In order to transform the model into a simpler and Markov-compatible form, several simplifications can be carried out.

The "F DU" state can be merged with the "F DU, M D" state without any influence on *PFH*, because the sum of their probabilities is not affected by the transition between them. It is, however, the probability sum only which determines the *PFH* contribution of these states or, respectively, of the merged state, since there is no other exit than via the demand process. Additionally, the ratio of the transition rates allows for some significant model simplifications without considerable loss of *PFH* accuracy. For instance, by neglecting the Mean Repair Time (*MRT*) the "operating inhibition" and "hazardous event" states can be merged with the "OK" state.

On the other hand, the most interesting state of the model is "F DD". It is fed by the very low rate *DC* ($\lambda_{FD} - \lambda_{CC}$) (detectable failures of F without common cause failures) but cleared by the diagnosis or the demand process on a regular basis with a much higher rate. As a consequence, "F DD" is nearly empty at any time and the probability of the state can be neglected. (It will though be used to calculate the outflow rates of this state, see below.) Moreover, the "F DD" state is additionally discharged by failures of the monitor M (rate λ_{MD}). The "F DD" state can be eliminated by making use of its very low probability and by determining the outflow rates as a function of the inflow rate.

This situation is sketched in Figure 3, where the related state is labelled "FPN", as it serves as "flow partitioning node".

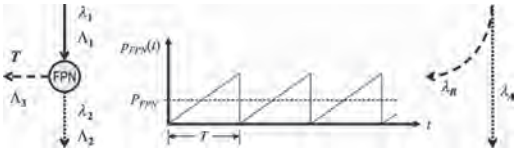

Figure 3. Flow partitioning node; λ_1 and λ_2 are nominal rates of exponentially distributed failure processes, T is the mean time between two clearings of FPN, Λ_1, Λ_2 and Λ_3 denote the corresponding absolute mean flow rates, λ_A and λ_B are the resulting mean surrogate outflow rates of the FPN node.

At "FPN" phases of duration T with feeding by the absolute rate Λ_1 and a small discharge by the rate λ_2 are interrupted by a complete clearing. "Absolute rate" means probability flow per time unit. In case of an exponentially distributed process, the absolute rate Λ is given by the probability of the source state, multiplied by the nominal rate λ of that process. During the interval [0, T] of the time t, for the probability of the state it holds true that

$$p_{FPN}(t+\Delta t) = p_{FPN}(t) + \Lambda_1 \cdot \Delta t - p_{FPN}(t) \cdot \lambda_2 \cdot \Delta t \tag{1}$$

For $\Delta t \to 0$ this yields:

$$\dot{p}_{FPN}(t) = \Lambda_1 - \lambda_2 \cdot p_{FPN}(t) . \tag{2}$$

With $0 \le t \le T$ and the initial condition $p_{FPN}(0) = 0$, the solution of this differential equation is:

$$p_{FPN}(t) = \frac{\Lambda_1}{\lambda_2}\left(1 - e^{-\lambda_2 t}\right) \tag{3}$$

The mean probability is calculated by integration over a time interval of duration T and division by T:

$$P_{FPN} = \frac{1}{T}\int_0^T p_{FPN}(t)\,dt = \frac{\Lambda_1}{\lambda_2} + \frac{\Lambda_1}{\lambda_2^2 \cdot T}\left(e^{-\lambda_2 T} - 1\right) \tag{4}$$

By replacing the absolute inflow rate Λ_1 by the nominal rate λ_1, Equation 4 allows to calculate the partitioning of the nominal inflow rate λ_1 of "FPN" to the two fractions λ_A and λ_B:

$$\lambda_A = \lambda_1\left(1 - \frac{1 - e^{-\lambda_2 T}}{\lambda_2 T}\right) \tag{5}$$

$$\lambda_B = \frac{\lambda_1}{\lambda_2 T}\left(1 - e^{-\lambda_2 T}\right) \tag{6}$$

Note that the splitting of λ_1 to λ_A and λ_B according to Equations 5 and 6 considers the exponential distribution function associated with λ_2 and the uniform distribution function associated with the clearing process with rate $1/T$.

The flow partitioning node "F DD" of Figure 2 is cleared by testing as well as by demand on the safety function. Hence, the following substitution in Equations 5 and 6 is necessary

$$T = \frac{1}{r_t + r_d} \tag{7}$$

According to Figure 2, λ_1 and λ_2 are given by $DC\,(\lambda_{FD} - \lambda_{CC})$ or λ_{MD}, respectively.

2.3 *Resulting model and analytic result*

Applying the above-mentioned simplifications to the model of Figure 2 yields the model shown in Figure 4.

The simple two-state model of Figure 4 is finally a Markov model since all occurring transitions are exponentially distributed. The related differential equation system can be solved for the initial conditions $p_{OK}(0) = 1$ and $p_{MD}(0) = 0$ whereupon, according to Figure 4, the instantaneous *PFH* value can be calculated by

$$\begin{aligned} pfh(t) \;=\; & \lambda_B \,\frac{r_d}{r_t + r_d}\, p_{OK}(t) \\ & + \left[(1 - DC)\,(\lambda_{FD} - \lambda_{CC}) + \lambda_A + \lambda_{CC} \right] p_{OK}(t) \\ & + \lambda_{FD}\; p_{MD}(t) \end{aligned} \tag{8}$$

Calculating the mean value of $pfh(t)$ over the mission time T_M eventually yields

$$\begin{aligned} PFH \;=\; & \lambda_{FD} \\ & - \left\{ DC \cdot TRTE \cdot \frac{(\lambda_{FD} - \lambda_{CC})}{(\lambda_{FD} + \lambda_{MD} - \lambda_{CC})^2\, T_M} \right. \\ & \cdot \left[\lambda_{FD}\,(\lambda_{FD} + \lambda_{MD} - \lambda_{CC})\, T_M \right. \\ & \left. \left. + (\lambda_{MD} - \lambda_{CC})\left(1 - e^{-(\lambda_{FD} + \lambda_{MD} - \lambda_{CC})\, T_M}\right) \right] \right\} \end{aligned} \tag{9}$$

where the common cause failure rate of the channels F and M is given by

$$\lambda_{CC} \;=\; \beta \cdot \min(\lambda_{FD}, \lambda_{MD}) \tag{10}$$

And *TRTE* is the time-related test efficiency. Making use of $\lambda_{MD} \ll r_t + r_d$ this quantity can be calculated by

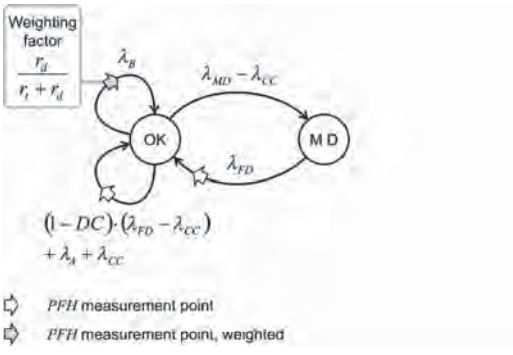

Figure 4. Graph of the Markov model for the single channel system with diagnostics.

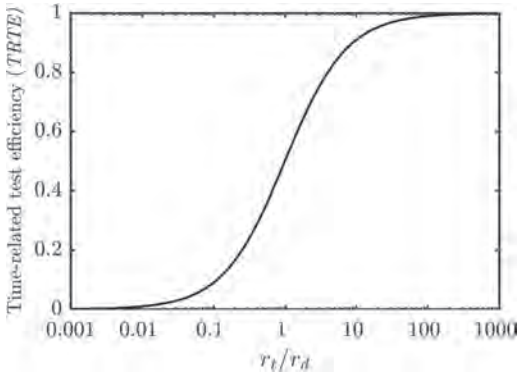

Figure 5. Time-related test efficiency as a function of rt/rd.

$$TRTE \;=\; \frac{r_t}{r_t + r_d} \tag{11}$$

TRTE is a measure for the test effectiveness under consideration of a temporal "race" of testing and demand on the safety function. System design should aspire to avoid such a race so as not to diminish the effect of testing. This is accomplished if the test is always executed in time and in this case *TRTE* can be set to its maximum value of 1. $TRTE = 0$ as well as $DC = 0$ lead to an untested channel F and $PFH = \lambda_{FD}$.

If time-optimal testing is not feasible, *TRTE* should be made as high as possible by implementing an adequate test rate. The model of Figure 2 assumes the absence of any synchronization of test and demand. Provided this, Equation 11 states the dependence of the time-related test efficiency *TRTE* on the ratio of the test rate r_t and the demand rate r_d. This dependence is depicted in Figure 5.

IEC 61508, IEC 62061 and ISO 13849 recommend a ratio r_t/r_d of ≥100 (IEC 61508-2, 2010, IEC 62061, 2015, EN ISO 13849-1, 2015). According to Figure 5 or Equation 11, this ensures a time-related test efficiency of >0.99.

2.4 *Other architectures*

The designated architectures of machine controls addressed by the standards for functional safety also comprise the two-channel architecture. Therefore, by applying the principles described in section 2.2, an analytic Markov model-based solution for the *PFH* was also derived for the asymmetric redundant 1oo2D structure. Due to limited space it is not reported here. A manuscript regarding this matter has been proposed for usage within standardization (Dorra, M., 2017).

3 PETRI NET BASED MONTE CARLO SIMULATION

Finite state machines are an efficient way to model the behavior and the dynamics of safety related systems (EN 61508-6, 2010). Since the 1960s Petri nets have been used for this purpose and since then have proven to be useful and versatile tool. While in the beginning (timed) Petri nets where mostly used to synthesize Markov graphs, Monte Carlo simulation of such nets became increasingly popular to investigate their dynamic behavior and to overcome the problem of the exploding state space of the Markovian approach (EN 61508-6, 2010). In case of Petri nets, the size of the model scales linear with the number of modeled elements. Beside their scaling properties, their easy graphical representation and the possibility to simulate the system graphically makes Petri nets a powerful tool for the modelling of safety-related systems. Results for the calculation of the average probability of dangerous failures on demand in case of the low demand mode (<1 demand/year) obtained with Markov models and Petri nets have proven to be similar (Brissaud & Oliveira 2012).

3.1 *Model*

The basic Petri net model of the 1oo1D architecture of Figure 1 is depicted in Figure 6. The model consists of:

- Two places "F_{OK}" and "F_D" representing the working and the failed state of the functional channel, respectively.
- Two places "MOK" and "MD" representing the working and the failed state of the monitor channel.
- The transitions "Failure F" and "Failure M" representing the failures of the functional and the monitor channel, respectively. Whenever the "Failure F" transition is fired, an assertion is used to generate a random number to classify detectable and undetectable failures (See description of the transition "Failure Detected").
- A transition "Failure CC" representing the common-cause failures of function and monitor channel.
- The transition "Demand" representing the demand of the safety functions (after a failure of the function channel). Any firing of "Demand" will reset the Petri net, assuming that the system will be brought to an "as-good-as-new-state" if a dangerous failure has occurred prior to a demand of the safety function. If the monitor channel is also in the failed state, it will be reset by the transition "Repair M on demand".
- The cyclic transition "Failure Detected" representing the periodic testing of the functional channel by the monitor. Predicates are used to distinguish detectable and undetectable failures by comparing the random number generated by the "Failure F" transition to the DC.
- Additional assertion and predicates are used, to assure the correctness of the model, while keeping the graphical representation as simple as possible.

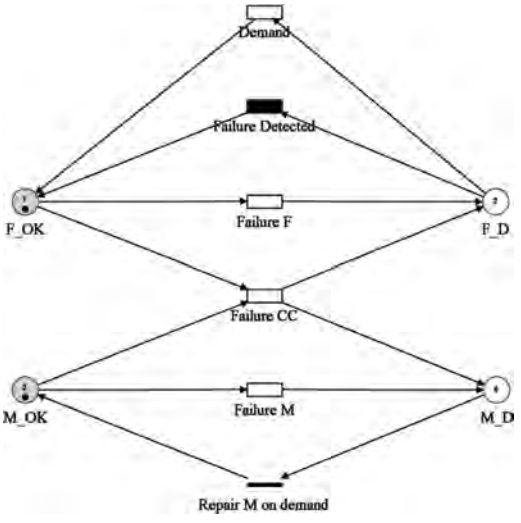

Figure 6. Petri net for single Channel system with diagnostics. For further details see text.

The Petri net model is investigated using the Monte-Carlo simulation engine of the GRIF software-framework (Satodev, 2017).

As argued earlier in this paper, any demand on the safety function from a failure state of "F" will contribute to the *PFH*. In case of the Petri net, the *PFH* of the system can hence be determined by the average frequency at which the "Demand" transition fires (Innal et al. 2010).

As the monitor channel itself is not monitored, a failure of this channel will not be detected and a subsequent failure of the functional channel will likewise remain undetected.

3.2 *Comparison*

Figure 7 shows the results of the Monte-Carlo simulations of the Petri net and compares them to the solution of the analytic Markov Modell (eq. 9) for the same sets of parameters. The results of the two methods are very similar and reproduce the table values of ISO 13849-1, Annex K, both for $DC = 90\%$ and for $DC = 60\%$ (EN ISO 13849-1, 2015). For the calculation, the following assumptions where made: Demand rate: $r_d = 360\ h^{-1}$, rate of diagnosis: $r_t = 100 \cdot r_d$, same $MTTF_D$, for

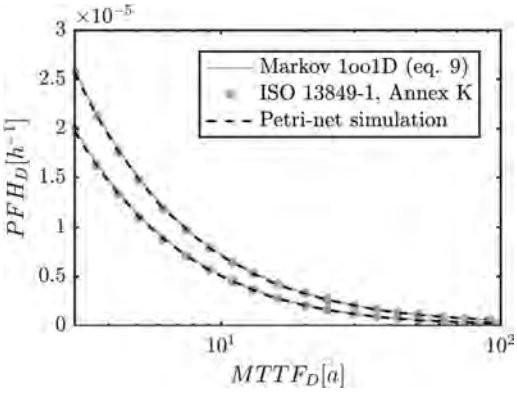

Figure 7. Comparison of *PFH* values calculated with the analytic Markov-Formula (see Equation 9) to the values of the table in ISO 13849-1, Annex K (EN ISO 13849-1, 2015), and the Petri net based Monte Carlo simulation. The two sets of curves correspond to $DC = 90\%$ (upper) and $DC = 60\%$ (lower). The results of the Markov and the Petri net approach are very similar and reproduce reasonably well the values of ISO 13849-1, Annex K.

function channel and monitor channel: $MTTF_{MD} = MTTF_{FD}$, common cause failure rate: $\lambda_{CC} = \beta \cdot \min(1/MTTF_{FD}, 1/MTTF_{MD})$, with $\beta = 2\%$, mission time: $T_M = 20$ a. These assumptions are in accordance with the prerequisites and assumptions of ISO 13849-1 and allow for a direct comparison of the results to this standard (EN ISO 13849-1, 2015).

3.3 *Failure sequences*

The properties of the 1oo1D System were further studied by a systematic investigation of the relevant parameters of the model. The Petri net model allows for the investigation of the relevance of the failure sequences to the overall frequency of dangerous failures.

In the simulation, the order of the fringing of the transitions was tracked by assertions. The clusters of firing sequences listed in the following list are investigated, where the order of the firing of transitions is indicated by arrows. Detectable and Undetectable failures are distinguished by assertions and predicates on the transition, as described above. To simplify reading, this implicit distinction is indicated by adding detectable/undetectable to the Failure transition in brackets:

1. F_{DD}-sequences:
   - Failure F(detectable)→Demand
   - Failure F(detectable)→Failure M→Demand
2. F_{DU}-sequences:
   - Failure F(undetectable)→Demand
   - Failure F(undetectable)→Failure M→Demand
3. M_D-sequences:
   - Failure M→Failure F(detectable)→Demand
   - Failure M→Failure F(undetectable)→Demand
4. CCF-sequence:
   - CCF→Demand

The demand is explicitly modeled in order to investigate the residual contribution of detectable failures to the overall failure rate due to the finite frequency of the diagnosis by the monitor channel.

Figure 8 shows the relative contribution of the major failure sequences to the *PFH* as a function of the $MTTF_D$ values for different *DC* values. The following assumptions were made for the system: The mean time to failure of the monitor channel was assumed to be half the $MTTF_D$ of the function channel (This ratio is suggested as a lower bound for the $MTTF_D$ of the monitor channel in (EN ISO 13849-1, 2015)). The fraction of common-cause failures of the functional channel and the monitor channel is assumed to be $\beta = 2\%$. The rate of demands of the safety function is $r_D = 360\ h^{-1}$, corresponding to a demand every 10 seconds. The mission time is $T_M = 20$ a.

While for a $DC = 60\%$, the *PFH* is dominated by F_{DU} for $MTTF_D$ values above approx. 48 years, the $M_D \rightarrow F_{D,D} \rightarrow$Demand sequence is dominant for lower $MTTF_D$ for DC = 60% and for all $MTTF_D$ values up to 100 years for $DC = 90\%$ and $DC = 99\%$.

Beside the influence of the finite frequency of the diagnosis on the *PFH* discussed earlier in this paper (see Equation 11) this shows how big the impact of failures of the monitor channel is and how important it is to integrate these failures correctly into *PFH* calculations. Furthermore, one could improve the system by introducing a diagnostic on the monitor channel itself, e.g. by the Functional channel. The necessary extension to the model and the results of the simulation will be discussed in the following chapter.

3.4 *Complex systems beyond designated architectures*

The properties of monitor channels become even more important for more complex systems which cannot easily be mapped onto designated architectures underlying the simplified formulas of established standards (EN ISO 13849-1, 2015, IEC 62061, 2015).

Traditionally, the architecture of a system was the basis criterion for the achievable safety level for Industrial safety systems. (EN 954, 1996). Even though the target measures for dangerous failures have been established as the defining criterion for Safety Levels (EN 61508-1, 2010) and have been introduced in the generic standards for safety of machinery (EN ISO 13849-1, 2015, IEC 62061,

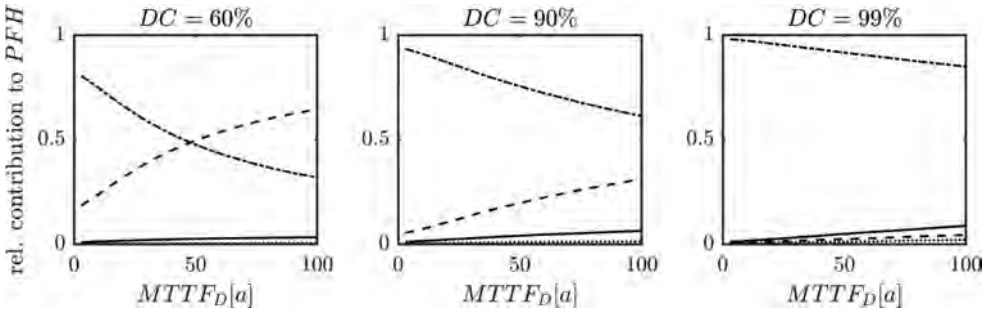

Figure 8. Relative contribution of the individual failure channels. Dotted line: F_{DD}, dashed line: F_{DU}, solid line: Common-Cause failure, dotted dashed line: M_D followed by F_D.

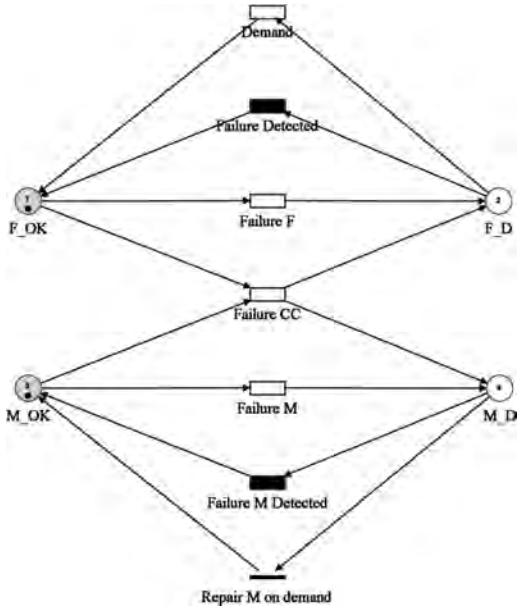

Figure 9. Petri net model of a system with a monitor channel which is monitored by the functional channel.

2015), the architecture is still an important criterion.

However, mapping modern software-intensive systems to the designated architectures of the established standards is not always easy. Programmable electronics introduce various levels of diagnostics into the systems, which can be hardly mapped to the assumptions of the designated architectures. Some standards (EN ISO 13849-1, 2015, IEC 62061, 2015, EN 61508-2, 2010) suggest the application of stochastic methods for these cases. However, due to the explosion of the state space for complex systems with many constituents, Markov Models are difficult to apply. Furthermore, the timing of monitor channels frequently does not follow exponential probability distributions. Monitor channels may in some cases even be synchronized to the potential demands of the safety function—especially in systems with cyclic working processes and the stochastic modelling of these systems becomes increasingly complex. Petri nets offer a very versatile tool to model even complex scenarios, where various monitor channels work concurrently—possibly on different time scales, with multiple different ranges of coverage and test conditions.

An example of such a system is depicted in Figure 9. The model is a slight extension to the established designated architecture of a 1oo1D system. The system comprises a monitor channel with a relatively high diagnostic coverage ($DC_F = 99\%$), which is in return monitored by the functional channel itself with a diagnostic coverage of $DC_M = 99\%$. The $MTTF_D$ of both channels is assumed to be equal.

Monte-Carlos simulation of the system reveals a substantial reduction of the *PFH* by the additional diagnosis of the monitor channel itself. In Figure 10 the relative reduction of the *PFH* is depicted as a function of the $MTTF_D$ (assumed to be equal for function and monitor channel). For low $MTTF_D$ values, the reduction exceeds 90%, while for a high $MTTF_D$ value of 100 a, the reduction still amounts to 69%.

The rate of the diagnosis of the functional channel is assumed to be 100 times the demand rate $r_d = 360\ \mathrm{h}^{-1}$. The monitor channel itself is checked with a frequency of $r_{t,M} = 1/24$ h.

The variation of this frequency is, however, less critical for the *PFH* value than the frequency of the diagnosis of the functional channel by the monitor channel. While the latter frequency has to be substantially higher than the demand rate to ensure the detection of failures of the function channel before any demand, the test of the monitor channel is efficient as long as the test rate is substantially lower than the failure rate of the functional

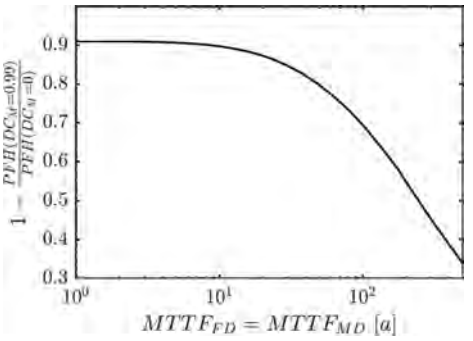

Figure 10. Effect of the additional diagnosis of the monitor channel itself. Depicted is the relative reduction of the *PFH* by the additional diagnosis on the monitor for a diagnostic coverage of the monitor of $DC_M = 99\%$ as compared to $DC_M = 0\%$ (no diagnostics on the monitor channel).

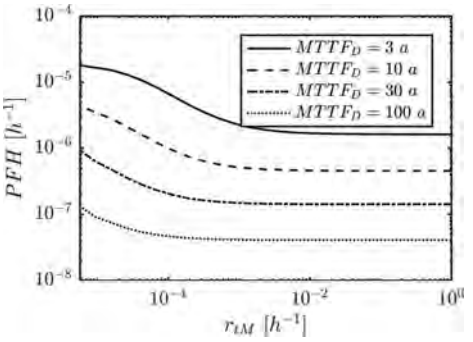

Figure 11. Dependency of the *PFH* on the rate at which the monitor channel is tested, r_{tM}, The four curves correspond to various $MTTF_D$ value (assumed to be equal for function and monitor channel): $MTTF_D = 10$ a (dashed line), $MTTF_D = 30$ a (dashed-dotted line), $MTTF_D = 3$ a (solid line) and $MTTF_D = 100$ a (dotted line).

channel. The dependency of the *PFH* on the rate at which the monitor channel is tested, r_{tM}, is depicted in Figure 11 for various $MTTF_D$ values (assumed to be equal for function and monitor channel). It is obvious, that the diagnosis of the monitor is efficient even for a very low $MTTF_D = 3$ a and a test rate as low as $r_{tM} = 10^{-2}$ h^{-1}. Higher test rates will not substantially decreased the *PFH* for the case of $MTTF_D = 3$ a.

4 SUMMARY

In this paper we presented two approaches for the determination of the *PFH* for single channel systems with diagnostics, one based on a Markov model, the second using Petri net based Monte-Carlo simulation. We introduced a detailed (non-Markovian) state transition model of the 1oo1D architecture with non-exponential distributions and sketched how this model can be transformed to an approximate 2-state Markov model by valid approximations and appropriate merging of states, and by use of a so-called flow partitioning node. For this 2-state Markov model we presented a general analytic formula for the calculation of the *PFH*, which includes important features of 1oo1D systems, e.g. it takes into account the effect of non-time-optimal testing of the functional channel performing the safety function.

We furthermore demonstrated how the same system can be modelled by a Petri net and obtained excellent conformity of the calculation results of the *PFH* between the Markov-based analytic formula and a Monte-Carlo simulation of the Petri net. Both approaches are also in excellent agreement with the *PFH* values given in ISO 13849-1 (ISO 13849-1, 2015) as table values.

The Petri net model was further used to investigate the importance of the contributions of the various failure sequences to the overall *PFH*. It revealed the large influence of sequences in which the Monitor fails prior to the Functional channel.

In the last part of the paper we argued how the Petri net model of 1oo1D could be extended to deal with architectures which are not covered by the dedicated architectures of standards on functional safety. We showed how additional diagnostics on the monitor itself could be used to substantially improve the *PFH* of the modeled system.

With Industry 4.0, modern, software-intensive systems with their versatile possibilities for online diagnostics will play an important role for the safety of machinery. Our results open up for a transparent and flexible determination of the *PFH* for these systems.

Failure rates of safety critical equipment based on inventory attributes

S. Håbrekke & S. Hauge
SINTEF Technology and Society, Trondheim, Norway

L. Xie & M.A. Lundteigen
NTNU, Trondheim, Norway

ABSTRACT: Reliable failure rate estimates of safety critical equipment is crucial for verifying performance requirements and for trending the safety performance of the equipment. Joint industry efforts, like OREDA, Exida and PDS handbooks, supported by international standardization on data collection such as ISO 14224, publish generic failure rates for selected equipment commonly used in the oil and gas industry. Such generic data builds on field experience and ensures a transfer of knowledge from the operational phase to new design projects. Currently, most generic data is generated for a specific equipment group, and not for separate inventory attributes, such as size, type/fabricate, service and flow medium. Some standards and methods, like MIL-HDBK-217F, suggest how to encounter effects of inventory attributes, but these approaches are also generic, and does not account for sector specific experience, i.e. from operation of oil and gas facilities. In light of the increased focus on digitalization, it is expected that the access to data will be improved, and it is therefore important to utilize these data more efficiently in the business sector in question. The PDS forum in Norway, who gathers most actors involved in Norwegian oil and gas industry, initiated a study to analyze operational data of safety critical equipment, with the purpose to study more specific and recent effects of inventory attributes. Data from several oil and gas facilities in Norway, both offshore and onshore, have been systematized and analyzed. The purpose of this paper is to present the approach used to analyze these data, including data collection and statistical methods, as well as the final results of the study. The starting point was inventory attributes suggested by expert judgments, and their effects were investigated with basis in the collected data. Information from the operating companies' maintenance system has been too sparse to support all suggested inventories, and the choice of inventory attributes were narrowed down for some selected equipment groups; fire and gas detectors, level transmitters, shutdown valves and pressure safety valves.

1 INTRODUCTION

1.1 *Background*

The Petroleum Safety Authority (PSA) in Norway requires (in Management Regulations, section 19) that the operators shall collect, process and use field-based reliability data to ensure that the safety systems perform according to specified requirements. A key task of safety management is therefore to register equipment failures and to use this information to verify that the systems are sufficiently reliable. For the oil and gas industry, it is vital to share field experience with new projects, to make realistic assumptions about the performance of new equipment in known operating environment. Equipment failures are therefore collected from several facilities under the framework of ISO 14224 (ISO 2016a), and generic failure rates based on operational experience are presented in PDS handbooks (SINTEF 2013a), OREDA handbooks (OREDA 2015a, OREDA 2015b) and Exida handbooks (Exida 2015).

Safety Instrumented Systems (SISs) perform safety critical functions such as to shut down the plant or isolate ignition sources. IEC 61508 (IEC 2010) and IEC 61511 (IEC 2016), which are mandatory standards to use for design and operation of SISs, suggest a risk-based approach to the formulation of reliability requirements. The starting point is a risk analysis, which defines the necessary risk reduction for each Safety Instrumented Function (SIF) carried out by a SIS. This risk reduction is translated into a Safety Integrity Level (SIL) requirement. Four different SIL levels are defined (SIL 1 – SIL 4), and for each level it is specified a required reliability performance interval. Probabilistic calculations are needed to demonstrate that each SIF meets the given SIL requirement. Since the risk analysis considers what is acceptable risk at a given facility it is important to use "realistic" reliability data when the performance

of the SIFs are estimated. Realistic in this context means to consider historic field experience data, rather than data obtained strictly from analyses and/or from testing in a laboratory with controlled environment—not covering all possible failure causes experienced in operation. In other words, the reliability calculated in design should as far as possible reflect the reliability that is experienced under typical conditions in the operational phase. This is a requirement that is also emphasized and strengthened in the new edition of IEC 61511 (IEC 2016); operators must ensure that data are both credible, traceable, documented, and justified.

A practical challenge with generic data, is the time from data are collected to publishing of updated handbooks and data bases. The time lag is often five years or more, and it is therefore of interest for operators to collect and systemize their own operational experience. Many operators in Norway now carry out regular (e.g. annual) reviews of reported failures. The results from these reviews are then used to monitor reliability performance in operation, to give feedback to manufacturers (about problems experienced) and to make decisions about changes in functional test intervals (Hauge & Lundteigen 2008).

Reviews of failures reported on various Norwegian oil and gas facilities, indicate that failure rates for similar types of equipment can be quite different between facilities, even if the operating environment is more or less the same. This result may be explained by some variations in technology used (e.g. detection principle for gas detectors), process medium, the external environment, quality and frequency of maintenance and inspection, etc. Care should therefore be taken to use generic failure rates in studies for reliability demonstration without considering such influencing factors. Consequently, it is desirable to supplement generic failure rates (that represent an "average performance" for comparable equipment) with equipment characteristic parameters that can identify more specific values of failure rates, i.e. *inventory attributes* of the equipment (e.g. size of valve, type of detector, etc.). The term inventory attribute is introduced for equipment attributes particularly important for the reliability performance. For example, it may be of interest to distinguish between failure rates for different sizes of shutdown valves.

We foresee at least two applications for failure rates based on specific inventory attributes: 1) Monitoring the reliability of existing SIFs, allowing for the specific characteristics of the equipment, and 2) Calculating the reliability of new SIFs, or existing SIFs considering the influences of design, operation, environment and maintenance characteristics.

1.2 *Objective and scope of paper*

The main objective of this paper is to identify which inventory attributes that may be relevant for the four equipment groups; fire and gas detectors, level transmitters, shutdown valves and pressure safety valves, and to analyze which of the suggested inventory attributes (if any) are significant based on systemized field experience gathered by SINTEF in the period 2006–2016.

The content of this paper is based on work performed as a continuation of a research project funded by the Norwegian Research Council and the members of the PDS forum (www.sintef.no/pds). SINTEF has previously systematized failure data for six offshore and onshore oil and gas facilities (a total of more than 13000 maintenance notifications) in Norway. These failure reports, supplemented by additional expert judgements, have been used for selecting possible inventory attributes influencing the failure rates of some selected equipment types. Then, data for these inventory attributes have been collected (as complete as possible) to be able to analyze the possible impact of selected inventory attributes.

2 FAILURE DATA COLLECTION AND DATA FORMAT

2.1 *Generic data sources*

Generic failure rates are mainly derived from data collected by an organization and published in handbooks or as computerized databases (Rausand 2014). The failure rates can often be regarded as an average of the experienced performance for specific equipment groups.

The oil and gas industry has collected failure data over many years and for several offshore facilities, mainly on the Norwegian continental shelf. Relevant generic data sources are the OREDA handbooks, ref. OREDA (2015a) and OREDA (2015b), PDS handbooks, ref. SINTEF (2013a) and SINTEF (2013b), and the safety equipment reliability handbook (SERH) published by Exida (2015).

2.2 *Operator's data*

ISO 20815 (ISO 2008) on production performance assurance, emphasizes that the systematic collection and treatment of operational experience is considered as an investment and means for improvement of production and safety critical equipment. The oil and gas industry has been in the forefront of developing international standards on data collection with ISO 14224 (ISO 2016a).

Reliability data can help operators to plan the preventive maintenance, e.g. to optimize test

intervals, avoid unscheduled stops and reduce the amount of corrective maintenance. Aggregated data, used to determine generic values of failure rates, represents an experience transfer from operation to analyses needed for new facilities and for installations of new systems.

Several operators are continuously working on systemizing their failure records, to have their own "preferred" data set. This data set can be used to estimate an average performance of equipment for a single facility or for several facilities with the same operator. If the amount of data is extensive, one can also estimate separate failure rates for specific equipment attributes.

2.3 *Failure data from operational reviews*

Failures revealed during operation and maintenance are reported by maintenance notifications. A notification allows some free text description of the failure and about the measures implemented to correct the failure. In addition, it is also possible to characterize the failure, by ticking off in lists of predefined classes of failure causes, failure modes, and detection methods. Most maintenance systems are aligned with ISO 14224 for data collection, and additional effort is needed to further classify the failures into Dangerous Detected (DD) failures, Dangerous Undetected (DU) failures and safe (S) failures, for alignment with IEC 61508 and IEC 61511 taxonomy. Information about inventory attributes of interest may be partly available in notifications and partly in SIS related documents, such as the Safety Requirements Specification (SRS), safety manuals, and Safety Analysis Reports (SARs).

The operating companies themselves can perform regular operational reviews, or they can use assistance from consultants or research institutes. In either case, it is important to involve personnel from key disciplines such as automation, safety and maintenance from the specific facility and company in question. The main purpose of the reviews is to verify the performance of SIL rated equipment and to give recommendations related to maintenance and testing. A secondary purpose of the review, as suggested in this paper, is to analyze such data in more detail to investigate the performance for various inventory attributes.

2.4 *Selection of equipment groups*

Several types of safety critical equipment are used in SIFs on an oil and gas facility. Operational reviews of safety critical equipment covers about twenty different equipment groups, however, some groups consist of few equipment units. To limit the scope of the analyses in the PDS project, it was decided to extract groups of equipment where:

- a certain amount of data (both failures and a certain amount of aggregated operational time) has been gathered.
- the equipment group is represented on several facilities.
- the equipment group is represented in several SIFs on a facility.
- the equipment types have some attributes that are considered as significant with respect to the failure rate.

The selection of equipment groups and inventory attributes was consulted with experts within the PDS forum participants in an experts meeting. The recommendation was to focus on fire and gas detectors, level transmitters, shutdown valves and pressure safety valves, since these groups both contain a significant amount of equipment and contain possible significant inventory attributes.

2.5 *Uncertainty & data collection challenges*

A major challenge when splitting up the failure rates according to inventory attributes is to obtain sufficient statistical confidence. If no DU failures have been experienced in an observation period, the statistical confidence is lower even if the observation time is quite extensive.

Quality of data is another challenge. It is important that we can rely on the information given in the notification, e.g. that the failure mode and the detection method have been classified correctly. Data collection is both time consuming and demanding; it is seldom straightforward to identify all relevant information from the maintenance records. To obtain correct information about the actual failure, it is often necessary to discuss individual notifications with operators and maintenance personnel. Such work is time consuming, but nevertheless rewarding, e.g. to avoid repeating (and thereby costly) failures. Many operational reviews reported repeating failures, where seemingly insufficient measures had been implemented to remove the cause of failure. For the purposes of analyzing inventory attributes, we have removed repeating failures, to avoid that these are given too high weight in the overall results.

From the operational reviews, we saw that the effects of local facility conditions were important and that based on our experience, should be considered. One facility may experience specific problems (e.g. icing) for some particular type of equipment, which are not observed at other facilities. Local conditions seem to be of particularly interest for the occurrence of Common Cause Failures (CCFs), i.e. failures that are dependent due to a shared cause and which occur close in time. An example of a local problem which turned out to be defined as a CCF, was a number of failures

for shutdown valves caused by wrong type (here viscosity) of hydraulic oil. Some of the failures related to specific problems at one facility (such as the hydraulic oil problem) which are not likely to occur at other facilities, have been removed from our data set for the analyses of inventory attributes. Other local problems, that were defined as CCFs, were icing problems. Icing is often more challenging for facilities in the Barents Sea compared to the North Sea, however, unfortunate design solutions may also allow for icing to occur. Failures related to such conditions that may occur on several facilities, have *not* been removed from our data set for the analyses of inventory attributes.

3 STATISTICAL METHODS

For the analyses of data from operational reviews, the focus has been on DU failures since these failures will influence the most important performance requirements related to SIF equipment, such as the Probability of Failure on Demand (PFD) for a SIF. The total data set for analyses comprises all equipment units that have been involved in the operational reviews, i.e. has been part of equipment groups considered in the reviews. For each unit, data on inventory attributes has been collected together with the information about if the unit has experienced a DU failure or not in a predefined observation period.

It was decided to introduce a Generalized Linear Model (GLM) based on a binomial distribution, where only two possible outcomes are considered. The response variable is a discrete variable with two possible outcomes; 0 and 1, i.e. "No DU failure" or "DU failure", such that GLM can predict failure probability and assess effect on failure probability from the predefined inventory attributes. Other methods, such as lifetime modelling was also considered. However, since the observation period for some of the facilities does not cover the entire lifetime of the item and the time an item was put into operation is unknown for most of the components, such methods were disregarded.

GLM describes the statistical relationships between *response variables* Y_1, Y_2, …, Y_N and *explanatory variables* x_1, x_2, … x_k by estimating the corresponding inventory attributes β_1, β_2, …, β_k. An explanatory variable is a type of independent variable that can affect response variables, which may be fixed by the experimental design. GLM are mostly based on maximum likelihood estimation and allows for regression modeling when response variables are distributed as one of the members of the exponential family. The model is given by:

$$y_i = \beta_0 + \beta_1 x_{i1} + ... + \beta_{ik} x_{ik} \quad (1)$$

and

$$y_i = g(\mu_i), \mu_i = E(Y_i). \quad (2)$$

Here, $g(\mu)$ is called the link function. Further, let $Yi \sim Binomial(n, p_i)$ express the response variables with failure probability p_i, i.e. the likelihood for an item to fail at a given time. Then the GLM model based on binomial distribution is given as:

$$\log(\frac{p_i}{1-p_i}) = \beta_{i0} + \beta_{i1} x_{i1} + ... + \beta_{ik} x_{ik}. \quad (3)$$

In this GLM, inputs are related to inventory attributes as well as failure data. Outputs of the model are related to failure probabilities that are used to check whether there is statistical significance. The formula of failure probability is:

$$p_i = \frac{\exp(\beta_{i0} + \beta_{i1} x_{i1} + ... + \beta_{ik} x_{ik})}{1 + \exp(\beta_{i0} + \beta_{i1} x_{i1} + ... + \beta_{ik} x_{ik})}. \quad (4)$$

We identify the parameters that significantly impact on the reliability performance by checking variables in the regression model with small p-values and large coefficients. A small p-value suggests that changes in the explanatory variable are associated with the changes in the response variable, i.e. the inventory attribute is significant and does influence the DU failure rate (based on our data and under the given assumptions). The exponential coefficient represents the change in the response variable when changing the categories of one inventory attribute holding the other explanatory variables constant.

4 DATA COLLECTION OF INVENTORY ATTRIBUTES

4.1 *General*

Collection of data for inventory attributes turned out to be a rather time-consuming activity. Only parts of the relevant information were (easily) found in the operator's maintenance system. It was necessary to supplement with information from other sources, such as process and instrument diagrams (P&IDs), data sheets and manufacturer specifications together with discussions with technical advisors and process engineers.

The manufacturer name was the most straightforward inventory attribute to obtain from the maintenance system. However, within an equipment group we would find some ("small") manufacturers that had not delivered more than a few equipment units each. Thus, to be able to achieve

some rational results, the number of manufacturers were kept to a minimum by grouping all the "small" manufacturers into an "other" group. Grouping the outcomes represented by a small number of units into a common "other" category, was also performed for other attributes with several outcomes/categories.

4.2 *Fire and gas detectors*

The expert review meeting suggested the following inventory attributes for fire and gas detectors: *Manufacturer*, *measuring principle*, i.e. which physical principle the detection is based on, and *model type*. Table 1 shows in more detail the inventory attributes for point gas detectors. The same types of inventory attributes were selected for line gas detectors, smoke detectors and flame detectors.

For the analyses of detectors, we were in the fortunate situation to access more data than from the six facilities where SINTEF was involved in operational reviews. For this particular equipment group, it was possible to add the inventory attribute "facility", due to the extensiveness of data, to allow comparison in failure rates and effects of inventory attributes between different facilities.

4.3 *Level transmitters*

Level transmitters are often placed in a group called "process transmitters", together with temperature transmitters and pressure transmitter. In our analyses, we wanted to focus on the level transmitters alone, mainly because they are more dependent on measuring principle and operating conditions (various medium, foaming, calibration challenges, etc.) than the other transmitters. Measuring principles for level transmitters are divided into the categories; displacer, pressure, radar (guided wave radar) and others (nuclear, ultrasonic, servo, capacitance and magnetostrictive).

Table 2 shows the list of inventory attributes agreed upon among the experts to include in the analyses. However, due to lack of details in collected data, we were left with three credible inventory attributes; *manufacturer*, *measuring principle* and *number of medium phases*. Regarding the measuring principle, we made the following assumptions based on the type of vessels for which the transmitters were installed: Level transmitters for 1st stage separators and test separators normally measure three types of medium (e.g. oil, MEG/water and gas) while level transmitters in scrubbers, 2nd stage separators and 3rd stage separators are supposed to be used to measure for two types of medium, e.g. liquid/gas. In case this information about vessel type was not evident, the number of vessel outlet lines was checked against e.g. P&IDs to obtain number of fluid phases inside the vessels.

Despite the effort, we were left with several transmitters where information was missing. E.g., measuring principle was not identified for 10% of the transmitters and manufacturer was not identified for 11%.

Table 1. Inventory attributes—Point gas detectors.

Attributes	Incl.	Examples of categories
Manufacturer	YES	Autronica, Dräger, Simtronics…
Measuring principle	YES	IR, Wireless, Acoustic…*
Model	YES	HC200, PIR 7000, GD10…

*Catalytic gas detectors have been removed from the data set due to significant more DU failures than the rest of the measuring principles.

Table 2. Inventory attributes—Level transmitters.

Attributes	Incl.	Examples of categories
Manufacturer	YES	Vega, Fisher-Rosemount…
Measuring principle	YES	Displacer, Pressure, Radar…
No. of medium phases	YES	1, 2 or 3
Type of medium	NO	Hydrocarbon, Water, Chemical…
Type of vessel	NO	Separator, Scrubber, Tank…
Special problems	NO	Foaming, Sand, Scale…

4.4 *Shutdown valves*

The data collected through operational reviews contains in total 1245 Emergency Shutdown (ESD) and Process Shutdown (PSD) valves. Table 3 shows the inventory attributes selected in the expert review meeting. Unfortunately, it was necessary to remove all data from one of the facilities due to very sparse information on the inventory attributes manufacturer and (valve) size.

Categories for *manufacturer*, *size* and *type* of valve were obtained from the maintenance system and equipment and facility specific information such as data sheets and P&IDs.

The process *medium* exposing the valves was assessed by experts at one of the facilities: It was suggested that for each system at the facility a corresponding (typical) medium could be assumed, and this "mapping" between system and medium was adopted for the rest of the facilities.

To avoid too many categories for valve size, group size intervals were decided together with an expert. Criteria for these intervals were based on the valve and process characteristics, rather than

Table 3. Inventory attributes—PSD and ESD valves.

Attributes	Incl.	Examples of categories
Actuation principle	NO	Electric, Hydraulic, Pneumatic…
Manufacturer	YES	Tai Milano, Swagelok, BIS…
Medium	YES	Gas, HC liquid, Water…
Size	YES	0–1″, 1–3″, 3–18″ and >18″
Special problems	NO	Corrosion, Icing…
Type	YES	Ball, Gate, Butterfly, Other

Table 4. Inventory attributes—Pressure safety valves.

Attributes	Incl.	Examples of categories
Actuation principle	NO	Pilot, Spring, Pressure-vacuum…
Dirty or clean service	YES	Yes or No
Manufacturer	YES	Petrolvalves, O.M.S.,…
Medium	NO	Gas, HC liquid…
Size	NO	

having equally sized categories: E.g., valves less than 1″ has been defined as a separated category since they normally are water-based and attached with lower risk compared to bigger valves. Thus, the number of valves in each size category varies.

The categories for inventory attribute "actuation principle" was not straight forward to retrieve. This would require time-consuming manual information, and was only performed for one of the facilities. Hence, the actuation principle inventory attribute was removed from the analyses. Also, the inventory attribute "specific problems" (corrosion, icing and temperature changes) was removed, as this information required manual and rather time-consuming effort.

Table 3 lists the examples of categories assigned to selected inventory attributes. Also for this equipment group, information was missing. For example, we found that 14% of the valves had unknown manufacturer, 13% had unknown size and 8% had unknown type.

4.5 *Pressure safety valves*

The inventory attributes that were selected for pressure safety valves (PSVs) based on expert meeting are presented in Table 4. *Manufacturer* and size of valve were obtained from the maintenance system and equipment and facility specific information such as data sheets and P&IDs. However, we faced major problems with missing category information. E.g. for about 50% of the PSVs, information about the valve size was not found in the maintenance system. Thus, the inventory attribute "size" was not part of the PSV analyses. Unfortunately, we also had to remove data for PSVs from one of the facilities due to missing information.

Dirty or clean service, i.e. if the medium flowing through a PSV is "dirty" (e.g. including sand, crude oil, etc.) or "clean" (e.g. pure gas), was together with the actuation principle pointed out by the experts as a possible significant inventory attribute for the PSVs. To simplify the analyses, it was assumed that all PSVs installed in the same system had the same category (either "dirty" or "clean"). The inventory attribute "medium" was not included, since it would be partly correlated to the inventory attribute "service".

The actuation principle of the PSVs was identified to some extent in the maintenance system. As for ESD and PSD valves, it was very time-consuming to extract this information and this has not yet been performed. Hence, the actuation principle was not part of the analyses.

Table 4 summarizes the selected inventory attributes. Note that examples of categories are not provided for the inventory attribute "size" since it was decided to omit this one from the analyses.

5 ANALYSES AND RESULTS

5.1 *Assumptions*

The data for all the finally selected inventory attributes were for the analyses combined with information about how many DU failures that had been registered for the equipment group and the aggregated time in operation. In the data set, we removed DU failures that had been repeated for the same equipment, to avoid double counting of the same failure event.

For some of the inventory attributes, e.g. medium for PSD and ESD valves and dirty or clean service for PSVs, the categories are based on the assumption that all equipment installed in one particular system share the same medium and service; e.g. all valves in system number 43 (Flare system) is assumed to share the medium "gas" and "clean" service.

The number of predefined categories and of course how they are defined, e.g. size intervals and which categories belonging to the "other" category, will also impact the results.

Some assumptions have also been made regarding the analyses and for the data to fit the statistical analyses as described in section 3. E.g., the DU failures are assumed to be identically distributed and to occur stochastically independent. It is also assumed that inadequate information and missing data do not have any effect on the results of the analyses.

The observation periods from each facility is not equal and varies from two to 11 years for those facilities included in the data set. Thus, some assumptions about observation periods had to be made to get observations periods as equal as possible and to utilize all DU failures: The final periods should not be too short such that there would be very few observation periods with failure compared to observation periods without failures—then it would be more difficult getting significant results. On the other hand, the periods should not be too large such that multiple failures of the same component often would occur within the same period—then we would not utilize all the DU failures. Also, different observation period intervals were concerned in data analyses for fire and gas detectors compared to other equipment groups:

For those equipment groups with data from five or six facilities (PSD and ESD valves, level transmitters and PSVs) three–four years was regarded as one observation period. Then, for a facility with observation period between three and four years, each equipment unit was counted once in the total data set. For a facility with 11 years of operational experience, the inventory data was counted for three times in the total data set (and the DU-failures were distributed on the correct observation period based on the notification date).

For fire and gas detectors, where data from several facilities was included and many of those with shorter observation periods, two–three years was regarded as one observation period.

The GLM model was implemented in software R, which is a free software for statistical computing and graphics.

5.2 *Results*

The aim of the analyses was for each equipment group to identify which inventory attributes and related categories that became statistical significant (if any).

Table 5 shows the results of the analyses for each equipment group, listing the most significant inventory attributes and associated categories—with respect to the DU failure rate. Note that not all attributes and categories have been found to be significant, and they are therefore not listed. Neither are those categories less significant compared to two or more other categories. "Significant" implies that the inventory attribute and its associated category(s) either contribute to significantly higher failure rate or significantly lower failure rate compared to the other attributes/categories.

From Table 5 we see that the manufacturer, typically represented by one or two of the largest manufacturers, is significant for most of the equipment groups. For ESD and PSD valves the largest valves seem to have a higher failure rate compared to small valves. Also, the medium may be important for the failure rate for ESD/PSD valves.

Table 5. List of most significant inventory attributes and categories.

Equipment group	Attribute	Category
ESD/PSD valves	Size	>18″
	Medium	Gas, Water, …
	Manufacturer	*Confidentially*
Line gas detectors	Manufacturer	*Confidentially*
Point gas detectors	Measuring principle	IR
PSVs	Manufacturer	*Confidentially*
	Dirty or clean service	Dirty, clean

One inventory attribute suggested by experts, and that we was able to analyze, was not found to be of significant in our analyses: "measuring principle" for level transmitters. This may be partly explained by inadequate level of details concerning inventory attributes in the applied data.

For the fire and gas detectors where data was available from several facilities, also the facility was included as a separate attribute. The results showed that some facilities turned out to contribute to significant higher or lower failure rates compared to the others.

6 RECOMMENDATIONS AND FURTHER WORK

Measures and means for improving the quality of data that are recorded into the maintenance system is an important area for further research. Today, the recording is mainly manual, and there lack a systematic way for consistent recording of information for more automatic extraction and analyses. Based on the results of this study, it is possible to suggest more specific categories of information to be recorded. It may be necessary to further investigate the implications of assumptions that were made for our analyses. Both those that were made to overcome practical obstacles, e.g. due to lack of information related to selected inventory attributes, and those made to simplify the selection of categories, e.g. about the relationship between categories for inventory attributes (e.g. clean service) and system number (e.g. flare system). It is also possible to perform other types of analyses, e.g. "big data" analyses, to identify significant inventory attributes particularly when the amount of data, inventory attributes and categories increases.

Operational experience indicates that similar equipment performs differently between facilities with a comparable operating environment. It is therefore desirable to supplement the generic data

with inventory attributes that can explain the varying performance, and enable the reliability analyst to better predict the variations. Due to the limited information about inventory attributes, it is recommended that the operators increase the amount of relevant inventory information in their maintenance systems, in particular for safety critical equipment part of operational reviews. Then, the failure data and data for inventory attributes can be combined to perform in depth analyses.

Data collection is becoming increasingly important both with respect to quantity and quality. It is an important activity to provide feedback on experience from the operational phase to designers of new systems and for monitoring the operational performance of safety barriers. It is also an important activity seen in relation to the increasing trend of lifetime-extension for existing facilities. SINTEF and PDS forum is also working on means for enhancing the digitalization of failure reporting, classification, and analyses, to update the generic failure rates more frequently and to reduce the manual effort in this process. A higher level of automatic analyses of data can help when prioritizing resources needed to improve the overall quality of data.

ACKNOWLEDGEMENT

Thanks to the members of the PDS forum (www.sintef.no/pds) that have contributed with valuable information, expert judgements and meaningful discussions. Special thanks to personnel from the operating companies that have contributed with data from operational experience, expert judgements, participation in workshops and valuable input and comments.

ABSTRACT: A significant fraction of current research in telecommunications is investigating new paradigms to guarantee high flexibility in deploying network infrastructures. Network Function Virtualization (NFV) is probably the most effective paradigm: it adapts tothe telecommunication networks the virtualization concepts originally conceived in the computer world. According to NFV specifications, network elements as switches or routers can be implemented as virtual machines called Virtual Network Functions (VNFs), and deployed in field by timely and cost-effective operations. Some Telco operators are already taking advantage of these virtualized resources, by aggregating more VNFs in order to provide new services. One example is IP Multimedia Subsystem (IMS), providing multimedia delivery services, that can be suitably deployed by means of interconnected VNFs. We consider a virtualized implementation of an IMS system (vIMS) that we characterize by an availability standpoint. First, we describe a vIMS system as a chain of virtualized network elements modeled by three components: hardware, hypervisor, and application. Subsequently, we model the probabilistic behavior of the network nodes by Stochastic Reward Nets, that account for failure and repair events characterizing each node. Innovating on previous formulations, part of the analysis is carried out by adopting non-Markovian models, thus allowing for more realistic (non-exponentially distributed) times between some state transitions. As final results, we determine the optimal redundant vIMS configuration able to guarantee a steady-state availability not less than 0.99999, and we provide a sensitivity analysis useful to evaluate the system robustness to variation of parameters from their nominal values.

1 INTRODUCTION

Network Function Virtualization (NFV) (ETSI 2012) represents one of the most innovative paradigms within the fifth generation (5G) of telecommunication systems. Basically, it has been designed to boost the deployment of new network services by exploiting the virtualization concepts. Within an NFV domain, traditional network equipments (e.g. firewalls, routers, switches, etc.) are replaced by their virtual counterparts named Virtualized Network Functions (VNFs). According to NFV logic, every VNF relies on a decoupled structure typically made of: *i)* a hardware part accounting for physical components; *ii)* a hypervisor part acting as an abstraction layer between hardware and application *iii)*; an application part that includes the software logic and runs on top of a VNF. An architecture that can profitably benefit from an NFV environment is the IP Multimedia Subsystem (IMS) (3GPP 2001). IMS exploits the all-IP-based paradigm to provide a plethora of multimedia services (audio/video sessions, online messaging, presence, IP TV, etc.) by taking advantage of Session Initiation Protocol (SIP) (Rosenberg et al. 2002). In the present work, the new virtualized IMS (vIMS) framework (namely, IMS in an NFV environment) has been characterized in terms of its availability. Accordingly, we find the optimal system configuration respecting the so-called "five nines" availability requirements. It consists in tolerating a maximum system downtime of 5 minutes and 26 seconds per year. The paper is structured as follows. Section 2 contains a brief *excursus* about relevant and pertinent works. Section 3 offers an overview about possible vIMS deployments. An availability analysis is then presented in section 4, where details about Stochastic Reward Nets (SRNs) and Reliability Block Diagram (RBD) methodologies are provided. Section 5 presents a numerical experiment, where characteristic system parameters as repair and failure rates of the vIMS

components have been set in accordance to scientific literature and expert hints. Finally, concluding remarks along with considerations about possible future work are drawn in Section 6.

2 RELATED WORK

Recently, the dependability and availability of novel telecommunication infrastructures are becoming critical issues since network operators are committed to strict Service Level Agreements. Accordingly, such issues have got attentions from scientific andtechnical literature. The work presented in (de S. Matos et al. 2012) is one of the first papers devoted to cope with the availability issues of virtualized infrastructures. In particular, the authors propose a three-level model of a generic system (hardware, software, hypervisor) analyzed by combining Continuous Time Markov Chains (CTMCs) and fault trees formalisms. A combination of approaches is also used in (Fernandes et al. 2012), where a dependability assessment of virtual networks is presented by exploiting both combinatorial and state-based models. A mathematical framework to model a restoration mechanism of virtual resources caused by failures is instead proposed in (Taleb et al. 2016). A stochastic model-driven approach to evaluate the availability of an Infrastructure-as-a-Service (IaaS) cloud system is presented in (Ghosh et al. 2014). The failure events have been managed by considering migration of physical machines among three types: hot (running machine), cold (turned off machine), and warm (turned on, but not yet ready machine). Some algorithms aimed at solving the Minimum Total Failure Removal (MTFR) problem have been proposed in (Liu et al. 2016), where a reliability evaluation of an NFV environment has been faced. The present work takes inspiration from some recent contributions proposed by the authors, see (Di Mauro et al. 2016), (Di Mauro et al. 2017), and, basically, provides two original developments. The first one concerns the stochastic modeling of a virtualized IMS (called vIMS) framework by considering a typical telecommunication network scenario. The second one pertains to the proposal of a more realistic model relaxing the assumption of exponentially distributed failure and repair times, characterizingMarkovian model: the choice of some non exponentially-distributed transition times has some influence on the transient analysis of systems.

3 OVERVIEW OF THE IMS ARCHITECTURE

IP Multimedia Subsystem was born as a framework able to providing access to a plethora of multimedia IP-based services with guaranteed quality of service (Camarillo and Garcia-Martin 2008). IMS architecture supports a broad range of services by exploiting the flexibility of SIP protocol, among which, multimedia and real-time sessions (such as phone calls), web messaging and enriched communications. The signaling flows are managed by the CallSession Control Function (CSCF) servers, that communicate by exchanging mainly SIP messages. The CSCF functionalities are distributed among three servers. The *Proxy* CSCF (P-CSCF) is a SIP proxy, and acts as an interface between the user device and the IMS network. The *Interrogating* CSCF (I-CSCF) forwards SIP requests or responses within the domain. The *Serving* CSCF (S-CSCF) is in charge of performing some core functions as session and routing control and user registration management. Another key element of the IMS infrastructure is the Home Subscriber Server (HSS), an advanced database containing users' profiles that can be queried by means of a specific protocol called Diameter. Such nodes are interconnected among them to provide basic and advanced services. An example is offered in Fig. 1, where a (simplified) Registration procedure (needed before exploiting IMS services) is depicted. Initially, a user device contacts P-CSCF via Register message (1). Such a message is passed to I-CSCF (3) that, in turns, sends it to HSS (3) in order to retrieve the address of S-CSCF in charge of current registration. Once obtained the information from HSS (4), the message is forwarded to the correct S-CSCF (5). Finally, an OK message indicating a correct device registration is back-propagated to the user device (6), (7), (8). Once completed the registration procedure, the device is ready to use IMS services as a real-time audio/video session for example. It is worth noting that, in Fig. 1 is depicted the signalling flow, but, typically media flows between two user devices (i.e. the content of an audio/video call) traverse a different path.

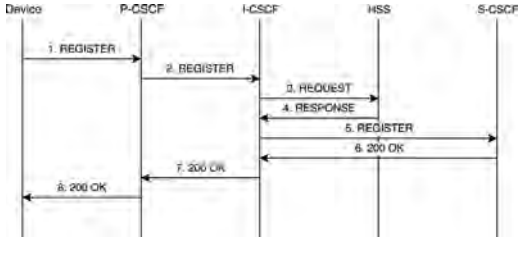

Figure 1. A simplified registration procedure in IMS domain. The *Register* message is propagated from device to S-CSCF. A 200 *OK* message is back-propagated to device if the procedure ends correctly.

3.1 *Virtualized IMS domain*

We recall that, in our proposal, the IMS framework is assumed as integrated in an NFV environment. Such a hybrid solution is getting recently attention either by technical literature (Duan et al. 2017), and by the industrial world (ETSI 2015). Accordingly, the involved nodes (P-CSCF, I-CSCF, S-CSCF, HSS) are modeled by VNFs composed, in turn, by three layers:

- *Hardware*: represents the aggregate of physical subsystems (CPU, RAM, Storage, etc.) that are often deployed in server farms;
- *Application*: represents the software logic deployed on top of a specific VNF (P-CSCF, HSS, etc.);
- *Hypervisor (or Virtual Machine Monitor)*: an intermediate (software-based) level allowing to deploy one (or more) virtual nodes on the same hardware and to manage the resource consumption of each VNF.

In our setting, the hardware and hypervisor layers are supposed to be the same for CSCF servers and for the HSS node, while the application layer is modeled separately for CSCF nodes and HSS.

4 AVAILABILITY MODEL

The system availability analysis is performed by taking into account a two-level hierarchy model combining two formalisms: Reliability Block Diagrams (RBDs) and Stochastic Reward Networks (SRNs). The former is useful to model the system in terms of interconnections among nodes (subsystems) of the considered vIMS infrastructure, and constitutes the first level. Figure 2 shows the RBD representation derived from the Registration scenario reported in Fig. 1, where a series model is necessary to represent the IMS, since all network functionalities must be active to guarantee the Registration service to users, whereas a parallel configuration for each node (replicas) are usefulto ensure a certain degree of redundancy in case of failures. Furthermore, we assume that HSS node is deployed in a *k-out-of-n:G* configuration, where

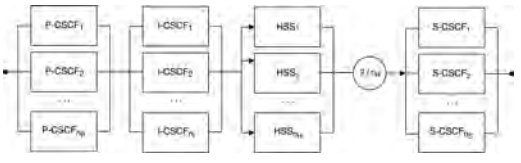

Figure 2. The Reliability Block Diagram representation of virtualized IMS domain, where HSS is deployed in a 2-out-of-n_H redundancy configuration.

k represents the number of HSS replicas that must work to make the HSS node to work. Henceforth, we assume $k = 2$, in accordance with most actual deployments.

On the other hand, the second level of the hierarchical model based on SRN is used to describe the internal behavior of a single node by characterizing the relationships among three layers (hardware, hypervisor, application). In the following subsection, after a brief description of the SRN formalism, we provide a specific model of a generic vIMS node. For further readings on the use of SRN for availability evaluation, refer to (Muppala et al. 1994)..

4.1 *Stochastic reward networks approach*

The SRN model derives from Markov Reward Model (MRM) which enhances the traditional Continuous-Time Markov Chain (CTMC) by adding a reward rate to each state. With state-space based models (such as MRMs), a classic problem of modeling real-world systems is related to the growth of state space. On the contrary, an SRN-based representation allows a more compact description of the underlying system, by identifying repetitive structures. In this way, it is possible to automatically generate the underlying MRMs (Bolch et al. 1998). SRN model adopts a bipartite directed graph representation where: *i) places* (represented by circles) specify a condition (e.g., the system is *down* or *up*), and *ii) transitions* (represented by rectangles) denote actions (e.g., a system crash). Places and transitions are connected by *arcs* denoted by directed edges. In the SRN formalism, the transition times are assumed as exponentially distributed since they take into account a probabilistic delay. A place typically contains a number called *token*, that represents an holding condition. In case of a condition change, a transition is *fired*, and the token is moved from one place to another. A measure of interest is the distributionof tokens, called *marking*, that denotes the possible assignment of tokens to all places of the underlying Markov model, and is useful to capture the dynamics of the overall system.

In the SRN context, the reward function, say $X(t)$, has a crucial role. It is a (non-negative) random process that represents system conditions, namely $X(t)$ varies with time t in accordance to the desired measures, for instance availability, dependability, or performance (Muppala et al. 1996). Being interested in availability evaluation, $X(t)$ is defined as: $X(t) = 1$ in case of working system (up condition) at t, and $X(t) = 0$ otherwise (down condition). Accordingly, it is possible to define the instantaneous availability $A(t)$ as the expected reward function at time t, i.e.

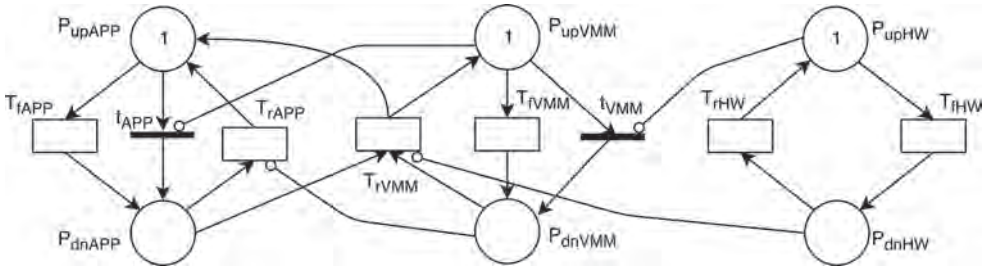

Figure 3. SRN representation of one generic node replica of vIMS network infrastructure.

$$A(t) = Pr\{X(t) = 1\} = E(X(t)) = \sum_{i \in S} r_i \cdot p_i(t), \qquad (1)$$

where S denotes the state space (namely, the set of markings within SRN) that can be broken in a subset of up states S_u (reward rate $r_i = 1$), and a subset of down states S_d (reward rate $r_i = 0$), whereas $p_i(t)$ is the probability of the system being in state i.

The SRN of a generic vIMS node replica (CSCF or HSS) is shown in Fig. 3, while the overall vIMS infrastructure is described by the RDB model presented in Fig. 2.

By inspection of Fig. 3 it is possible to distinguish the following entities:

- *Places* (circles): the group of places P_{upHW}, P_{upVMM}, and P_{upAPP}, takes into account the working conditions of hardware, hypervisor (VMM subscript stands for Virtual Machine Monitor), and application layers respectively. The numbers inside the three places indicate the corresponding initial (working) conditions. Conversely, the group of places P_{dnHW}, P_{dnVMM}, and P_{dnAPP}, represents the failure conditions of hardware, hypervisor, and application layers respectively.
- *Timed Transitions* (unfilled rectangles): such transitions take into account the various layers behavior; in particular, $T_{fAPP}[T_{rAPP}]$, $T_{fVMM}[T_{rVMM}]$, and $T_{fHW}[T_{rHW}]$ denote the failure [repair] events of the application, the hypervisor, and the hardware, respectively.
- *Immediate Transitions* (thin and filled rectangles): such transitions take into account the instantaneous actions, namely, actions characterized by zero transition time. In the proposed SRN, two immediate transitions appear: t_{APP} and t_{VMM}.

4.2 *Evolutionary model of SRN*

In this section we analyze the dynamics of the system, namely, the conditions arising when events such as failures or repairs emerge. In particular, we focus on the evolution of the SRN model of a single vIMS node. For the sake of simplicity, it is useful to consider an initial fully working condition for the node characterized by a token in each P_{up} place of the SRN. If an application failure happens, it means that the software function representing the logic of a vIMS node (a CSCF node or the HSS node) breaks. In this case, the transition T_{fAPP} is fired, and the token leaves place P_{upAPP} to enter place P_{dnAPP}. Once the application gets repaired (sometimes a trivial reboot procedure could solve the problem), the transition T_{rAPP} is fired, and the token comes back to initial place P_{up}. In case of hypervisor failure, instead, the transition T_{fVMM} is fired, and the token is moved from P_{upVMM} place to P_{dnAPP} place. It is worth noting that the place P_{upVMM} is connected to immediate transition t_{APP} by an *inhibitory* arc (the segment with a small circle close to t_{APP}). Such an arc forces t_{APP} to get fired in order to model an application failure. The application layer, in fact, needs a working hypervisor layer to work correctly. On the contrary, when the hypervisor gets repaired, the token is again moved from P_{dnAPP} to P_{upVMM} place, and the inhibitory arc is now ineffective. A similar reasoning holds for the failure of hardware. The token passes from P_{upHW} to P_{dnHW} place as transition T_{fHW} gets fired. In such a case, an inhibitory arc (between P_{upHW} and t_{VMM}) forces t_{VMM} to move the token from P_{upVMM} to P_{dnVMM} since the hypervisor layer needs an underlying functioning hardware to work properly. It is interesting to note that, another inhibitory arc connects P_{dnHW} and T_{rVMM}. Such an arc inhibits the firing of transition T_{rVMM} (and consequently the firing of transition T_{rAPP}), until the hardware layer gets repaired.

Let now be $r_{i,j}$ the reward rate assigned to marking i (i-th distribution of tokens), and $p_{i,j}(t)$ the probability of a generic node replica j modeled by the SRN depicted in Fig. 3 to be in marking i at time t. Being the markings mutually exclusive, it is possible to express the instantaneous availability $A^{(j)}(t)$ according to (1), namely

$$A^{(j)}(t) = \sum_{i \in I} r_{i,j} \cdot p_{i,j}(t), \qquad (2)$$

with I identifying the set of so-called *tangible markings* (markings with no immediate transitions enabled). The reward rate $r_{i,j}$ associated to the tangible marking i is given by:

$$r_{i,j} = \begin{cases} 1 & \text{if } \left(\#P_{upAPP} = 1\right) \\ 0 & \text{otherwise.} \end{cases}$$

It is worth noting that such a reward rate condition does not need to account for up condition of hypervisor and hardware because it is intrinsically embedded in the SRN model in Fig. 2, where inhibitory arcs avoid having a working application layer coupled with failed hypervisor and/or hardware layers. A steady-state analysis for the SRN-based model of the generic vIMS node replica j can be simply obtained by (2) for long runs ($t \to \infty$) and the corresponding steady-stateavailability $A^{(j)}$ has the form:

$$A^{(j)} = \lim_{t \to +\infty} A^{(j)}(t) = \sum_{i \in I} r_{i,j} \cdot p_{i,j}, \tag{3}$$

where $p_{i,j}$ represents the steady-state probability given by $p_{i,j} = \lim_{t \to +\infty} p_{i,j}(t)$. .

We recall that the overall vIMS system can be modeled as a series/parallel of *independent* subsystems as shown in Fig. 2 and the availability of all subsystems is derived from (3). Accordingly, by exploiting the power of RBD representation, the overall vIMS steady-state availability can be expressed as

$$A_{vIMS} = \left[1 - \prod_{j=1}^{n_P}\left(1 - A_P^{(j)}\right)\right] \cdot \left[1 - \prod_{j=1}^{n_S}\left(1 - A_S^{(j)}\right)\right]\left[1 - \prod_{j=1}^{n_I}\left(1 - A_I^{(j)}\right)\right] \cdot \sum_{j=2}^{n_H}\binom{n_H}{j} A_H^j \left(1 - A_H\right)^{n_H - j}, \tag{4}$$

where $A_P^{(j)}$, $A_S^{(j)}$, and $A_I^{(j)}$ are the steady-state availabilities of j-th replica of nodes P-CSCF, S-CSCF and I-CSCF, respectively, while the steady-state availability of HSS node replicas is $A_H^{(j)} = A_H, \ \forall j$; the numbers of redundant subsystems of each network functionality are n_P, n_S, n_I, and n_H, respectively. Being the vIMS a series system of network functionalities, vIMS steady-state availability (4) is a product of single node availability, where P-CSCF, S-CSCF and I-CSCF nodes are in parallel configuration and provide the first three terms in (4). The last factor, instead, takes into account the *k-out-of-n:G* configuration of the HSS node, where $k = 2$ and $n = n_H$. .

5 NUMERICAL ANALYSIS

This section presents a numerical analysis of the proposed IMS framework over an NFV environment by exploiting two software tools: SHARPE (Symbolic Hierarchical Automated Reliability and Performance Evaluator) (Sahner and Trivedi 1987) and TimeNet (German et al. 1995). It aims to single out the minimal-cost redundant configuration of the virtualized IMS system able to guarantee the "five nines" requirement for telecommunication systems availability. The parameters used for this analysis, and, representative of the mean time of failures and repairs as regards the various components (hardware, hypervisor, application) are reported in Table 1. The adopted values are derived in part from the experience of telecommunication experts, and in part from technical literature. For the sake of simplicity we assume that: *i)* hardware and hypervisor are supposed to be the same for all the nodes; *ii)* all the software instances running on CSCF nodes (P-CSCF, I-CSCF, S-CSCF) are characterized by the same failure and repair times. On the contrary, the software instance running on the HSS is supposed to have a different mean time of failure, being the database a more delicate and prone to failures element. As common in literature, the symbols λ and μ denote failure and repair rates, respectively. To characterize the stationary availability of the vIMS system in long runs, a steady-state analysis is carried out by considering some exemplary settings as shown in Table 2. The first column of Table 2 indicates the setting identifier $\left(S_1, \ \ldots, S_5\right)$. The second column indicates the considered redundancy level; for example, the setting S_3 is characterized by two (whatever) CSCF nodes having redundancy of 2, the remaining CSCF node having redundancy of 3, and the HSS node having redundancy of 3. The third column indicates the steady-state availability value of the whole virtual-

Table 1. Input parameters for the hardware subsystems.

Parameter	Description	Value
$1/\lambda_{HW}$	mean time for hardware failure	60000 hours
$1/\lambda_{VMM}$	mean time for hypervisor failure	5000 hours
$1/\lambda_{CSCF}$	mean time for CSCF node failure	3000 hours
$1/\lambda_{HSS}$	mean time for HSS node failure	2000 hours
$1/\mu_{HW}$	mean time for hardware repair	8 hours
$1/\mu_{VMM}$	mean time for hypervisor repair	2 hours
$1/\mu_{CSCF}$	mean time for CSCF software repair	1 hour
$1/\mu_{HSS}$	mean time for HSS software repair	1 hour

Table 2. Availability results of the whole virtualized IMS.

Setting	Redundancy Level	A_{vIMS}
S_1	$CSCF = [2,2,2]$, $HSS = 3$	0.99999416
S_2	$CSCF = [2,2,2]$, $HSS = 4$	0.99999756
S_3	$CSCF = [2,2,3]$, $HSS = 3$	0.99999497
S_4	$CSCF = [3,3,3]$, $HSS = 3$	0.99999659
S_5	$CSCF = [2,3,3]$, $HSS = 4$	0.99999918

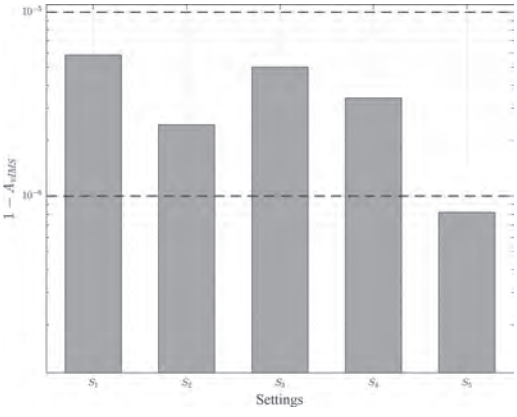

Figure 4. Steady-state unavailability for different settings $S_1, S_2, \ldots, S_5$. The above horizontal dashed line represents the required unavailability: $1 - A_{vIMS} = 10^{-5}$.

ized IMS system in Fig. 2. In order to visualize in a more comfortable manner the steady-state availability results, we show in Fig. 4 the unavailability of the virtualized IMS system $1 - A_{vIMS}$, and it is possible to observe that each setting S_i satisfies the "five nines" requirement, namely, each bar lies below the horizontal dashed line at $1 - A_{vIMS} = 10^{-5}$. In the case of setting S_5, the system is even able to satisfy the more challenging "six nines" requirement, being the corresponding bar lying belowthe horizontal dashed line at $1 - A_{vIMS} = 10^{-6}$. Among the considered settings, S_1 entails the minimum number of deployed replicas, namely, 2 replicas for each CSCF node and 3 replicas for the HSS node. Consequently, setting S_1 represents the optimal redundant configuration in terms of minimum number of deployed replicas while fulfilling the desired high availability requirement.

5.1 *Transient non-Markovian analysis*

The performed regime analysis is useful to evaluate the system behavior as $t \to \infty$, but it cannot capture the dynamics of the system when, for example, some node instances are changing their states from failed to repaired. We approach this issue analyzing the dynamics of the system when software instances (namely the application parts) of both P-CSCF node replicas are down and ready to be repaired. This is the typical case of a contemporary (and often unplanned) update of operating system that forces both software instances to be rebooted.

Actually, in order to consider a more realistic scenario, we replace the classical hypothesis of exponentially distributed software repair transition times with a Weibull-distributed one. In particular, the transient analysis evaluates the behavior of theinstantaneous availability $A_{vIMS}(t)$ and the interval availability $\overline{A_{vIMS}(t)}$ of vIMS system in (0, t], that is defined as

$$\overline{A_{vIMS}(t)} = \frac{1}{t}\int_0^t A_{vIMS}(u)\,\mathrm{d}u. \tag{5}$$

The interval availability represents the time average of the instantaneous availability function over the interval (0, t]. Figures 5 and 6 show the behavior of $A_{vIMS}(t)$ and of $\overline{A_{vIMS}(t)}$ when a Markovian process (all exponential transition times) and a non-Markovian process (Weibull software repair transition times) are considered, respectively. In the case of Weibull software repair transition times, we consider the same mean repair time used in the case of exponentially distributed software repair transition times. Therefore, we set the shape parameter of the Weibull to $\alpha = 3$ (as reported in (Guida et al. 2013)), while the scale parameter β turns out to be 1.1198. Besides, Fig. 7 highlights the different behavior of

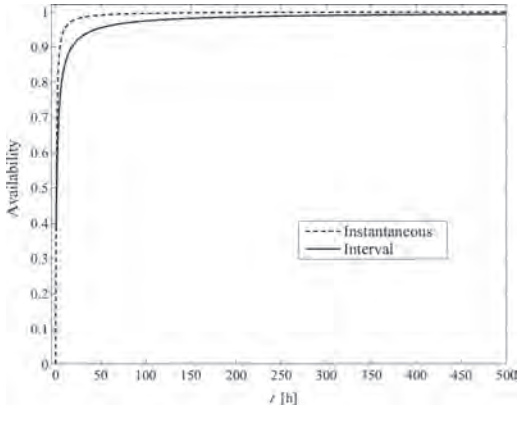

Figure 5. Instantaneous ($A_{vIMS}(t)$) and interval ($\overline{A_{vIMS}(t)}$) availability in case of exponential repair times of P-CSCF application part.

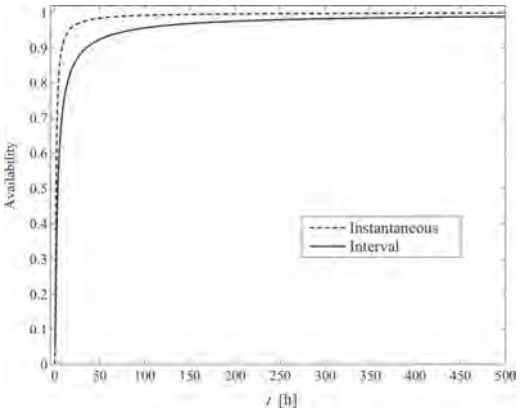

Figure 6. Instantaneous ($A_{vIMS}(t)$) and interval ($\overline{A_{vIMS}}(t)$) availability in case of non-Markovian process with a Weibull repair time of P-CSCF application part.

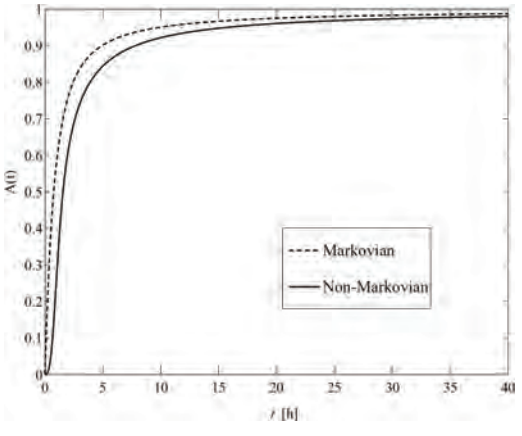

Figure 7. Instantaneous availability comparison in case of Markovian process (all exponential transition times) and non-Markovian process (Weibull repair time of P-CSCF application part).

instantaneous availability $A_{vIMS}(t)$ during the transient, in the case of exponential and Weibull failure rate (of application part). It is worth noting that the transient of $A_{vIMS}(t)$ in the Weibull case is slower than the transient of $A_{vIMS}(t)$ in the exponential case. This behavior is compatible with real-world effects (Ayers 2012). In both cases, as expected, the interval availability $\overline{A_{vIMS}}(t)$ in (5) converges more slowly to the steady-state availability with respect to the instantaneous availability $A_{vIMS}(t)$.

5.2 *Sensitivity analysis*

As far as the last part of the considered experiment, we perform a sensitivity analysis with respect to deflections of two system parameters from their nominal values: λ_{P-CSCF} and λ_{HSS}. Such an analysis has been carried out by considering the minimal cost setting S_1 obtained as a result of the regime analysis. In Fig. 8, the influence of the P-CSCF application part failure time has been considered. The nominal value amounts to 3000 hours (see Table 1), but if we relax such a value to about 1500 hours, we are still able to satisfy the "five nines" requirement. At $1/\lambda_{P-CSCF} = 1500$, in fact, the value A_{vIMS} lies approximately around to 0.9999935. Figure 9, instead, shows the influence of the HSS application part failure time. In this case, the nominal value amounts to 2000 hours, and no side effects are notable unless $1/\lambda_{HSS}$ undergoes the value 1000 (approximately). In this case, the horizontal dashed line at 0.999990 is useful to identify the *breakpoint* across the high availability requirement.

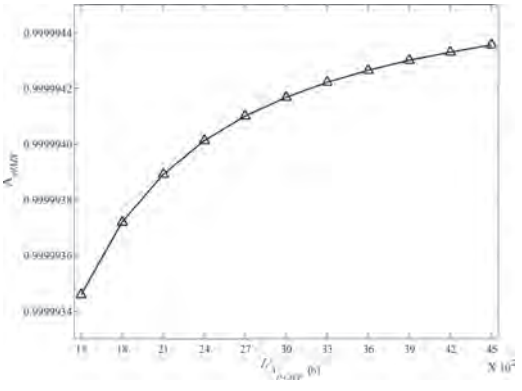

Figure 8. Influence of $1/\lambda_{P-CSCF}$ failure rate over system availability, in case of optimal setting S_1.

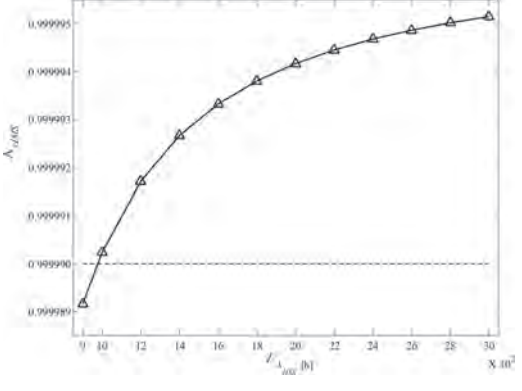

Figure 9. Influence of $1/\lambda_{HSS}$ failure rate over system availability, in case of optimal setting S_1.

6 CONCLUSIONS

Network Function Virtualization and IP Multimedia Subsystem represent two fundamental concepts within the 5G telecommunication world. The former is exploited to virtualize network functions into building blocks, that can be connected or chained in severalways. The latter is designed to provide advanced and IP-based multimedia services. By combining these two paradigms it is possible to derive a virtualized IMS (vIMS) infrastructure that, in this work, has been characterized in terms of availability. Eachvirtual block of vIMS framework has been modeled as a three-layer structure considering: hardware, software (or application) and hypervisor. From a macroscopic viewpoint, the vIMS has been described by exploiting the Reliability Block Diagram (RBD) representation, useful to capture the relationships among the blocks. On the other hand, each virtual block has been modeled by a Stochastic RewardNets (SRN), able to characterize the probabilistic functioning of the underlying system in terms of failure and repair events. Such a modeling phase is preparatory to perform: *i)* a steady-state availability analysis aimed at finding out the minimal-cost redundant configuration that guarantees the "five nines" availability requirement; *ii)* a transient analysis focused on capturing the vIMS dynamics, where a more realistic repair distribution (Weibull) for software layer has been taken into account; *iii)* a sensitivity analysis aimed at evaluating the robustness of vIMS in case of some fluctuation of the critical parameters with respect to nominal values or estimation errors in real data sets. Future work will be devoted to the availability analysis of a more realistic vIMS infrastructure, where some network nodes are co-located, and common mode failures arise.

AltaRica 3.0 code generation from SysML models

Nga Nguyen
Quartz Laboratory, EISTI, Cergy, France

Faida Mhenni & Jean-Yves Choley
Quartz Laboratory, SUPMECA, Saint-Ouen, France

ABSTRACT: In order to bridge the gap between Model-Based Systems Engineering and Model-Based Safety Assessment, we propose in this paper a language transformation between SysML semi-formal models and the formal language AltaRica 3.0. Meta-data of SysML Block Definition Diagram and Internal Block Diagram that describe system architecture as well as meta-data of SysML State Machine Diagram that represent system behavior (in a limited formalism with respect to AltaRica's Guarded Transitions System) are used to generate AltaRica classes, blocks, events, transitions, etc. Flow port directions and connectors are used to create flow propagation assertions. The object and prototype-oriented paradigm of AltaRica 3.0 with class, composition, inheritance, etc. will be respected since SysML and AltaRica's System Structure Modeling Language share commonalities in structuring constructs. It is obvious that one modeling language cannot be replaced by the other because their goals and domains are different, but the mapping between languages such as SysML and AltaRica allows better understanding and communication between systems engineers and safety experts. Once the preliminary AltaRica 3.0 code is generated with structural and behavioral information, safety experts will complete and validate the code with stochastic models, synchronization, common cause failures and redundancy mechanism to carry out safety assessment based on the expressive power of the language, thanks to its mathematical framework.

1 INTRODUCTION

Model-Based Systems Engineering (MBSE) (INCOSE 2015) is a common approach supporting the design and management of complex systems. Various modeling tools and languages can be used according to the different domains involved in the system, the level of detail, the system aspects to be modeled, etc. SysML (OMG 2015) is a general-purpose modeling language adapted to systems engineering since it allows to express the main concepts inherent to the different aspects of system development. It provides a unified standard for specifying, analyzing, designing, and validating complex systems. The language also allows a multi-viewpoint model and building traceability links.

Model-Based Safety Assessment (MBSA) aims at using high level modeling languages to integrate risk analysis with system architecture. Classical safety modeling formalisms such as Fault Trees, Blocks Reliability Diagrams, Event Trees, Markov Chains and Stochastic Petri Nets can provide efficient assessment algorithms and/or expressive power but suffer from the distance with the architecture of the system. AltaRica (Point 2000) is a formal language that supports MBSA approach. An earlier version of the language, AltaRica Data Flow (ADF) (Arnold et al. 2000) has already been embedded in some commercial integrated modeling environments such as Safety Designer, Cecilia OCAS and Simfia. In ADF, a model is composed of nodes that are characterized by their reachable states, in and out flows, events, transitions and assertions. Once a system model is specified in the AltaRica language, it can be compiled into a lower level formalism such as finite-state machines, fault trees and stochastic Petri Nets and different safety assessments can be performed.

A more recent version of AltaRica, AltaRica 3.0 (Prosvirnova 2014) (Batteux et al. 2015) improves the language with the underlying mathematical framework Guarded Transition Systems (GTS) and new structure constructs via System Structure Modeling Language (S2ML). GTS (Rauzy 2008) is a general states/events formalism which handles looped systems by using fix-point calculation mechanism. Compositions such as free product and synchronization between GTS allow to build hierarchical and modular systems. Meanwhile, S2ML assembles constructs coming from object and prototype-oriented modeling languages such as classes, prototypes, composition, inheritance, etc. A flattening algorithm is needed to collapse the hierarchy of nested blocks and instances of

classes into a single program in order to compile and execute AltaRica 3.0 models.

The first objective of this paper is to study the existing work concerning the automatic translation between SysML and AltaRica in order to integrate the reliability analysis with the design process. Secondly, we will introduce our approach to generate AltaRica 3.0 code from SysML models that takes into account the new features of the language while being consistent with the previous work to not reinvent the wheel. The paper is organized as follows. Section 2 presents some related work on SysML and AltaRica mapping. The new version of AltaRica is introduced briefly in Section 3 with an example taken from AltaRica 3.0 training material. Section 4 describes SysML elements used for AltaRica 3.0 mapping as well as the generated code for the given example. Discussions and future work are given in Section 5.

2 RELATED WORK

The link between SysML and AltaRica has been studied in several research work such as David et al. (2009), Belmonte and Soubiran (2012), Ruin et al. (2012), Yakymets et al. (2013) and Hecht et al. (2015).

David et al. (2009) proposed, as a continuation of their MéDISIS methodology integrating systems engineering and safety analysis, a mapping between SysML models and AltaRica Data Flow (ADF) language, so that existing tools to quantify reliability indicators such as the global failure rate, the mean time to failure, etc., can be used directly on the failure modes identified in the previous step of the methodology. An architecture translation was first carried out by exploiting SysML architectural view through Block Definition Diagram (BDD) and Internal Block Diagram (IBD). A SysML block with its properties is translated into an ADF node with its sub nodes (parts), flow variables (ports) and state variables (values). The synchronization of flow exchange is performed by IBD analysis. Limited variable types and unidirectional flow directions in ADF obliged the authors to propose some adaptations to perform an automatic translation. For the behavioral part, an exhaustive list of SysML elements that depict the comportment (operations, actions, messages, etc) is proposed to guide the creation of events, transitions, guards, assignments or assertions in ADF. However, SysML state-charts diagrams whose mathematical framework is close to the transitions/events mechanism of AltaRica are not considered in this work that can facilitate the automatic translation.

Belmonte and Soubiran in (Belmonte & Soubiran 2012) proposed a translation from Obeo Designer's Domain Specific Modeling Language (DSML) for Preliminary Hazard Analysis (PHA) and Failure Mode and Effects Analysis (FMEA) as well as SysML for system functional models into AltaRica to enable formal verification. A node in an Altarica model can be expressed as an octuple (l, SI, F, S, E, I, T, A) where the components correspond to respectively identifier, subnode instances, flow definitions, state variable definitions, events, initial state, guarded transitions and boolean assertions. Different transformation rules concerning the current operational context, the environment nodes (functional activities or operations), the FMEA nodes (dysfunctional specifications)and the PHA node (top level node) are given. However, no real system has been studied yet in order to prove the scalability of the method.

In the context of Complex Maintenance Program Quantification, Ruin et al. (2012) proposed a framework using SysML to model the static and interaction part of production systems, and AltaRica Data Flow formal language to model the concept behavior part. The model building language and the model execution language are related to each other by a transformation step. The SysML Sequence Diagram representing interactions between blocks and the Parametric Diagram describing relationships between attributes of blocks are used to generate ADF parts made up with nodes, states, events, initial states and transitions. According to their algorithm: a node is created for each lifeline in the sequence diagram; an event corresponds to a reflexive message (looped back message) to the same lifeline; and when a transition takes place, the state variable will change from one "condition mark" to another. Synchronization is made via messages sent from one lifeline to the other and the looped back messages. However, no algorithm is given for the parametric diagram and the case study in the paper is not an industrial scale system. As cited in Ruin et al. (2012), ADF presents some restrictions like the impossibility to model looped systems and acausal connection where the direction of the flow propagation depends on the states.

Yakymets et al. (2013) presented a safety modeling framework for fault tree generation and analysis SMF-FTA. This framework includes meta-models, profiles, model transformation, verification, and Fault Tree Analysis (FTA) tools. In this approach, several steps are needed. First, the system to be analyzed is designed and its structural models are built using the SysML BDD and IBD diagrams. Second, these models are annotated with failure behavior. Then the entire model is converted into AltaRica language by using transfor-

mation rules. A SysML block is translated into an AltaRica node containing flows that correspond to the block's ports. Expressions showing how output port errors can be derived from internal failures of the block and/or possible deviations in the input ports are stored in SysML opaque expressions and used to generate AltaRica internal component transitions. Connection between components via the connectors are used to create assertions. An algorithm already existing in the ARC tool analyzes the AltaRica model and derives the different minimal cut sets from the model. These cut sets are assembled to form the final fault tree. The resulting fault tree can be represented either with open-Probabilistic Safety Assessment (PSA) or a SysML dedicated profile

In Hecht et al. (2015), Hecht et al. generated FMEA from AltaRica code, and this code is created from a series of interacting SysML state machines. However, no detail is given about the mapping elements, except an example of text export from SysML models showing: i) a block and its ports coming from an IBD and ii) states, events and transitions deriving from a state machine diagram of the corresponding block. This SysML output parameter file is transformed into an AltaRica input file where the specific block becomes a node with its own state variable, events and transitions.

No related work concerns yet the latest version of AltaRica with which new theoretical framework and structural constructs have been established. Generating AltaRica 3.0 code directly from SysML models while being consistent with existing related work would be the next step to verify the feasibility of the approach.

3 ALTARICA 3.0 LANGUAGE

AltaRica 3.0 is currently under specification in the framework of the OpenAltaRica project (http://openaltarica.fr). In this paper, we are only focused on the main concepts of the language. Advanced notions such as functions, operators and records are not considered at the moment.

A *block* in AltaRica is used to encapsulate a finite state automaton whose state variables will have type and initial value. A *transition* is made of an *event*, a guard and an action to be performed when the transaction is fired. To illustrate the language, an example taken from Open AltaRica training document is given in Fig. 1. The system has an environment with a true input value and an observer which is the output of the system. The five components *a*, *b*, *c*, *d* and *e* are identical, each one having an input and an output flow connected to each other. Each component can fail and be repaired and the state machine is given in Fig. 2.

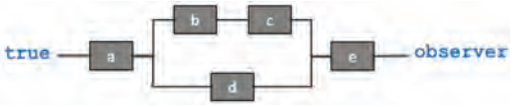

Figure 1. Case study from OpenAltaRica training session.

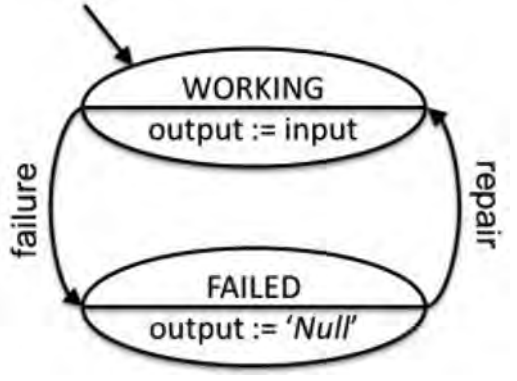

Figure 2. Component finite state machine.

We can define a *class* in AltaRica code that represents a generic component as in Fig. 3. The class Component has a boolean state variable "working" and two flow variables "input" and "output". The two events "failure" and "repair" will change the value of the component state from true to false and inversely. The assertion represents the internal transfer function of the component: if the component is working, the output is equal to the input. Otherwise, it is false.

The case study system can be defined by using the instances of the class Component. Since the model of the whole system is unique, it is denoted by a structural construct *block* that represents a prototype (Fig. 4). An observer is added to model the system output. The assertion part describes the relations between components. Since there are redundant sub-systems, component *e* fails only if there is no output from both *c* and *d* (*e:input:= c:outputord:output*).

For the events, we can add stochastic or deterministic delays as well as parameters used in the corresponding law to define different failure rates for the components as in the updated version in Fig. 5. This allows to associate with each event a delay, a memory policy and a weight in order to have stochastic timed model. To generate fault trees from the AltaRica model, we need to declare the top event with the observer. Also, a common cause failure (CCF) on components *b* and *c* can be defined with its dedicated parameter and used

```
class Component
 Boolean working (init = true);
 Boolean input, output (reset = false);
 event failure,  repair;
 transition
  failure: working -> working := false;
  repair: not working -> working := true;
 assertion
  output := if working then input else false;
end
```

 parameter Real pLambdaCCF = 1.0e-6;
 event eventCCF(delay=exponential(pLambdaCCF));
 observer Boolean topEvent = e.output==false;
 transition
  eventCCF: ?b.failure & ?c.failure;
 assertion
   ...
end
```

Figure 6. System code: version 2.

in the transition to synchronize the components. The prefix ? or ! mean that the event is optional or mandatory, respectively. The updated code for the system is given in Fig. 6. With these information, we can compute the different minimal cut sets, the probability of the top-event for a given mission time, etc. with the OpenAltaRica platform.

AltaRica 3.0 supports also more advanced concepts such as inheritance between classes, acausal connection for bidirectional flows and cold redundancy. The mechanism to update flows uses a fix-point algorithm that allows to detect modeling errors at run time if no fix point is reached.

4 SYSML MODELS AND ALTARICA CODE GENERATION

Table 1 shows our proposal of basic elements mapping from SysML to AltaRica. This model-to-model transformation is based on previous work in Section 2 and takes into account new concepts of the current version of AltaRica.

We have modeled the AltaRica 3.0 case study with SysML. Figures 7, 8 and 9 show respectively the Block Definition Diagram, Internal Block Diagram and State Machine Diagram of the example.

To generate code for the Component class, the different states in the state machine will become an enumeration ComponentState {working, failed}, with a specific initial value. The two flow ports "input" and "output" become automatically typed flow variables in AltaRica. Actually, they have a boolean type, with *reset* made to false by default.

Table 1. SysML and AltaRica 3.0 mapping.

SysML	AltaRica
generic block with several instances	class
specific block with unique occurrence	block
block inheritance	extends
flow port	flow variable
states	a state variable with enumeration domain
initial state	init
transition	event
guard	guard
connector	assertion

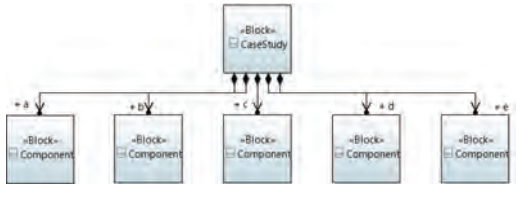

Figure 7. Case study block definition diagram.

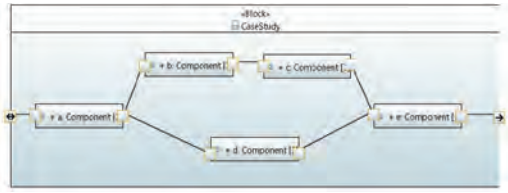

Figure 8. Case study internal block diagram.

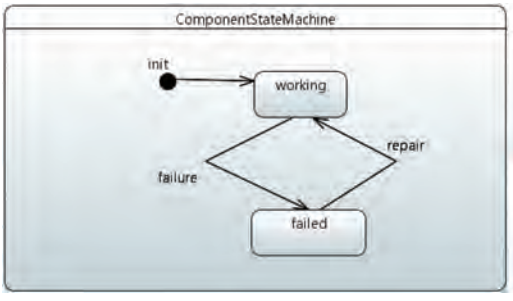

Figure 9. Component state machine diagram.

```
domain ComponentState {working, failed}

class Component
 ComponentState stateVar (init = working);
 Boolean input, output (reset = false);
 event failure,  repair;
 transition
  failure:stateVar==working->stateVar:=failed;
  repair:stateVar==failed->stateVar:=working;
 assertion
  output:=if (stateVar==working) then input
```

Figure 10. Generated component code.

The events and the transitions in AltaRica will be created automatically according to the information in the state machine. Boolean expressions for the guard conditions are added if available. The transfer function of the component that calculates the value of the output flow variable from the value of the state variable and the input flow variable is generated automatically in the *assertion* part. The generated code for the Component class is given in Fig. 10.

The information from IBD is used to generate code for the whole system which is made of 5 components. The interactions between the components are modeled through the connectors and the flow direction (in, out and inout). The input flow of a component depends on the output flow of another component if there is a directed link between them. Since AltaRica 3.0 supports acausal components, i.e. components for which inputs and

```

 assertion
   a.input := true;
   b.input := a.output;
   c.input := b.output;
   d.input := a.output;
   e.input := c.output or d.output;
end
```

Figure 11. Generated system code.

outputs are decided at run time like the inout port of SysML, we can also create an acausal connection in the *assertion* part. For an input port that receives information from different output ports (the case of the component *e* that is linked to two components *c* and *d*), we have to verify if they come from redundant sub-systems or not. We have proposed in another paper (Nguyen, Mhenni, & Choley 2016) the Redundancy Profile, a SysML extension which allows integrating redundancy-relevant properties in the system model in order to better represent system architecture. So these data can be used to generate the assertion *e:input:= c:outputord:output*. For the case when there is no redundancy, the equation should be *e:input:= c:outputandd:output*. An *observer* has been created to observe the final output of the whole system that takes the value of *e:output*. The generated code for the case study is showed in Fig. 11.

5 DISCUSSION AND FUTURE WORK

Currently, our transformation handles just simple concepts of AltaRica 3.0 language with what we can perform a direct mapping. The next step of our work is the completion of the Safety Profile (Mhenni et al. 2016) that contains the Redundancy Profile in order to integrate information concerning stochastic models (delays, parameters, expectations) as well as redundancy mechanism. AltaRica code can be generated with more precise data. The model-to-model transformation will be implemented in a proof of concept tool to validate the approach.

Failure behavior analysis of hot standby system based on BDD method

Z. Wang, Y. Chen, W. Men & R. Kang
Reliability and System Engineering School, Beihang University, Beijing, China

ABSTRACT: Hot standby technology becomes a popular method for improving the reliability of a crucial component, and a significant system. Considering the failure mechanisms of components, this paper proposes a binary decision diagram-based method for modeling the failure behaviors of hot standby systems. The failure probability of the component what fails firstly among the primary and hot standby component is discussed. We find that under the condition of that one component fails firstly, as time goes by, the transient and cumulative failure probabilities of that the primary and hot standby component fail firstly change. Besides, after one component fails firstly, the reliability of the system sharply decreases and totally depends on the statuses of those remaining functional components. With the help of the method proposed in this paper, more practical work about the maintainability and design optimization can be done.

1 INTRODUCTION

In some safety or mission-critical applications, such as nuclear power plants, aerospace, telecommunications and so on, the redundancy technology is a main method for ensuring the reliability or safety of the systems. The redundancy technology can be divided into 3 types, hot, cold, and warm standby, due to the differences of working conditions of redundancy components (Levitin et al. 2015). In hot standby systems, a hot standby component is exposed to the same operational and environmental stresses as the primary component's. And when the primary one fails, a hot standby component will be switched into the system immediately, and start to output its function and guarantee the mission finished successfully. With the applications of hot standby systems in engineering products, the study about how the hot standby system fails becomes more and more critical.

When the lifetime distributions of all the system's components follow exponential distributions or the failure rates are known, Ren & Zhang (2009) modeled and analyzed the hot standby system's structure by using Markov process method. Though the Markov process method can be applied for the reliability analysis easily, it still has a strict limitation on the lifetime distribution of the components (Xing et al. 2015). Ebrahimipour et al. (2010) obtained the reliability expression of k-out-of-n multi-state series-parallel systems by using the universal generating function. Levitin et al. (2015) analyzed the reliability of 1-out-of-n heterogeneous standby system, and a corresponding mathematical expression is derived. Besides, Levitin also considered two different kinds of failure propagation, selective and global propagation, into the reliability modeling. But when the system's scale is large or its logical relations are complicated, that kind of analyzing method will be extremely difficult for applying.

The modeling or analyzing method for a hot standby system is mainly based on the assumption that the probability density functions (pdfs) or the cumulative distribution functions (cdfs) of components are known (Levitin et al. 2015, Ardakan & Hamadani 2015, Levitin et al. 2014). And most papers pay attentions to the final results of systems' reliability, not how the components' failure develop and affect the entire system's failure. To overcome the difficulty of collecting components' lifetime data and find the nature of failure, physics of failure (PoF) is proposed (Hassan & Aldemir 1990). Because the lifetimes of failure mechanisms simulated by PoF method are constant, Probabilistic Physics of Failure (PPoF) is developed for obtaining the probabilistic distributions of those lifetimes (Zoran & Vlado 2008, Hall & Strutt 2003). Based on those key theories of PoF and PPoF, Chen Y et al. (2015) proposed five correlations among failure mechanisms, which are competition, trigger, acceleration, inhibit, and accumulation. And Chen also provided an effective way, failure mechanism tree (FMT), for analyzing the failure behaviors of components and systems.

In chapter 2, this paper will introduce the failure behaviors of a hot standby system and give a series of expressions for all behaviors. In chapter 3, a hot standby system in the supply module of an

electronic control system will be analyzed as an example for showing the characteristic of the hot standby system.

2 FAILURE BEHAVIOR OF A HOT STANDBY SYSTEM

2.1 *Equations for the reliability of a hot standby system*

Failure behavior is used for describing how the failure mechanisms of components develop with the effect of correlations among themselves, and eventually cause the failure of the entire system. This paper focuses on analyzing failure behaviors of the hot standby system consisting one primary component and one hot standby component. And the switch what is used for switching the hot standby component to be operational after the primary component fails is supposed to be perfect. Assume that the failure probabilities of components are irrelevant with usage or switch intensity.

Because of the same operational conditions that both primary and hot standby components are exposed to, the failure mechanisms of the components develop and influence each other since the system starts to work. The failure sequences of those components are probabilistic and not determined till some components fail, which also means each component has the possibility to fail earlier than the other. So, according to whether the failures of components happen, the working phase of a hot standby system can be divided into two parts, phase I and II.

In phase I, no component fails. The failure mechanisms start to develop since the system begins its working, but none of them reaches its failure threshold. So, the reliability of the entire system is influenced by the developments of failure mechanisms and in-time reliability of both components. Only if both of the components fail, the failure of a hot standby system will occur. The reliability of the system can be described as (1).

$$\begin{aligned} R(t) &= 1 - F_P(t) \bullet F_S(t) \\ &= 1 - \int_0^t f_P(t_P)dt_P \int_0^t f_S(t_S)dt_S \end{aligned} \tag{1}$$

where f_P(t) and f_S(t) are the probability density functions of the failures of primary and hot standby components, respectively.

In phase II, the primary or hot standby component fails at time t_f, but the other one is survived and switched to be operational for ensuring the system finish its function. The entire system will fail if the survived one fails. So, the reliability of the system is equal to the survived one's, which also shown in (2).

$$R(t) = \begin{cases} 1 - F_P(t) & \text{a hot standby component} \\ = 1 - \int_0^t f_P(t_P)\,dt_P & \text{fails at } t_f \\ 1 - F_S(t) & \text{a primary component} \\ = 1 - \int_0^t f_S(t_S)\,dt_S & \text{fails at } t_f \end{cases} \tag{2}$$

From the discussion above, we know that the component failing at t_f is a primary or hot standby component will lead to a different reliability level of the system. So, the study on the distribution function of t_f is a significant job for learning the changes of the system's reliability and adjusting maintenance strategy. t_f equals the minimum failure time among a primary and hot standby component's, which is shown as (3).

$$t_f = \begin{cases} t_P & t_P \le t_S \\ t_S & t_P > t_S \end{cases} \tag{3}$$

where t_P and t_S are the failure times of the primary and hot standby component, respectively.

When the primary component fails firstly, which means $t_P \le t_S$, t_f equals the failure time of primary component. And at time t, the transient probability of that the primary component fails, but the hot standby component is survived can be obtained as (4). Besides, the cumulative probability of that the primary component fails firstly is (5).

$$\begin{aligned} P_P(t) &= P\left(t_f = t_P = t, t_S \ge t\right) \\ &= f_P(t)dt \cdot \int_t^\infty f_S(t_S)dt_S \end{aligned} \tag{4}$$

$$\begin{aligned} F_P(t) &= \int_0^t P_P(t_{FP})dt_{FP} \\ &= \int_0^t f_P(t_{FP})dt_{FP} \cdot \int_{t_{FP}}^\infty f_S(t_S)dt_S \end{aligned} \tag{5}$$

When the hot standby component fails firstly, which means $t_P > t_S$, t_f equals the failure time of the hot standby component. So at time t, the transient probability of that the hot standby component fails, but the primary is survived can be derived as (6). And the cumulative probability of that the hot standby component fails firstly is (7).

$$\begin{aligned} P_S(t) &= P\left(t_f = t_S = t, t_P > t\right) \\ &= f_S(t)dt \cdot \int_t^\infty f_P(t_P)dt_P \end{aligned} \tag{6}$$

$$\begin{aligned} F_S(t) &= \int_0^t P_S(t_{FS})dt_{FS} \\ &= \int_0^t f_S(t_{FS})dt_{FS} \cdot \int_{t_{FS}}^\infty f_P(t_P)dt_P \end{aligned} \tag{7}$$

For further discussion, if there is a component fails firstly at time t, the probability of that the failed component is the primary component is $P_{P|F}(t)$, and the probability of that the failed component is the hot standby component is $P_{S|F}(t)$, which can be calculated as (8) and (9).

$$P_{P|F}(t) = P_P(t) / \left[P_P(t) + P_S(t) \right] = \frac{f_P(t)\,dt \cdot \int_t^{\infty} f_S(t_S)\,dt_S}{f_P(t)\,dt_P \cdot \int_t^{\infty} f_S(t_S)\,dt_S + f_S(t)\,dt \cdot \int_t^{\infty} f_P(t_P)\,dt_P} \tag{8}$$

$$P_{S|F}(t) = P_S(t) / \left[P_P(t) + P_S(t) \right] = \frac{f_S(t)\,dt \cdot \int_t^{\infty} f_P(t_P)\,dt_P}{f_P(t)\,dt_P \cdot \int_t^{\infty} f_S(t_S)\,dt_S + f_S(t)\,dt \cdot \int_t^{\infty} f_P(t_P)\,dt_P} \tag{9}$$

When one component fails, the reliability of the system will decreases and equals to the survived one's reliability. Whether the system's reliability after t_f reaches the desired level or not will influence the optimal choice of actions for preventing and reducing the losses caused by the system's failure. So, the cumulative probability of t_f can be obtained as (10).

$$F_f(t) = \int_0^t f_P(t_P)\,dt_P \int_{t_P}^{\infty} f_S(t_S)\,dt_S + \int_0^t f_S(t_S)\,dt_S \int_{t_S}^{\infty} f_P(t_P)\,dt_P \tag{10}$$

2.2 *Binary Decision Diagram (BDD) for simulation*

The binary decision diagram (BDD) is proposed on the Shannon decomposition theorem (Xing L. et al. 2012). As a matter of fact, the BDD model has been widely applied for simplifying logical analysis on large static fault trees. For a Boolean formulation, f is defined upon a set of Boolean variables: $x_1, x_2, \ldots, x_n$, and it can be equivalently decomposed by the Shannon expansion rule as (11).

$$f = x_i \cdot f_{x_i=1} + \overline{x_i} \cdot f_{x_i=0} = ite(x_i, f_{x_i=1}, f_{x_i=0}) \quad (1 \le i \le n) \tag{11}$$

where $f_{xi=b}$ represents f when $x_i = b$, and b is a Boolean constant 0 or 1; *ite* denotes the compact if-then-else format. Equation (11) also can be illustrated as Fig. 1.

To build a BDD model of a fault tree, an efficient recursive generating algorithm through a depth first left traversal of the fault tree is presented as (12).

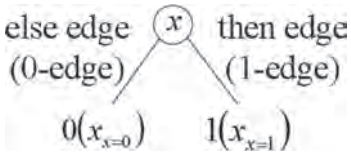

Figure 1. Shannon decomposition and *ite* format of x.

$$G \lozenge H = ite(x, G_1, G_0) \lozenge ite(y, H_1, H_0) = \begin{cases} ite(x, G_1 \lozenge H_1, G_0 \lozenge H_0) & index(x) = index(y) \\ ite(x, G_1 \lozenge H, G_0 \lozenge H) & index(x) < index(y) \\ ite(x, G \lozenge H_1, G \lozenge H_0) & index(x) > index(y) \end{cases} \tag{12}$$

where G and H are two Boolean formulations representing structure functions of the traversed subtrees, and G_i and H_i (i = 1,0) are the subfunctions of G and H. $\lozenge$ indicates logic operation of AND or OR, and *index*(x) and *index*(y) denote an argument index of the variable x and y.

This paper will model the failure behavior of the hot standby system by adjusted BDD models. The basic and important issue is dealing with the correlations among failure mechanisms. According the method of modeling a FMT model (Chen et al. 2015), the FMT models of all components in hot standby systems can be generated, which can be transformed into BDD models with the approaches listed in Table 1.

In hot standby systems, only if both the primary and hot standby components fail, the entire systems will fail, which means the logic relations between the primary and hot standby ones can be described as the logic AND. On the other hand, the logic OR may exists among different components. So, the fault tree (FT) model of the different components can be generated, and the exact methods about how to build the FT and transform it into a BDD model are shown in Table 2 (Levitin et al. 2015).

In Table 2, A_i (i = 1, 2,...,n) represents the components of a system.

To analyze the BDD model, a Monte-Carol based method is used in this paper. Firstly, a large number of random lifetimes of failure mechanisms should be generated. Secondly, the logical expressions about the failure times of components and the entire systems must be derived. The exact method is listed in Table 3. Finally, lots of the random failure time will be computed and some corresponding reliability curves can be generated.

In Table 3, T_a is the lifetime of the failure mechanism M_a, T_i (i = 1,2,…,n) is the lifetime of the failure mechanism M_i (i = 1,2,…,n), T_i' (i = 1,2,…,n)

Table 1. FMT and BDD models of mechanism correlations.

Mechanism correlation	FMT model	Corresponding BDD model
Competition		Trigger		Acceleration or inhibit		Accumulation		
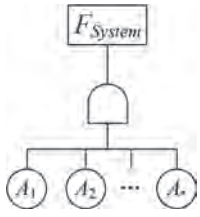
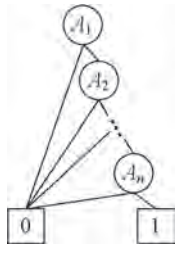
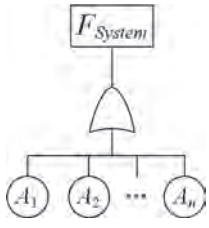
is the lifetime of the failure mechanism M_i (i = 1,2,…,n) after being accelerated or inhibited, T_{Ai} (i = 1,2,…,n) is the lifetime of the component A_i (i = 1,2,…,n), t_C is the time when event C happens.

Table 2. FT and BDD models of logic AND and OR.

FT model	Corresponding BDD model
		






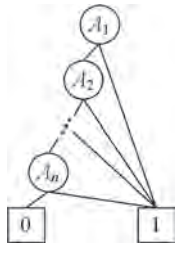


Table 3. Logical expressions for the mechanism correlations, logic AND and logic OR.

Mechanism/logic correlations	Logical expressions
Competition	$t_A = \min\{T_1, T_2, \cdots, T_n\}$
Trigger	$t_A = \min\{T_a, t_C + T_1, t_C + T_2, \cdots, t_C + T_n\}$
Acceleration or inhibit	$t_A = t_C + \min\{T_1' - \frac{T_1'}{T_1} t_C, T_2' - \frac{T_2'}{T_2} t_C, \cdots, T_n' - \frac{T_n'}{T_n} t_C\}$
Accumulation	$t_A = \frac{1}{\frac{1}{T_1} + \frac{1}{T_2} + \cdots + \frac{1}{T_n}}$
Logic AND	$t = \max\{T_{A1}, T_{A2}, \cdots, T_{An}\}$
Logic OR	$t = \min\{T_{A1}, T_{A2}, L, T_{An}\}$

3 A CASE STUDY

3.1 *Description of the case*

This section takes a supply system in an electronic control system of an aircraft as an example for discussing the failure behavior of a hot standby system. The supply system contains two identical supply modules consisting 6 components, which is

simplified and shown in Fig. 2. The exact meanings of all components in Fig. 2 are shown in Table 4.

The components in primary and hot standby supply systems are the same component, but different in their lifetime distribution's parameters. According to the FMMEA result of the example supply system, main failure mechanisms, correlations among those mechanisms, and the effect for every component are shown in Table 5.

According historical data or the PPoF method, the distributions and parameters of those failure mechanisms' lifetimes in different components are shown in Table 5.

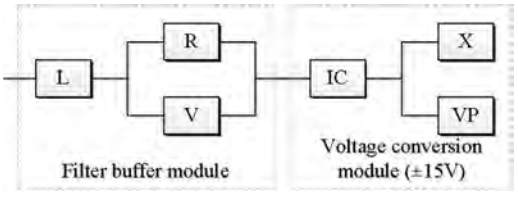

Figure 2. The supply module in the supply system.

Table 4. Components in the supply module.

Component symbol	Definition and details
L	Inductance
R	Resistance
V	Thyristor
IC	DC-DC supply converter (PWM switching mode power supply)
VP	Optocoupler
X	Perfect socket

In Table 5, TF is thermal fatigue, EC is electrolytic corrosion, MM is metal migration, HCI is hot carrier injection, VF is vibration fatigue, EM is electrical migration, TDDB is time-dependent dielectric breakdown, and EB is electrical breakdown.

3.2 *Failure behavior modeling*

With the method of generating a FMT model (Chen Y. et al. 2015), the FMT model of the supply system can be generated as shown in Fig. 3.

After transforming the FMT into BDD model, the failure behavior model is obtained as shown in Fig. 4.

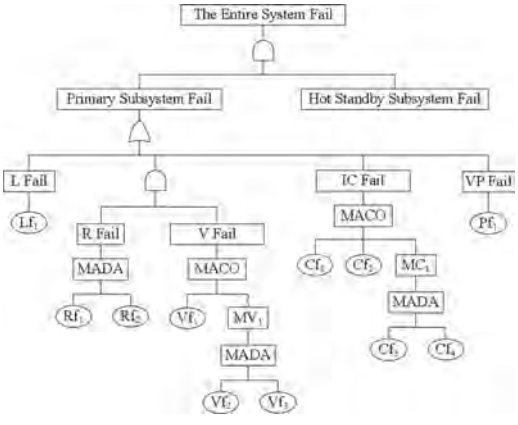

Figure 3. The FMT model of the entire system.

Table 5. Failure mechanisms and correlations in components, and distribution types and parameters of mechanisms.

Component	Mechanism	Mechanism symbol	Failure effect	Failure mechanism correlations	Effect symbol	Failure mechanism correlations	Distribution type	Distribution parameter: Primary subsystem β(θ)	Primary subsystem η(σ)	Hot standby subsystem β(θ)	Hot standby subsystem η(σ)

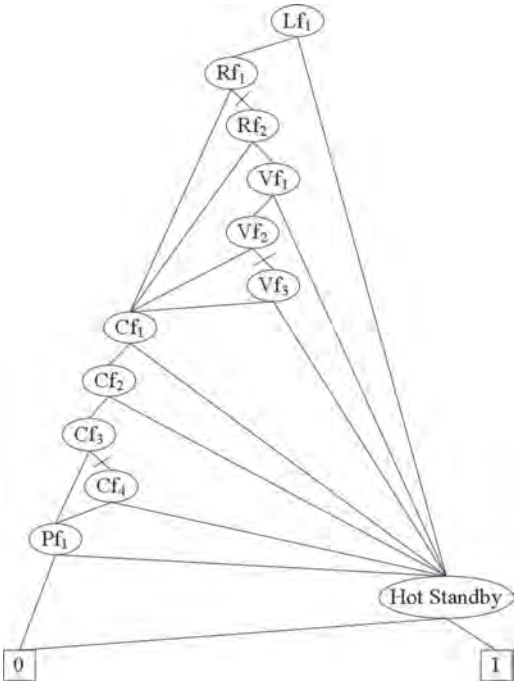

Figure 4. The BDD model of the failure behavior of the example supply system.

3.3 *Simulation*

Using the Monte-Carlo method, 2,000,000 random lifetimes of all mechanisms are generated. From the BDD model of the example system in Fig. 4, the logical expressions of the primary, hot standby subsystems and the entire system are shown in (13)-(15).

$$T_{\text{primary}} = T_{\text{standby}} = \min\{\max\{T_{\text{MR1}}, \min\{T_{\text{Vf1}}, T_{\text{MV1}}\}\}, T_{\text{Lf1}}, T_{\text{Cf1}}, T_{\text{Cf2}}, T_{\text{MC1}}, T_{\text{Pf1}}\} \tag{13}$$

$$T_{\text{fail-firstly}} = \min\{T_{\text{primary}}, T_{\text{standby}}\} \tag{14}$$

$$T_{\text{system-failing}} = \max\{T_{\text{primary}}, T_{\text{standby}}\} \tag{15}$$

Calculating the random lifetimes by those logical expressions, the exact failure times of the system are obtained. The reliability curve of primary and hot standby subsystem, and the entire system are shown in Fig. 5.

In Fig. 5, the reliability of primary subsystem is bigger than the hot standby one's at the same time, and both of them are smaller than the supply system's, which means the hot standby technology used in this system works and the hot standby subsystem may fail firstly.

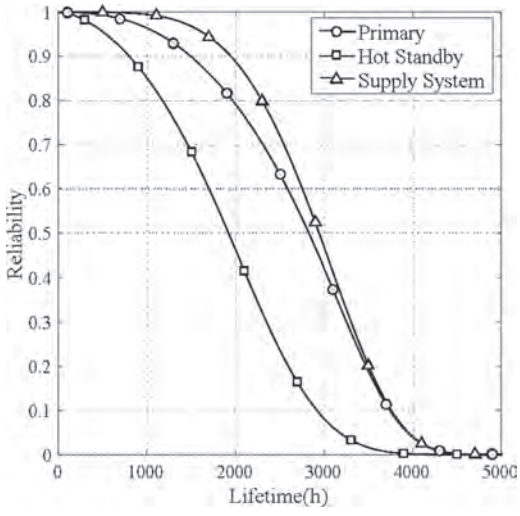

Figure 5. The reliability curves of the primary and hot standby subsystems and the entire system.

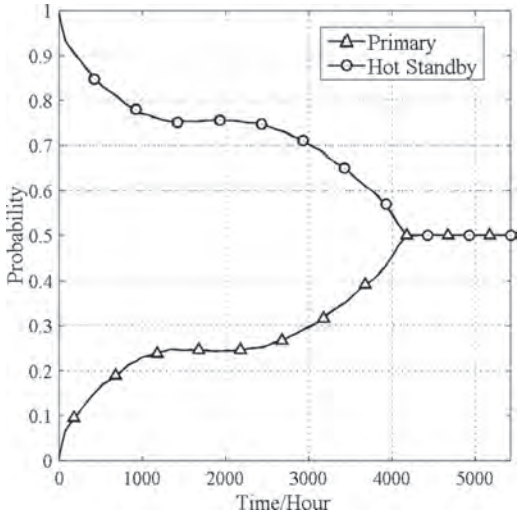

Figure 6. The transient failure probability curves of that the primary and hot standby system fail firstly.

Besides, if there is a subsystem fails firstly, the transient failure probability curves of that the primary and hot standby system fail firstly are shown in Fig. 6. And the cumulative failure probability curves of that the primary and hot standby system fail firstly are shown in Fig. 7.

In Fig. 6, we can learn that during the early period of the system's lifetime ($0 < t < 1000$ hours), $P_{S|F}(t)$ is nearly 75% ~ 100%, which decreases

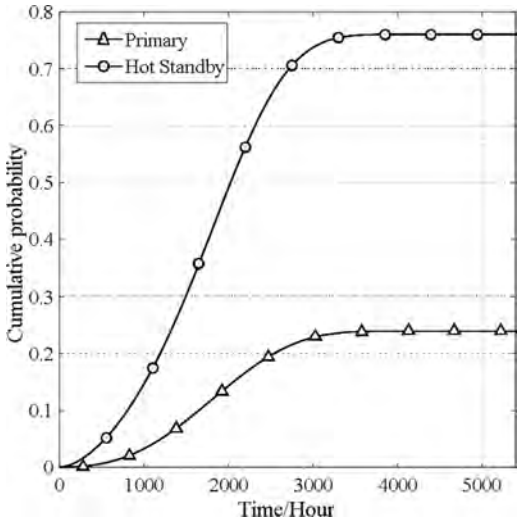

Figure 7. The cumulative failure probability curves of that the primary and hot standby system fail firstly.

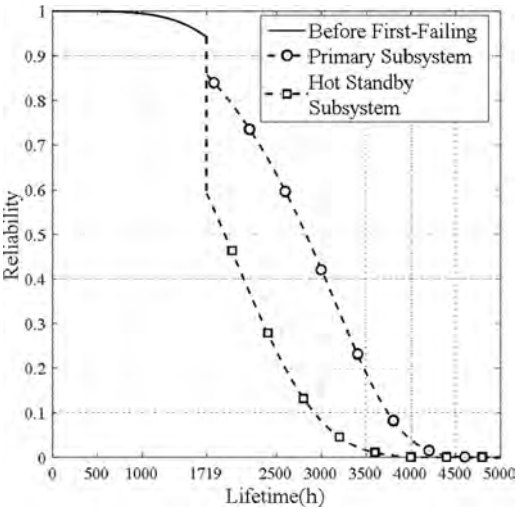

Figure 9. The reliability of the supply system after one subsystem's failing at t = 1719 hour.

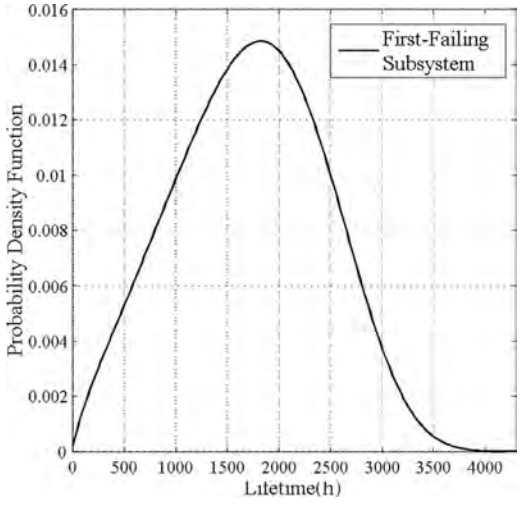

Figure 8. The pdf probability curve of the first-failing subsystem.

as time goes by. And if there is a supply module fails firstly, the probability of that the failed module might be the hot standby module. During 1000 < t < 2500 hours, $P_{S|F}(t)$ is nearly stable at 75%, and decrease after 2500 hours. During the last period of the system's lifetime (t > 4000 hours), $P_{S|F}(t) = P_{P|F}(t) = 50\%$.

In Fig. 7, we learn that in summary, the hot standby supply system is more likely to fail firstly at the probability of nearly 77%. Moreover, the pdf curve of that one supply module fails firstly is shown in Fig. 8.

From Fig. 8, the probability of one of the subsystems fails at about t = 2000 hour is biggest. So at that moment, the reliability of the supply system should be paid enough attentions, and the frequency of checking the working conditions of the two subsystems should be greater. Besides, the mean time of the failure time of first-failing subsystem is about 1719 hours. Suppose that there is a subsystem fails at t = 1719 hour, the reliability of the entire system will have totally different results as shown in Fig. 9.

If primary subsystem fails at t = 1719 hour, the reliability will equal to the hot standby subsystem's; if hot subsystem fails at t = 1719 hour, the reliability will equal to the primary one's, which has a more dramatic decline and may not reach the requirement of the reliability and the hot standby subsystem should be replaced.

4 CONCLUSION AND FUTURE WORK

This paper discussed the failure behavior of a hot standby system and proposed a BDD-based method for evaluating the hot standby system's failure behavior. We derived some functions for describing the transient and cumulative failure probabilities of that the primary or hot standby component failed firstly, which may be helpful for the optimizations of the maintenance allocation and functional design. The sharply decrease of the

reliability of a hot standby system after some components fail firstly are analyzed.

Next, we will optimize this kind of analyzing method, and try to apply it to the failure behavior analysis of more complex systems, like 1-out-of-n hot standby system.

Dependability analysis of a product line using its model

B. Chieb, V. Idasiak & F. Kratz
Laboratoire PRISME, INSA Centre Val de Loire, Bourges, France

ABSTRACT: The objective of this study is to introduce safety studies as soon as the engineering information is available. Safety studies require the use of formalisms. SysML begins to be a good vector of System Engineering activities, and Feature Model seems like an excellent candidate for the product line description. In order to perform a safety analysis, the required information is extracted from the Feature Model/SysML models of the product line. To reduce the number of studies, we provide FMECA (Failure Modes, Effects and Criticality Analysis) of product line (parametric FMECA) type analysis support, which allows conducting an analysis at the level of the product line, and provides rapid analysis synthesis for each product. In this study, we introduce a new process dedicated to product line in the MéDISIS method. We design a meta-model of System Engineering to help the information management related to the product line variability from the functional and organic point of view. We define the parametric FMECA which carries all relevant information from the models. It allows the decisions and choices capitalization during the safety analysis, especially the impact of variability of the product in terms of dependability. The new MéDISIS process automatically generates from both models a parametric FMECA of the product line. Finally, the process is finalized by the Dependability Engineer using the consolidation tool from MéDISIS in order to generate the final FMECA. The synthesis method of a parametric FMECA from models will be presented. In particular, we will discuss how a variability by its presence or absence can influence a dependability analysis, and how the rules used to define variabilities are taken into account for the final FMECA synthesis.

1 INTRODUCTION

In the current commercial and industrial context, the industrial strategies are often based on the definition of line of products. The objective is the decrease of the costs and of the delays while favoring a better offer adaptation to the expectations of the market, and an increase of the products or systems quality. Such an industrial strategy impacts naturally on organizations, in particular on the processes and on the methods of System Engineering (SE). Indeed, one of SE qualities is to allow the capitalization of the convergent validated solutions of the product creation. Thus, the SE so offers a natural support to the approaches by product line characterizing a set of products having common elements and variabilities.

A product line defines a set of products having common characteristics and architecture related to components and functions, with which are associated by variabilities, which is necessary for the satisfaction of a range of needs.

The capitalization of common parts knowledge is then one of engines of studies rationalization, while artifacts stemming from the management of the variabilities and from their coherences constitute a brake.

The works made during the definition of the method MéDISIS (Method of Integration safety analyses in the process of System Engineering) and its platform (David et al. 2010) and (Cressent et al. 2013), established the bases of an exploitation of the Model Based Systems Engineering (MBSE) to generate partially models of operating safety analysis. More recently, (Kajdan & Idasiak 2015) allowed by the definition of minimal set information of MBSE, the rationalization of the techniques of generation of pre-FMECA. Furthermore, this rationalization gave the possibility of following the evolution in a unique one FMECA of the modifications carried out on a system model. The variant part of SE models of product line escapes this type of generation process. Thus, our objective consists in adapting the methodology to products designed in the form of a product line, and in allowing so to build generic studies of the operating safety.

A product line, for the SE analysis and design steps, is to identify the common elements of all products in the range in order to make significant gains through the capitalization and reuse of artifacts produced by the SE processes implemented: cost reduction, development time reduction and, testing, and in our case, dependability analyzes. But every product in the product line has to adapt

to a wide variety of needs, which are then differentiated by specificities. The set of specificities characterizes the product line, and constitutes the variabilities. An example of use cases in section 4 will support our explanations.

If the common part requires a few changes in practices in modeling techniques and methods, it is not the same for variability. Product line models provide a solution to clearly identify the set of common elements of all variant elements and their dependencies. In fact, the variation models also introduce a logic allowing the configuration expression of each product that only uses a subset of variants.

In this article, we will propose two approaches to dependability analysis based on product line models. We will extend our reflection on the generation of pre-FMECA process of the MéDISIS method in order to provide for each product line model a FMECA declinable for each product. Section 2 presents the engineering system concepts used for product line model. Section 3 presents the standard processes of MéDISIS and the proposed processes. Section 4 presents a case study conducted to evaluate the tow processes. Section 5 presents the conclusion.

2 THE PRODUCT LINE AND ENGENEERING SYSTEM MODEL

The concepts of the product line modeling are known in the computer under the name of SPL (Software Product Line) (Lee et al. 2009), they introduce Feature Model. The Feature Model (FM) modeling technique is based on logical concepts between the model's features. It is used to define similarity and variation in models and provide support for consistent variability management.

Some authors have defined their own variability management (Berrebi 2013) in the field of aeronautics. In particular, at the level of the architectural organization of the model. The variant management proposed is an alternative to the variation point that has less logic operator than their equivalent with FM. Moreover, (Sierla et al. 2014) shows the applicability of FM in areas other than software, including the HiP-HOPS approach (based on the dysfunctional model) for product line safety analysis (De Oliveira et al. 2014). This variant management is explained in the approach proposed by (De Oliveira et al. 2014), which uses the Hephaestus/Simulink tool (Steiner et al. 2013) to manage variability in a product line model.

(Le put 2016) presents a proposal for integrating the definition steps and the conceptualization of the product line in the field of the ES. Here the product line is presented as a generic product reusable and scalable according to the need. This method definition is based on the properties present in the FM.

Some ES tools and MéDISIS use a modeling paradigm like SysML (Friedenthal 2014) to represent the model of a product or system. Among the works that make it possible to use the SysML language to model a product line, we find in particular (Grönniger et al). This work presents an approach to modeling an automobile system using FM and an internal organic modeling defined by the internal block diagram IBD (SysML). The authors of (Grönniger et al. 2008) propose a translation of a product line model using the FM technique, in SysML language, which makes it possible to model the variables of automobile systems in internal block model in order to be able to analyze the generic system and its variability. In (Höfig et al. 2014), the authors propose a structuring of data by instantiation with a meta-model to obtain a reusable FMECA. However, they do not define the constraints between the variant elements. Through this analysis, we are interested in using the FM and the SysML modeling language to represent a product line model in different technology areas. We must now define the nature of the information needed to build a FMECA.

The authors of (Kajdan & Idasiak 2015) introduce a system model analysis support, defining sets of artifacts (needs, functions, components, and requirements) and dependency relationships between them. This hierarchical view, necessary for a functional or organic analysis, must be adapted to take into account the artifacts introduced by FM. Similarly (David et al. 2010) defines the meta-model supporting the generation of pre-FMECA, it will be adapted to build the parametric FMECA associated with a product line.

(Mazo 2014) shows the possibilities offered by the FM syntax. Indeed, FM can be likened to the superimposition of different product models for which are highlighted the common artifacts and variants, as well as the relationships between the latter which are at the point of variation according to (Le put 2016). These relationships are constraints on the configurations that a product can have.

2.1 *Model concepts*

Figure 1 shows the different concepts needed in system model for realizing dependability analysis. These concepts are identified as follows: the need that is represented in the system need view, the function realized by system represented in functional view, the component that makes up the system and that is represented in component view and the requirement system which can be applied

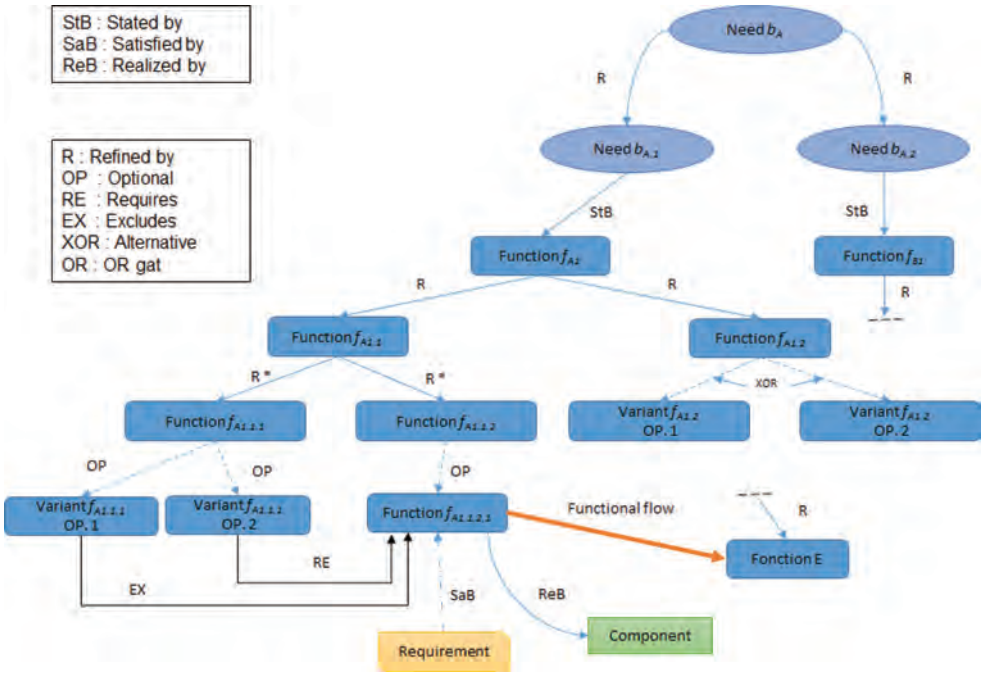

Figure 1. SE mathematical model for product line.

to it (requirement view). They are identified and matched when a model is being established thanks to the following relationships: Stated by (*Need **StB** Function*), Satisfied by (*Function **SaB** Requirement*), Realized by (*Component **ReB** Function*), Refined by (*Concept(x) **R** Concept(x)*). In addition to previous relationships, we introduced or modify six relationships to define the product line SE model.

Either the functions used in the model: $f_i, f_j \in F$:

- Refined by (R or MA): $f_i \xrightarrow{R} f_j$ (noted also f_i R f_j): means that f_i is necessarily refined by f_j.
- Optional (OP): $f_i \xrightarrow{OP} f_j$ (noted also f_i OP f_j): means that f_i is maybe refined by f_j.
- Requires (RE): $f_i \Rightarrow f_j$ (noted also f_i RE f_j): means that the use of f_i implies the use of f_j. Note: f_i do note refine f_j and f_j do note refine f_i.
- Excludes (EX): $f_i \Rightarrow \overline{f_j}$ (noted also f_i EX f_j): means that the use of f_i excluded the use of f_j. Note: $f_i \Rightarrow \overline{f_j}$ is equivalent to $f_j \Rightarrow \overline{f_i}$, or $\overline{(f_i \wedge f_j)}$.
- Alternative (XOR): $f_i \xrightarrow{XOR} f_j$ (noted also f_i XOR f_j): means that only one of f_i and f_j maybe are used. Note: $f_i \Rightarrow \overline{f_j}$ and $f_j \Rightarrow \overline{f_i}$
- OR gate (OR): $f_i \xrightarrow{OR} f_j$ (noted also f_i OR f_j): means that among f_i and f_j minimum one is used.

After identifying the SE relationships needed between the concepts that make up the product line model to conduct a dependability analysis on that model. These new relations will allow describing a new meta-model of the database which helps to generate a PL's FMECA and to formalize its semantics.

This meta-model Figure 2 builds on that presented by (Cressent et al. 2013) and coordinates three categories of information useful for a product line FMECA construction, the information elements derived from the activities of: product SE, product line SE and Safety Analysis. The failure mode part makes it possible to capitalize the decisions and choices of the dependability analysis associated with the studied elements.

2.2 *Product line composition element*

System variants modeling is a basic technique for model based systems engineering for the product line. We need to model variants to: analyze design alternatives; evaluate variants via configurations; product family modeling. So the challenge is to separate the variant from the common part and manage the dependencies.

The product line elements are decomposed into three parts as shown in Figure 3:

– *Core part*: contains the invariant elements of the system and contains all elements that are used in all system configurations. These elements do not depend on any variant element;

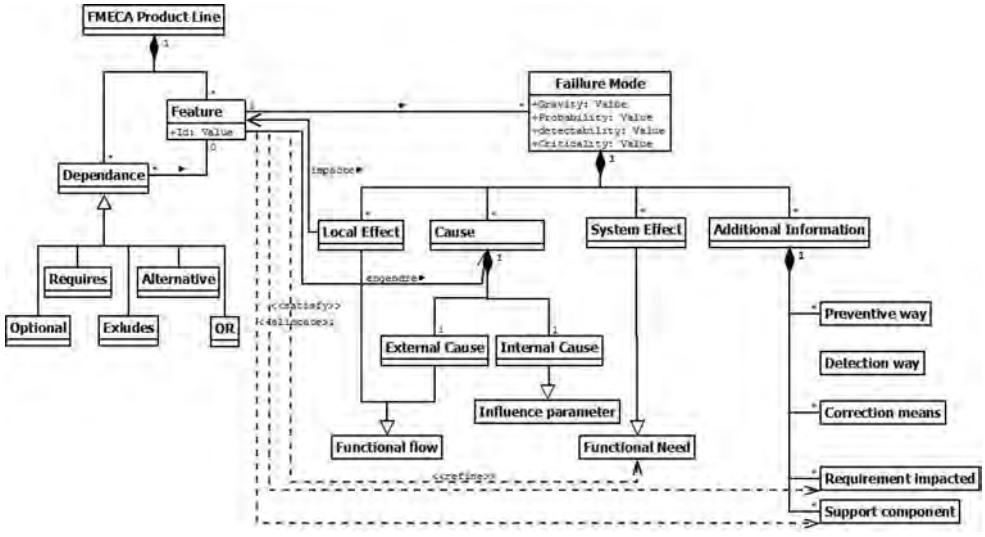

Figure 2. FMECA meta-model of product line.

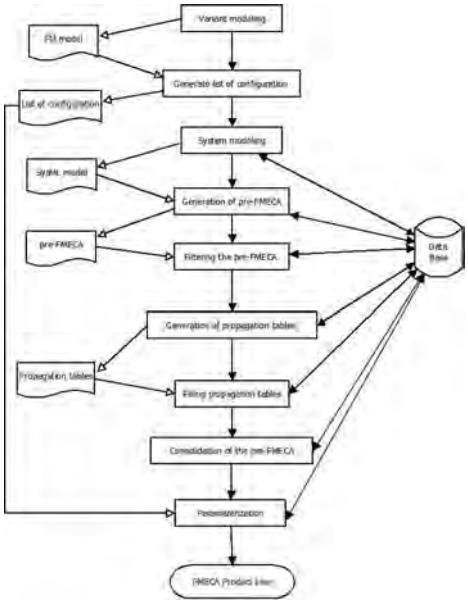

Figure 3. Flowchart describing the proposed process in MéDISIS methodology.

– *Variant-Core Part*: contains the invariant elements of the system which are related at least on variant element;
– *Variants Part*: contains the variant elements of the system, only occurs in some configurations and is part of the system.

This architecture makes it possible to set up a safety analysis strategy on the product line model, with the prioritization of data-flow present in the architecture.

2.3 *Product line safety analysis*

From the dependability standpoint, the system has three types of elements which represents the triplet of a line in the FMECA:

– E_s: Studied element;
– E_c: failure Cause element;
– E_e: failure Effect element.

The variation in product line model may change the analysis for each product configuration because it changes the functional or organic structure of a product. For study the impact of variations in a product, it is necessary to classify the FMECA's lines according to the type triplet studied. Indeed, some of this line can be done earliest in the design process, that is linked to the variability can't be done only when the variability choose is done.

The product line FMECA contains 8 types of line. Each line type in FMECA of product line has a specific characteristic represented in Table 1. The type lines T1 and T8 are composed of the same type of elements set. Such line is analyzed with the same method, which will allow a saving of time in the safety analysis using the standard methodology MéDISIS.

The variation in the product line is presented in line type T2, T3, T4, T5, T6 and T7. This line may include in his triplet (E_c,E_s,E_e) a variant element and core element. T1 and T8 FMECA lines

Table 1. Product line FMECA composition lines.

E_s	E_c	E_e	Line type	Set type
Core	Core or IC	Core	T1	{*Core*}
Core	Core or IC	Variant	T2	{*Core*} ∪ {*Variant*}
Core	Variant	Core	T3	{*Core*} ∪ {*Variant*}
Core	Variant	Variant	T4	{*Core*} ∪ {*Variant*}
Variant	Core	Core	T5	{*Core*} ∪ {*Variant*}
Variant	Core	Variant	T6	{*Core*} ∪ {*Variant*}
Variant	Variant or IC	Core	T7	{*Core*} ∪ {*Variant*}
Variant	Variant or IC	Variant	T8	{*Variant*}

Note. *IC*: Internal Cause (component-specific).

can be analyzed as soon as the core elements or variant elements are designed, even before the end of the total definition of the product line. Whereas, the lines T2 to T7 cannot be analyzed only when the association of the elements variant with the core elements.

3 PRODUCT LINE DEPENDABILITY ANALYSIS PROCESS

This section focuses on the comparison of two dependability analysis processes based on a product line model. For that, we must deploy a sequence of information processing available allowing a progressive contribution of the information held by the system engineer and the dependability engineer, this is what is called a MéDISIS process. These processes are done to make possible the following principles:

– As soon as information is available during an ES step, it must be able to be used in a step of the dependability MéDISIS process;
– As soon as the information is required, the process clearly identifies it so that the expert can provide it.

3.1 *Standard process*

The description of the product line model must be complete in FM modeling to begin the SE process. The FM concepts represent the variation in the model. Our ES process show on Figure 3 begins with FM modeling for the product line which represents a variant model. Among the results obtained of this model, we find a configuration list of the possible product model in the line. The configuration list is composed of two sets of elements, a set of common elements that are represented by the '*Mandatory*' relation in the FM model and a set of variant elements represented by the '*Optional*' relation and the orthogonal relations like '*OR*', '*XOR*' and '*EX*' relations. Selecting variant elements allows you to specify a valid model among the models in the product line. After this step, we will use these configurations for the system modeling of the products of the line in SysML (it is a modeling language specific to system engineering to model different views of the system). A model produced in SysML corresponds to one configuration (one product) in the FM model. The SysML model must respect to some basic modeling rule in (Kajdan & Idasiak 2015) to ensure consistency between the artifacts used in the model.

The next step is to generate a preliminary FMECA (pre-FMECA) from each product model (the SysML "*Functional, Structural and Behavioral View*" model). The pre-FMECA produced is generated automatically thanks to MéDISIS, it is a transformation of the product model.

Each pre-FMECA undergoes a set of operations directed by the dependability engineer in order to obtain the final FMECA. Indeed, pre-FMECA is then finalized by using the MéDISIS consolidation tool. The consolidation process consists of linking several lines of the pre-FMECA. Each merged line makes it possible to follow the propagation of a failure, starting from the internal cause of a studied function to final system effect. This process contains several tasks:

– Annotation and filtering of the pre-FMECA;
– Generation of failures propagation tables;
– Filling failures propagation tables;
– Consolidation of the pre-FMECA.

The first task is to filter the pre-FMECA. For this, the System Engineer chooses what the lines he considers relevant are or not, and he may make comments to record the reasons for his choices or to provide additional information. In order to be taken into account in the other tasks of the consolidation (Versioning tool).

The second task is to generate the failures propagation tables from the pre-FMECA annotated and filtered.

These correspond to the propagation tables of each element of the pre-FMECA. The dependability engineer must choose from the database a failure mode that will be propagated to studied element linked with a functional flow with an upstream element.

The final task of the process is carried out using the propagation tables and the pre-FMECA annotated and filtered. In fact, to do the consolidated pre-FMECA, the process performs two main steps:

– search for possible paths of failure propagation, i.e. consolidated FMECA lines are one of propagation graph paths;
– for each paths (i.e. FMECA lines) each step of the path allows to concatenate the corresponding pre-FMECA lines.

The MéDISIS database has been set up in the processing process. The database allows consistency of dependability analyzes thanks to the architecture of its meta-model that links functional or dysfunctional information to one another. This database interacts during all stages of the process (from filtering, the propagation tables until the consolidation of the FMECA).

The database is used to complete the pre-FMECA of a new product in the product line, a previous product of which had already allowed FMECA generation. Indeed, the database is developed to be initialized during the first generation pre-FMECA after completion by the expert. Subsequently, with each successive generation, this database will allow:

– to restore the filtering of the expert for the elements of the functional analysis that have not been modified;
– highlight the data that has been modified since the previous version.

This database joins the main principals of ISO 26550 'Asset Base', thus makes it possible to offer consistent information throughout the evolution of the products in the line, specifically designed to facilitate the work of the operating safety expert and to guide the realization of fault analysis.

At the end of the process, we get a specific FMECA for each product in the line.

3.2 *Proposed process*

This process is also based on FM model of the product line. The model will be able to represent the different elements of the line product set. It thus makes it possible to identify the common and the variant parts which constitutes the product line.

However, this model does not represent the flow of data between the elements that are necessary to perform a functional analysis on the system that represents the product line. Although this modeling allowed managing variation in the product line, these limitation of FM modeling require completing the FM modeling with SE concepts (c.f. Figure 1).

To ensure a good basis of the study, we used the SysML language to complete the product line model. The product line model in SysML contains all the elements defined in the FM model and describes them from functional and/or organic point of view. This model makes it possible to represent the system model of the product line containing all the variations identified in the FM model. This model is composed in two parts, a Core part which represents the common elements of the set of products of the range which are identified by the relation '*MA*' in the FM model and the variant part which represents the elements varying from the set of products of the range and which are identified by the relation '*OP*' and orthogonal relations ('Alternative' and '*OR*').

The next step is to generate a preliminary FMECA (pre-FMECA) from the product line model. The pre-FMECA has generated automatically thanks to MéDISIS. The latter must be supplemented by the relations resulting from the FM model in order to present the identified constraints of the modeling of the product line. So, the pre-FMECA obtained will contain all the variant part of the product line. This part is identifiable by the relation '*OP*' in the column "Hierarchical relationship" in pre-FMECA. Similarly, the common part is to identify by the relation '*MA*'.

Therefore, the added concepts from the FM model of the product line present in the last two columns of the parametric pre-FMECA underline the association between the variants and the valid configuration scenarios. These concepts present the dependence relationships (hierarchical and orthogonal), in order to be able to build a pre-FMECA which corresponds to a model of the product line. The hierarchical relationship column defines the optionality '*OP*' or the refine '*MA*' (mandatory). These two properties make it possible to identify the invariant elements presented by the sign '*MA*' belonging to the Core part and the variant elements presented by the sign '*OP*' belonging to the variation part. As for the orthogonal relations column, this one represents the relations of implication '*RE*' and exclusion '*EX*' between the elements to be studied (the variable elements). These two properties make it possible to expose the dependencies between the elements. In particular, we have the relations '*OR*' and '*XOR*' which are also considered as orthogonal relations.

Through this overall representation of the FMECA, we will be able to perform the dependability analysis on products derived from the product line without using their model, on which we could apply the existing FMECA MéDISIS process. However for each product, it would be necessary to redo an identical analysis part. However, we seek to capitalize FMECA type analyzes in the case of a product line. These relationships make it possible to represent constraints between a set of elements in the same point of variations.

Parallel elements that have the same input elements and output elements can be implicitly identified. Given that the principle of redundancy that

is presented by the parallel structure makes it possible to provide several resources to achieve the same function. This principle is a sufficient condition for variant modeling. On the other hand, the '*XOR*' relation complements this principle to become a necessary and sufficient condition in the analysis and modeling of the product line.

The next step is to generate the FMECA from the product line, we will follow the same tasks as the first process. The filtering task consists of selecting the FMECA lines used for the analysis (The elements that make up the lines of this pre-FMECA will all be taken into account in the filtering task). After filtering the product line pre-FMECA, the next task is devoted to generating the propagation tables. The same conditions are taken with respect to the standard process. The association between failure modes and the element under study as well as their causes and effects may be specific to each of these configurations. After obtaining the product line FMECA, the final step can be done. This last step which is setting the FMECA using configuration lists to get a FMECA for a specific product.

4 CASE STUDY

The Winch-PL is a lifting system that has an Operational Safety Brake for Hoist Winch (FOST) (Chieb et al. 2017). This system was chosen to evaluate the two approaches based on a proposed product line model to support the automatic analysis of the dependability of several products in the line. The results of applying the proposed approach to Winch-PL products were used as proof of concept.

The system consists of three parts: the transmission part subsystem which includes the two elastic couplings 1 and 2 with torque limiter which is an alternative with the elastic couplings 1, the chain reducer and the drum. The control subsystem includes the electric motor, two speed sensors (one for the drum and another for the motor) this part contains no variation. The safety subsystem is composed by a safety automata to ensure the braking when there will be a shift of speed between the drum and the engine, and finally, the standard brake and the safety brake.

From the product line model of the Figure 4, we obtain 6 valid possible configurations. The six configurations are obtained using the constraints and relationships applied in the product line model. We focus our study only for the three main configurations.

We began our case study by applying the standard process to the study system. We define the Winch-PL product line model in FM, then create system models for each configuration of the three selected from the configuration list obtained. For each model produced, we generate a pre-FMECA in order to carry out the consolidation tasks (c.f. section 3.1). In the end, we obtained FMECA that corresponds on each product in the product line. Using the database we generate a product line FMECA that brings together all FMECA products.

The saving of time during the realization of the first FMECA of the product is the order 50% thanks to the MéDISIS tools. During the realization of the following FMECA, the versioning tool allows the recovery of the information and the elements present in both lines type 1 and 8. The type 2 to 7 of line in FMECA depends on the number of different variability between the two products and of their functional or organic connection with the core elements.

In the second part of our case study, we applied the new process. We followed every step of this process. At the end of the process, a parametric FMECA of the product line FMECA is obtained. Table 2 is the overview of the parametric FMECA of the Winch-PL system. It contains the Id column which represents the line's identifier and the Element column which contains the name of the studied element, the cause, local effect, and failure mode column. This parametric FMECA thus comprises the note column for the selection of the valid lines, the HR and OR columns for the relationships related to the variability and at the end the column type of line for the classification of the lines of the product line.

To obtain a FMECA of a product from the parametric FMECA of the product line, we made the selection of the lines that are product specific and then proceed to the step of propagation of the failures.

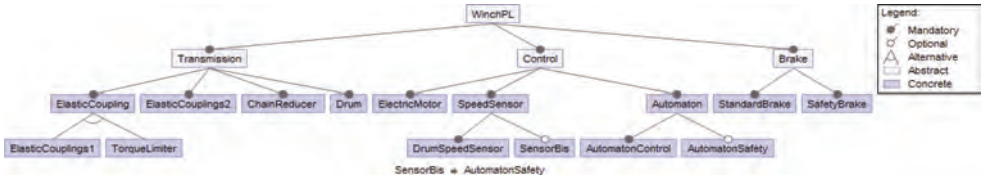

Figure 4. The Winch-PL system in FM.

Table 2. A product line FMECA overview.

Id	Element	Cause	Local Effect	Failure mode	Note	HR	OR	Line type
01	brake	IC	drum	LF	ok	MA	/	T1
02	e_coupling1	IC	ch_reducer	LF	ok	OP	ec1 *xor* tl	T7
03	sensor_bis	IC	saf_automat	LF	ok	OP	as = >sb	T8
04	spd_sensor	IC	automat	LF	ok	MA	/	T1
05	ele_motor	IC	e_coupling1	LF	ok	OP	ec1 *xor* tl	T2
06	trq_limiter	ele_motor	ch_reducer	LF	ok	OP	ec1 *xor* tl	T6

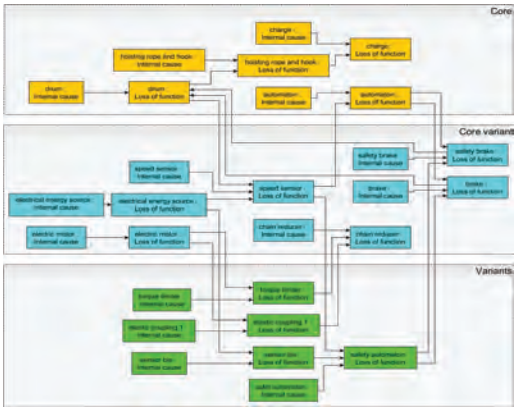

Figure 5. Failure propagation graph for the Winch-PL system.

For example, if we analyze, the "Require" relation who is used to manage the variation of the optional elements 'safety automaton' and 'sensor bis'. The impacted FMECA lines have several types (T6, T7, and T8). These elements must be optional in order to apply this relationship. The alternative choice between two elements is presented in the pre-FMECA of our case study by the relation "*XOR*". For example, the presence of the element '**elastic coupling 1**' excludes the presence of the element '**torque limiter**' and vice versa. Indeed, the analysis is done in the case of a product configuration on a single element among the set of alternative elements. The alternative relationship is applied to optional elements.

Figure 5 shows the failure prognosis graph for Winch-PL system. For our study, we chose only one failure mode that is "loss of function", over the internal failure of the element that is represented by its internal cause. A color code was established to distinguish each part. This graphic representation is automatically generated from pre-FMECA or consolidated FMECA. This representation is synchronized to the standard tabular representation of the FMECA and help the analyst to make his decisions faster.

5 CONCLUSION

When products are defined in the product line, it is difficult to not repeat the same FMECA type study for the common elements of these products. In order to optimize the time needed to produce FMECA for each product, we first studied how product line models influence information needed for SE modeling and then their dependability analysis.

We have adapted the MéDISIS method to take into account a product line model. We compared two automated analysis processes by the MéDISIS tools, the first uses the ability of the MéDISIS versioning tools but uses product models. The second allows to start analyze with a product line model, which makes it possible to realize the dependability analysis earlier.

These results allowed us to have a very important gain in time of analysis time and to be able to reuse parts of this analysis for another product system of the same product line.

In this first experimentation, we note an acceleration of the dependability studies from standard FMECA. Without other feedback, it's difficult to quantify this gain because it depends on the number and the nature of each variability. Moreover, make a FMECA at product line stage allow an earlier starting of dependability studies.

ACKNOWLEDGMENT

The research leading to these results has received funding from the French single inter-ministry fund, sixteenth framework program (F1407032) for the FOST project.

Preliminary safety assessment of circular variable nacelle inlet concepts for aero engines in civil aviation

S. Kazula, D. Grasselt, M. Mischke & K. Höschler
Brandenburg University of Technology, Cottbus, Germany

ABSTRACT: A safe design process and its application are introduced to a concept study for circular variable aero engine inlets. The paper highlights the tasks of inlets, the compromise in designing them and how using variable inlets could solve this compromise and allow for faster and more efficient commercial aircraft. However, high safety and reliability requirements bring up disadvantages. Tackling these disadvantages, a systems engineering approach is complemented by a safety assessment process, according to Aerospace Recommended Practice ARP 4754A. Safety methods that are applicable during early phases of the product development process are presented and applied to develop feasible variable inlet concepts. Hence, safety requirements, potential failure events and resulting failure modes are systematically identified, assessed and mitigated. The mitigation of a failure condition by the means of redundancy within the adjustment control system is presented.

1 INTRODUCTION

Improvement of efficiency and thus emissions as well as travelling speed are major goals in civil aviation (European Commission 2001, European Commission 2011). These goals also depend on the aero engine and its subsystems. One of these subsystems is the inlet that supplies the aero engine with air. The geometry of these inlets is designed as a fixed compromise regarding aerodynamic drag. Significant work on the optimisation of the surface geometry of rigid inlets has been carried out (Luidens et al. 1979, Pierluissi et al. 2011, Albert & Bestle 2014, Schnell & Corroyer 2015), however, a rigid inlet can only achieve the best compromise between optimal geometries for different flight conditions.

Using aero engine inlets with a variable lip and duct geometry for different flight conditions is perceived as a possibility to reduce aerodynamic drag and therefore to have a positive effect on aircraft efficiency and speed (Baier 2015). Therefore, studies, e.g. (Kondor & Moore 2004), da Rocha-Schmidt et al. (2014) and Ozdemir et al. (2015), have been conducted on concepts for variable inlets for commercial aircraft. Additionally, first patents for variable inlets, e.g. US 4075833 and US 5000399, exist.

The only commercial aircraft that used variable inlet systems are the Concorde and the Tupolev Tu-144. Their variable inlet systems consisted of movable ramps and flaps for supersonic flight. Compared to subsonic aircraft both aircraft models had huge deficits concerning range, efficiency and noise, which is why they have been retired.

Within the scope of this study, in contrast to inlets with ramps and flaps, variable inlets with a closed contour that can adjust the lip and duct geometry are investigated. From the beginning, the development process is accompanied by a safety

and reliability process. The aim of this study is to achieve technical feasible concepts for this kind of variable inlets, related to Technology Readiness Level (TRL) 3.

Although those variable inlets have been investigated in first research studies they did not find its way in modern civil aviation yet. This can be justified by the trade-off between the positive and negative effects of the usage of variable inlets on commercial aircraft. Besides additional weight and production costs, negative effects are the increased complexity and thus potential safety and reliability issues. These issues are related to the numerous requirements and boundary conditions regarding inlets.

In contrast to earlier studies, it is reasonable to supplement the utilised systems engineering approach for product development with a safety assessment process to identify and fulfil the safety requirements in aviation right from the beginning. Thusly, possible events as well as resulting failure conditions can be identified and possible safety issues remedied during early phases of the product development process. Such an approach has been carried out successfully within a project concerning coupled actuation systems for thrust reversers and variable nozzles of aero engines (Grasselt & Höschler 2015, Grasselt et al. 2017). As a result, variable aero engine inlets could be utilised in civil aviation, whereby these aircraft could be more efficient and faster, while maintaining high safety and reliability.

Therefore, this paper deals with the safety assessment process within concept development and preliminary design of variable inlets in civil aviation. First, the inlet system and its necessary functions are described. Afterwards, the utilised safety assessment process referring to ARP4761 is introduced and applicable safety analysis methods, e.g. Functional Hazard Assessment (FHA) and Fault Tree Analysis (FTA), are presented. Some selected results of the applied methods are shown and discussed. These results contain the identification of safety-relevant requirements, failure conditions and events. Finally, the influence of this assessment on the design of the investigated concepts is shown.

2 AERO ENGINE INLETS

2.1 *Tasks and implementation*

The main purpose of nacelle inlets for aero engines is to divide the free stream in front of the aero engine, depending on the capture stream tube as a function of operating conditions, into an internal and an external airflow. The external airflow shall flow over the nacelle surface while avoiding flow separation and other sources of drag (Mattingly 2006). The objective of the internal airflow is to supply the aero engine during each operating condition with the correct quantity of air at a desired flow velocity (Rolls-Royce Plc 2015). The axial flow velocity that is required by the compressor system of the aero engine is around Mach 0.5 (MacIsaac & Langton 2011). Hence, a deceleration of the internal airflow is required at flight speeds above Mach 0.5 to ensure a highly efficient and safe operation of the compressor system. Thus, the inner contour of the inlet duct has to be designed as a diffuser (Farokhi 2014). The efficiency and operational stability of the compressor system also depends on the uniformity of the airflow. Therefore, flow separations should be avoided under all conditions, as they can lead to vibration excitations, rotating stall and engine surge concatenated by a loss of thrust and reduced aero engine durability.

Moreover, the fan and compressor induced noise emissions have to be reduced by the inlet, which is achieved by integrating acoustic treatment into the diffuser wall, see Figure 1.

Furthermore, probes for pressure and temperature measurement at the fan level can be part of the inlet. Hence, these measured data must be provided to a flight control system.

Additionally, the inlet has to protect itself and the compressor system from icing and its consequences, e.g. impact damage and flow separation.

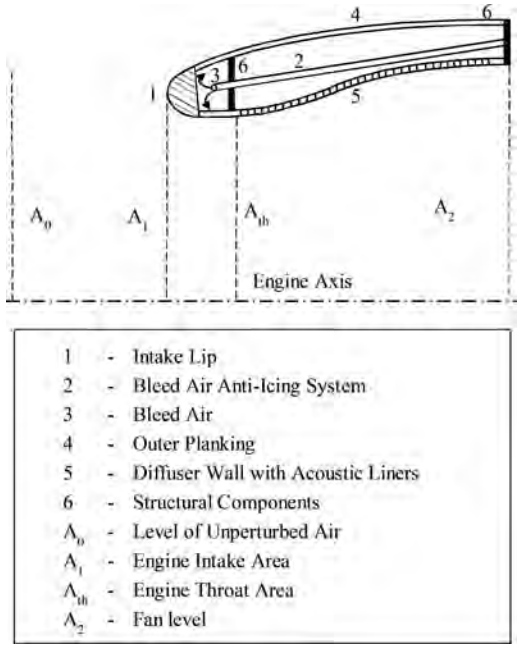

Figure 1. Typical design of a rigid subsonic nacelle inlet.

An anti-icing system is installed in the inlet to ensure this. Most commonly, electrical or bleed air anti ice systems are used (Rolls-Royce Plc 2015). Bleed air anti ice systems transfer hot air from the compressor to the inlet lip to prevent icing. Aluminium is typically used for the inlet lip, due to its good heat conductivity. Furthermore, aluminium is light and resilient to foreign object damage, sand erosion, hail and bird strikes. It is to prove during certification that thrust can be maintained to a certain level to assure that the flight can be safely continued after a single bird strike (Hedayati & Sadighi 2016).

The outer planking as well as the inner boundary with the acoustic linings is made of composites, which minimises weight. Thereby, the inlet should withstand stipulated loads and be robust against damage (EASA 2016).

This way, incidents like the Air France Flight AF-66, where the fan and the engine inlet were separated from the aircraft during flight, should occur at a very low rate to minimise the risk for passengers and crew (Aviation Herald 2017).

2.2 *Trade-off in design and variable inlets*

Ensuring reliable operation during all flight phases must be unified with aerodynamic requirements during the geometric design process of nacelle inlets (Seddon & Goldsmith 1999). On the one hand, the inlet should be highly efficient at high flight velocities above Mach 0.8 during cruise operation. On the other hand, it is necessary to avoid flow separations and hazardous events during take-off and climb operation up to Mach 0.3.

Figure 2 presents, optimal aerodynamic contours of an inlet for different flight conditions. Optimal efficiency at high flight velocities can be achieved by a thin or sharp lip contour combined with a small entry area A_1 to minimise wave and spillage drag (Farokhi 2014). As the entry area is reduced, a longer diffuser is required at high velocities to avoid flow separations. Sharp inlet lips can be used for flight Mach numbers up to 1.6 without significant losses (Farokhi 2014). However, at low aircraft velocities, where high angles of incidence and crosswind can occur, a sharp or thin lip contour is sensitive to flow separations and its potential negative consequences. For these operating conditions, a round and thick inlet lip with a large inlet area is optimal. Such a 'blunt' lip geometry causes higher drag and thus less efficiency during operation at higher flight Mach numbers (Bräunling 2015). Hence, conventional rigid subsonic inlets can only accomplish a compromise geometry that produces increased losses during high flight velocities.

Using a variable inlet, which applies the optimal contour for each flight condition, can improve efficiency and maximum aircraft speed during cruise

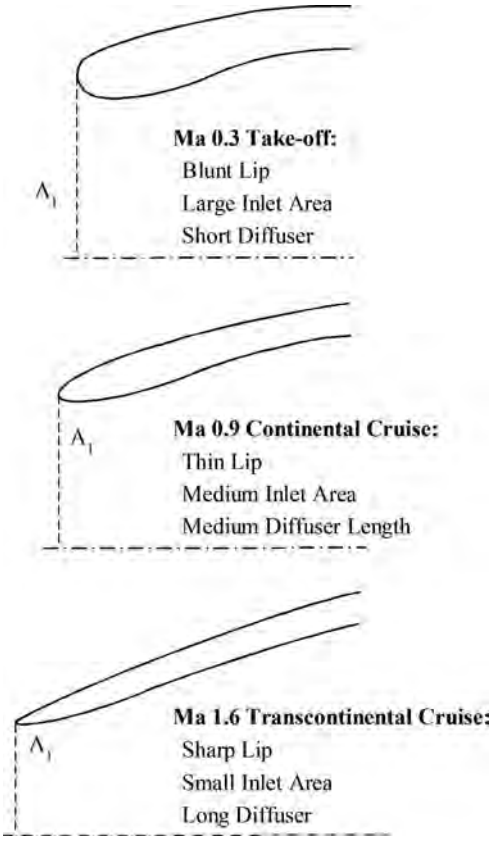

Figure 2. Tendencies of optimal inlet contours for different flight phases and velocities.

flight, while ensuring reliable operation during take-off and climb. However, it needs to be considered that the variation of the inlet presents an additional function, which can entail further reliability and safety issues (SAE Aerospace 2010).

Therefore, variable nacelle inlets for Mach numbers up to 1.6 are investigated focussing on safety and reliability in the context of an internal research project at the chair of Aero Engine Design at the Brandenburg University of Technology. Within the scope of that project, a methodical safe design approach is developed and utilised to perform a feasibility study for concepts for variable inlets up to TRL 3. The safe design approach for variable inlet concepts has been presented in Kazula & Höschler (2017). These concepts can be divided into three geometry adjusting mechanism groups: movement of rigid segments, deformation of elastic surface material and boundary layer control. The preliminary safety assessment in chapter 4 focusses primarily on the first group.

3 SAFE DESIGN APPROACH

3.1 *Systems engineering*

When designing complex systems, it is favourable to utilise a systems engineering approach, e.g. Design for Six Sigma and VDI Guideline 2221. Methodical design approaches allow for improved requirements, interface and risk management, complexity reduction as well as more efficient solving of the design task. Furthermore, weaknesses during development can be minimised. Most methodical design approaches are based on a common iterative structure:

- starting with analyses concerning requirements and functions of the desired product,
- continuing with the allocation of solution principles to functions, preliminary design and preselection of potential solution architectures
- and concluding with detailed design, as well as validation and evaluation of the design.

As the desired product functions in modern industries become increasingly complex, particular safety efforts, such as safety assessments and tests, should be considered to ensure safety and reliability (Bertsche & Lechner 2004).

3.2 *Safety and reliability engineering*

The safety and the reliability of a product play important roles in various industries for reasons of efficiency and business sustainability up to social acceptance. These industries, all of them using a separate safety approach, include the power, rail, shipping, automotive and aviation industry (Verein Deutscher Ingenieure 2000). The most effective time to improve product safety and reliability is during early development phases (Bertsche & Lechner 2004). On the one hand, this can be achieved by using a mature design approach according to design guidelines, which contains a precise and complete requirements document and early testing. On the other hand, analytical methods can be utilised to forecast reliability and to find weaknesses in design. Analytical methods are divided into qualitative methods and quantitative methods. Whereas quantitative methods, e.g. Markov Analysis are used to predict probability of faults, qualitative methods like the FHA are utilised to identify and assess potential failure events and resulting conditions. The safety and reliability of a product can be positively influenced by utilising appropriate safety and reliability methods during each step of the development process. For this purpose, multiple authors, e.g. Bertsche & Lechner (2004) and Meyna & Pauli (2010), as well as organisations, e.g. International Organization for Standardization (2011) in ISO 26262 for automotive industry, propose safety processes for different areas of application.

3.3 *Safety process in aviation*

In aviation, failures could lead to fatal accidents. The risk for accidents can be reduced by improvements in the areas of airplane design, flight operations, maintenance, air traffic management, regulations and design methodologies (Hasson & Crotty 1997). Since the Chicago Convention in 1944, local aviation authorities have been publishing regulations to ensure a safe operation. The European Aviation Safety Agency (EASA), for instance, releases Certification Specifications (CS), e.g. CS-25 – Large Aeroplanes. Paragraph CS-25 AMC 25.1309 describes the safety assessment process in aviation that is based on the process in ARP 4754A (SAE Aerospace 2010) and the methods in ARP 4761 (SAE Aerospace 1996). The design approach for variable inlets of Kazula & Höschler (2017) utilises safety methods of the ARP 4761, see Figure 3.

3.4 *Safety methods for variable inlet development*

The first of the methods presented in Figure 3 is the preparation of a requirements document that is as complete and accurate as possible. Therefore, all requirements that could be introduced by the different stakeholders should be identified and quantified (Sadraey 2013). A product with high safety and reliability as well as low development costs can be achieved during early stages of development by focussing on the Type Certificate Program and its entailed requirements. These requirements are set by the aviation authorities and have been considered within this study. However, the creation of a requirements document is an iterative process as some safety requirements are only identifiable during the safety assessment.

To comply with a requirement, a product must fulfil a function. A function is defined as the conversion of input material, energy or data into desired output (Roth 2001). Within the scope of the development process it is usual to perform a functional structure analysis. This way, the necessary main and secondary functions are identified and broken down up to elementary functions like ‘convert’ or ‘increase’ (Koller & Kastrup 1998). A detailed functional structure can contribute to a high product safety by preventing design flaws, however, a too detailed breakdown should be avoided, as this limits the solution variety during development (Verein Deutscher Ingenieure 1993). Hence, it is reasonable to start with a simple functional structure and iteratively increase the level of detail within the development process (Roth 2000). The most common means to create a functional

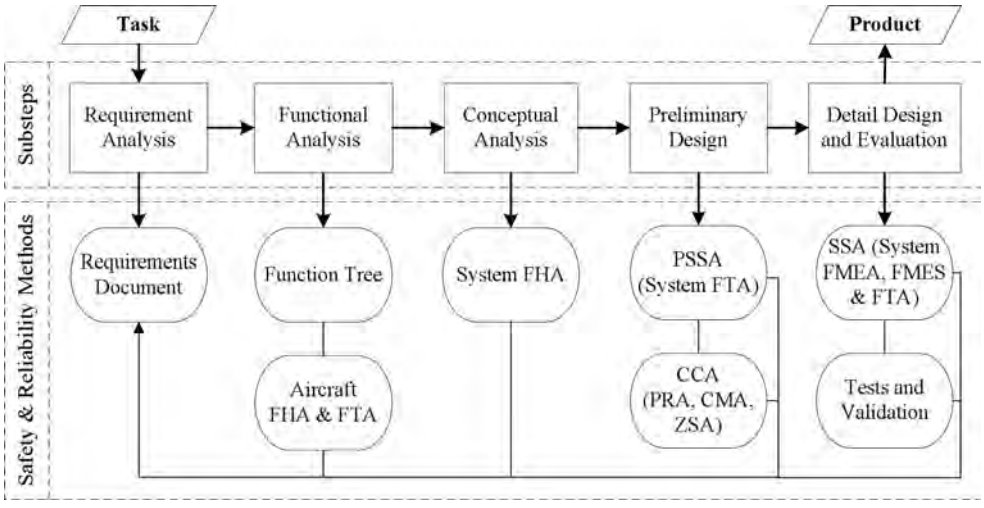

Figure 3. Suitable safety and reliability methods for the separate phases of the methodical design approach.

structure are the FAST-diagram (Function Analysis System Technique), the function net and the function tree. While all of these methods are quite similar, function trees are the recommended choice, because of their structure that synergises well with the Functional Hazard Assessment (FHA) (Verein Deutscher Ingenieure 2000).

The FHA is a qualitative method that should be performed at the beginning of the safety process. At this point, it is reasonable to carry out qualitative safety methods, as they support the systematic investigation of failure conditions, causes and consequences. During later phases of the development process these qualitative methods can be replaced by quantitative methods to investigate reliability in more detail (SAE Aerospace 2010). The main objective of the FHA is to systematically assess functions of a systems and to identify and classify failure conditions as well as their effects. It is performed on Aircraft, System and if required subsystem level. Similar to the function tree, a disadvantage of this method is that it can be difficult for inexperienced users to apply this method appropriately as it allows for an easy deployment of enormous tables and as the classification of hazards can be rather subjective. Kritzinger (2016) describes the advantages of an FHA, one of them being the provision of top level events for the following Preliminary System Safety Assessment (PSSA).

The PSSA is used to analyse which single or multiple system, subsystem or component failures lead to the functional hazards that have been identified within the FHA. This way, safety related design requirements can be determined and concept designs can be evaluated. A PSSA is performed by utilising the Fault Tree Analysis (FTA), the Dependence Diagram (DD) or the Markov Analysis (MA), supplemented by a Common Cause Analysis (CCA) (SAE Aerospace 1996). While the most commonly used FTA, which is an iterative top down method, presents the relationship between failures through logic gates, the DD uses paths and the MA time dependant probability functions. On the one hand, FTA, DD and MA have many advantages, which are discussed for instance in Kritzinger (2016) and SAE Aerospace (1996). On the other hand, all of these methods lack a systematic that assures completeness (Verein Deutscher Ingenieure 2000).

Therefore, within the System Safety Assessment (SSA) it is reasonable to combine the top down method FTA with the bottom up method Failure Modes and Effects Analysis (FMEA), that is simple to use but iterative and time consuming (Kritzinger 2016). The SSA evaluates the compliance of the investigated system with the safety requirements from the PSSA by applying analyses and test methods. In addition to the FMEA, the SSA includes quantitative FTAs and a CCA. A CCA comprises of a Zonal Safety Analysis (ZSA), a Particular Risk Analysis (PRA) and a Common Mode Analysis (CMA). A PRA is utilised to identify external events and a ZSA to determine individual failure modes that can cause hazards. A CMA is used to verify independence of functions, as this is not done within the FHA (SAE Aerospace 1996). Finally, tests must be performed to validate the results from earlier analyses and to comply with the requirements set by the aviation authorities. It is reasonable that the less experience

the product developer has, the more tests should be performed for a successful certification.

4 SELECTED RESULTS

4.1 *Function trees*

The Aircraft has to fulfil different 1st level or top level functions according to SAE Aerospace (2010) and Kritzinger (2016), one of them being 'control thrust', see Figure 4. Thrust control is achieved by generating, adjusting, ensuring and determining thrust. The inlet system influences all of these functions, e.g. to generate thrust, the inlet system has to provide the aero engine with an airflow.

The function tree that is presented in Figure 5 contains a few important functions of the nacelle inlet system. Different flight phases require for different geometries to achieve minimal drag and an internal airflow with high uniformity and the appropriate velocity. An inlet geometry adjustment system can improve the achievability of these functional requirements. Additionally, an adjustment system could be used to prevent negative effects of icing by detaching ice. Furthermore, it could utilise existing systems for data and energy transfer. The influence of the variability on other inlet subsystems has to be investigated, as the inlet would not be a rigid enclosed structure anymore and the installation space for acoustic treatment

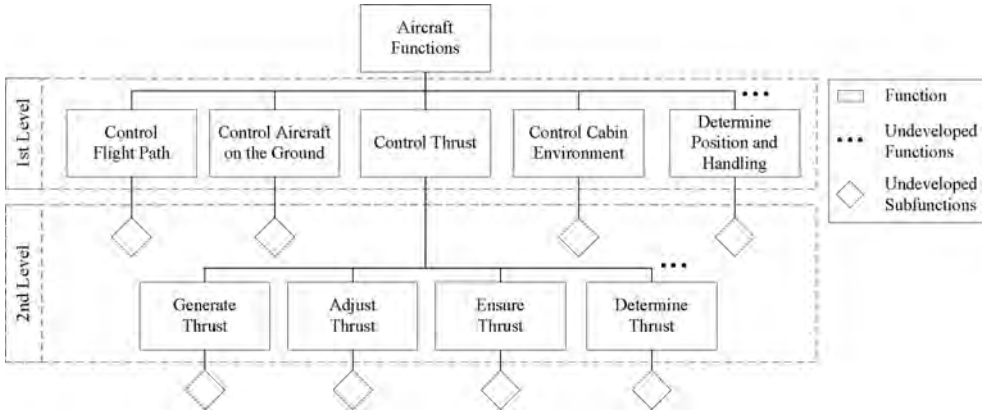

Figure 4. Simplified aircraft function tree.

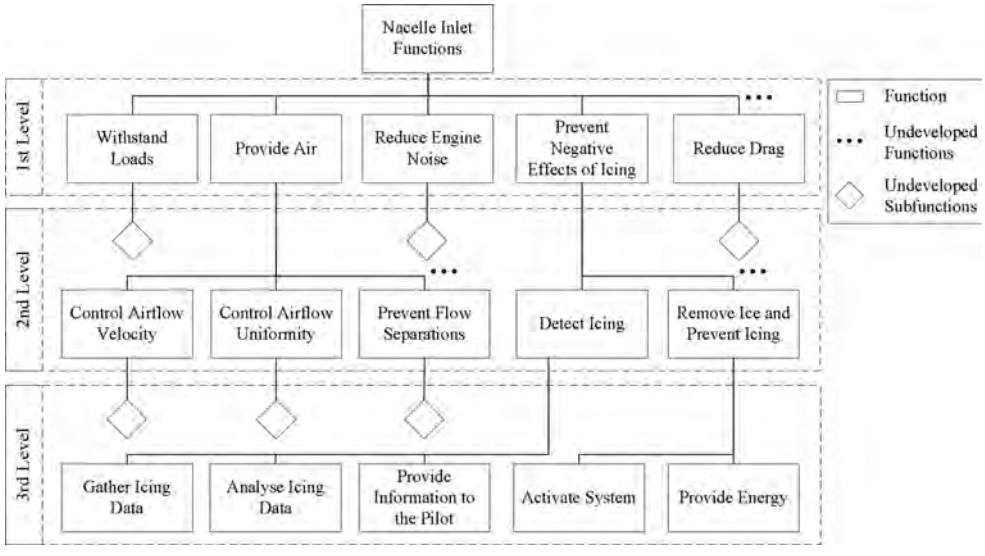

Figure 5. Simplified aero engine nacelle inlet system function tree.

could be reduced. The essential functions of an inlet adjustment system are change and locking of the inlet geometry as well as gathering, transferring and processing geometry data.

4.2 *FHA*

The function trees can be used to determine the input for the FHA. For clarity reasons, only the function 'adjust inlet geometry' and its impact on the aircraft is presented in the following. After identifying the functions, associated failure conditions and their effects must to be determined regarding single and multiple failures during normal, e.g. take-off, climb and cruise, as well as special conditions, e.g. windmilling. The main failure condition of the adjustment system is that an undesired geometry is adjusted, what could affect a single engine or all engines.

A further categorisation is possible concerning:

- which geometry is adjusted,
- is the system either incapable to maintain the desired geometry or to adjust the geometry on time or in general,
- is the failure occurring either announced or unannounced, either abruptly or anticipated.

Then, the effects of these failure conditions must be identified and classified. Possible effects of the presented failure conditions are 'loss of thrust' or 'reduced efficiency'. The classification is conducted according to CS-25 AMC 25.1309 regarding the severity of an effect on aircraft, crew or occupants and is divided into 'catastrophic', 'hazardous', 'major', 'minor' and 'no safety effect'. Each of these classifications entails a specific probability requirement concerning occurrence of a failure mode. Table 1 presents the failure classification for an undesired, abrupt but announced

Table 1. Failure classification for the event 'undesired geometry is adjusted' on a single engine.

		Probability requirement
Flight phase	Classification	Events per flight hour
Start	No Safety Effect	No Probability Requirement
Idle	No Safety Effect	No Probability Requirement
Taxi	No Safety Effect	No Probability Requirement
Take-off	Minor	<1.0E-03
RTO	No Safety Effect	No Probability Requirement
Climb	Minor	<1.0E-03
Cruise	No Safety Effect	No Probability Requirement
Descent	No Safety Effect	No Probability Requirement
Approach	No Safety Effect	No Probability Requirement
Go-around	Minor	<1.0E-03
Landing	No Safety Effect	No Probability Requirement
Brake	No Safety Effect	No Probability Requirement

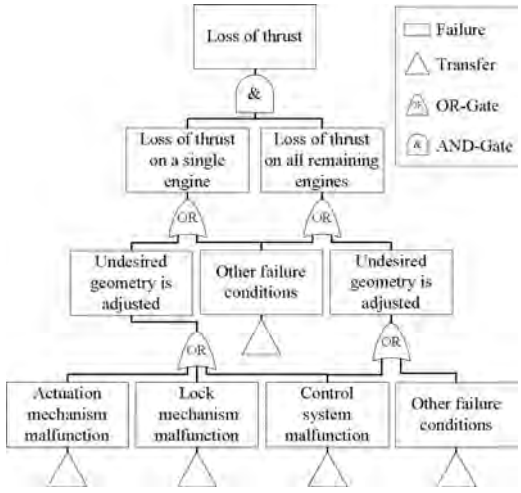

Figure 6. Simplified fault tree for the inlet adjustment system.

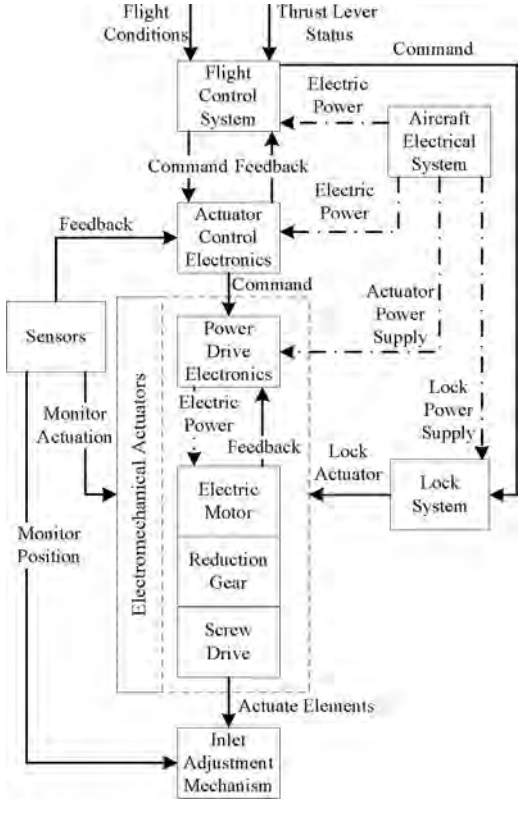

Figure 7. Control flow chart for a variable inlet system.

adjustment of a sharp thin cruise geometry on a single engine. Commercial aircraft must be able to fly with one engine inoperative. A failure of the adjustment system of a single engine can only cause surge and therefore loss of thrust on a single engine. Hence, this event only leads to a slight reduction of the aircraft functional capability and a slight increase in workload for the flight crew. However, a failure of the adjustment system on multiple engines could lead to loss of thrust on more than one engine. For instance, during take-off this can result in a rejected take-off (RTO). This is classified as a hazardous mode with a probability requirement of less than 1.0E-07 events per flight hour (EASA 2016).

4.3 *FTA and failure prevention*

The fault tree in Figure 6 shows how the hazardous event 'loss of thrust' is based on the loss of thrust on all engines. This is caused by the incapability to provide air sufficiently due to the adjustment of an undesired inlet geometry. This could be caused by a single control system failure.

Single failure conditions can be avoided by a redundant design. This can be achieved by design modifications. Therefore, the adjustment system is protected by a locking system, which is independent from the actuator control electronics, see Figure 7. Furthermore, the individual engines should be controlled separately.

5 CONCLUSIONS

While being able to improve the speed and efficiency of modern aircraft, variable inlets did not find its way in commercial aviation yet due to potential safety and reliability issues. These issues can be reduced by applying a coupled design and safety process that is integrated in the early phases of the product development process. Moreover, the methods of this process are discussed and an FHA as well as an FTA are applied to variable inlet concepts. This results in the identification of failure probability requirements and design adjustments.

It is still impossible to ensure that every failure is identified during the development, but the probability of design faults can be reduced significantly. During the investigation of variable inlets, the bottom up method FMEA should be applied to complement the top down approach of the FTA. A CCA, especially a PRA, should be performed to investigate independence and external events. Finally, validation and verification tests must be carried out in consultation with the aviation authorities.

It should be considered that some safety regulations, guidelines and expert opinions could be too conservative and thus limit the solution variety of new technologies. Furthermore, safety and reliability is often neglected during academic studies.

Due to the safe design approach of this study, function trees, an FHA and an FTA have been described in this paper. This results in the identification of safety requirements and design faults. These faults can be mitigated by the means of redundancy within the adjustment control system. This way, the negative effects of variable inlets can be reduced during early stages of the product development. Hence, variable inlets could be applied in commercial aviation. This could allow for faster and more efficient aircraft, while maintaining safety and reliability. Moreover, the safe design approach could be applied to other product developments in aviation or other industries, as there is currently no general safe design approach.

ABSTRACT: Multi-State Phased-Mission Systems (MS-PMSs) are Multi-State Systems (MSSs) that accomplish different missions in a series of consecutive and non-overlapping time durations, called phases. Many practical PMSs are non-repairable, such as the spacecraft working in the outer space. In the non-repairable MS-PMS, the dependence among phases are more complicated, like the components' states cannot be better in the latter phases. The paths of the MMDD model generated by traditional MMDD manipulation rules cannot consider this kind of dependency and part of the paths may have the self-conflict problems. To solve this problem, a MMDD algorithm for MS-PMS and PMS-MMDD model are proposed. By the PMS-MMDD model, the system MMDD model can be generated without any additional steps. At last, the Monte Carlo simulation method is used to certify the proposed PMS-MMDD model.

1 INTRODUCTION

The PMSs are systems that need to complete different missions in multiple, consecutive, non-overlapping time durations, known as phases (Xing and Amari, 2008). The PMSs are commonly seen in the aerospace industry, like the spacecraft, whose lifetime can be divided into several phases: launching, orbit-transfer, on-orbit operation, back-to-earth. The systems/components in the PMSs can exhibit multiple performance levels or states, called MS-PMS. The reliability of the MS-PMS is defined as the probability that the system state stays above the failure states in all phases. The challenges in analyzing the MS-PMS are mainly due to two aspects (Shrestha et al., 2011):

1. The phase dependence, the states at the end of one phase should be equal to the beginning of the consecutive phase and the components failed in one phase will remain in the failure state in the following phases;
2. The dynamic behaviors, the working components, system structure and the working environment are different in different phases, so the distinct model for each phase are necessary.

The existing PMS analysis methods can be divided into two classes: the analytical methods and the simulation methods. The analytical methods can be further categorized into three types: (1) the combinatorial methods, like the Binary Decision Diagram (BDD), (Zang et al., 1999), or MMDD method (Shrestha et al., 2011); (2) state space model, such as the Continuous Time Markov Chain (CTMC) (Wu et al., 2012); (3) modular method (Ou and Dugan, 2004), which combines the combinatorial methods and the state space model and possess advantages of both. But most of the existing methods are limited into the binary state systems/components on the other hand, many research efforts have been developed in the analysis of the Multi-State Systems (MSSs) (Liu et al., 2008, Liu and Huang, 2010), but all of these works do not consider the system multi-phased behaviors.

The researches on the MS-PMS are very few until now due to the complexity of both PMS and MSS. And the multi-state behaviors renders more

complicated the phase dependence and the dynamics leading to the state explosion problem. Recently, the MMDD method is used to assess reliability of MS-PMS with multi-state repairable components (Shrestha et al., 2011). The system MMDD model is generated by the general MMDD manipulation rules and all the path probabilities are evaluated by the CTMC. In the paper by (Shrestha et al., 2011), only the repairable MS-PMS is considered and only the first kind of the phase dependence (the state of component at the beginning of one phase should be identical to the state at the end of last phase) is considered. So the paths generated by this method may have the self-conflict problems in the non-repairable PMS. In this paper, a MMDD algorithm for the MS-PMS and PMS-MMDD model are proposed to evaluate system state probabilities of the MS-PMS. By the MMDD algorithm for the MS-PMS, the self-conflict paths can be cancelled automatically in the model generation process without any additional steps, which makes the system modelling more efficiently.

This paper is organized as follows. Sections 2 introduces the basic concepts of MMDD model. Section 3 introduces a simple example in detail. In section 4, the proposed MMDD algorithm and the model generation process by the PMS-MMDD model are introduced. The path probability evaluation method and the result certification are shown in section 5. The section 6 gives the conclusions and future works.

2 BASIC CONCEPTS OF MMDD MODEL

The MMDD model, an extension of the BDD, is proposed in (Shrestha et al., 2011) and applied to analyze the MSS and MS-PMS. Like BDD, MMDD is also based on the Shannon's decomposition and manipulation of the multi-valued logic function. The multi-valued logic function F of component A with m states is,

$$\begin{aligned} F &= case\left(A, F_1, F_2, \cdots\cdots, F_m\right) \\ &= A_1 \bullet F_{x_A=1} + A_2 \bullet F_{x_A=2} + \cdots\cdots + A_m \bullet F_{x_A=m} \end{aligned} \tag{1}$$

There are two kinds of nodes in the MMDD model: (1) the non-sink node, which is labeled with a multivalued variable x_A, which representing the behaviors of component A, and its corresponding multiple outgoing edges; (2) the sink node, '0' and '1', representing the system is in one specific state or not. And each disjoint path from the root node to the sink node '1' represent the system is in one specific state.

The generation of the MMDD model is based on the manipulation rule (Xing and Dai, 2009),

$$\begin{aligned} g \lozenge h &= case\left(x, G_1, \cdots G_m\right) \lozenge casey\left(y, H_1, \cdots H_m\right) \\ &= \begin{cases} case\left(x, G_1 \lozenge H_1, \cdots, G_m \lozenge H_m\right), index\left(x\right) = index\left(y\right) \\ case\left(x, G_1 \lozenge h, \cdots, G_m \lozenge h\right) \quad , index\left(x\right) < index\left(y\right) \\ case\left(y, g \lozenge H_1, \cdots, g \lozenge H_m\right) \quad , index\left(x\right) > index\left(y\right) \end{cases} \end{aligned} \tag{2}$$

where $\lozenge$ represent a logic operation (OR, AND) and the *index* represents the predefined variable orders.

3 A SIMPLE EXAMPLE

In this paper, the non-repairable MS-PMS is studied, which is common seen in the aerospace industry. A simple example system is used to show the proposed method. The system consists of three components, A, B and C and their state transition graphs are shown in Figure 1. The $\lambda_{i,j}$ represents the transition rate of the component transit from state i to state j. And the parameters are shown in Table 1.

The example PMS consists of three consecutive missions phases: τ_1, τ_2 and τ_3. Mission τ_1 needs component A in state 3 or component C in state 2; Mission τ_2 needs component A above state 2 or component B in state 3; Mission τ_3 needs component B above state 2 or component C in state 2. The entire mission is successful if all the three consecutive missions are completed successfully. The system structure function describing can be specified as,

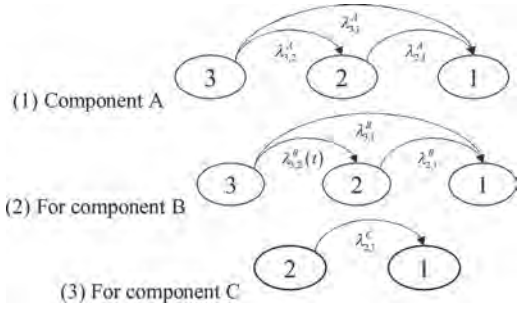

Figure 1. The state transition graphs for the components in the example system.

Table 1. The parameters of components in the example system.

	A	B	C
$\lambda_{3,2}$	1/100	1/120	
$\lambda_{3,1}$	1/150	1/160	
$\lambda_{2,1}$	1/200	1/200	1/160

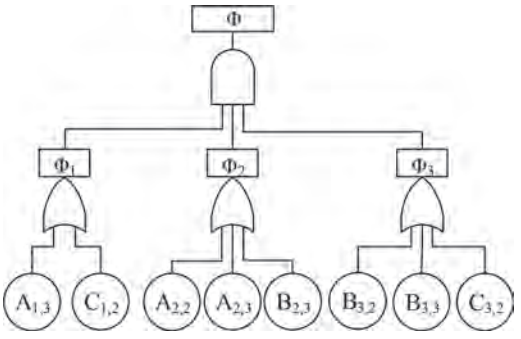

Figure 2. The MFT model for the example system.

$$\Phi = \Phi_1 \cdot \Phi_2 \cdot \Phi_3 = \left(A_{1,3} + C_{1,2}\right)\left(A_{2,2} + A_{2,3} + B_{2,3}\right)\left(B_{3,2} + B_{3,3} + C_{3,2}\right) \quad (3)$$

According to the descriptions of the system structure above, the multistate fault tree (MFT) model for the example system is shown in Figure 2.

Each of the bottom event in Figure 2 represents one component in one specific phase and state. For example, $A_{1,3}$ means component A stays in state 3 in phase 1.

4 MMDD MODEL FOR MS-PMS

4.1 *The MMDD algorithm for PMS*

In the paper (Shrestha et al., 2011), only the repairable MS-PMS is studied and the MMDD model is generated by the general MMDD manipulation rules, but part of paths have self-conflict problems in the non-repairable PMS. For example, in the path '$N_{10} \to N_9 \to N_4 \to N_1 \to 1$' of Figure 6 in the paper (Shrestha et al., 2011), the component c is in state 1 in phase 3 and in state 0 in phase 1 simultaneously, which cannot happen in the non-repairable MS-PMS. To address this problem, a MMDD algorithm for the MS-PMS extended from the BDD algorithm for the binary nonrepairable PMS (Zang et al., 1999) is proposed. Firstly, a phase algebra for the MS-PMS is proposed based on the phase dependency among phases in the non-repairable MS-PMS, shown in Table 2.

The physical meaning of the elements in Table 2 are,

1. $A_{i,m} \bullet A_{j,m} \to A_{j,m}$, component A is in the perfect state m both in phase i and phase j implies component A is in state m in phase j.
2. $A_{i,1} \bullet A_{j,1} \to A_{j,1}$, component A is in worst state 1 both in phase i and phase j implies component A is in worst state 1 in phase i.

Table 2. The phase algebra for the MS-PMS.

$A_{i,m} \bullet A_{j,m} \to A_{j,m}$	$A_{i,m} + A_{j,m} \to A_{i,m}$
$A_{i,1} \bullet A_{j,1} \to A_{i,1}$	$A_{i,1} + A_{j,1} \to A_{j,1}$
$A_{i,S_i} \bullet A_{j,S_j} \to 0$ $(1 \le S_i < S_j < m)$	$A_{i,S_i} + A_{j,S_j} \to 1$ $(1 \le S_j < S_i < m)$

3. $A_{i,S_i} \bullet A_{j,S_j} \to 0$ $(1 \le S_i < S_j < m)$, component A is in state S_i in phase i and is in state S_i in phase j simultaneously is not exist.
4. $A_{i,m} + A_{j,m} \to A_{i,m}$, component A is in the perfect state m in phase i or phase j implies component A is in state m in phase i.
5. $A_{i,1} + A_{j,1} \to A_{j,1}$, component A is in state 1 in phase i or phase j implies component A is in state 1 in phase j.
6. $A_{i,S_i} + A_{j,S_j}$, has no physical meaning if the components are not repairable.

4.2 *The MMDD operation for the MS-PMS*

With the above phase algebra for MS-PMS, the phase dependence operation (PDO) for the MS-PMS can be derived for both the forward PDO and backward PDO: (1) forward PDO, the order of the variables are the same as the phase order; (2) backward PDO, the order of the variables is reverse of the phase order (Zang et al., 1999).

Assume that component A with m states works both in phase i and phase j $(i < j)$, and the case format of component in phase i and phase j, E_i and E_j, can be written as,

$$E_i = case\left(A_i, \left(E_i\right)_{A_{i,m}}, \cdots, \left(E_i\right)_{A_{i,1}}\right) = case\left(A_i, G_m, \cdots, G_1\right) \quad (4)$$

$$E_j = case\left(A_j, \left(E_j\right)_{A_{j,m}}, \cdots, \left(E_j\right)_{A_{j,1}}\right) = case\left(A_j, H_m, \cdots, H_1\right) \quad (5)$$

where $A_{i,m}, G_m = 1$ means component A is in state m in phase j and $A_{i,m}, G_m = 0$ means component A is not in state m in phase j.

For the forward PDO $\left(index\left(A_i < A_j\right)\right)$, the proposed MMDD manipulation rule for the MS-PMS is,

$$case\left(A_i, G_m, \cdots, G_1\right) \Diamond case\left(A_j, H_m, \cdots, H_1\right) = case\left(A_i, G_m \Diamond E_{j,1}, G_{m-1} \Diamond E_{j,2}, \cdots, G_1 \Diamond H_1\right) \quad (6)$$

where

$$E_{j,n} = case\left(A_j, \underbrace{0, \cdots, 0}_{n-1}, H_{m-n+1}, \cdots, H_2, H_1\right), \ 1 \le n \le m$$

For the backward PDO $\left(index\left(A_i > A_j\right)\right)$, the proposed MMDD manipulation rule for the MS-PMS is,

$$\begin{aligned} &case\left(A_i, G_m, \cdots, G_1\right) \Diamond case\left(A_j, H_m, \cdots, H_1\right) \\ &= case\left(A_j, G_m \Diamond H_m, E_{i,2} \Diamond H_{m-1}, \cdots, E_{i,m} \Diamond H_1\right) \end{aligned} \tag{7}$$

where

$$E_{i,n} = case\left(A_i, G_m, G_{m-1}, \cdots, G_{m-n+1}, \underbrace{0, \cdots, 0}_{m-n} \right),\ 1 \le n \le m$$

5 SYSTEM EVALUATION

In this section, the system evaluation process by the proposed MMDD model and CTMC are shown in detail, with the following two steps: model generation and path probabilities evaluation.

5.1 *Model generation*

Firstly, the basic events of the MFT model in Figure 2 are transferred into MMDD basic events. For example, $case\left(A_i,1,0,0\right)$, $case\left(A_i,0,1,0\right)$, $case\left(A_i,0,0,1\right)$ represent component A in state 3, state 2 and state 1 in phase i, respectively. Then, with the MMDD basic events and the system structure shown in Figure 2, the MMDD models for each phase are generated by the general MMDD manipulation rules. The MMDD models for phases of the example system are shown in Figure 3. Then, the system MMDD model is generated by the proposed MMDD model for the MS-PMS, shown in Figure 4.

The grouped solid lines and dashed lines in Figure 4 represent the working states and failure states of the corresponding non-sink nodes. According to the definition of the MMDD model, each path from the root node to the sink node '1' represent that the system stays in one specific state in all phases. From Figure 4, we can get all the paths that represent the example system stays in the working state in all 3 phases. There are totally 9 paths, shown as,

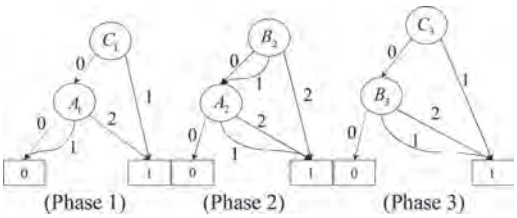

Figure 3. The MMDD model for each phase.

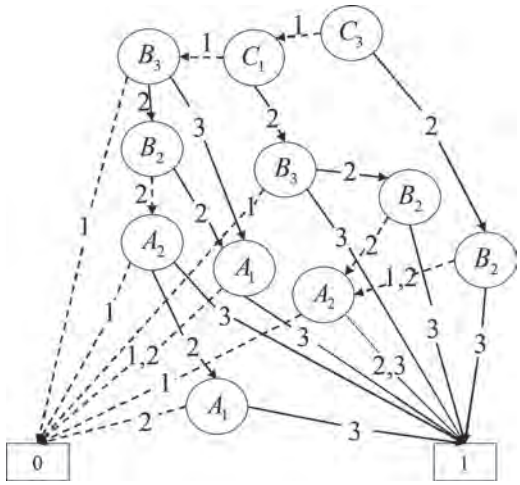

Figure 4. The grouped MMDD model for all three phases of the example PMS.

$$\begin{aligned} &\eta_1 = C_{3,(2)}B_{2,(3)},\ \eta_2 = C_{3,(2)}B_{2,(1,2)}A_{2,(2,3)} \\ &\eta_3 = C_{3,(1)}C_{1,(2)}B_{3,(3)},\ \eta_4 = C_{3,(1)}C_{1,(2)}B_{3,(2)}B_{2,(3)} \\ &\eta_5 = C_{3,(1)}C_{1,(2)}B_{3,(2)}B_{2,(2)}A_{2,(2,3)} \\ &\eta_6 = C_{3,(1)}C_{1,(1)}B_{3,(3)}A_{1,(3)} \\ &\eta_7 = C_{3,(1)}C_{1,(1)}B_{3,(2)}B_{2,(3)}A_{1,(3)} \\ &\eta_8 = C_{3,(1)}C_{1,(1)}B_{3,(2)}B_{2,(2)}A_{2,(3)} \\ &\eta_9 = C_{3,(1)}C_{1,(1)}B_{3,(2)}B_{2,(2)}A_{2,(2)}A_{1,(3)} \end{aligned} \tag{8}$$

5.2 *Path probability evaluation*

In this section, the probabilities of the disjoint paths generated in the last section are evaluated by the CTMC. All the components are independent on each other, so the probability of each path can be evaluated by multiplying the components' transition probabilities in the different phases. For example, the probability of path η_6 can be evaluated as,

$$\begin{aligned} \Pr\left(\eta_6 = 1\right) &= \Pr\left(C_{3,(1)}C_{1,(2)}B_{3,(3)}A_{1,(3)}\right) \\ &= \Pr\left(C_{1,(2)}C_{3,(1)}\right)\Pr\left(B_{3,(3)}\right)\Pr\left(A_{1,(3)}\right) \end{aligned} \tag{9}$$

In this paper, only the non-repairable components are studied, so the state of one component cannot be better in the latter phases and the state at the beginning of one phase should be equal to the end of last phase. Let S_j represent the state of one component in phase $i\left(1 \le i \le m\right)$. Due to the memoryless property of the homogeneous CTMC (Lisnianski and Levitin, 2003), the path probability of the component can be evaluated as,

$$\begin{aligned}&\Pr\left(S_1=c_1,S_2=c_2,\cdots S_m=c_m\right)\\&=\Pr_{N,c_1}\left(T_1\right)\Pr_{i_1,c_2}\left(T_1\right)\cdots\Pr_{i_{m-1},c_m}\left(T_m\right)\end{aligned}\tag{10}$$

where c_i means the specific state of component A at the end of phase i and $c_i\in[1,2,\cdots,N]$.

For example, in path η_6 component C is in state 2 in phase 1 and transit to state 1 in phase 3,

$$\Pr\left(C_{1,(2)}C_{3,(1)}\right)=p^c_{2,1}\left(T_1\right)\cdot p^c_{1,1}\left(T_3\right)\tag{11}$$

Component B is in state 3 in phase 3 and it works both in phase 2 and phase 3, so component B is in state 3 in both phase 2 and phase 3,

$$\Pr\left(B_{3,(3)}\right)=p^B_{3,3}\left(T_2+T_3\right)\tag{12}$$

Component A is in state 3 in phase 1,

$$\Pr\left(A_{3,(3)}\right)=p^A_{3,3}\left(T_1\right)\tag{13}$$

$\boldsymbol{P}(t)$, in which $P_{i,j}(t)$ represent the probability of component A transit from state i to state j during the time interval $[0,t]$. $p_{i,j}(t)$ can be evaluated by the CTMC with the state transition rate $\lambda_{i,j}$,

$$p^A_{i,j}(t)=\exp(\boldsymbol{Q}t)\tag{14}$$

$$\boldsymbol{Q}=\left|\lambda_{i,j}\right|\tag{15}$$

Then, the probability of path η_6 can be computed as,

$$\begin{aligned}\Pr\left(\eta_6=1\right)&=\Pr\left(C_{1,(2)}C_{3,(1)}\right)\Pr\left(B_{3,(3)}\right)\Pr\left(A_{1,(3)}\right)\\&=0.0228\end{aligned}\tag{16}$$

Similarly, the probabilities of other eight paths can be evaluated, and the reliability of the example system at the end of phase 3 can be computed as,

$$R_{sys}=\sum_{i=1}^{9}\Pr\left(\eta_i=1\right)=0.5819\tag{17}$$

5.3 *MC simulation validation*

In the previous sections, the reliability of the example PMS is evaluated by the PMS-MMDD model and the CTMC. To certify the correctness of these methods, the MC simulation method (Zio, 2013) is applied. The components' transition time and system failure time realizations simulation procedure is shown in Figure 5.

Then, the system reliability can be evaluated by statistically analyzing the system failure time realizations. In this paper, the amount of the realization is $N_{\max}=2\cdot10^6$. And the system reliability evaluated by the simulation method is,

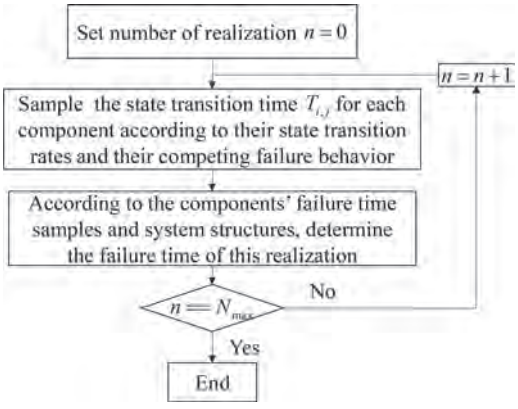

Figure 5. The grouped MMDD model for all three phases of the example PMS.

$$R^{sim}_{sys}=0.5817\tag{18}$$

Furthermore, the calculation time of the analytical approach and simulation approach are 0.07s and 74s, respectively, which illustrate that the analytical approach is more computationally efficient.

6 CONCLUSIONS AND FUTURE WORKS

In this paper, the non-repairable MS-PMSs are studied. In the non-repairable MS-PMS, the components' states cannot be better in the latter phases. To address this dependency in the system modelling, a MMDD algorithm for PMS and MMDD-PMS model are proposed to analyze the reliability of the MS-PMS with non-repairable components. By the proposed method, the self-conflict paths can be cancelled automatically and the system MMDD model can be generated without any additional steps. With the paths from the MMDD model, the system reliability is evaluated by adding all the path probabilities evaluated by the CTMC. At last, the result is certified by the MC simulation method and the comparison also illustrate the computational efficiency of the proposed analytical method.

Similar to the PMS-BDD model, the scale of the MMDD model is also heavily dependent on the predefined variable orders. As a part of the future works, the relationship between variable orders and the model scale of the PMS-MMDD model will be explored. On the other hand, the non-exponential transition time distribution is more general

in practice, the reliability evaluation considering non-exponential transition time distribution will be studied.

Reliability modeling for dependent competing failure processes between component degradation and system performance deterioration

Yugang Zhang, Jingyi Liu, Bifeng Song & Tianxiang Yu
School of Aeronautics, Northwestern Polytechnical University, Xi'an, China

ABSTRACT: Mechanical systems are usually subjected to multiple dependent competing failure processes. The processes were categorized two type of failures: soft failure caused by continuous component degradation together with additional abrupt degradation due to a shock process, and hard failure caused by the instantaneous stress from the same shock process. The models in open literature have simulated the aforementioned processes. However in practice, some mechanical systems have phenomena that all the components still in the good states, but the system functions cannot meet the requirements of performance. This paper studies reliability for multi-components system subject to dependent competing risks of components degradation, components random stress shocks and system performances deterioration. These failure processes are dependent in three respects: 1) the component stress shocks over certain critical threshold affects the component degradation process, 2) the component degradation impacts the component catastrophic failure threshold level, and 3) the component degradation influences the system performances. Based on component degradation, component random shocks and system performance modeling, a reliability model for systems considering three dependent failure patterns is derived. Then an application example using an electro-mechanical system illustrates the effectiveness of the proposed approach with sensitivity analysis. The results whether considering system performance deterioration or not are compared and discussed.

1 INTRODUCTION

The mechanical system is subjected to external random loads during the working process. At the same time there are internal wear, fatigue, aging degradation processes. The system is under multiple failure processes including catastrophic failures and degradation failures due to external shock loads and degradation processes. The two failure processes are dependent and competing against each other. Correlation means that there is a mutual influence between the two failures and competition means that any type of failure can result in system failure. The catastrophic failure mode (fracture, yielding, plastic deformation, etc. also called hard failure mode) and degradation failure mode (wear, corrosion, fatigue, and etc. also called soft failure mode) are competing with each other and whichever occurs first may make system fail. It is impossible that both risk modes occurs simultaneously due to the competing (Li & Pham 2005).

In the literature, there mainly exist five typical categories of random shock models and lots of mixed models based on them. An extreme shock model (Gut & Hüsler 1999, Cirillo & Hüsler 2011) supposes system failure occurs when the magnitude of any shock load exceeds a critical value. A cumulative shock model (Sumita & Shanthikumar 1985, Montoro-Cazorla & Pérez-Ocón 2015) assumes system failure occurs when the cumulative damage from extern shock loads exceeds a specified threshold. A run shock model (Mallor & Omey 2001, Eryilmaz 2016) supposes system failure occurs when there is a consecutive run of *m*-shocks exceeding a critical magnitude. A δ-shock model (Rangan & Tansu 2010, Wang & Peng 2017) assumes system failure occurs when the time interval between two successive shocks is less than a specified threshold δ. A mixed shock model (Gut 2001, Rafiee et al. 2015, 2017) includes two or more basic shock models in which the system is supposed to fail either because of one large shock, or as a result of many smaller ones.

Gut et al. expanded the shock model further and considered that some shocks may harm the system and lead to the threshold change. Accordingly, the failure rate would also change (Gut & Hüsler 2005). Jiang et al. supposes shocks with different magnitudes might have different impacts on the failure of the system and proposed a zone shock model (Jiang et al. 2015).

The degradation models can be classified into disperse process and continuous process. Xue et al. extended 2-state reliability analysis method to multi-state. The system multi-state reliabilities are analyzed by combining Markov processes and

s-coherent multistate system structure functions (Xue & Yang 1995). Li et al. developed a generalized multi-state degraded system reliability model which operating condition of the multi-state systems is characterized by a finite number of states (Li & Pham 2005). Zhang et al. introduced multiple discrete function theory considering the monotone and coherence of the multi-state system to describe the structure function of system state. The law of Demogen and a new block diagram algorithm are developed to simplify the expression for the system reliability (Zhang et al. 2017).

For continuous degradation model, there are two categories to describe the process: degradation path model and stochastic process model.

Bagdonavičius et al. used a general nonparametric, nonlinear path model to simulate degradation process in which supposing that the intensities of failures depend on degradation level (Bagdonavičius et al. 2005). Xu et al. proposed a class of general path models to incorporate time-varying usage and environmental variables for modeling of degradation paths. They used nonlinear functions to describe the degradation paths, and random effects to describe unit-to-unit variability (Xu et al. 2016).

Yan et al. proposed an improved time-variant reliability model considering stochastic process of strength degradation based on semi-stochastic-process. The parameters are determined based on the model of Gamma degradation process with independent increments. This method can avoid the redundant and complex calculations and obtain accurate reliability results (Yan et al. 2016). Huang et al. proposed an adaptive skew-Wiener model to simulate the degradation drift of industrial devices and predict the remaining useful life. A two-stage algorithm is adopted to estimate unknown parameters as well (Huang et al. 2017).

There may exist competing between system catastrophic failure and degradation failure.

Peng et al. developed a reliability model based on degradation and random shock modeling for systems subject to Multiple Dependent Competing Failure Processes (MDCFP). Two dependent failure processes, soft failures and hard failures, were considered in the model. Hard failure occurs when the size of external shock exceeds its threshold. Degradation is composed by pure degradation and instantaneous increase lead by shocks. Soft failure happens if the degradation exceeds its specified threshold. The two failures are competing with each other based on which the system reliabilities are analyzed (Peng et al. 2010). Jiang et al. supposed that the system withstanding shocks is deteriorating, and its resistance to failure is weakening. They introduced shift failure thresholds to the competing failure model (Jiang et al. 2012). Similarly, Rafiee proposed a reliability model for systems subject to dependent competing failure processes of degradation and random shocks with a changing degradation rate. The degradation rate will change when the system becomes more susceptible to fatigue and deteriorates faster (Rafiee et al. 2014). Besides, Song studied the reliability of multi-components system subject to multiple dependent competing failure processes considering dependent shock damage on failure processes among components. They developed reliability models considering different patterns for dependent shock damage for more realistic and accurate prediction of system reliability (Song et al. 2016).

There are many other researchers studied the competing failure models. For all we know, the degradation threshold is only for the soft failure of the component. There is no constraint on system performance parameters, supposing that system failure occurs when component's degradation exceeding a critical magnitude. This assumption is reasonable for a system composed of structural parts, but there are some problems for the system contains mechanisms.

Firstly, that a component of system occurs soft failure does not mean system must fail. For example, a simple slider crank mechanism contains frame, crank, connecting rod, and slider. Usually, there exist multiple wear degradation processes in the kinematic pairs of the mechanism. The performance parameters of the system are affected by each wear degradation process. When a wear degradation value has exceed its specified threshold, the performance parameter value of the system may exceed the system requirement, or it may not exceed the requirement and be in a normal state. The system's state is only determined by the performance of the system.

Secondly, some mechanisms have phenomena that all the components still in the good states, but the system functions cannot meet the requirements of performance. The degradation of wear may increase the coefficient of friction. Although the soft failure of all components of the system has not occurred, the increase of friction coefficient can lead to stagnation failure of the mechanism.

Finally, the degradation of some system components is difficult to measure directly, especially for mechanism, but the performance value of the mechanism output is easy to acquire.

Based on the above problem, we will study the reliability for multi-components system (especially for mechanism) subject to dependent competing degradation of components, random stress shocks of components and performances deterioration of system. A reliability model for systems considering three dependent failure patterns is derived based on component degradation, component random shocks and system performance modeling. Then an application example will illustrate the effectiveness of the proposed approach with sensitivity analysis. The results whether considering system performance deterioration or not will be compared and discussed.

2 SYSTEM FAILURE DESCRIPTION

As shown in Figure 1, the component of a mechanical system are in the process of degradation. The degradation trajectory may be linear or non-linear. In addition, the stress shocks of component *i* over certain critical threshold will affect the component degradation process with additional abrupt degradation damage. At the same time, the degradation of component will impact the component hard failure threshold level. So the hard failure threshold of the component will degrade accordingly. When the strength of the component is less than the load stress, the component catastrophic failure will occur.

For a mechanism, the degradation of components will influence the system performances based on topological relationship of mechanical composition. As shown in Figure 2, the system performance of the mechanism will degrade according to the degradation value of component 1, 2, …, *n* and their topological function. When the system performance exceeds the threshold range, the system performance degradation failure will occur.

The component catastrophic failure and the system performance degradation failure are dependent because of the same load stress environment. There also exists a competition for the two types of failures. Any type of failure occurs, the mechanism will fail.

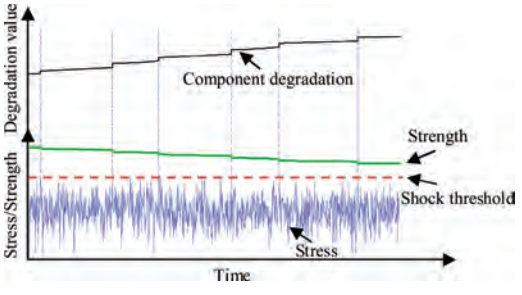

Figure 1. Dependent degradation processes for component i.

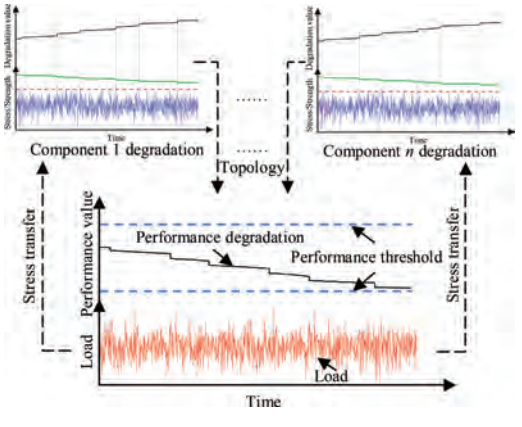

Figure 2. Dependent competing failure processes between components' catastrophic failure and mechanism's performance degradation failure.

3 RELIABILITY MODELLING FOR MULTI-COMPONENTS SYSTEM

3.1 *System load stress analysis*

Typically speaking, the mechanism system is always under its necessary working loads. However, the magnitude of loads are not fixed values due to several reasons including randomness of shock, vibration of system and etc. The system load will be transferred to component level by specific ways. The transmitting ways are determined by the basic structure form and total degradation of all the components for mechanical system.

Supposing the transfer laws is expressed by

$$S_i = f_i(B, \boldsymbol{L}, \boldsymbol{F}, t) \qquad i = 1,2,\cdots,n \tag{1}$$

where S_i is the stress size of the *i*th component; $f_i()$ is the transfer function between the *i*th component stress and system loads; B indicates the basic structure form of the mechanical system; $\boldsymbol{L}$ is the total degradation vector of all the components; $\boldsymbol{F}$ means the system load spectrums vector; t is time variable.

The transfer laws may be explicit or implicit form. For a simple mechanism can get explicit transfer function, the analytical method can be used to get component level stress. For a complex mechanism cannot get explicit transfer function, we can use multi flexible body dynamics method to get the stress.

The oversized stress is more attractive because the larger the stress, the more dangerous the component. A larger stress may cause the component additional abrupt degradation.

Due to the randomness of system external loads, the component stress with magnitude larger than a fixed threshold is subjected to a Poisson process. Concretely, the *i*th component stress shocks arrive with a Poisson process $\{N_i(t)|S_i(t) > H_i, t \geq 0\}$ with rate λ_i. The probability that the *i*th component stress shocks equal k is expressed as

$$P(N_i(t) = k) = \frac{\exp(-\lambda_i t)(\lambda_i t)^k}{k!} \tag{2}$$

where H_i is the abrupt degradation threshold of component *i*.

The magnitude of component stress larger than the fixed threshold can be statistically obtained. The type and parameters of stress shocks distribution may obtain by using the maximum likelihood method.

3.2 *Reliability modeling for component*

Components are subjected to two kinds of processes, the catastrophic failure process and degradation process as we mentioned above. The catastrophic failure happens when the size of stress of component exceeds its threshold. The threshold is changing with time. It is related to the degradation of the component.

3.2.1 *Degradation process modeling*

The component degradation is consisted by two parts, the pure degradation $X_i(t)$ and abrupt degradation Z_i. The exponential degradation path is used to model the pure degradation. The degradation path is expressed by

$$X_i(t) = \varphi_i + \gamma_i t^{\zeta} + \varepsilon(t) \tag{3}$$

where φ_i is the initial value; γ_i and ζ are the degradation parameters; ε is a standard Brown motion $\varepsilon \sim B(0, \sigma^2 t)$.

The cumulative abrupt degradation Z_i caused by random stress shocks is

$$Z_i(t) = \sum_{j=1}^{N_i(t)} Y_{ij} \tag{4}$$

where $N_i(t)$ is the total number that the *i*th component stress shocks occur; Y_{ij} is the abrupt degradation value of component *i* stress shock *j*.

The abrupt degradation value Y_{ij} is dependent on the component stress shocks. If the shock is larger, the abrupt degradation value is more likely deteriorating. We assume a positive linear correlation between the abrupt degradation value and the component stress shock. Their relation is expressed as

$$Y_{ij} = \alpha_i S_{ij} \tag{5}$$

where S_{ij} is the component stress shocks greater than H_i until time *t*. Which can be determined by equation (2). α_i is the degradation conversion coefficient.

Thus, the total degradation of component *i* is expressed by

$$\begin{aligned} L_i(t) &= X_i(t) + Z_i(t) \\ &= \varphi_i + \gamma_i t^{\zeta} + \varepsilon(t) + \sum_{j=1}^{N_i(t)} \alpha_i S_{ij} \end{aligned} \tag{6}$$

3.2.2 *Catastrophic failure process modeling*

Catastrophic failure occurs once a stress of component exceeds its strength threshold. The probability that no catastrophic failure happens is

$$P(S < D_i) = F_S\left(D_i(t)\right) \tag{7}$$

where S is a random variable of component stress; $D_i(t)$ is the current strength threshold which changes with time due to the degradation of the component.

The current strength threshold is related to the total degradation of the component. The greater the total degradation of the component, the smaller the residual strength is. So we suppose the current strength threshold is a linear function of the total degradation of the component, as showed in Figure 3.

$$D_i(t) = D_0 + \beta_i L_i(t) \tag{8}$$

where β_i is the threshold conversion coefficient; D_0 is initial threshold value.

The randomness of Poisson process indicates that there may be any shock times, from 0 to ∞, until time *t*. For a better illustration, there is an assumption that there are *j* shocks until time *t*. Besides, the coming moment of the *j*th shock is indicated by T_j. Thus, the probability that no catastrophic failure occurs for the *i*th component is expressed by

$$\begin{aligned} &F_S\left(D_i(t)\right) = P\left(N_i(t) = 0\right) \\ &+ \sum_{j=1}^{\infty} \int_0^t \int_{T_1}^t \cdots \int_{T_{j-1}}^t \left(\prod_{k=1}^{j} P\left(S_{ik} < D_i(T_k)\right) \middle| \right. \\ &\left. N_i(t) = j, t_1 = T_1, t_2 = T_2, \cdots, t_j = T_j \right) \cdot P\left(N_i(t) = j\right) \end{aligned} \tag{9}$$

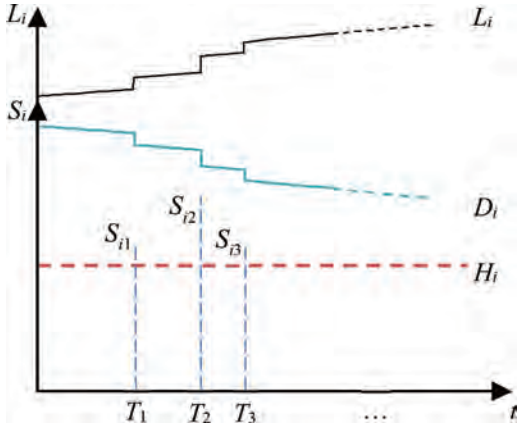

Figure 3. Catastrophic failure process for component *i*.

3.3 *Reliability modeling for system*

3.3.1 *System performance degradation modeling*

Mechanism is designed for specific performance such as load transmission and displacement shifting. The achievement of system performance is combined action of all the units of including all components, all pairs, all loads and etc.

Typically speaking, the system performance value is a function of relevant units:

$$P_e = f_e\left(B, \mathbf{L}, \mathbf{F}, t\right) \tag{10}$$

where P_e is the system performance value; $f_e()$ is the function between the components parameters and system performance.

This function is the same as the system load transfer function (1). Its result needs to be solved iteratively with the load transfer function.

3.3.2 *System performance degradation failure modeling*

As we have analyzed above, there are some degradation in components. The degradation may deduce the system performance deterioration. In other words, the performance value will also degrade due to the degradation of components. Thus, performance value is also a variable of time t which is expressed by $O_s(t)$.

If the mechanical system performance wants to meet requirements, the performance value need to conform to the ideal value. Namely, the error of performance value and its ideal value is under a threshold. The performance reliability is indicated by

$$P_s = P(\left|O_s - O_{si}\right| < \delta) \tag{11}$$

where O_{si} is the ideal value of performance and δ is the maximum allowable performance error.

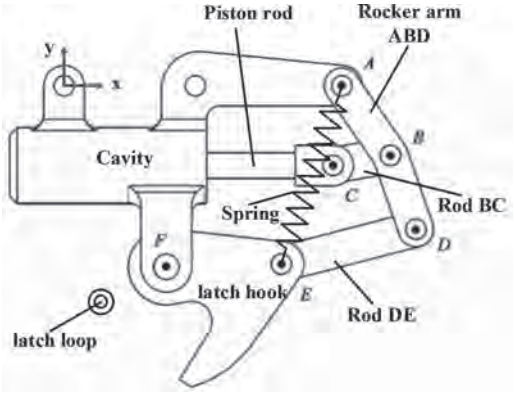

Figure 4. The composition of GDLM.

3.4 *System reliability modeling*

All in all, mechanical system may fail due to two kinds of failure types, the catastrophic failure of components and the degradation failure of system performance. This two failures are dependent and competing with each other.

If the system keeps in good state, neither the catastrophic failure nor the performance failure can happen. The reliability is expressed by

$$R_s = P_s \cdot \prod_{i=1}^{n} F_S\left(D_i(t)\right) \tag{12}$$

4 NUMERICAL EXAMPLES AND RESULTS

An aircraft gear door lock mechanism (GDLM) example is used to illustrate the competing reliability model. The GDLM consists of seven parts, which are a cavity, piston rod, latch hook, rocker arm ABD, rod BC, rod DE and spring, as illustrated in Figure 4. They are connected by six revolute joints (A, B, C, D, E and F). In the opening process, the piston rod experiences the pressure of the hydraulic oil moves towards the right. The rocker arm ABD rotates anti-clockwise. Meanwhile, the latch hook rotates anti-clockwise until the latch hook is separated from a latch loop. The opening process is investigated in this paper. There are mainly two kinds of failure modes in the opening process: component fracture and mechanism seizure.

The latch hook experiences the gear door load from the latch loop when the mechanism is in closed state. In the opening process, the latch hook rotates anti-clockwise. The friction force and friction moments are caused by the joints. The friction force and friction moments are determined by the contact stress and friction coefficients. The magnitude of the contact stress can be determined by the dynamics of the mechanism.

When the driving force from the piston rod cannot overcome the resistance from the mechanism, the seizure of the mechanism will happened.

Hence, the failure criterion for seizure is:

$$O_s - O_{si} < 0 \tag{13}$$

where O_s donates the maximum force that the piston rod can provide; O_{si} presents the resistance of the mechanism, which is 2700 N.

It is difficult to present the explicit expression for the performance function O_s due to the complexity of the GDLM and the diversity of the influence factors. Therefore, based on Virtual.Lab software, a multi-body dynamic simulation model of the

GDLM is established. The relationship between the unlocking force O_s and the influence factors is constructed by the response surface method.

$$\begin{aligned} O_s = & -4416.10 + 187.16X_1 + 0.3378X_2 + \\ & 1382.69X_3 + 0.0617X_4 - 2.02X_1^2 + 4.9339 \times 10^{-8} \\ & X_2^2 - 261.53X_3^2 + 2.7067 \times 10^{-9} \\ & X_4^2 - 0.00239X_1X_2 - 23.93X_1X_3 - 3.9136 \\ & \times 10^{-4} X_1X_4 + 0.3236X_2X_3 - 1.062 \times 10^{-6} \\ & X_2X_4 - 0.0238797X_3X_4 \end{aligned} \tag{14}$$

where X_1, X_2, X_3, X_4 are influence factors, the meanings and values of the parameters are listed in Table 1.

Typically, total load is distributed to each component according to the construction of mechanism system. For this GDLM, the load distributed to each component can be obtained by dynamic analysis. For simplicity, we assume that the proportion of stress per component is constant. The value is listed in following Table 2.

According to equation (9), (11), (12), the reliability of GDLM is calculated at various time. Numerical method based on Monte Carlo is used for calculation due to the lack of analytic solution.

The reliability and failure probability density results are showed in Figures 5 and 6. The x-label is the working time which is stated by number of working circles. The y-label is reliability value and failure probability density respectively for GDLM with performance deterioration considered.

From Figure 6 we can obtain that component catastrophic failure is less probable than system performance failure. The system total reliability is dependent on the competing results of component catastrophic failure and system performance failure. When considering system performance deterioration, the reliability reducing rate is quite fast at high reliability level.

This appearance manifest that the deterioration influences equipment with high reliability seriously. For mechanical system requiring precision and dependability, it is of vital importance to control the deterioration and accident shock load.

Figure 7 presents sensitivity analyses of latch hook friction coefficient on system total reliability. From Figure 6, by increasing the value (γ_3 increases from 3×10^{-7} to 7×10^{-7}), $R(t)$ shifts to the left. At

Threshold of joint F of latch hook X_{10}	normal	1.2 GPa	0.06 GPa	$\beta_{10} = -1.0$; $\alpha_{10} = 0.1$; $\gamma_{10} = 5.6 \times 10^{-7}$; $\varphi_{10} = 0$; $\zeta_{10} = 1.05$; $\sigma_{10} = 5.5 \times 10^{-5}$

Table 2. Ratio of each component stress.

Components	Joint A	Joint B	Joint C	Joint D	Joint E	Joint F
Stress ratio	0.4	0.15	0.15	0.35	0.35	0.7

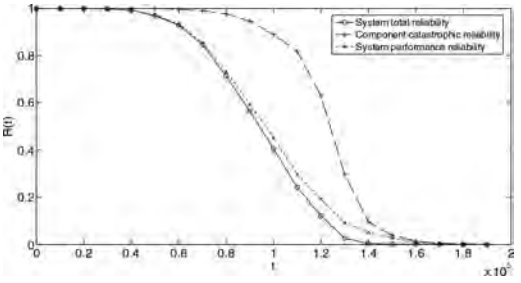

Figure 5. The reliability of GDLM at various time.

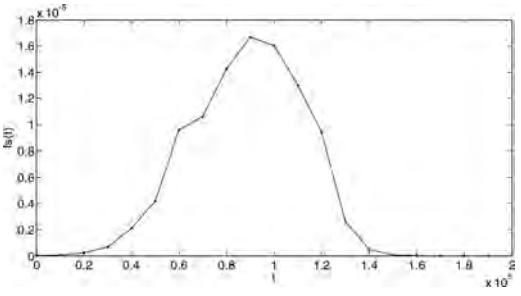

Figure 6. The failure probability density of GDLM.

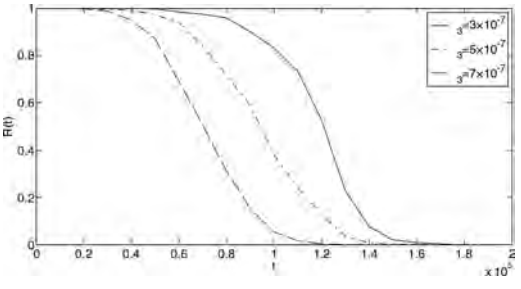

Figure 7. Sensitivity analysis of $R(t)$ on latch hook friction coefficient.

reliability level 0.8, The number of working circles decreases from 1.04×10^5 to 0.55×10^5 by nearly half.

It can be inferred that increased degradation coefficient γ_3 decreases the system reliability. For the comparisons, the degradation rate parameters have a very obvious impact on the reliability of the system.

5 CONCLUSIONS

The reliability model for multi-components system subject to dependent competing risks of components catastrophic failure and system performances deterioration failure has been developed. These failure processes are dependent in three respects: 1) the component stress shocks over certain critical threshold affects the component degradation process, 2) the component degradation impacts the component catastrophic failure threshold level, and 3) the component degradation influences the system performances.

This reliability model mainly for mechanism considered the relationship between the system and its component. Through this relationship and the degradation models of components, the system performance deterioration failure model has been proposed. The system performance deterioration failure process and the components catastrophic failure process are dependent and competing. The system total reliability is the competing result of the above two processes.

It is more realistic and difficult due to the failure processes being dependent not only due to a common load but also due to constraints between components. We presented a numerical example to demonstrate the effectiveness of the proposed approach and observe the reliability with sensitivity analysis for an aircraft gear door lock mechanism. The results whether considering system performance deterioration or not are compared and discussed.

For more accurate, the reliability model need consider the actual latch hook friction coefficient decreasing rate. This may be extended for future.

ABSTRACT: This paper proposes a new quantitative reliability analysis method for repairable systems with multiple correlations based on Goal Oriented (GO) method. First, the solving methods for repairable systems with shutdown correlation, maintenance correlation, standby correlation and common cause failure in GO method are presented. And the reliability analysis process of this paper's GO method is formulated. Then, the hydraulic oil supply system of heavy vehicle is taken as an example to conduct reliability analysis by this paper's GO method. Finally, in order to verify the feasibility and advantage of the proposed GO method, its analysis result compared with those by GO method for system without considering correlations and system with considering a single kind correlation. All in all, this study not only improves the theory GO methodology; but also provides a new reliability analysis approach for repairable systems with multiple correlations.

1 INTRODUCTION

The reliability of repairable systems is a prerequisite for its normal operating. Correlations are universal characteristic in the repairable system, and affect the system reliability directly, such as shutdown correlation, maintenance correlation, standby correlation and common cause failure. If the repairable systems with correlations are not considered these correlations, the reliability analysis result will have a large bias. Different from Fault Tree Analysis (FTA), Failure Mode, Effects Analysis (FMEA), and Monte-Carlo Simulation (MCS), Goal Oriented (GO) methodology is a success-oriented method for system reliability analysis. It has three obvious advantages [1], as follows:

i. GO model is directly developed according to system principle diagram, flowchart or engineering drawing, so it is more objective.
ii. GO method can combine with other technologies to improve the GO method easily so that it can solve various kinds of practical engineering problems, such as multi-fault modes [2–4], Closed-Loop Feedback [5–7], multifunction [8, 9], multi-state [10–12], and so on.
iii. Both of the accurate quantitative analysis result and qualitative analysis result can be obtained by GO method.

GO method has become increasingly popular in recent years because of its advantages in aspects of establishing system model and its stronger analysis power. Indeed, a large number of engineering applications have established its value [1, 13]. It is an efficient technology approach to conduct reliability analysis [14], reliability optimization allocation [15, 16] and reliability assessment [17, 18]. Although the basic theory of GO method has been improved so that it can solve some single correlation, such as standby correlation [19], the existing GO methods are not suitable for repairable systems with multiple correlations, which are shutdown correlation, maintenance correlation, standby correlation and common cause failure. Above all, the main contributions of this study are as follows:

i. The new quantitative reliability analysis method for repairable systems with multiple correlations, which are redundancy structure with shutdown correlation, maintenance correlation, standby correlation and common cause

failure based on GO method, is expounded in detail.

ii. The reliability analysis process of this paper's GO method is formulated.

iii. The hydraulic oil supply system of heavy vehicle is taken as an example to conduct reliability analysis by the proposed GO method firstly.

The remainder of the paper is organized as follows. The GO method for quantitative reliability analysis of repairable systems with multiple correlations is proposed in Section 2. Section 3 illustrates a practical example, which is a hydraulic oil supply system of heavy vehicle, based on the proposed GO method. Section 4 provides results analysis in order to verify the feasibility, advantage and reasonability of this paper's GO method. Section 5 provides some conclusions on the findings of the research.

2 GO METHOD FOR REPAIRABLE SYSTEMS WITH MULTIPLE CORRELATIONS

The quantitative reliability analysis result by using GO method is obtained based on GO model by adopting GO algorithm according to the reliability analysis process of GO method. So, the GO algorithm and the reliability analysis process of GO method are the key factors for conducting GO analysis. In this section, the GO algorithm for redundancy structure with multiple correlations and the reliability analysis process of this paper's GO method are proposed, respectively.

2.1 *GO algorithm for repairable systems with multiple correlations*

The redundancy structures are often used in complex repairable systems, and the shutdown correlation, maintenance correlation, standby correlation and common cause failure affect the reliability of such structure directly.

1. GO algorithm for redundancy structure with shutdown correlation, maintenance correlation and standby correlation

In quantitative GO analysis, the redundancy structure with shutdown correlation, maintenance correlation and standby correlation is equivalent to a unit, which is represented by Type 1 operator, which is used to describe two-state unit. And the reliability parameters of such unit are obtained by GO algorithm for redundancy structure with shutdown correlation, maintenance correlation and standby correlation [20], as shown in Eq. (1)–(5).

$$\begin{cases} a_i = \begin{cases} (M-i+1)\lambda, & J=0 \text{ OR } \quad M-i+1<K \\ K\lambda, & J=1 \text{ OR } \quad M-i+1\geq K \end{cases} \\ b_i = \begin{cases} i\mu, & i \leq L \\ L\mu, & i > L \end{cases} \end{cases} \tag{1}$$

$$P_i = P_0 \prod_{j=1}^{i} \frac{a_j}{b_j} \tag{2}$$

$$P_R = \sum_{i=0}^{M-K} P_i \Big/ \sum_{i=0}^{I} P_i \tag{3}$$

$$\lambda_R = P_{m-k} \cdot a_{m-k+1} \Big/ \sum_{i=0}^{M-K} P_i \tag{4}$$

$$\mu_R = P_{M-K+1} b_{M-K+1} \Big/ \sum_{i=M-K+1}^{I} P_i \tag{5}$$

where M is the unit number of redundancy structure, K is the operating unit number of redundancy structure, I is the faulting unit number of redundancy structure, J is the standby indicator, $J = 0$ represents no standby unit in redundancy structure, $J = 0$ represents the redundancy structure has standby units, P_0 is the success probability of redundancy structure at the condition of all unit operating, P_i is the state probability of redundancy structure, P_R, λ_R and μ_R are the success probability, failure rate and maintenance rate of equivalent unit for redundancy structure, respectively.

2. GO algorithm for repairable systems with common cause failure

In quantitative GO analysis, the quantitative analysis result can be obtained by using GO algorithm for repairable systems with common cause failure [21], as shown in Eq. (6).

$$R_S = R_I + \sum_{m=1}^{M} C_m (R_{00\ldots} - R_{11\ldots}) \tag{6}$$

where R_S is the system availability by GO operation according to the basic GO algorithm [22], R_I is the system availability without considering common cause failure by GO operation according to the basic GO algorithm [22], C_m is the common cause failure probability of *mth* redundancy structure with common cause failure, $m = 1, 2, \cdots, M$, $R_{00\ldots}$ and $R_{11\ldots}$ are the system availabilities at the situation of the availabilities of all units in each redundancy structure with common cause failure as 0 and 1, respectively.

2.2 *Reliability analysis process of proposed GO method*

The reliability analysis process is the criterion and prerequisite for conducting quantitative GO

analysis. While, the reliability analysis process of basic GO method is not suitable for repairable systems with multiple correlations [23], so the reliability analysis process of repairable systems with multiple correlations based on this paper's GO method is formulated, and its process diagram is shown in Fig. 1.

1. Analyzing system
   Besides the contents of system analysis in the existing GO methodology [21], the redundancy structure with multiple correlations should be determined.
2. Developing GO model
   According to the results of system analysis, the function GO operator and logical GO operator are selected to represent the unit and the logical relationship in system. Then, the GO model of system is established by using signal flow to connect the GO operators.
3. Obtaining reliability parameters
   a. To obtain the reliability parameters of unit. They mainly contain the failure rate, maintenance rate and availability of unit.
   b. To obtain the reliability parameters of redundancy structure with shutdown correlation, maintenance correlation and standby correlation according to Eq. (1)-(5).
   c. To obtain the reliability parameters of redundancy structure with common cause failure. They mainly contain the parameters of common cause failure model, common cause failure probability, and availability.
4. Conducting quantitative GO analysis
   According to Eq. (6), the system availability can be obtained. If the shared signal does not exists in GO model, the GO operation can be conducted by the direct algorithm. If the shared signal exist in GO model, the GO operation can be conducted by the exact algorithm with shared signal [22].

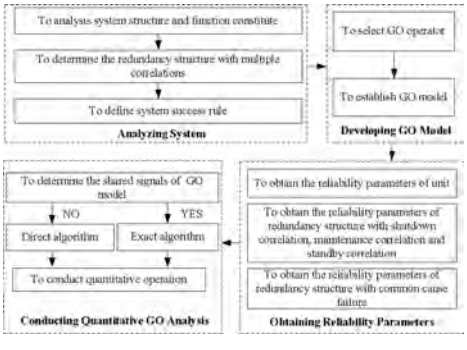

Figure 1. Reliability analysis process diagram of proposed GO method.

3 EXAMPLE

In order to illustrate the usage of this paper's GO method, the quantitative analysis of a hydraulic oil supply system for a military vehicle is conducted based on the proposed GO method.

3.1 *Analyzing hydraulic oil supply system*

1. To analysis structure and function constitute of hydraulic oil supply system
   The hydraulic oil supply system is used to supply working oil for variable speed control system, steering control system, hydraulic torque converter and lubrication system. And its schematic diagram is shown in Fig. 2.
2. To determine the redundancy structure with multiple correlations
   In hydraulic oil supply system, LF1 group and LF2 group are redundancy structures with shutdown correlation, maintenance correlation and standby correlation. The P1 group, LF1 group and LF2 group exist common cause failure because of external disturbance, such as extremely heavy impact, oversize oleo contaminated particle, and so on.
3. To define success rule of hydraulic oil supply system
   According to above analysis, the success rule of hydraulic oil supply system can be defined as that system can supply working oil to variable speed control system, steering control system, hydraulic torque converter, and lubrication system of a military vehicle under high steering speed condition without considering overload protection.

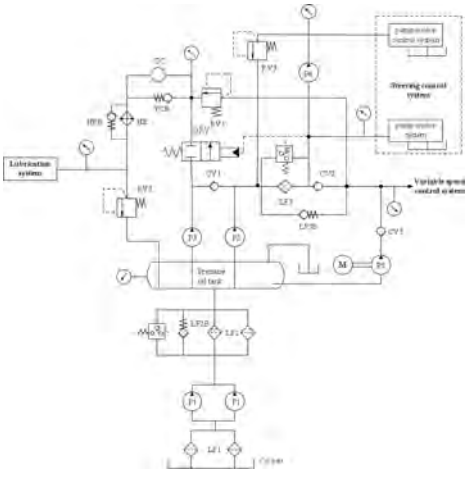

Figure 2. Schematic diagram of hydraulic oil supply system.

3.2 *Developing GO model of hydraulic oil supply system*

According to above analysis, the GO model of hydraulic oil supply system is developed, as follows:

1. To select GO operator
   There are 5 kinds of GO operators. And the GO operators corresponding units and logical relations are presented in Table 1.
2. To develop GO model
   According to analysis result of hydraulic oil supply system and Table 1, the GO model of hydraulic oil supply system is established, as shown in Fig. 3. In operators, the former number and latter number are type and serial number of GO operator, respectively. And the number on a signal flow is serial number of signal flow. The signal flow 37 is system output.

3.3 *Obtaining reliability parameters*

1. To obtain the reliability parameters of unit, as presented in Table 2. In Table 2, the failure rate and maintenance rate of unit are determined according to engineering statistic.
2. To obtain the reliability parameters of LF1 group and LF2 group by Eq. (1)-(5). In LF1 and LF2 group, $M = 2$, $K = 2$, $I = 2$, $L = 2$, $J = 0$. The reliability parameters of LF1 group are illustrated in detail, as presented in Table 3.
   In the same way, the reliability parameters of LF2 group can be obtained, i. e. its availability, failure rate and maintenance rate are 0.999981809, 0.000018341533 and 1.008264462, respectively.
3. To obtain the reliability parameters of redundancy structure with common cause failure, as presented in Table 4. In this case, we adopt the common cause failure β model [23].

Table 1. Operator type of unit.

No.	Unit	Type	Description
1	Oil pan	5	Input unit

3.4 *Conducting quantitative GO analysis of hydraulic oil supply system*

According to the definition of shared signal [22], the signal flow 1, 4, 7, 8, 14, 15, 16, 25 and 31 are shared signals in Fig. 3. Thus, the exact algorithm with shared signals is adopted to conduct GO operation. And the system availability is obtained by Eq. (6), as presented in Table 5.

4 RESULT ANALYSIS

In order to verify the feasibility and advantage of the proposed GO method, its analysis result compared with those by GO methods for system without considering correlations, system considering redundancy structure with shutdown correlation, maintenance correlation and standby correlation and system considering common cause failure. And the quantitative analysis results are presented in Table. 6.

Table 6. Quantitative analysis results by different GO methods.

Method	System availability
This paper's method	0.9840524683
Method without considering correlations	0.9845210823
Method considering redundancy structure with shutdown correlation, maintenance correlation and standby correlation	0.9840869188
Method considering common cause failure	0.9844857454

According to Table 6, we can see

1. The analysis result by this paper's method is smaller than the result by GO method without considering correlations. It meets engineering practice. It shows that if the correlations in systems are neglected, the reliability analysis result will have a bias.
2. The analysis result by this paper's method is smaller than the result by GO method considering redundancy structure with shutdown correlation, maintenance correlation and standby correlation. It meets engineering practice. It shows that the shutdown number, maintenance man, and standby structure affect the system reliability directly.
3. The analysis result by this paper's method is smaller than the result by GO method considering common cause failure. It meets engineering practice. It shows that the reliability analysis for system with redundancy structure should consider the common cause failure.

The reliability analysis process of example shows that the GO model is developed according to the system principle, system structure and function constitute, and the quantitative analysis result is obtained by multiple GO operations. It indicates that the GO method has obvious advantages in terms of establishing system model and conducting quantitative analysis.

5 CONCLUSION

This study proposes a new quantitative reliability analysis method for repairable systems with multiple correlations based on GO method. First, the solving methods for repairable systems with multiple correlations in GO method are presented, which are GO algorithm for repairable systems with common cause failure, and GO algorithm for redundancy structure with shutdown correlation, maintenance correlation and standby correlation,

respectively. On this base, the reliability analysis process of the proposed GO method is formulated. Then, the hydraulic oil supply system of military vehicle is taken as an example to conduct reliability analysis by this paper's GO method firstly. Finally, its quantitative analysis result compared with those by GO method for system without considering correlations and system with considering a single kind correlation. The analysis results show that the correlations affect the system reliability directly. And the reliability analysis process of example shows that the GO method has obvious advantages in establishing system model and conducting quantitative analysis. All in all, this study not only improves the theory GO methodology; but also provides a new reliability analysis approach for repairable systems with multiple correlations.

ABSTRACT: The network topological optimization, developing the scheme of pipelined connections needs to find the best layout of all links in the urban sewage system, makes the whole system cost-effective with the satisfaction of some special criteria. In this paper, the application of constraints based on some priori knowledge, including the requirement to link the components in network systems, reduces the solution space of the optimization substantially, unlike most literatures focus on improving the efficiency of optimization algorithms through the modification of the algorithm itself. In order to evaluate it, the network topological optimization of a sewage system, serving two different cities, is investigated. Performance of the solution based on the application of priori knowledge is validated through the sewage system. It indicates that the application of priori knowledge can be efficient for the solution.

1 INTRODUCTION

Urban sewage systems are important infrastructures for modern cities. A successful design of the urban sewage system is a guarantee for its availability, economy, and reliability. As the critical content of the design, developing the scheme of pipelined connections needs to find the best layout of all links in the urban sewage system, which makes the whole system cost-effective with the satisfaction of some special criterions. This design problem is defined as the optimization of network topology [1].

The objective of network topological optimization is to find the optimal layout of links among components in the system, and some requirements should be met such as the performance of networks, transmission delay. This paper considers the network topology optimization of the urban sewage system. In particular, its design should have a minimal cost under the constraint that the reliability of the system based on the design is not less than a given system reliability.

In general, the study of network topological optimization concentrates on three aspects: the choice of a measure of reliability, the algorithm adopted to calculate the system reliability and the solution of the optimization model. The measures of reliability in network systems include the connectivity measure [2], the connectivity measure with the consideration of the performance [3], and the measure based on capacity [4]. At the same time, the exact algorithms based on these measures of system reliability are widely investigated [5]. However, the increased size of network systems poses a new challenge to the computation of system reliability. Approximation algorithms are adopted to address this challenge [6–8].

The solution of the optimization model, unlike the choice of a measure of reliability and the algorithm adopted to calculate the system reliability, is mainly about how to solve the optimization model effectively. In this aspect, many optimization algorithms are proposed to the solution of network topological optimization [9–17]. However, most literatures focus on improving the efficiency of optimization algorithms through the modification of the algorithm itself.

In this paper, the application of constraints based on prior knowledge, including the requirement to link the components in network systems, reduces the solution space of the optimization substantially. In order to evaluate it, the network topological optimization of a sewage system, serving two different cities, is investigated. The constraints in optimization are that the system reliability should be larger than a given threshold, and the total cost of the sewage system is minimized. In

addition, performance of the solution based on the application of priori knowledge is validated through the sewage system. It indicates that the application of priori knowledge can be helpful for the solution.

2 MODELING FOR RELIABILITY BASED TOPOLOGY OPTIMIZATION DESIGN PROBLEM

In most research about reliability based the topology optimized design, it is often given that: (a) location of sewage treatment plants in different levels, (b) the reliability of sewage treatment plants, (c) the cost of pipelines that connect sewage treatment plants, (d) the constraint of sewage treatment system reliability. The layout of the sewage treatment system is actually determined by the connection relationship among cities and sewage treatment plants in different levels. The connection relationship is often defined by topological relation, and it is represented by graph in graph theory. The objective of reliability based topology optimization design is to find the optimal graph that enables the sewage treatment system has the minimal cost and the required reliability. Therefore, the optimization is adapted to model for reliability based topology optimization design. In the optimization model, the decision variable is the graph representing the topological relation of the sewage treatment system. The objective function is to evaluate the cost of the sewage treatment system; the constraint is used to guarantee the reliability of the sewage treatment system that meets the requirement.

2.1 *Representation of the topological characteristic of the sewage treatment system*

This paper adopts graph to represent the layout of the sewage treatment system. Graph may reveal the topological characteristics of the sewage treatment system, in particular the connection relationship among cities and sewage treatment plants in different levels. In addition, the adjacent matrix, a representation of graph, is a very useful data structure for Genetic Algorithm to solve the problem.

In the research about reliability based topology optimization design, the graph is used to represent the layout of systems, such like social networks, power networks. A graph g consists of the nodes set V and the arcs set E. The elements in the nodes set are nodes in graph, and the components of the sewage treatment system, such as cities and sewage treatment plants, are usually represented by nodes. The elements of the set E represent the pipelines in the sewage treatment system.

$$Adjacent\ Matrix = \begin{array}{c} \\ 1 \\ 2 \\ 3 \\ 4 \\ 5 \\ 6 \\ 7 \end{array} \begin{array}{c} \begin{array}{ccccccc} 1 & 2 & 3 & 4 & 5 & 6 & 7 \end{array} \\ \begin{pmatrix} 0 & 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 \end{pmatrix} \end{array} \quad (1)$$

Although graphs are very intuitive to show the layout of sewage treatment system, it is hard for a graph to participate in an operation as the part of Optimization Algorithm. To address the challenge, the adjacent matrix, a representation of graph, is adopted in this paper. The adjacent matrix is a very useful data structure, and it enables the graph to participate in the operation of Optimization Algorithm to solve the problem. The dimension of an adjacent matrix is determined by the amount of nodes in the graph. The row number or column number is consistent with the node number. For example, the adjacent matrix of the graph in Fig. 1 is shown in Eq. (1). The elements in an adjacent matrix can be 0 or 1. The element 0 means that

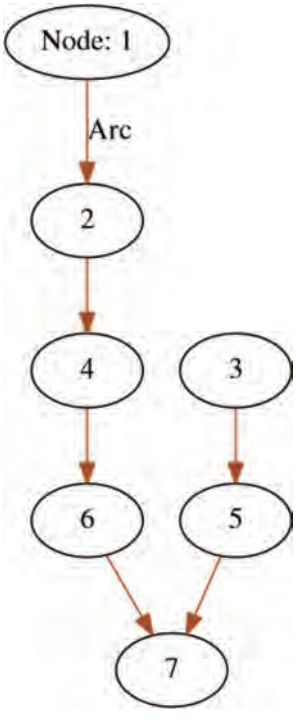

Figure 1. The graph referred to adjacent matrix in Eq. (1).

there is no connection between the node whose number equals to the row number and the node whose number equals to the number of columns number, and the element 1 means that there is a link between them. Therefore, the adjacent matrix is equal to the graph, and it can be adopted to represent the layout of the sewage treatment system.

2.2 *Solution space in optimization model*

In fact, the objective of solving the optimization model is to find an optimal solution that satisfies the constraint in solution space. Therefore, defining a reasonable solution space is helpful for optimization algorithm to solve efficiently. In this paper, the solution space is all the possible layout of sewage treatment system, and these layouts meet the design requirements. It consists of the necessary components of the whole sewage treatment system and the join sequence of cities and sewage-treatment plants. The normal sewage treatment system of a city includes a primary sewage treatment plant, a secondary sewage treatment plant and a tertiary sewage treatment plant. Therefore, the sewage treatment system must contain all the three plants. In addition to this, the join sequence of cities and sewage-treatment plants must be correct. The sewage of cities must be disposed first by the primary sewage treatment plant, and then the secondary sewage treatment plant is used for the process. The process of sewage treatment finishes at the tertiary sewage treatment plant.

According to the design requirements of sewage treatment system, this paper proposes a method that restricts the value of elements in adjacent matrix to limiting solution space. It is often given that the locations of cities and sewage treatment plants, therefore the amount of nodes in graph is known. Based on that, the dimension of the adjacent matrix can be determined. At the other hand, there is no connection between sewage-treatment plants and themselves, therefore diagonal elements in the adjacent matrix is 0. Based on the information above, the amount of unknown elements in the adjacent matrix is decreased. The adjacent matrix can be represented like Eq. (2).

$$\begin{array}{c} \\ 1 \\ 2 \\ 3 \\ \vdots \\ n-2 \\ n-1 \\ n \end{array} \begin{array}{c} \begin{array}{ccccccc} 1 & 2 & 3 & \cdots & n-2 & n-1 & n \end{array} \\ \begin{pmatrix} 0 & a_{1,2} & a_{1,3} & \cdots & a_{1,n-2} & a_{1,n-1} & a_{1,n} \\ a_{2,1} & 0 & a_{2,3} & \cdots & a_{2,n-2} & a_{2,n-1} & a_{2,n} \\ a_{3,1} & a_{3,2} & 0 & \cdots & a_{3,n-2} & a_{3,n-1} & a_{3,n} \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ a_{n-2,1} & a_{n-2,2} & a_{n-2,3} & \vdots & 0 & a_{n-2,n-1} & a_{n-2,n} \\ a_{n-1,1} & a_{n-1,2} & a_{n-1,3} & \vdots & a_{n-1,n-2} & 0 & a_{n-1,n} \\ a_{n,1} & a_{n,2} & a_{n,3} & \vdots & a_{n,n-2} & a_{n,n-1} & 0 \end{pmatrix} \end{array} \tag{2}$$

In fact, the amount of unknown elements is decreased from n^2 to $n^2 - n$, which means that the solution space is limited. Therefore, the solution space is determined by the $n^2 - n$ elements, and they can be represented by $X = (x_1, x_2, \cdots, x_{n^2-n})$.

2.3 *Objective function in optimization model*

The objective function is to calculate the cost of the sewage treatment system. In this paper, the construction cost of the sewage treatment system is ignored; therefore the cost of the sewage treatment system is determined by the connections among the plants. The length of pipelines for connections mainly affects the cost. According to the requirements of design, the primary sewage treatment plant is near the cities, but the secondary sewage treatment plant and the tertiary sewage treatment plant are far from the cities. Fortunately, the cost of different connections among them is usually known, and they are often represented by a matrix that is called cost matrix **A**, as shown in Eq. (3).

$$\begin{array}{c} \\ 1 \\ 2 \\ 3 \\ \vdots \\ n-2 \\ n-1 \\ n \end{array} \begin{array}{c} \begin{array}{ccccccc} 1 & 2 & 3 & \cdots & n-2 & n-1 & n \end{array} \\ \begin{pmatrix} c_{1,1} & c_{1,2} & c_{1,3} & \cdots & c_{1,n-2} & c_{1,n-1} & c_{1,n} \\ c_{2,1} & c_{2,2} & c_{2,3} & \cdots & c_{2,n-2} & c_{2,n-1} & c_{2,n} \\ c_{3,1} & c_{3,2} & c_{3,3} & \cdots & c_{3,n-2} & c_{3,n-1} & c_{3,n} \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ c_{n-2,1} & c_{n-2,2} & c_{n-2,3} & \vdots & c_{n-2,n-2} & c_{n-2,n-1} & c_{n-2,n} \\ c_{n-1,1} & c_{n-1,2} & c_{n-1,3} & \vdots & c_{n-1,n-2} & c_{n-1,n-1} & c_{n-1,n} \\ c_{n,1} & c_{n,2} & c_{n,3} & \vdots & c_{n,n-2} & c_{n,n-1} & c_{n,n} \end{pmatrix} \end{array} \tag{3}$$

The cost of different connections can be obtained by the cost matrix **A** and the connections that exist in layout are obtained by the decision variable **X**. Therefore, the objective can be represented by the Eq. (4).

$$Min: c = F(\mathbf{A}, \mathbf{X}) \tag{4}$$

2.4 *Constraint in optimization model*

The constraints in optimization model are used to guarantee the layout that is solved by the model meets the reliability requirement and the design requirements.

When the layout of the sewage treatment system is determined, the reliability of the sewage treatment system can be calculated using the computational method of the network reliability. At present, there are four computational methods of the network reliability: 1) calculate the probability of connectivity, 2) calculate the probability of connectivity with the consideration of the network capacity, 3) calculate the probability of connectivity with the consideration of the network performance, 4) calculate the reliability based on mission. This paper adopts the method of calculating the probability of connectivity to calculate the reliability of the sewage treatment system. This result of this method is also called s-t reliability, and it is

determined by the probability of the connectivity of all the path from the source node to the terminal node. In this paper, the source node is the city, and the terminal node is the tertiary sewage treatment plant. In addition, it is not necessary to consider the reliability of pipelines; therefore the reliability of the sewage treatment system is determined by the components of the sewage treatment system. In this paper, the reliability of the components is represented by $R=(R_1,R_2,\cdots,R_n)$, and they are actually given in most study. Using the reliability of components R and the connection information X, the constraint is defined in Eq. (5). The system reliability R^* is the threshold in requirement.

$$s.t. \quad g(R,X)\geq R^* \tag{5}$$

According to the content above, the optimization model is defined in Eq. (6).

$$\begin{aligned} &Min: c=F(\mathbf{A},\mathbf{X}) \\ &s.t. \quad g(R,X)\geq R^* \end{aligned} \tag{6}$$

3 A CASE STUDY

A sewage treatment system, serving for two cities, is proposed in this paper to be analyzed. There are two primary sewage treatment plants, two secondary sewage treatment plants and one tertiary sewage treatment plant. Their information about the node number and reliability are shown in Table 1. It should be noted that there are some pressurization equipment in cities, therefore the cities also have the reliability. Because the location of cities and sewage treatment plants are given in Fig. 2, the cost matrix is also known, and it is shown in Eq. (7). At the same time, the threshold R^* is 0.8.

$$A=\begin{array}{c} \\ 1 \\ 2 \\ 3 \\ 4 \\ 5 \\ 6 \\ 7 \end{array}\begin{array}{c} \begin{array}{ccccccc} 1 & 2 & 3 & 4 & 5 & 6 & 7 \end{array} \\ \begin{pmatrix} 0 & 100 & 11 & 43 & 30 & 55 & 60 \\ 100 & 0 & 39 & 14 & 42 & 28 & 58 \\ 11 & 39 & 0 & 50 & 28 & 37 & 42 \\ 43 & 14 & 50 & 0 & 25 & 19 & 32 \\ 30 & 42 & 28 & 25 & 0 & 34 & 37 \\ 55 & 28 & 37 & 19 & 34 & 0 & 35 \\ 60 & 58 & 42 & 32 & 37 & 35 & 0 \end{pmatrix} \end{array} \tag{7}$$

3.1 *Building the optimization model*

There are seven nodes in this case, therefore the dimension of adjacent matrix is 7×7. In addition, there are some more design requirements about the join sequence of cities and sewage-treatment plants, and these requirements are: 1) city can only connect with the other city or the primary sewage treatment plants, 2) the primary sewage treatment plant can only connect with the other primary sewage treatment plant or the secondary sewage treatment plants, 3) the secondary sewage treatment plant can only connect with the other secondary sewage treatment plant or the tertiary sewage treatment plant. Thus, the adjacent matrix is defined in Eq. (8). And the decision variable $\mathbf{X}$ in this case is defined as $X=(x_1,x_2,\cdots,x_{16})$.

Table 1. The node number and reliability information.

Component name	Node number	Reliability
City A	1	0.9895
City B	2	0.9882
Primary sewage treatment plant A	3	0.9535
Primary sewage treatment plant B	4	0.9886
Secondary sewage treatment plant A	5	0.9328
Secondary sewage treatment plant B	6	0.9761
Tertiary sewage treatment plant	7	0.9585

Figure 2. The location cities and components in the sewage system.

$$Adjacent\ Matrix=\begin{array}{c} \\ 1 \\ 2 \\ 3 \\ 4 \\ 5 \\ 6 \\ 7 \end{array}\begin{array}{c} \begin{array}{ccccccc} 1 & 2 & 3 & 4 & 5 & 6 & 7 \end{array} \\ \begin{pmatrix} 0 & x_1 & x_2 & x_3 & 0 & 0 & 0 \\ x_4 & 0 & x_5 & x_6 & 0 & 0 & 0 \\ 0 & 0 & 0 & x_7 & x_8 & x_9 & 0 \\ 0 & 0 & x_{10} & 0 & x_{11} & x_{12} & 0 \\ 0 & 0 & 0 & 0 & 0 & x_{13} & x_{14} \\ 0 & 0 & 0 & 0 & x_{15} & 0 & x_{16} \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 \end{pmatrix} \end{array} \tag{8}$$

The cost is calculated by the objective function through Hadamard product between the cost matrix and the adjacent matrix. The Hadamard product is new matrix that its dimension is still 7×7. These non-zero elements are the cost of connections

which exist in the designed layout. The sum of these non-zero elements is the total cost of the layout.

There are some more constraints in this optimization model except the reliability requirement. It should guarantee: 1) the sewage of city A and B must be discharged, 2) the sewage discharged by city A and B should be disposed by the primary sewage treatment plants, 3) the sewage discharged by primary sewage treatment plants should be disposed by secondary sewage treatment plants, 4) the sewage discharged by secondary sewage treatment plants should be disposed by the tertiary sewage treatment plant. All the requirements are defined in Eq. (9). Therefore, based on all above, the Optimization Model is defined in Eq. (10).

$$\begin{aligned} &x_1 + x_2 + x_3 \geq 1 \\ &x_4 + x_5 + x_6 \geq 1 \\ &x_2 + x_3 + x_5 + x_6 \geq 1 \\ &x_8 + x_9 + x_{11} + x_{12} \geq 1 \\ &x_{14} + x_{16} \geq 1 \end{aligned} \tag{9}$$

$$\begin{aligned} Min: \quad & c = F(A, X) \\ s.t. \quad & g(R, X) \geq R^* \\ & x_1 + x_2 + x_3 \geq 1 \\ & x_4 + x_5 + x_6 \geq 1 \\ & x_2 + x_3 + x_5 + x_6 \geq 1 \\ & x_8 + x_9 + x_{11} + x_{12} \geq 1 \\ & x_{14} + x_{16} \geq 1 \end{aligned} \tag{10}$$

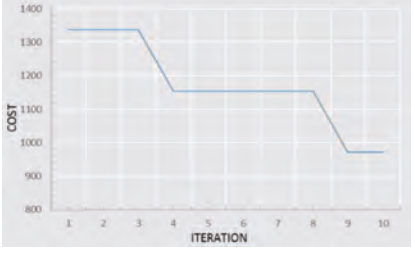

Figure 3. Cost in iterations.

Figure 4. The layout of the sewage treatment system.

3.2 *Solving the optimization model*

Genetic Algorithm is adopted to solve the optimization model. The population size in algorithm is 200. The crossover rate and mutation rate are 0.8 and 0.5 respectively. The stopping criterion of Genetic Algorithm is set to execute 200 iterations. In order to evaluate the performance of the application of constraints based on prior knowledge, the set of parameters is chosen for an efficient solution. The result shown in Fig. 3 indicates that the cost converges to a value, and the value is 971. The layout of the sewage treatment system is shown in Fig. 4, according to the decision variable **X**. Obviously, the cost in previous generations such as 1338 in the third generation and 1154 in the eighth generation shows that the global optimized result is obtained.

At the same time, the solution without these constraints in Eq. (8) is obtained. Although the final solution is the same with the solution with the application of constraints based on prior knowledge, the process of solving the optimization model should execute many times to find the solution meets which the requirements of the design.

4 CONCLUSION

This study has formally defined a reliability based topology optimization design problem through a sewage treatment system to find the optimal layout of the sewage treatment system that serves for two cities. The optimal layout of the sewage treatment system should have the minimum cost subject to the reliability constraint R^*. A modeling and analyzing method is proposed in this paper for the reliability based topology optimization design problem. The method can be used to build the objective function and the constrains. In addition, the priori knowledge about the design requirements is used to determine the elements in adjacent

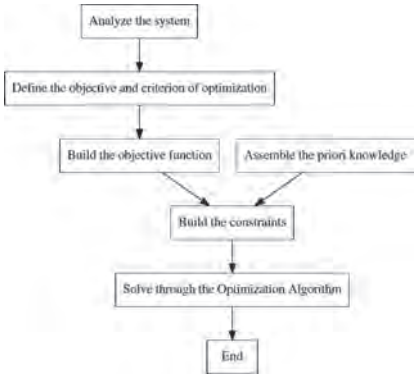

Figure 5. The procedure of the method.

Figure 6. The original design of the sewage system.

Table 2. The comparison between the original design and the optimal design.

Type	Decision variable
The original design	1 0 0 0 0 1 0 0 0 0 1 0 0 1 0 0
The optimal design	0 0 1 1 0 0 0 0 0 0 0 1 0 0 0 1

matrix, which limits the solution space, and this makes the algorithm efficient for solving the problem. Finally, Genetic Algorithm is adopted to solve the optimization model. According to the procedure above shown in the Fig. 5, the optimal layout of the sewage treatment system is obtained. The cost based on the optimal layout is 971, and its reliability 0.8266 that meets the reliability requirement. Compared with the original design shown in Fig. 6, the significant change in the optimal decision variable is presented in Table 2. Obviously, the method makes the design change toward the direction of more feasibility. In particular, the application of constraints based on prior knowledge makes the solution efficient. Therefore, this method is proved to be helpful for the reliability based topology optimization design problem.

ABSTRACT: Risk reduction can be conducted through constructive, technical, organizational or personnel measures. State of the art is to determine the necessary risk reduction, taking into account control dependent protective measures in the sense of functional safety. Complementary protective measures are a special subgroup of protective measures.

Such additional safety functions extend the usual quantified sensor logic actuator chain of safety functions by the operator and the necessary human-machine interface. Standard methods of quantification only apply to the reliability of the technical part of such complementary safety functions. This paper deals with the challenge of taking into account large extent through the human-machine interface. It proposes a systematic approach using a combination of methods offered by standards and literature to determine and quantify the risk reduction of the overall complementary safety instrumented functions. The paper summarizes the proposal of an extension for the assessment of complementary protective functions.

1 INTRODUCTION

1.1 *Motivation*

The ongoing technological changes affect traditional workplaces. Workers change their role from part of the production chain to part of the control system as the level of automation is ever increasing. This affects how safety is ensured. Therefore it is important that human-machine interfaces fulfil the requirements of safety-related functions.

Some of these interfaces are represented by mechanical control elements that initiate electronic safety functions. These functions are grouped together under complementary protective measures. Typically these measures are not operated as often as a control-dependent safety function, and are considered to be a complementary safety device.

ISO 12100 provides details on complementary protective measures. These are measures which are neither inherently safe design nor safeguarding, but are required due to intended use or reasonably foreseeable misuse of the machine (ISO 12100, 2010).

Nevertheless, these human-machine interfaces must be taken into account for an overall risk assessment of machinery and systems.

Within the scope of the IEC 61508 is the overall risk assessment of systems for which electrical/electronic/programmable electronic safety-related systems significantly contribute to the overall risk reduction. This standard also defines human error as a systematic failure which has to be considered in the overall risk assessment (IEC 61508, 2011). Hence, if complementary safety functions are part of the risk reduction strategy in integration, operation or maintenance they have to be considered in the overall risk assessment and evaluation. This is independent of the decision whether complementary safety functions are to be treated as standard safety functions as well as their risk reduction effect. For instance, their risk reduction could be considered as a safety buffer (safety factor, back up safety function) in addition to more automated safety functions.

Other standards like the EN 61511 also require that the design of a safety instrumented function shall take into account human error (IEC 61511, 2004). This means that the assessment of the control elements of human-machine interfaces are part of the overall assessment of safety functions.

Nonetheless, the available standards do not give a sufficient answer to the question of how asses the human machine interfaces. For instance, it has to be discussed if the assessment should be qualitative or quantitative.

For this reason, there is a need for research to asses such interfaces as part of the safety chain.

1.2 *Challenge/main topic*

The Machinery Directive 2006/42/EC prescribes a hierarchy of measures for risk reduction (Machinery Directive 2006/42/EC, 2006):

- Inherently safe design measures,
- technical protective measures, and
- information for users.

Technical protective measures could be divided into control independent and control dependent measures. If risks are then reduced by control dependent measures, a validation must be conducted to proof sufficient risk reduction.

For this verification, the assessment results usually are summarized in a Reliability Block Diagram (RBD) (IEC 61508, 2011). Based on stochastic data, calculations and estimation procedures, a quantitative reliability value (e.g. called SIL_{claim}) is determined for each safety function block and the overall system.

However, complementary protective measures take a special position. They are initialized by an operator and not by a sensor. Hence, in order to evaluate complementary protective measures, the reliability block diagram is proposed to be extended as shown in Figure 1 to include the operator and the human-machine interface.

It is necessary to review in which form the operator and the mechanical interface are included in the standards of reliability assessment. Therefore states of the art for both areas are reviewed in the paper, with focus on quantitative approaches:

- State of practice to assess the operator is to use the human reliability analysis approaches.
- State of practice to assess electrical/electronic/programmable electronic safety-related systems is to use component failure values, calculation and estimation methods.

It has to be discussed which of both method sets can be used to assess the design of the human-machine interface properly.

To do so, complementary protective measures are first of all introduced in section 2 and subdivided into different technologies and operating procedures.

In section 3 a taxonomy is developed to choose appropriate methods and requirements for needed extensions are listed.

Section 4 then reviews the appropriate methods presented by standards and literature and discusses approaches to extend existing methods, i.e. methods that are not yet mentioned in standards and thus are beyond current best practices.

This extension should enable determining and quantifying the reliability of mechanical human-machine-interfaces. Aim is to support the determination of a total reliability value for complementary protective measures.

In section 5, the most suitable methods for determining human reliability analysis and technical safety for complementary protective measure interfaces are listed. Finally suitable additions to the existing methodology to assess safety functions with human-machine interfaces are described.

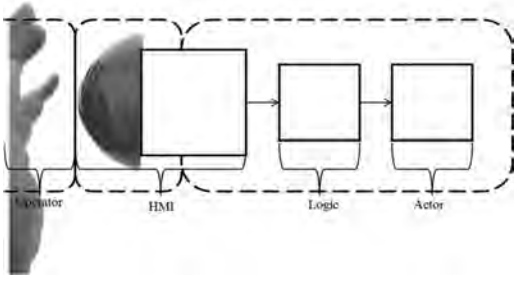

Figure 1. Extended reliability block diagram.

2 HUMAN MACHINE INTERFACE

Complementary protective measures are used as one of the few safety human-machine interfaces. Directory 2006/42/EG stipulates that any machine must be equipped with one or more complementary protective measures, unless the risk cannot be reduced without complementary protective measures.

Areas of application of complementary protective measures include machines, process engineering or emergency braking devices on trains. Disconnectors as used in the automotive sector. Emergency shut downs in laboratories or control rooms are integral part of such facilities.

Since these control elements initialize a safety function, they need to be highly available. For this reason they have to be clearly recognizable, easily visible and quickly accessible (ISO 13850, 2014; Machinery Directive 2006/42/EC, 2006).

The design of the control elements depends on the requirements of the application. Due to this, they can be designed as pushbuttons, wires, ropes, rails, handles or handlebars (Gehlen and Rudnik, 2015). In addition, there are also large scale control elements or specially designed foot switches.

The selection depends also on the type of actuation, e.g. by hand or foot. However, other extremities such as elbows or knees are less common but also used (ISO 13850, 2014; IEC 60947, 2015; Gehlen and Rudnik, 2015).

Special designs are becoming increasingly important in order to ensure adaptation to the operator or the working environment, for example as compensation for the physically disabled or applications on control elements to prevent accidental actuation.

Due to that variety of common control elements, an extension of the methodology is necessary in order to allow to inclusion of control elements when determining reliability.

In doing so, section 3 defines requirements to choose suitable methods. These requirements are needed to categorize and select promising existing and emerging methods of human reliability and technical safety.

3 CLASSIFICATION TAXONOMY OF METHODS FOR HUMAN-MACHINE INTERFACE ASSESSMENT

The necessity to assess the human-machine interface was described in section 1. This section develops a taxonomy for choosing appropriate assessment methods and points out requirements for the needed extensions.

To support an overall risk assessment in the sense of IEC 61508, valid input data are necessary. Due to the fact that IEC 61508 does not list many methods for risk assessment, those listed by ISO/IEC 31010 are discussed.

In order to use the output of the methods within the reliability block diagram, the output should be able to be transferred into quantitative values.

For the human-machine interface of complementary protective measures there is a lack of this kind of data.

The method or a combination of methods to be selected should be able to submit an essential contribution to the quantification of such interfaces.

The method should consider design requirements as defined in directive 2006/42/EG. Interface devices must be

- clearly identifiable,
- clearly visible and
- quickly accessible.

This has to hold for different product types and all kinds of actuations mentioned in section 2.

Furthermore performance shaping factors like design, temperature, noise or workflow should be measurable by the selected set of methods.

The set of methods should build on at least partially validated approaches as documented in reviewed literature and be already accepted or acceptable by experts as well as practitioners.

In summary, the methods are examined with regard to the applicability of the following items:

1. Delivery of quantitative data;
2. Existing scientific acceptance and level of validation to build on;
3. The method set should allow to link to the concept of Safety Integrity Levels (SIL) as defined in IEC 61508 and related standards;
4. The methods should allow the assessment of the fulfillment of existing design requirements as of Machinery Directive 2006/42/EC;
5. High expected scientific acceptance and practical feasibility of methods.

4 REVIEW OF METHODS

This section reviews and discusses methods, techniques and measures offered by major standards in general and in the domain of functional safety and machine safety. First methods for human reliability prediction will be reviewed and discussed. In doing so all mentioned aspects of section 3 are considered.

4.1 *Standard of human reliability analysis*

Human Reliability Analysis (HRA) is commonly divided into three categories. The first generation focuses on quantification in terms of success/failure of actions. The second generation focuses on cognitive aspects that cause errors by taking into account performance shaping factors. The third generation focuses on human performance factor relations and dependencies (Di Pasquale et al., 2015).

Methods of all generations are divided into analytical and expert estimation procedures, as characterized by (Sträter, 1997).

Examples of methods for expert estimation methods are Human Error Assessment and Reduction Technique (HEART) (Swain and Guttmann, 1983) and SLIM and Standardised Plant Analysis Risk-Human Reliability Analysis (SPAR-H). In these procedures, the cognitive area is the main focus. The employed data bases on studies, surveys and extensive literature research.

Exemplarily analytical methods are Technique for Human Error Rate Prediction (THERP) and Accident Sequence Evaluation Programme (ASEP) (Swain and Guttmann, 1983) as well as Méthode d'Evaluation de la Réalisations des Missions Opérateur pour la Sureté (MERMOS), Connectionism Assessment of Human Reliability (CAHR), Cognitive Reliability and Error Analysis Method (CREAM) (Zhang and Tan, 2018), Systematic Human Error Reduction and Prediction Approach (SHERPA) (Bligård and Osvalder, 2014) and A Technique for Human Error Analysis (ATHEANA). In such methods, the assessment of the human error probability (HEP) is based on lists of error probabilities and uncertainty factors (Kirwan, 1998). Values for these lists were determined by observations and tests in simulation and fake-real situations.

To evaluate human errors scenarios, fault tree analysis can be used as it was done with maintenance

procedures of a pump in (Noroozi *et al.*, 2014). *Quantitative* data of human error prediction tables as it was first introduced by THERP are the empirical basis of this method. Also the output of these methods can be presented quantitative.

However, the data presented by human error prediction tables consider only the operator and not the human machine interface, in particular not the interface of complementary protective measures.

Nonetheless, these methods deliver interesting approaches to quantify qualitatively estimated data and interpret data from test scenarios. They can furthermore be used to define test settings. Pursuing the project it is proposed to further scrutinize the HRA methods (Petruni *et al.*, 2017).

Design requirements are not in the scope of these methods, because of their focus on human error prediction. Because of this focus, they are of limited applicability for the assessment of the mechanical part of the human-machine interface and its interaction with humans.

4.2 *Standard technical safety methods*

ISO 31010 provides risk assessment methods. They are categorized in look-up methods, statistical methods, control assessment methods, function analysis, scenario analysis, supporting methods and others (IEC/ISO 31010, 2009; Tixier *et al.*, 2002).

Look-up methods basically use hazards lists to generate input for further analysis. It is common to use these methods in early phases of risk identification, construction or design processes. Therefore, they deliver only indications if risks are possible or not. Exemplarily methods are check-lists, preliminary hazard analysis (PHA) and brainstorming (IEC/ISO 31010, 2009).

Delivering quantitative output is not their purpose. This leads to no approaches to quantify the output. Through their simple structure they are not qualified for the proof of reliability of complementary protective measures. Nevertheless, in an assessment process they are seen as a valid starting point and to achieve completeness of risk assessments.

Control assessment methods take into account all layers of protection to assess risks (IEC/ISO 31010, 2009). Exemplarily methods are bow-tie analysis and layer of protection analysis (LOPA). These methods are also used for risk assessment in the field of functional safety as in IEC 61508.

These methods evaluate systems and their different protection measures concluding the wide range of technically, intercompany, organization, emergency response and so on (Gowland, 2006).

Typical output data are management recommendations and priorizing of risk measures. The kind of output cannot be used for SIL quantification. Therefore a transfer to evaluate complementary protective measures is not indicated.

Due to their alignment on global protection layers, the methods do not focus on single design factors.

Function analysis deals with the functional units or main functions of technical systems. Exemplarily methods are Hazard and Operability study (HAZOP) and Hazard Analysis and Critical Control Points (HACCP) (IEC/ISO 31010, 2009).

The approach of these methods is that the considered system is divided into components, units or subsets. Nominal functions are assigned to these subgroups.

Subsequently, parameters are formulated that lead to a deviation of the nominal function. The qualitative discussion takes place on the extent to which the identified deviations lead to an increase of risks (IEC/ISO 31010, 2009).

These methods are also used for risk assessment in the field of functional safety as in IEC 61508. However, the focus is on the identification of risks that could be minimized later on by control-independent protection measures. This approach therefore determines the necessary degree of risk reduction and thus the requirements for standard safety integrated functions. They do not assess the achieved value of the actual technical implementation or the human-machine interface.

Finally in functional analysis, a level of the necessary risk reduction is given. That leads to further requirements of the assessment process, like to use statistical data in the reliability block diagram describing the proposed architectures.

According to the discussion given, this method type cannot be used to proof the achieved level of reliability of the human-machine interface. Due to this, also the scope of the method does not cover design and performance shaping factors.

Other methods are e.g. consequence/probability matrix and risk indices.

These methods assign the values of a system in matrixes or tables to determine a risk index.

Delivering quantitative values depends on quantitative input data. When using convertible data a quantitative overall value can be determined. Normally semi-quantitative scales are used (IEC/ISO 31010, 2009).

Due to their general approach these methods are not specified, instead they only rank input data. In general these methods are no stand-alone method but in combination with other methods they will be interesting for complementary protective measures. In this way it would be possible to rank the design data.

Scenario analysis summarizes scenario based methods. To define solutions these methods define possible effects and causes for defined scenarios.

In doing so, top event can be analyzed but not all risks can be identified.

Event tree analysis (ETA) follows an inductive approach to identify consequences which result from an initiating event. Due to this approach, this method is not useable for risk evaluation (Stapelberg, 2009).

Fault tree analysis (FTA) is a deductive process. By subdividing a system into its basic components this method identifies factors which contribute to an undesired event (Vesely, Goldberg, Roberts, Haasl, 1981). Beside software and hardware failures also human error failures can be considered.

In order to be able to create fault-trees there must be detailed knowledge of the system. To obtain additional detailed quantitative values, quantitative input data is required. For complementary protective measures these cannot be provided.

By using quantitative input data FTA is able to predict failure probability for a specific event. However, used stand-alone, it cannot be used to predict SIL values.

Due to its general approach, it is possible to use FTAs for many application areas. The scope can be laid on design and performance shaping factors. In this way, fault tree analysis could be used to assess design failures which can lead to a delayed response.

Supporting methods are methods guided by a survey manager. In contrast to normal survey methods, negative group effects can be counteracted with a survey manager. Exemplarily methods are structured or semi structured interviews and the Delphi technique (IEC/ISO 31010, 2009).

These methods deliver no quantitative data but they can be used to provide input data for other methods. In combination with fault tree analysis, using supporting methods could identify factors which contribute to an undesired event.

Supporting methods deliver no data to proof the achieved SIL level.

Supporting methods are applicable to every area. Through the survey manager, the scope can be laid on design and performance shaping factors.

Besides contributing input for fault tree analysis, supporting methods could be used in test scenarios to determine subjective opinions by the test persons.

Statistical methods use mathematical models. By using reliability data (e.g. failure rates), these methods are able to predict the possible development of a protective measure. Exemplarily methods are Markov chains, Monte Carlo simulation and Bayes nets (IEC/ISO 31010, 2009).

In the field of functional safety, methods like parts-count and parts stress are also used in Failure Modes Effects and Diagnostic Analysis (FMEDA) (Smith, 2017) and fault tree applications. Often such methods highly resolve, at least for simple components (as opposed to complex components such as ASICs or microcontrollers). With respect to failure modes, e.g. short cut, drift, and interruption failures. With such very standardized methods an overall reliability value of the safety functions is calculated by single values form each component as well as diagnostic coverage, safe failure fraction and hardware failure tolerance values (Smith, 2017).

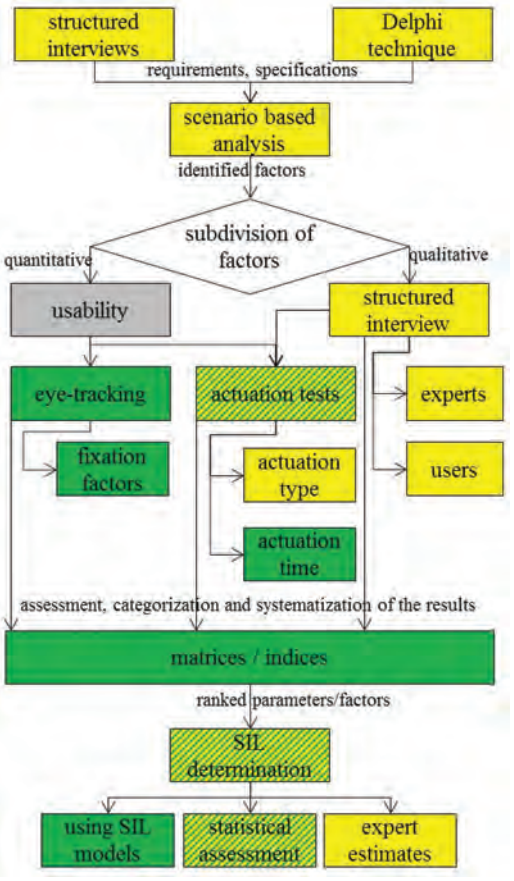

Figure 2. Planned method chain.

Statistical methods cannot be used in the first instance, if there is no quantitative reliability data available. However, if such values can be determined by other methods, system state analysis and reliability prediction methods can be used to determine the listed overall reliability values.

Due to the generic mathematical model these inductive and deductive methods are suitable for almost every area of application.

A special coverage of design or performance shaping factors is not possible, but if corresponding input data is connected to these mathematical models, they can consider these factors. For

instance, depending on the design of the physical interface, certain failure modes are feasible.

5 EXTENSION BY MEASURING METHODS

As shown in section 4, the influence of the physical design of the mechanical human-machine interfaces for complementary protective measures is neither sufficiently taken into account by methods for human reliability analysis nor for technical safety.

This fact requires broadening the reviewed methods with a new method of measurement in order to evaluate the interface. The result should allow for a more precise evaluation of this type of protective measures and for the development of the silk models.

The following method chain is proposed for assessing the physical human machine interface of complementary protective measures. The listed methods are subdivided into quantitative and qualitative (cf. Figure 3) assurance methods and their use for the assessment is explained. Subsequently, the possibility of transferring the gained data to SIL values is explained.

5.1 *Qualitative methodological approaches*

First, qualitative methods are used to evaluate requirements and specifications that influence the reliability of the mechanical part of a human machine interface as complementary protective measures. These have to adhere to legal requirements as defined in directive 2006/42/EG and normative regulations.

With these, input scenario based analyses are conducted to identify contributing factors which influence fault free and highly available usability of complementary protective measures.

Figure 3. Exemplarily heatmap for emergency stop button.

Exemplary factors are size, shape and color. In the further procedure, these factors are subdivided in qualitative- and quantitative measureable factors.

Qualitative factors are analyzed e.g. by structured expert interviews and test persons of the test procedure. In addition, types of actuation are video—monitored during the test procedure.

The aim is to evaluate the subjective impressions of the evaluators and the test persons and with the measured values from the usage test. Compliance with legal and normative regulations is part of the evaluation process.

5.2 *Quantitative methodological approaches*

The quantitative measurable factors determined from the first steps will be examined in depth.

One auspicious approach to measure these parameters is eye-tracking (Harezlak et al., 2014; Guo et al., 2016; Khalighy et al., 2015). This video analysis approach from the area of usability can be used to measure different parameters include (Khalighy *et al.*, 2015):

- Appropriateness, which indicates what design elements are preferred by consumers for a certain function
- Novelty, which includes unexpected and unexperienced design elements for a certain function

Eye-tracking also provides quantitative output such as number of fixations, standard deviation of fixation or common area of fixation (Khalighy *et al.*, 2015; Takahashi *et al.*, 2017). An example can be seen in Figure 3.

Easy to use in simulations, fake test scenarios and real test scenarios (Hahn and Lüdtke, 2013) are further advantages of this method.

Eye tracking can be used to measure the reaction and the behavior of humans but also their interaction with the mechanical elements of human-machine interface (Khalighy *et al.*, 2015; Kim *et al.*, 2017). Due to this eye tracking is good suitable to measure the defined design requirements identifiability, visibility and accessibility (cf. Machinery Directive 2006/42/EC, 2006).

In addition to the parameters that can be measured in the eye tracking procedure, the actuation time is also measured during the test settings, since it can be used to assess accessibility, for example.

Depending on their importance, certain qualitative and quantitative factors are evaluated, categorized and systematized. Matrices or indexes can be used for this purpose. The final goal is to develop a way to make use of the parameters examined in SIL assessments.

Table 1. Comparison table based on IEC 61508, 2011.

Actuations time	No. of fixations	Area of fixation	Factor
12 ms	16	3 cm²	0,01
20 ms	10	5 cm²	0,05
….	….	….	….

5.3 *Transfer to SIL*

Transferring the measured data, e.g. reaction and response times, to values of functional safety can be achieved in several ways.

- One to one transfer (using SIL models)
- Statistical assessment
- Expert estimations

An attempt can be a one-to-one transfer into existing SIL values. But so far, there is no indication that such a transfer is easily possible beyond the assessment of the fulfillment of specified requirements of safety functions, e.g. reaction within 1 sec.

It is more likely that statistical assessment of multiple eye tracking experiments is necessary. In this way, probabilities of failure of the human or the physical human-machine interface are feasible.

The measurements can be used to determine comparison tables similar to the table for calculating the beta factor according to IEC 61508. In this way, an analogical transfer of the results can be proposed. A simplified example table is shown in Table 1.

Experts can estimate frequencies of the observed reaction types, thus resulting in an overall reliability assessment. This approach can be further supported by historical accident data analysis.

6 CONCLUSION

Complementary protective measures need a proof of reliability according to IEC 61508. It is needed for overall risk assessment as well as overall safety evaluation. To deliver a proof of reliability quantitative data is required.

It was shown that there is a lack of such data for complementary protective measures.

After reviewing typical methods from the field of human reliability analysis and technical safety no directly applicable method is identified. However, several methods are supporting the quantification of the reliability of the mechanical human-machine interface.

To deliver quantitative data the use and extension of standard existing methods are described. To this end a tool chain was proposed with the main methods intended to be used.

In particular, the video analysis based tool eye tracking is identified as promising key method, to deliver the searched data.

Since it does not directly generate reliability data, it was also discussed how the measured values can be further evaluated and combined with standard reliability values from IEC 61508.

In conclusion, a way forward the present work sketches a way forward how to address the challenge of the reliability quantification for physical human machine interfaces as complementary safety functions for safety relevant systems.

Simulation analysis of aerodrome CNS system reliability

M. Kozłowski, J. Skorupski & A. Stelmach
Faculty of Transport, Warsaw University of Technology, Poland

ABSTRACT: Ensuring safety, regularity and continuity of air traffic are priority objectives of aeronautical regulations and procedures. They concern, among others, Air Traffic Control services (ATC), Communications, Navigation and Surveillance systems (CNS), Visual/Instrumental Flight Rules (VFR/IFR), minimal Meteorological Flight Conditions (FMC) and air traffic procedures. This paper focuses on aerodrome CNS systems reliability in relation to aerodrome traffic operations and ATC procedures. The aerodrome CNS system has complex technical and functional structure. The elements forming the system are very reliable and accurate. However, the possibility of their operational use depends not only on the technical state. Aerodrome ATC unit (TWR) can issue a clearance for performing an operation (approaching, landing, take-off and climbing) only when the requirements meet the actual conditions specified by FMC, ATC procedures and air traffic rules, approved Flight Plan and operational status of CNS devices. This means that different combinations of operational situations and reliability status of CNS devices should be considered. In this paper Petri nets are proposed to model the aerodrome CNS system reliability structure. The model was used to perform simulation analysis of CNS system reliability for different air traffic and meteorological conditions. Applicability of the method has been shown on the example for selected scheduling season.

1 INTRODUCTION

Ensuring safety, regularity and continuity of aerodrome operations is a fundamental requirement of aviation law. This results in specific tasks for the aerodrome managing body. They include appropriate planning and maintenance of airport infrastructure elements as well as implementation of appropriate technical and operational procedures. The realization of these tasks is connected with the necessity of incurring costs, which are an important element of the budget of the aerodrome operator. Aviation law regulations do not specify the requirements for the categories of procedures and navigational aids that must be implemented and installed at a given aerodrome. This is the decision of the aerodrome operator. These decisions are related to the safety and economic objectives taken into account in the aerodrome's investment plans. Usually, investment decisions are based on cost-benefit analyzes, which consider the issue of aerodrome continuity. It can be effectively analyzed on the basis of reliability theory with the use of operational readiness measures (Kozłowski, 2015, 2016). The obtained results allow defining adequate investment processes including cost aspects. This also applies to the decision to leave actual or increase the category of procedures and navigation aids, which entails significant costs but gives the opportunity to increase revenues from serviced air traffic and transport. An element of these analyzes is the assessment of the reliability of the CNS system in relation to meteorological flight conditions and planned air traffic.

This work aims at finding an effective and objective method of assessing the adequacy of CNS infrastructure to FMC and ATC procedures and traffic rules. This will help identification of necessary changes and verification of investment plans.

2 AERODROME INFRASTRUCTURE

2.1 *Airside infrastructure*

Aerodrome is an area on a land, including any buildings, installations and equipment intended to be used for the arrival, departure and surface movement of aircraft (Annex 14 ICAO). The aerodrome infrastructure includes two basic groups of elements:

– the movement area,
– communications, navigation and surveillance (CNS) devices.

All elements of the aerodrome infrastructure has specific characteristics which must meet the requirements and be consistent with the specifications (nominal values and tolerances of parameters) given in legal regulations. These characteristics define technical, operational and

reliability parameters, and their values must be consistent with the established requirements specified, e.g. in: Annex 10 ICAO, Annex 11 ICAO, Annex 14 ICAO.

Movement area is that part of an aerodrome to be used for the take-off, landing and taxiing of aircraft, consisting of the maneuvering area (including runways and taxiways) and the aprons (Annex 14 ICAO). A runway is rectangular area on the aerodrome intended for the landing and take-off aircraft operations. Depending on the types of installed CNS and their parameters, two types of runways are established: non-instrument runways (NI) intended for the operation of aircraft using visual approach procedures and instrument runways for instrumental approach procedures. The latter may be divided into following types:

- non-precision (I-NP) runway, served by visual aids and a non-visual aid providing directional guidance adequate for a straight-in approach,
- category I (I-PI) runway, served by ILS or MLS and visual aids intended for operations with a decision height (DH) not lower than 60 m (200 ft) and either a visibility not less than 800 m or a runway visual range (RVR) not less than 550 m,
- category II (I-PII) runway, served by ILS or MLS and visual aids intended for operations with a DH lower than 60 m (200 ft) but not lower than 30 m (100 ft) and a RVR not less than 300 m,
- category III (I-PIII A/B/C) runway, served by ILS or MLS and: (A) — intended for operations with a DH lower than 30 m (100 ft), or no decision height and a RVR not less than 175 m, (B) — intended for operations with a DH lower than 15 m (50 ft), or no DH and a RVR less than 175 m but not less than 50 m, (C) — intended for operations with no DH and no RVR limitations.

2.2 *CNS infrastructure*

CNS systems are three technologies that are used at the Air Traffic Management (ATM) to perform air operations.

1. Aerodrome control radio station (COM) is the standard aerodrome air-ground communication device ensuring two-way voice communication between TWR and aircraft.
2. The aerodrome navigation systems include the following device groups:
   - visual aids for navigation (VAN),
   - radio aids for navigation (NAV).

   The standard aerodrome VAN aids consist of:
   - indicators and signaling devices,
   - markings,
   - signs (mandatory and information),
   - lights: approach lighting systems (ALS) - Calvert or ALPA-ATA, visual approach slope indicator systems—VASIS or PAPI, lights installed on runways, taxiways and aprons.

   The standard aerodrome NAV aids consist of:
   - non-directional radio beacon (NDB),
   - the VHF omnidirectional radio range (VOR),
   - distance measuring equipment (DME),
   - instrument landing system (ILS) or microwave landing system (MLS).
3. The surveillance radar (SUR) is an equipment used by air traffic control (ATC) to determine the position of an aircraft in range and azimuth. The standard aerodrome SUR systems used by TWR are:
   - primary surveillance radar, which uses reflected radio signals (PSR),
   - secondary surveillance radar, which uses transmitters/receivers (interrogators) and transponders (SSR).

All of the CNS facilities, in accordance with the requirements of legal regulations (Annex 10 ICAO), are characterized by very high technical reliability. However, their operational status depends on many various factors. These factors determine operational reliability considered as operational readiness. The CNS facility failure is understood as any unanticipated occurrence which gives rise to an operationally significant period during which a facility does not provide service within the specified tolerances.

Aerodrome CNS devices reliability depend and is achieved by a combination of factors, especially:

- flight meteorological conditions (FMC), expressed in terms of visibility, distance from cloud, and ceiling,
- aerodrome infrastructure maintenance programs and procedures (AMP),
- level of redundancy in the reliability structure.

The general formula of the CNS facility (for which the failures follow a Poisson distribution) reliability (as a percentage) – R, defined as a probability that the facility will be operative within the specified tolerances for a time t formula is expressed as:

$$R = 100e^{-t/MTBF} \tag{1}$$

where:
e = base of natural logarithms,
t = time period of interest,
$MTBF$ = mean time between CNS device failures.

The following reliability values of CNS devices were adopted, as shown in Table 1.

Table 1. Exemplary values of CNS facility reliability.

COM	NAV	VAN	SUR
R_{COM} = 0,9995	R_{NDB} = 0,9950 R_{VOR} = 0,9900 R_{DME} = 0,9900 R_{ILS} = 0,9970	R_{ALS} = 0,9990 R_{PAPI} = 0,9980 R_{RWYI} = 0,9995 R_{TWYI} = 0,9990	R_{SUR} = 0,9800

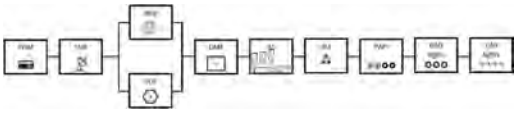

Figure 1. Operational structure of aerodrome CNS system.

CNS devices are needed in accordance with established procedures to ensure safe operations in aerodrome traffic, their functional structure is shown in Figure 1. This structure has been mapped in the model presented in Section 4.

3 AERODROME TRAFFIC

3.1 *Aircraft operations and procedures*

Aerodrome traffic is defined as all traffic on the aerodrome maneuvering area and all aircraft flying in the vicinity of an aerodrome (Annex 11 ICAO). Aircraft may flight in accordance with the visual flight rules (VFR) or instrument flight rules (IFR), and conduct approach to landing, landing, taxiing, take-off and departure operations. The largest range of operational requirements is assigned to approach and landing operations.

In this paper, special attention is paid to approach and landing procedures, in particular to instrument approach procedure (IAP), i.e. a series of predetermined maneuvers from the initial approach fix or from the beginning of a defined arrival route to a point from which a landing can be completed (ICAO Doc 4444). Instrument approach procedures are classified as follows:

- non-precision approach (NPA), it utilizes lateral guidance but not the vertical guidance,
- approach with vertical guidance (APV), it utilizes lateral and vertical guidance but does not meet the requirements established for precision approach and landing operations,
- precision approach (PA) using precision lateral and vertical guidance with minima as determined by the category of operation.

Some standard procedures are usually implemented in aerodrome traffic (Annex 11 ICAO):

- standard instrument arrival (STAR) - an IFR arrival route linking a point on an ATS route with a point from which an instrument approach procedure can be commenced,
- standard instrument departure (SID) - an IFR departure route linking the aerodrome with a specified point on a designated ATS route.

Analysis presented in this paper applies to a controlled aerodrome, where the air traffic control service is provided by TWR (ICAO Doc 4444). To perform an operation in controlled aerodrome traffic, the aircraft needs TWR clearance, i.e. authorization to proceed under specified conditions. Before issuing the clearance, TWR checks the compliance between the requirements and specifications, procedures, operational status of CNS devices, traffic situation, current FMC and aerodrome operating minima (AOM).

3.2 *Aerodrome operating minima*

Aerodrome operating minima express the limits of usability of an aerodrome for:

- take-off, expressed in terms of RVR or visibility and cloud conditions,
- landing, expressed in terms of RVR and DH or minimum descent height (MDH) and cloud conditions as appropriate to the category of the operation (Annex 6 ICAO).

The Aerodrome Operator (AO) establishing the AOM should take into account and consider the following factors:

- types, performance and handling characteristics of the aircraft,
- dimensions, characteristics and categories of the runways,
- categories and performance of the available CNS devices and systems,
- aerodrome ATC/TWR procedures,
- obstacles locations and dimensions and obstacle clearance height (OCH) and necessary MDH,
- shape and sizes of obstacle free zone (OFZ) and normal operating zone (NOZ),
- descent profile determined for vertical guidance during a final approach (glide path—GP).

To ensure the adequate level of safety the Aerodrome Operator shall specify incremental values for height of cloud base (CB) and visibility (RVR), to be added to the operator's established AOM. The following AOM were adopted, as shown in Table 2.

For the given RWY and approach procedure categories and the for aerodrome operating minima, the minimal alternative path of operational readiness were determined, as shown in Figure 2.

Table 2. Controlled aerodrome operating minima.

RWY Cat/ PA Cat	min RVR	min CB (DH)
NI	5000 m	450 m
I-NP	550 m	150 m (OCH)
I-PI	550 m	60 m
I-PII	300 m	30 m
I-PIIIA	175 m	30 m
I-PIIIB	175 m	15 m
I-PIIIC	0 m	0 m

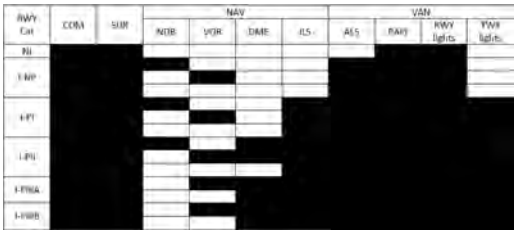

Figure 2. Identified minimal paths of operational readiness at controlled aerodrome Cat IIIB.

Table 3. Time percentage of FMC occurrence in SS and SW.

FMC	Scheduling period SS	WS
RVR > 5000 m and CB ≥ 450 m	18%	6%
5000 m > RVR ≥ 550 m; 450 m > CB ≥ 150 m	27%	12%
5000 m > RVR ≥ 550 m; 150 m > CB ≥ 60 m	18%	19%
550 m > RVR ≥ 300 m; 60 m > CB ≥ 30 m	13%	23%
300 m > RVR ≥ 175 m; 60 m > CB ≥ 30 m	10%	16%
300 m > RVR ≥ 175 m; 30 m > CB ≥ 15m	11%	13%
175 m > RVR and 15 m > CB	3%	11%

3.3 *Operation of the aerodrome*

The subject of research presented in this paper is in fact the airport i.e. aerodrome intended for service commercial air transport.

The operation process of the airport is carried out in two scheduling period i.e. either the summer (SS) or winter (WS) scheduling season as used in the schedules of air carriers. The operating conditions and structure of the air traffic are different in the scheduling seasons.

In subsequent studies, the following data and assumptions were adopted, as shown in Tables 3 and 4.

Table 4. Percentage of IFR and VFR operations in SS and SW.

FR	Scheduling period SS	WS
IFR	90%	95%
VFR	10%	5%

4 MODEL OF AERODROME CNS SYSTEM

As indicated above, calculation of the operational readiness of the aerodrome depends not only on the reliability of the CNS system, but also on other factors described by random variables, the nature of which has been identified. The form of the density function of these random variables indicates the need to use simulation methods to study the operational readiness of the aerodrome.

Model of aerodrome CNS system for reliability and operational readiness analysis was created using Petri nets (Jensen, 1997, Marsan et al, 1999, Reisig, 2013). Originally, they were developed for modeling computer systems working synchronously. However, their high versatility has resulted in their having many other applications in recent years, including modeling and support of air traffic management processes (Davidrajuh & Lin, 2011, Oberheid & Söffker, 2008, Skorupski, 2011, 2015a, 2016, Werther et al., 2007) and systems reliability (Vismari & Camargo, 2011, Pinna et al., 2013, Song et al., 2017, Nývlt et al., 2015, Skorupski, 2015b).

The model of aerodrome CNS system has been implemented as a colored, hierarchical, priority Petri net. The network hierarchy is represented in the form of so-called "pages" responsible for different parts of the model: *I-NP* or *I-PIIIB*, *CNS*, *FMC*.

4.1 *General characteristics of Petri nets*

The basis for building a Petri net is a bipartite graph containing two disjoint sets of vertices called places (designated by ellipses) and transitions (rectangles). The arcs in this graph are directed. A characteristic feature of the graph used in Petri nets is that the arcs have to combine different types of vertices.

The set of places P corresponds to CNS systems operational states or FMC parameters observed at the airport. The set of transitions T corresponds to the generators of these values. The set of arcs defines the process of changing CNS and FMC parameters in subsequent experiments.

4.2 *Petri net for modeling airport operations*

The airport traffic model presented in this paper can therefore be written as

$$S_{AT} = \{P, T, I, O, H, M_0, \Gamma, C, G, E, B\} \quad (2)$$

where:
$M_0: P \to \mathbb{Z}_+ \times R$ – initial marking,
Γ – nonempty, finite set of colors,
C – function determining what color of tokens can be stored in a given place: $C: P \to \Gamma$,
G – function defining the conditions that must be satisfied for the transition before it can be fired; these are the expressions containing variables belonging to Γ, for which the evaluation can be made, giving as a result a Boolean value,
E – function describing the so-called weight of arcs, i.e. expressions containing variables of types belonging to Γ for which the evaluation can be made, giving as a result a multiset over the type of color assigned to a place that is at the beginning or the end of the arc,
$B: T \to \mathbb{R}_+$ – function determining the priority of transition t; this function applies only for transitions that are simultaneously active; in this situation a free choice of transition to be fired is possible.

4.3 *Mapping the aerodrome CNS system reliability*

The model of aerodrome CNS system reliability represents operational states of individual CNS devices, FMC parameters (visibility and height of cloud base) and aerodrome operating minima through the use of colored Petri nets. The main advantage of such approach lies in that the tokens located in places which determine the system states allow one to easily calculate the whole aerodrome CNS system reliability.

For example, in Figure 3 the reliability structure of the CNS system implemented for controlled aerodrome of category Cat IIIB is presented.

Places *COM*, *SUR*, *NDB*, *VOR*, *DME*, *ALS*, *PAPI*, *RWY*, *ILS*, *TWY* contain a token describing operational state of the corresponding system. Places *CNS*1 and *CNS*2 are responsible for storing the current reliability status of the entire CNS system. The determination of this state takes place in the *rel*() procedure. In addition, there is a place *S* whose task is to synchronize the control in the simulation program.

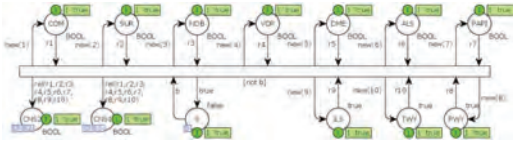

Figure 3. Petri net (*CNS* page) representing reliability structure of the CNS system of controlled aerodrome Cat IIIB.

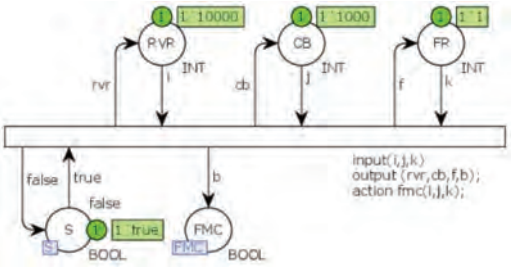

Figure 4. Petri net (*FMC* page) representing the flight meteorological conditions for controlled aerodrome Cat IIIB.

Figure 4 shows the part of the model responsible for simulating atmospheric conditions. It is represented by the *FMC* website.

Places *RVR*, *CB* and *FR* represent visibility, height of cloud base and flight conditions (IFR or VFR) respectively. The place *S* is used to synchronize the control (similarly as on the *CNS* page) and the place *FMC* stores information on whether the current meteorological conditions are sufficient to perform the landing operation in accordance with the current flight conditions. The determination of compliance of these conditions is implemented in the *fmc*() procedure.

4.4 *Computer tool in CPN Tools environment*

The presented model has been implemented as a computer software using CPN Tools 4.0 environment (Jensen et al. 2007). It is a very convenient tool because it allows at the same time creating a model, simulating at different input parameters and simultaneously analyze the results in the state space.

The model of aerodrome CNS system reliability is implemented as the hierarchical Petri net in which different parts of the model are created independently and during the simulation are synchronized by means of special mechanisms.

Figure 5 shows the page *I-PIIIB* responsible in the model hierarchy for calculating the results. Places marked with *CNS*1, *CNS*2 and *FMC* labels in the bottom left corner, called "fused places", are used to synchronize with relevant pages representing the remaining levels in the hierarchy. All fused places marked with the same label are identical, regardless of which part of the model they are placed in. The mechanism of fused places also

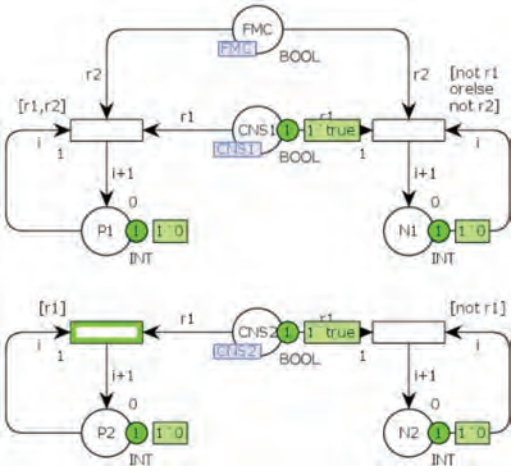

Figure 5. Petri net for calculation of the results.

gives the ability to synchronize the elements within one page of the model.

Place $P1$ counts those simulation experiments in which the landing operation could be performed, and the place $N1$ counts those experiments in which the meteorological conditions or the reliability state of the CNS system were insufficient to perform the operation. Similarly, the $P2$ and $N2$ places register situations of full reliability of all CNS system components and partial failure of the system.

The model and the computer tool have been validated with the use of real data by comparing the data obtained from measurements with the probabilities obtained from the model. Due to the volume of the paper, details of the validation are not shown.

5 SIMULATION EXPERIMENTS

Using the developed model and computer tool, a series of simulation experiments were performed to determine both the reliability of the CNS system at the airport and the possibility of performing air operations, i.e. operational readiness of the airport.

The first experiment was made for a poorly equipped airport of category Cat NP. The following elements of the CNS system must be able to perform the landing operation under IFR conditions: COM, SUR, ALS, PAPI, RWY lights and at least one of the following: NDB, VOR, DME. In addition, the FMC conditions must be at least 550 m visibility and 150 m cloud base. Landing in VFR conditions requires visibility of at least 5000 m and cloud base of at least 450 m.

The experiment consisted in simulating 10^7 landing operations taking into account the real parameters of random variables. The reliability of the CNS system obtained from the simulation is 0.976 and operational readiness is only 0.41.

The second experiment concerned a well-equipped airport of category Cat IIIB. The following elements of the CNS system must be able to perform the landing operation under IFR conditions: COM, SUR, DME, ILS, ALS, PAPI, RWY lights, TWY lights. In addition, the FMC conditions must be at least 175 m visibility and 15 m cloud base. As before, landing at VFR requires at least 5000 m visibility and at least 450 m cloud base.

The experiment consisted in simulating 10^7 landing operations taking into account the real parameters of random variables. The reliability of the CNS system obtained from the simulation is 0.962 and operational readiness is 0.857.

The reliability of the CNS system is slightly lower for the Cat IIIB airport, which is due to the larger number of necessary devices. At the same time, these devices allow for much more precise navigation, which allows to significantly increase operational readiness.

6 CONCLUSIONS

Comparison of the obtained results of conducted simulation experiments indicates the lack of dependence between the reliability of the CNS system and the aerodrome operational readiness. It proves that decisions regarding the modernization of the CNS infrastructure, and thus the change of the airport category and investment projects, should be made in the aspect of ensuring business continuity.

Obtained results and conclusions from the use of the Petri nets model will be used for further research on the determination the airport minimum business continuity and other parameters, such as minimum recovery time or maximum tolerable period of disruption (ISO 22301).

ABBREVIATIONS AND ACRONYMS

ALS – Approach lighting system.
AMP – Aerodrome maintenance program.
AO – Aerodrome operator.
AOM – Aerodrome operating minima.
APV – Approach with vertical guidance.
ATC – Air traffic control.
ATM – Air traffic management.
ATS – Air traffic services.
Cat. – Category.

CB – Cloud base.
CNS – Communications, navigation and surveillance.
COM – Communications.
DH – decision height.
DME – Distance measuring equipment.
FMC – flight meteorological conditions.
FR – Flight rules.
ft – Feet (dimensional unit).
ICAO – International Civil Aviation Organization.
IFR – Instrument flight rules.
ILS – Instrument landing system.
I-NP – Instrumental Non-precision approach.
I-P – Instrumental Precision approach.
MTBF – Mean time between failures.
NDB – Non-directional radio beacon.
NI – Non-instrumental approach.
PAPI – Precision approach path indicator.
R – reliability.
RVR – runaway visual range.
RWY – Runway visual range.
SID – Standard instrument departure.
SS – Summer schedule season.
STAR – Standard instrument arrival.
SUR – Surveillance.
TWR – Aerodrome control tower.
TWY – Taxiway.
VFR – Visual flight rules.
VOR – VHF omnidirectional radio range.
WS – Winter schedule season.

ABSTRACT: As a result of the digitalization of the power business in Norway and Europa, a lot of new possibilities and challenges arise. In 2014 an expert committee one outlined a proposal for the future grid company structure in Norway (Reiten, 2014). In addition, new technologies are being implemented in the system. Wind power, solar power, un-regulated small hydro power production, battery storage domestic and industrial and electrification of transport. Transmission System Operators (TSOs) have a responsibility to supply industry and communities with reliable electric power. However, the operators have been virtually blind to slowly occurring changes in the load profile that reduce the expected regularity of the power supply. This paper will focus on the possibilities and challenges the power business are facing. The paper will describe what technologies is needed i.e Real time probabilistic risk calculations, artificial intelligence, machine learning and smart grid technology. The main question is: can the power business and the introduction of new system tools manage without probabilistic risk calculation for making use of the digitalization and the corresponding big data?

1 INTRODUCTION

1.1 *History of the electric grid*

Modern Norway was built and industrialized by the fact that we managed to utilize rivers and waterfalls for power generation. Hydropower is still the cornerstone of the Norwegian power system, but wind power and solar energy is becoming an increasing part of the energy system. The grid has been developed over 150 years since the first small hydro plants were installed to supply small local industries. Hydro power plants were constructed over time as the industrial development moved forward. Initially the generation supplied local and regional consumers, but as transmission technology developed regions were connected via high voltage lines.

Now, the main grid is the most important part of the grid system, as failure here could mean power outage for very many consumers. The main grid was built largely from the 1950s to the 1980s. However, regional islands existed until 1994 when the main grid was finally established throughout Norway. Deregulation and competition was introduced in 1991 with the purpose of improving the socio-economic efficiency in the energy sector Now, the Norwegian main grid is aging and in the process of being replaced and upgraded by construction of new 420 kV lines in combination with digitalization of the power system. (Statnett, 2017).

1.2 *The change in the power system, smart grid, solar, wind, battery etc.*

The energy system is a critical part of a well-functioning society. Norway is largely electrified and power transmission is an important prerequisite for value creation.

Although the power grids are largely built as before, the power system changes at a rapid pace. Hence, the Transmission System Operator (TSO) must be an enabler and be prepared for the future. The Norwegian aging main grid is in the process of being replaced and upgraded. The power grid takes a long time to plan and build, and have a long lead time, which contrasts strongly with an energy sector in a rapid change. The load is increasing and more generation is being installed. The Green Certificate Scheme provides incentives to expand renewable power generation, including small scale

hydropower, wind power and solar power. Implementation of Automatic Meter Reading and Control Systems at the consumer level will allow for activation of consumer flexibility. Consumption patterns in the energy sector are changing rapidly (NVE, 2016).

Hence, the growing expansion of renewable energy and activation of flexible loads increases the complexities in balancing generation and demand in the power system. The energy-shifting and fast-ramping capability of energy storage has led to increasing interests in batteries to facilitate the integration of renewable resources (Amrouche, 2016).

The future power system will become even more dynamic and the need for real time information for monitoring the system status and for taking the proper control actions are increasing

1.3 *The need for a solution*

Global challenges regarding energy and climate change, the environment, safety, technology and renewable solutions, use and conservation of energy, use of batteries and the connection of electrical vehicles requires greater effort. The changing landscape of the power and utilities industry is resulting in new expectations for IT. Transmission system operators are struggling to fulfil their traditional mission of maintaining security of supply in a rapidly evolving environment driven by digitalization. Digital transformation is something that has become a common trend, and it is one that has reached the Power & Utilities sector moving rather quickly (Digitalization & Energy, 2016). The physical power system cannot function effectively without a well-functioning power market with smart ICT systems. The power system must be able to cope with the increasing variability in load and generation. Hence, in a complex power system, new solutions in the field of ICT and new market models are required to ensure the reliability and security of supply, to ensure that the transmission capacity is optimally utilized and that control actions are taken when needed.

2 DIGITALIZATION OF THE POWER BUSINESS—THE SOLUTION?

2.1 *The goal with digitalization*

The concept of a Digital Power System (DPS) has been discussed for many years. The DPS may be defined like the digital power system being the digital, figuration and real-time description and reappearance of physical structure, technical characteristic, management system as well as personal information system of a real power system which is in operation. The DPS will be able to make a significant contribution to administrating and decision-making more scientifically (Chakrabortty, 2017).

The share unregulated renewable power generation is rising and the power system is changing rapidly. Changes like this must be able to handle tomorrow's energy system. Hence, the reasons and goals for implementing the digital power systems are multiple:

- Monitoring g and controlling all components by equipping them by sensors
- Measure the condition of the power system flows, angle differences, stability margins, and hence the reliability and security
- improving security and stability online, online making and implementing economical operation strategy and carrying out emergency and anti-fault control, etc.
- Better utilization of the facilities
- Precise state information results in increased capacity and fewer faults
- More efficient maintenance and increased lifetime

In the end, the primary goal is to increase the value creation while maintaining the reliability and security of the system.

2.2 *Big data*

Data has always been an important asset in every industry. Since the early days of the information age, business intelligence and descriptive statistics have been used as the standard tools for extracting information and make important decisions from all kinds of collected data. However, as the cost of collecting, storing, and processing data has been dropping exponentially, the amount and the diversity of the data has reached the point where traditional approaches are no longer feasible. The term Big Data is often used to refer to any data that requires new techniques and tools in order for it to be processed and analyzed. Big Data could also be looked from the point of view of the new set of technologies that are helping to solve the challenges in collecting, managing, and analyzing Big Data. These technologies include cloud computing and cluster computing for data storage and manipulation, Artificial Intelligence (AI) and machine learning for data analysis (L'Heureux, 2017).

As in many other sectors big data analytics and machine learning are also getting involved in the energy sector and tools are being developed. They are for example used to forecast electricity demand at substation level, segment customers based on their power consumption patterns, implement demand response strategies, for power system condition monitoring and controls.

The value of big data may come from several use cases: as a source of analytics, as a source for control actions and as an enabler for new products and serv-

ices. An energy company could e.g. track, collect, and store all available data from their system from customers, from components, from system data, from GPS trails to geographical and meteorological data, then combine them together and use big data analytics to produce high value actionable insights and controls.

Use of big data technologies may also open up completely new business models and introduce new products and services in the energy sector.

2.3 *Smart grid*

The smart grid would be an enhancement of the electrical grid, using two-way communications and distributed intelligent devices (Smart Grids European Technology Platform, 2011). Two-way flows of electricity and information could improve the delivery network. A smart grid would allow the power industry to observe and control parts of the system at higher resolution in time and space. One of the purposes of the smart grid is real time information exchange to make operation as efficient as possible. It would allow management of the grid on all time scales from high-frequency switching devices on a microsecond scale, to wind and solar output variations on a minute scale, to the future effects of the carbon emissions generated by power production on a decade scale.

The management system in smart grid is the subsystem that provides advanced management and control services. Most of the focus aim to improve energy efficiency, demand profile, utility, flexibility, cost, based on the infrastructure by using optimization, machine learning and game theory. Within the advanced infrastructure framework of smart grid, more and more new management services and applications are expected to emerge and eventually revolutionize consumers' daily lives.

The protection system of a smart grid provides grid reliability analysis, failure protection, and security and privacy protection services. While the additional communication infrastructure of a smart grid provides additional protective and security mechanisms, it also presents a risk of external attack and internal failures (Pandey, 2017).

3 POWER SYSTEM OPERATION

3.1 *Balancing the system*

Electricity must be produced at the same time as the power is consumed. In addition, the production must be equal to the power consumed. This is called the instantaneous balance of the power system. The power market is the central tool for balancing supply and demand for power. The results of the daily pricing calculation in the day-ahead market are the basis for the Norwegian TSO Statnett's planning and maintenance of current balance in the following operating day. The continuous balancing of production and consumption is very important for the reliability of the system. In case of imbalances, system administrators implement measures to restore the balance, such as adjusting output or consumption.

Statnett has been given the system responsibility in the Norwegian power system. System Requirements in the Power System (Regulations on system responsibility in the power system, 2002) emphasize that the system operator shall provide frequency regulation, ensure instantaneous balance in the power system, develop market solutions that contribute to the efficient development and utilization of the power system, and to the greatest extent possible use of instruments based on market principles. The System Responsible company coordinates the operation of the power system, provides for the determination of capacity for the market, bottleneck handling and trade with other countries.

A well-designed power system has the following characteristics:

- Provide all consumption regardless of geographical location
- Provide consumption at all times
- Must be able to handle variability in consumption and production
- Supply must be of good quality and meet defined quality requirements
- Must be based on economic 'optimal' principle
- Must meet required and defined security goals

The delivered power must meet certain minimum delivery quality requirements. The following determines the quality:

- System frequency must be kept around the specified 50 Hz with variation within + –0,1 Hz
- The voltages are kept within narrow, prescribed limits around the normal value. Generally, the voltage variation should be within + –10% (or 5% in some systems)

To ensure that voltages and frequencies are kept within their limits, voltage and frequency regulation is required for efficient operation of the power system (Gjengedal, 2017).

3.2 *Traditionally operation and planning N-1*

Operating the network according to the N-1 criterion means that failure of a component does not result in interruptions in the supply to the end user. It is referred to as reduced reliability when the N-1 criterion is no longer met, in cases where it should normally be met. Statnett as a system administrator has the means through the system liability regulation (Regulations on system responsibility in the power system, 2002) to be able to change the grids configurations, as well as demand up-or

down regulation of production. Such means can help ensure operation according to the N-1 criterion. However, the authorities are not requiring that the main network should meet the N-1 operation safety at all times.

3.3 *Power system operation challenges*

In power system operation, traditionally slow-changing and predictable parameters are now changing fast. In addition, new system parameters are being introduced in the power system. This will influence the inherent properties of the system as well as the risk for outages. While the power system complexity is increasing, the operational available response time is decreasing fast. Example: The introduction of solar and wind production represents a power production which is difficult to manage when the wind stops or clouds cover the sun.

Combine this with a high degree of automation and smart grid technology, and the existing operational «know how» may not be sufficient to deal with the properties of the current and future power system.

What the neighboring power system is doing, will affect the current power system in regards of dynamics and risk. Until now power system operators have evaluated the system risk for loss of load qualitative, based on experience. This "gut feeling" based on such an experience approach, will not be valid in the future without nurturing new skills and competencies.

The first step is to be able to assess the system risk level equally for each power company. The only way to achieve this is by assessing this quantitatively with probabilistic approach.

The power business has lacked tools to evaluate quantitatively the system risk level in near real-time, and to assess possible risk reducing actions. This challenge was addressed by the GARPUR project 2017 (GARPUR, 2017).

3.4 *How will the future power system risk develop?*

New production with challenging properties, like solar and wind are put into the power system in an increasing rate. These alone will increase the risk in the system due to the characteristic intermittency property. It is expected more severe weather affecting the power system, resulting in higher risk. It is expected higher peak load as consequence of electrifying transportation and petroleum production, and this will increase risk in period of peak loads. New smart grid technology like disconnection of loads when needed, will reduce the risk in the system. The IoT (internet of things) technology may also increase the challenge of balancing the system due to rapid in and out connection of load driven by new sets of criteria not known by the system operators. This technology alone represents a threat to the system based on the possibility that third parties can hack into the equipment and connect/disconnect technology without anybody noticing, resulting possible outage of large areas.

Furthermore, battery storage is being introduced. This will most likely reduce the risk of outages in the system. In addition, artificial intelligence and machine learning is already on our door step. This can both help the system if done right, or increase the risk done wrong.

All these factors combined is a large order for the human mind to process in real-time. It is often seen that the risk driver is the combination of many seemingly unrelated factors and events, and not a single cause and effect scenario.

Example: A given power system has a unique dynamic characteristic and inherit risk property. The power system will typically be in a N-0 situation in periods with high peak load. Depending on the size of the load(s) affected by the reduced power delivery reliability, the total system risk is affected (see Figure 1). Above the red line the expected "not delivered energy" exceeds the acceptable level in regards of expected cost due to outage or the power companies' goals. Increase the system load for the same power system and the risk for outage will increase (see Figure 2). By operating the same

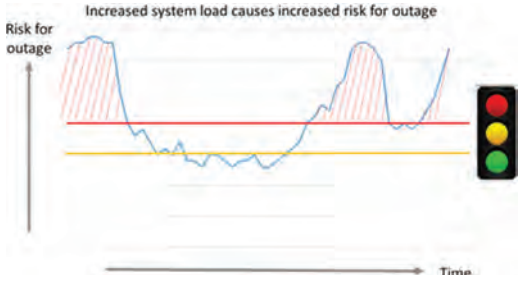

Figure 1. System risk for a given power system.

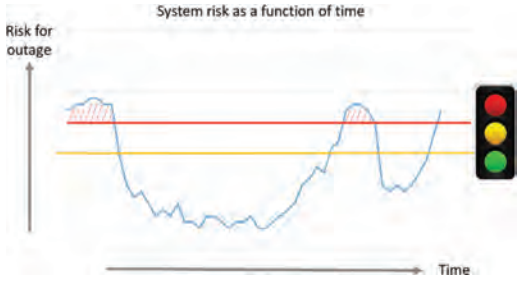

Figure 2. Increase only the load and the risk for outage increases.

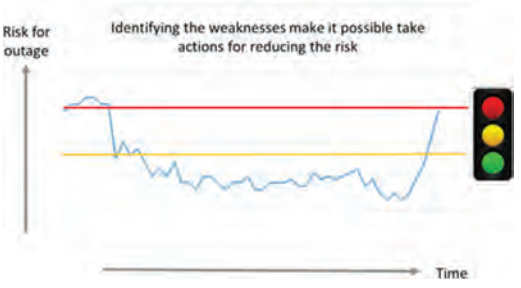

Figure 3. Operate the power system optimally, and the same increase in load can me managed in terms of risk for outage.

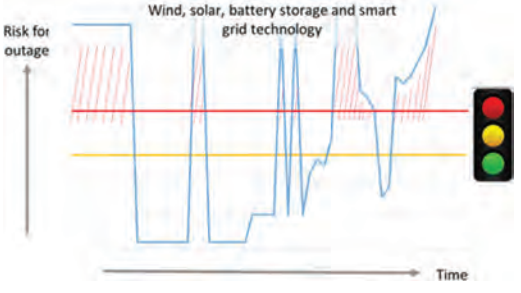

Figure 4. Prediction for future system risk development.

power system with the increased load more optimally, the total risk can be reduced to being within the acceptable risk level (see Figure 3).

With all the changes that are being introduced in the power system, our prediction is that the power system will experience system risk levels that goes from a very high level to the theoretical lowest level, and changing continuously by the minute (see Figure 4).

4 PROBABILISTIC RISK ASSESSMENT

4.1 *The starting point for a consistent risk management for the whole value chain*

To have a consistent risk management throughout to value chain, it is vital to be able to calculate the risk level of the current state of the power system. The current state will as it is in any power system analysis, be the base case for the next step analysis and evaluation. Furthermore, everything that is being done and planned, is being done for keeping the power system in operation. Therefore, the risk assessments done in the operation of a power system by operators or planning of operation, should be the foundation of risk evaluation to be communicated in the power grid company as input for all future evaluations and analysis.

4.2 *Identifying the power system inherit risk properties*

To be able to identify the power system's inherent risk properties, the following objects and parameter has to be included in a mathematical representation of the power system:

- Production – Spinning reserve – Location
- Production type
- Power system configuration
  - load flow
  - load demand
  - system dynamics
- Component reliability
- Maintenance interval and prioritizing
- Weather influence
- Energy storage possibilities and Smart grid technology
- System operators action and strategy
- Influence of other grid company's actions in their own power system

These factors have the characteristic of slow changing and fast changing properties. Since a power system is changing every minute of the year's 8760 hours, the total system risk graph will also vary by the minute. It is therefore, important to model the power system in great detail so that every change that occurs is reflected by the mathematical model. Furthermore, since historical data of the power system is stored (i.e. configuration, production, load flow, load level and failure rate for each component in the system) is available, validation of the mathematical model is possible to test against previous recorded risk levels.

4.3 *Calculation of the probabilistic risk level in near real time*

A short description of the calculation sequence in PROMAPS:

1. Calculate reliability of each grid segments. Each component in a grid segment can be described with multiple possible states, for instance Functioning, Intermediate fault or Lasting fault. PROMAPS use Markov models to represent each individual component in the grid segments:

$$\dot{p}_i = A_i p_i \tag{1}$$

   where A_i is a Markov model containing fault rates and repair rates.
2. It is possible to build reliability models of whole grid segments by simply combining all the

Markov models of each individual component as Kronecker sums, as follows:

$$A = A_1 \oplus A_2 \oplus ... \oplus A_n \quad (2)$$

is combined into common states, thus reducing the number of states in the grid segment model to a few unique states.

3. Calculate the probability of each system states. A system reliability model is calculated by combining all grid segments models using Kronecher sums, as described in the last step.
4. Discard all system states with probability below some probability threshold. The probability threshold is dependent on how many states should remain in the set for further assessments.
5. Calculate maximum power transmission capacity for each state in set.
6. Calculate expected power shortage at each load point
7. Calculate expected power supply reliability, and mean time between loss of supply
8. Calculate various auxiliary variables including economic data.

The analysis can be performed for various load profiles. For online reliability assessments, parts of the calculation sequence are repeated whenever new online data is available.

Promaps risk assessment principles for online calculations has been presented in detail in PMAPS2012 (Svendsen, 2012). The concept has also been researched in the recently completed pan-European project GARPUR (GARPUR, 2017). Common for these methodologies for real-time risk assessments is that they consist of two main parts:

1. Calculate the probability of all sequences of events in the power grid
2. Calculate the consequence of these events.

Since there is a "infinite" number of possible events in a power grid, there also need to be some principle of discarding events with negligible risk. The simplest approach is to discard all contingency with probability below some probability threshold. The uncertainty of the risk assessments is related to the sum of risk of all events that has been discarded.

5 AI AND MACHINE LEARNING IN OPERATION OF POWER SYSTEM

5.1 *What data is needed*

There are numerous data available as input for AI and machine learning such as e.g.: current and historical: load, production, spinning reserve, sensor data (current, voltage, frequency) load flow, configuration of the power system, component data (type, characteristic, age), component health indexes, all previous outages and causes, weather type at the point of outage, dynamic data of the strength of the system form PMUs, protection schemes and other functionalities.

In addition, also near real time probabilistic risk calculation are available as input (Tollefsen, 2015). This represents big calculated data sets that gives a new insight in the inherit property of the power system.

Essential data for operation of the system: Voltage, frequency, production, spinning reserve and regulation possibilities.

5.2 *AI agents assigned to perform tasks in the power system*

Artificial Intelligence in general and supervised deep learning in particular tends to work well with large amounts of data (Schmidhuber, 2015). In supervised scenarios, the deep learning algorithms learn from known correct examples, and pick up trends and patterns that depict specific scenarios. In these cases, there is a trade-off between data quality and data size. The lower the quality of the data, the more data is needed extract the correct patterns. The most common example where this works is social media such as Facebook which contains enormous data of varying quality, enabling complex artificial intelligence algorithms.

The same basic concept is true for power systems, and it is therefore crucial that large amounts of data from power systems, including smart meters, is collected. The Norwegian power system manager Statnett has a particularly important role here. A concrete example of an application area artificial intelligence is expected to play a pivotal role is predicting electrical consumption peaks to avoid power outages (Goodwin, 2016). Over consumption may have serious consequences such as power outage. By predicting future peaks in the consumption, techniques such as load balancing could be carried out to avoid the problems. This clearly has to be carried out before the consumption peak happens, but knowing the consumption before occurrence is difficult. For this particular case, positive and negative examples should be collected, which in this case is examples of normal power flow, and over consumption. The artificial intelligence networks are trained with the data, and learns to understand which consumption trends lead to peak in the data. After the training phase, the network is put into practice and predicts future peaks which could either be used directly in an automated system to initiate load balancing, or as input to a decision support system. Other examples where artificial intelligence could play

a similar role are operation of power system and production prediction.

The operation of a power system is based on a set of rules and constraints that the power system operator must operate the system within. The constraints are at set of limits that is related to the physical properties for the different power system components. This can e.g. be thermal limits for power lines/transformers or other components, the normal frequency deviation should be within ± 0,1 Hz, voltage variations within ± 10% and the angle difference in three-phase current should be within maximum limits when reconnecting different part of the power system.

The rules and constraint connected to operation of a power system is notably different than the rules of board games such as chess. A power system is a stochastic system influenced by physical laws and human behavior such as consumption. The rules in a chess board and the behavior of the game are deterministic which means that future states are easily predictable, albeit many. However, there are similarities as well. The number waste amounts of states and complex behavior is identifiable in both complex board games and power systems. We can imagine that a machine learning also can be applied for operation of power systems based on the principle applied by Deep Mind with the new chees Alpha Zero program (Silver, 2017) and by the improved operation strategy obtained for Googles data center by use of Machine Learning Applications for Data Center Optimization (Gao, 2016).

5.3 *How can we evaluate the AI actions and gain trust?*

The artificial intelligence techniques vary from being statistically based on probabilistic induction, to knowledge based, and neuron based deep learning. For deep learning, which is undoubtedly, the most promising artificial intelligence technique in use, a confidence level is available as part of the supervised classification output. This confidence is very different from a probability, but can in any case be used as part of a trust schemes. If a deep learning network were to predict future problems, whenever it outputs an expected problem it can at the same time output how confident it is that is an actual problem. If this is part of a decision support system, the confidence can be used to inform a human decision maker in a decision support control room.

6 HUMANS, DECISION SUPPORT SYSTEM AND AI

6.1 *Decision support for system operation*

The ability to deal with the real-time fluctuations of the power system is not only a question of creating new technology and algorithms. Humans are still in the loop and the energy system is thus not only a technical system. It is a socio-technical system where the sense making, decisions and interventions of control room operators play an important part in the reliability of the system as a whole. This means that decision-support technology can play a key role in upholding the security of supply, but also that we need to take into account the human part of decision-making in control rooms. New decision-support systems will meet existing competence and experience, both at the individual and team level. In order to make sure that decision-support systems have the intended effects, the human perspective must be included in the development of the systems to ensure a good match between humans, technology and the organization of decision-making.

Advances in modelling and machine learning allow for information processing and problem solving that surpasses the capacity of an individual human decision-maker. Nevertheless, there is a need to find a balance between man and machine in the distribution of decision-making functions. Also, any period of technological transition will face challenges related to the competence of the existing workforce in the use of new technology, as well as a warranted level of trust into what new technology can and cannot do.

The importance of taking into account the relationship between human decision-making and algorithms can be illustrated by an example from New Scientist Volume 236, describing the domination of robots in the financial markets resulting in the human trader era is fading: “There are still a lot of unanswered questions surrounding the last bond market ‘flash crash’. On 15 October 2014”, “the US Treasury market crashed for about 10 minutes. Experts hypothesized that “activities of electronic trading algorithms” bore part of the blame, but reserved judgement for when they had more information. Three years later, no one is any wiser” (Adee, 2017).

This can also be the case for the future power system where smart grid technology, IoT and machine learning is put into operation. In order to avoid similar algorithm-induced “flash crashes” in the power system, it is vital to ensure the understanding of the system dynamics, the inherent risk properties and applying deep learning approaches as decision support.

7 CONCLUSIONS

The power system is rapidly changing towards the digital power system by using advanced ICT solutions, big data, smart grid, AI, machine learning and other advanced instruments.

The digitalization of the power business in Norway, Europe and other parts of the world, arise numerous new possibilities but also challenges.

To gain trust in the machine learning technology being introduced to power system, and to avoid similar problems in the power system as the financial markets experienced with the 'flash crash' from 2014, new insight is needed. The need for understanding and tracking in near real time the power systems inherent system property in regards of power system dynamics and risk level, becomes evident.

ABSTRACT: Nowadays, a fundamental requirement for a prosperous society is a reliable energy supply. The complex network theory provides an excellent basis to explore the functionality of such systems in response to severe component failures. In this case study, the European natural gas system is analyzed. The actual natural gas consumption is geospatially allocated to the infrastructure network. The network is abstracted and the flow capacity of the network is computed. A scenario analysis is conducted in order to identify the impact of storage facilities on the actual maximum possible flow. Furthermore, the natural gas supply shortage caused by each pipeline in case of a potential pipeline shut-down or failure is estimated. Finally, potential strategic locations of storage facilities for a more reliable natural gas network are identified.

1 INTRODUCTION

The consistent and continuous flow of goods and energy is an essential requirement for a reliable and prosperous economy in today's world. Looking at Europe, for instance, a notable share of more than 20% of the primary energy consumption is covered by natural gas (Eurostat, 2017). However, this causes also dependency on reliable supply, which cannot always be guaranteed to the full extent. In the last decade, several unforeseen natural gas disruptions with consequences on the economy occurred (Austvik, 2016). For example, the terrorist attack on the Amenas natural gas plant caused a reduction of more than 10% of the natural gas production of Algeria (Chrisafis et al., 2015). A very recent example is the explosion happened in Austria, where the accident disrupted natural gas flows toward Croatia, Italy and Slovenia. (Tirone and Wabl, 2017). Not only actual disruptions can cause damage, but also the awareness of a potential supply shortage can trigger uncertainty about business continuity. This happened for example in March 2013 in the United Kingdom, when natural gas supply equivalent to only six hours of supply was available in the storage facilities (Plimmer and Chazan, 2013).

Natural gas is transported and distributed by a well-developed system. The design of such a system requires long-term planning and large infrastructure investments. This kind of investments locks the capital in long-term contracts involving often policy decisions and agreements on national or regional levels (e.g. Carvalho et al., 2014, Mišík and Nosko, 2017). The European natural gas system became over time a large infrastructure network with many components, such as compressor stations, storage facilities, gas processing plants, Liquefied Natural Gas (LNG) terminals, LNG liquefaction and regasification facilities, aiming at assuring high reliability of the supply system. These components should be well planned and coordinated to guarantee a continous and adequate natural gas flow.

The natural gas demand cannot be covered by the European countries' available natural gas resources (BP, 2016). Therefore, it is necessary that natural gas is transported by pipelines from the East and South to Europe. Complementary, natural gas is also imported via LNG terminals.

The natural gas infrastructure network has to be able to compensate for potential pipeline shutdowns or failures, among others. This can be achieved through the construction of strategic

storage facilities and by increasing the network connectivity by means of new pipelines or diversification of entry points (e.g. LNG terminals).

Because of its importance, the European natural gas network is under constant analysis in order to improve the network's security of supply capacity. Besides natural hazard analysis (Poljansek et al., 2012, Lustenberger et al., 2017), a transmission network model, the so-called ProGasNet was developed (Praks et al., 2015) and complex network methodologies employed for analysis of the network properties (Carvalho et al., 2009). All the applied methodologies are based on graph theory. Moreover, Monte-Carlo-based reliability and vulnerability assessments of the network are applied (Praks et al., 2017), different flow algorithms and ways to allocate the natural gas in case of a disruption are tested (Carvalho et al., 2014). All the developed methodologies enable the identification of bottle-necks in case of a network component failure. A methodology to systematically analyse the impact of natural gas storage facilities on the network, however, is not developed yet. Furthermore, the impact of natural gas storage facilities on the entire European natural gas network has not been previously investigated.

The aim of this study is to develop a methodology to analyse the European natural gas infrastructure network's capacity to cover the demand not only during full operational conditions, but also in case of a long-duration pipeline shutdown or failure. Because storage facilities can be considered as consumption or supply infrastructure components in the network, the impact of feeding natural gas from natural gas storage facilities into the network in case of a potential long-term pipeline shutdown or failure is examined. The analytical framework employed in the current study comprises four steps to achieve this goal:

1. extending the natural gas infrastructure network model with geo-referenced storage facilities,
2. allocating natural gas demand according to geospatial consumption distribution,
3. analysing the extended natural gas infrastructure network by applying complex network theory, and
4. conducting scenario analysis with and without storage facilities to analyse the potential impact of pipeline failures on the overall network flow.

This study builds on Lustenberger et al. (2017). The focus is on the European Network of Transmission System Operators for Gas (ENTSOG) because sufficiently detailed data was available for the analysis. The network is abstracted, and the impact in case of a pipeline failure causing supply losses is estimated for each pipeline segment. Based on this, the specific impact for each pipeline segment is quantified. Moreover, the effect of storage facilities, to compensate such a potential failure, is analysed.

2 METHOD

In this section, the considered network system, including its components, is described, and the methods applied are explained.

2.1 *Geospatial natural gas infrastructure network model and its components*

The European natural gas infrastructure network consists of several thousand components including pipeline segments, entry and exit points, storage facilities and LNG terminals. In the present study, these infrastructure components are taken into account.

The natural gas infrastructure network data on geospatial basis can be abstracted as graph (e.g. Carvalho et al., 2014, Praks et al., 2015), while important features as the network topology are retained. This enables to employ a maximum flow algorithm well known in graph theory (Heineman et al., 2016). The graph can be defined as $G = (V, E, c)$, whereas G is an undirected graph with the vertices V and the edges E and c denotes the capacity of each edge. The vertices V can be sinks (e.g. consumer vertices) or sources (e.g. natural gas drilling platforms, LNG import terminals, and import pipelines).

A special case are the storage facilities and the natural gas power plants, which are discussed in section 2.2.

$E(u,v)$ represents the pipeline, connecting V_u and V_v. Whereas u and v are unique vertex identities. The flow capacity of $E(u,v)$ is defined as $c(u,v)$, while the natural gas flow through $E(u,v)$ is $f(u,v)$. If V_u and V_v are connected by multiple edges, $E(u,v)$ represents the sum of these edges. In this case, $c(u,v)$ is the sum of the involved pipeline capacities. The graph is then built according to Equation 1 and Equation 2.

$$E(u,v) = E(v,u) \tag{1}$$

$$c(u,v) = c(v,u) \tag{2}$$

With this abstraction, the natural gas infrastructure network can be transformed into an undirected (bidirectional edges) graph.

2.2 *Allocation of natural gas demand*

The actual natural gas consumption is allocated to the identified sink vertices. This is done considering

the geospatial distribution of the population density. It is assumed that the population density represents the geospatial distribution of the natural gas consumption of all the demand sectors, such as households or industries. The exception is the actual consumption of the natural gas power plants, which are identified as additional large consumers. The latter distinction is done because a linear allocation of the natural gas consumption at the country level to the population density on raster grid cell resolution does not necessarily reflect the spatial distribution of the natural gas power plants. Moreover, natural gas power plants constitute large consumers, which need to be taken into account separately for the spatial natural gas consumption allocation. The consumption allocation is conducted according to the following steps.

First, the population density for each country is estimated based on the corresponding population maps (CIESIN, 2016) and the country boundaries (zones) (GADM, 2016).

Second, the natural gas consumption of the natural gas power plants is estimated for each country. The consumption for each power plant is derived according to its CO_2 emissions provided by Enipedia (2016) and summed up at the country level.

Third, the natural gas consumption at the country level for the other demand sectors (e.g. industries and households) is estimated. This consumption (OD-Consumption) can be represented by subtracting the natural gas consumed by natural gas power plants from the total annual natural gas consumption at the country level (IEA, 2017). The resulting OD-Consumption is normalized per capita at the country level. The per capita consumption can then be allocated to the population density for each grid cell (~1 km) resulting in the OD-Consumption map of natural gas.

Fourth, the European area is split into demand areas applying a Voronoi algorithm (also called Thiessen algorithm) considering the identified sink vertices. The Voronoi algorithm cuts the connection line to the nearest neighbour of a vertex into half and connects the cutting point to an area around the corresponding vertex (Aurenhammer, 1991). The resulting Voronoi diagram is a partitioning of Europe into demand areas, in such a way that all points within a given Voronoi cell are closer to the corresponding vertex than to any other vertex. With this procedure, consumption can be allocated to the network, while the topology of the network remains the same.

Fifth, demand areas are spatially joined with the the OD-Consumption map. For this, all the raster grid cells are summed up within each demand area.

Finally, the natural gas consumption of the power plants is added to the corresponding demand areas.

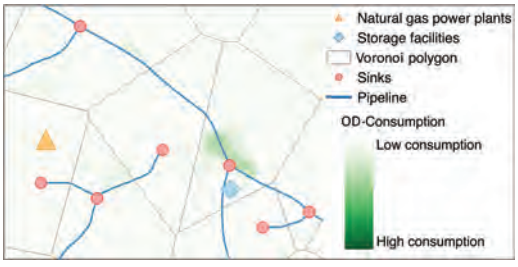

Figure 1. Map of the network infrastructure, demand areas (Voronoi polygons) and other demand sectors' consumption (OD-Consumption) on raster grid for illustration purpose.

This procedure provides an estimate of the natural gas consumed in each demand area on an annual basis. The data used and the spatial distribution are illustrated in Figure 1.

The power plants are connected to the network by assigning their consumption to the corresponding demand area. Storage facilities can serve as sinks or sources depending on the actual operation of the facility.

The storage facilities are assigned to the corresponding demand area. Depending on the scenario definition (see section 2.4), the corresponding demand area vertex is considered as source and/or sink.

The result of this procedure is a graph defined as $G(V,E,c)$ with $s,t \in V$, where s represents the source vertices and t denotes the sink or targeted vertices. Moreover, storage facilities can be switched on or off by turning the corresponding vertex from a sink to a source.

2.3 *Complex network theory—maximum flow estimation*

The abstract network poses a multi-source/sink problem because there are more than one identified source and sink. The multi-source/sink problem is commonly solved introducing a virtual super source and a virtual super sink, connecting all the corresponding sources and sinks as illustrated in Figure 2 (e.g. Ford and Fulkerson, 1956).

Moreover, flow capacity can be assigned representing the sink or source. This can be done by allocating flow capacities to the resulting virtual edges connecting the virtual super sink or the virtual super source to the corresponding vertex. In this study, the virtual edges connecting the source vertices to the virtual super source are assumed to be infinite, but the virtual edges connecting the sink vertices to the virtual super sink are limited by the actual consumption estimated at each corresponding vertex.

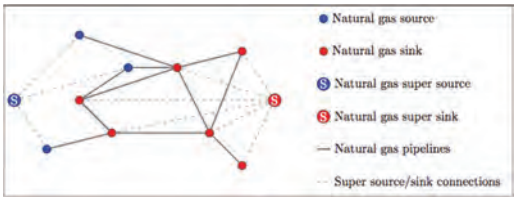

Figure 2. Illustration of the graph transformation from a multi-sink/source problem to a single sink/source problem.

Table 1. Ford-Fulkerson algorithm as applied in this study.

Algorithm: Ford-Fulkerson algorithm (Ford and Fulkerson, 1956)

Data: $G(V,E,c)$ $s,t \in V$
Result: F_{max}
while $p(s,t) \mid f(s,t) \leq c(s,t)$ exists **do**
1. Find path with unexploited flow
   $p_{unExp} = p(s,t) \mid f(s,t)$;
2. Find unexploited capacity
   $c_{unExp} = min(c(u,v)-f(u,v))$ for $u \in p_{unExp}$ and $v \in p_{unExp}$
3. Add unexploited capacity to flow on p_{unExp}
   $f(u,v) = f(u,v)+c_{unExp}$ for $u \in p_{unExp}$ *and* $v \in p_{unExp}$

end

$F_{max} = \sum_{u \in V} f(u,s^*) = \sum_{u \in V} f(t^*,u)$

The maximum possible flow between the virtual super sink and source is computed as described in Table 1 is derived from Heineman et al. (2016).

2.4 *Scenario analysis*

To estimate the impact in case of a pipeline failure, each pipeline is once deleted resulting in $\bar{G} = (V,\bar{E})$. Whereas $\bar{E} = E \backslash E_k$ with k representing the number of removed edges, which is in this case $E_k = E_i$. With this the impact in case of a single pipeline loss on the maximum possible flow is estimated. Hence, cascading failures in the network are not investigated. The dependencies of the network components in the sense of pipeline capacity to compensate a potential flow loss, however, are considered. As the maximum possible flow is not only limited by the pipeline capacity, but also by the actual consumption, the resulting difference can be considered as the loss of service of the European natural gas infrastructure network. This impact is estimated according to Equation 3.

$$\Delta F_{\max,i} = \frac{F_{\max} - F_{\max,i}}{F_{\max}} \cdot 100\% \quad (3)$$

where $\Delta F_{max,i}$ is representing the impact of pipeline i in percentage in case of a failure of pipeline i. F_{max} stands for the initial maximum flow and $F_{max,i}$ for the computed maximum flow without the pipeline i.

To estimate the impact of a storage facility considering a potential pipeline failure, a scenario analysis is conducted. For this purpose, the above-mentioned simulation is carried out twice, once without and once with storage facilities as natural gas sources. The storage facilities are added to the vertex in the corresponding demand area. The identified vertices in the corresponding demand areas are then connected to the virtual super source, representing not only a sink but also a source vertex.

The defined scenarios are with and without storage facilities. In this way, the impact of a storage facility on the network, and the service loss in case of a potential pipeline failure can be calculated.

3 DATA

In this section the datasets employed and the data acquisition is described. The used data is listed in Table 2. All data were available in a format directly usable in this study, except for the European natural gas infrastructure network data. The acquisition of this data and its processing is described in section 3.1.

3.1 *European natural gas infrastructure network*

The natural gas infrastructure data was extracted from three map layers, each consisting of 1024 high-resolution raster map tiles (images) from ENTSOG (2016). The three map layers represent three different ranges of pipeline diameters to which approximate flow capacities can be assigned.

First, the high-resolution images were georeferenced. Second, the raster cells were reclassified and the raster-grids vectorized. This resulted in a pipeline network in a digital map format (Lustenberger et al., 2017). To each edge a flow capacity c can be assigned according to the given diameter of the corresponding pipeline using the information from Carvalho et al. (2009).

The identification of the sources was done according to the provided map of ENTSOG (2016). Drilling platforms and LNG terminals were identified as source vertices. In addition, the entry points of the pipelines running from the East and from the South to Europe were identified as source vertices. This was concluded from the natural gas import statistics according to BP (2016).

In addition, natural gas storage information is processed from (ENTSOG, 2016). The storage facilities' information, including facility name and ENTSOG-ID, are downloaded via the ENTSOG Transparency Platform's API (Application Programming Interface). The point coordinates

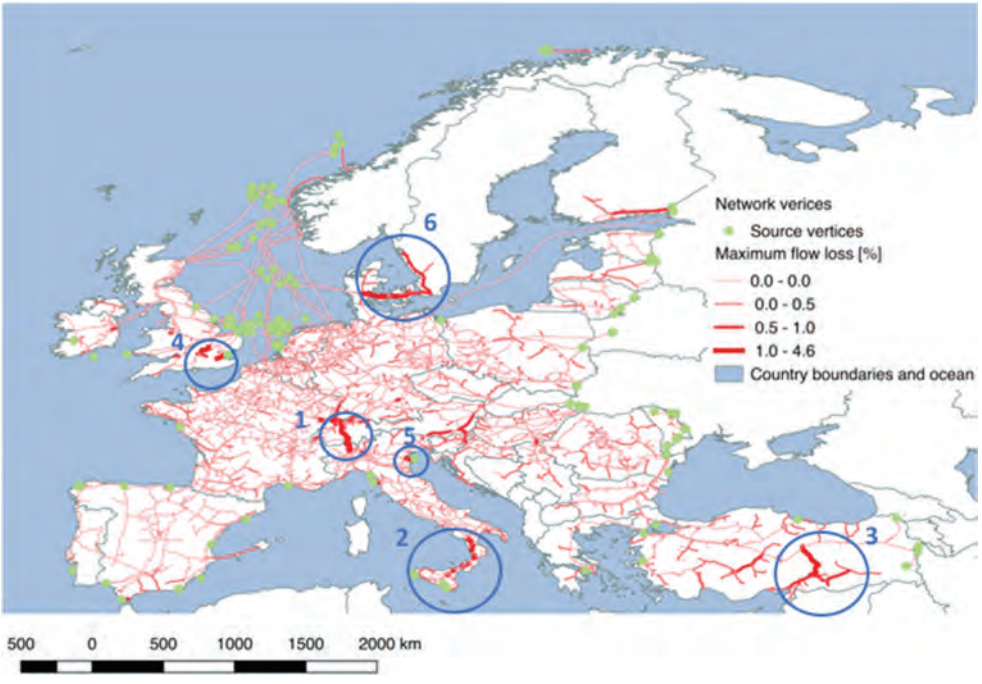

Figure 3. Impact of a potential pipeline failure or shutdown on the maximum flow for the scenario without storage facilities.

were then georeferenced according to the map provided from ENTSOG (2016).

4 RESULTS AND DISCUSSION

Figure 3 displays the resulting maximum flow loss ($\Delta F_{max,i}$ [%]) without storage facilities. The maximum flow loss can also be interpreted as loss of service. For six pipelines (labeled 1 to 6) the estimated loss is higher than 1% (~4.5 10^9 m^3/year). Similarly, Figure 4 shows the resulting maximum flow loss considering the storage facilities in addition as source vertices. The cases shown in Figures 3 and 4 are discussed in Table 3.

As illustrated in Table 3, the introduction of storage facilities is an effective measure to reduce the system service loss in case of a long-duration pipeline failure or shutdown. This is because storage facilities can compensate a potential failure and provide natural gas during the time of reduced flow capacity of the network.

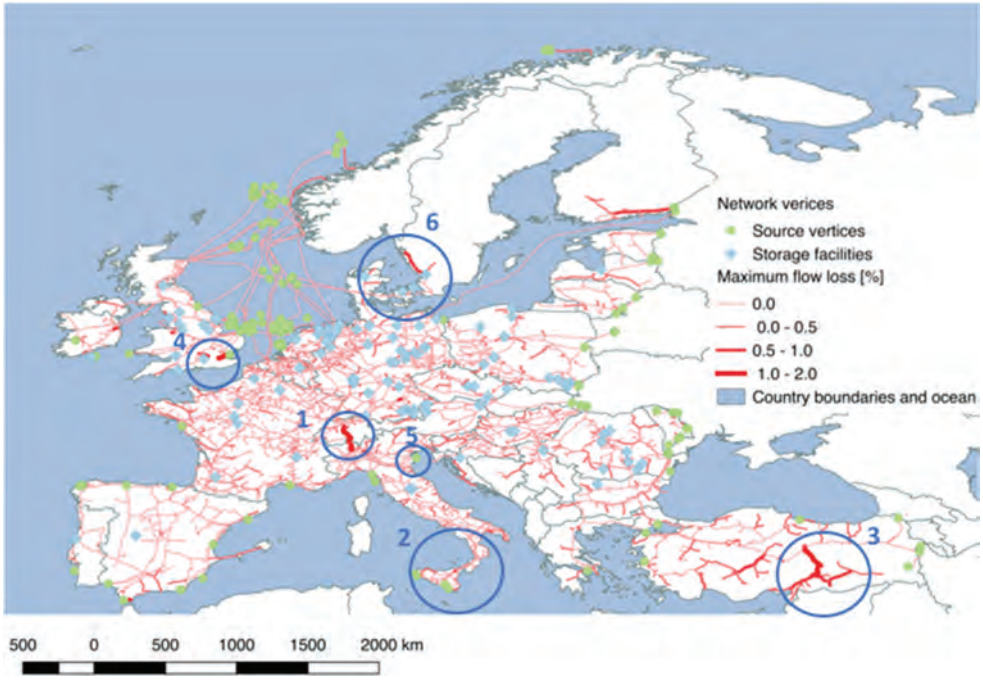

Figure 4. Impact of a potential pipeline failure or shutdown on the maximum flow for the scenario with storage facilities.

Table 3. Description of the pipelines with $F_{\max,i}$ higher than 1% resulting from the scenario without natural gas storages. The index is referring to Figure 3 and Figure 4.

	Scenario without storage facilities (Figure 3)		Scenario with storage facilities (Figure 4)	
Index	$\Delta F_{\max,i}$ [%]	Description	$\Delta F_{\max,i}$ [%]	Description
1	*4.6*	The Transit Gas pipeline and its southern extensions have the highest impact on the maximum flow in case of a failure. The pipelines connect northern Italy via Gries Pass through Switzerland with the German and French natural gas networks (Transitgas, 2017). The high maximum flow loss results from the fact that this pipeline is the only one crossing the central Alps providing a North/South connection.	*2.0*	With the introduction of the storage facilities the loss in case of a failure of the Transit Gas pipeline can be reduced from 4.6% to 2.0%. Several storage facilities are available in Germany and France to cover the remaining demand at the northern end of the pipeline, while two storage facilities are identified in central Italy (ENTSOG, 2016) to absorb demand reduction at the southern part of the pipeline.
2	3.5	The pipelines connecting Sicily and Calabria have the second highest impact on the maximum flow in case of a failure. The reason is that those pipelines are a part of the Trans-Mediterranean pipeline system (Transmed, 2017) and the Green-Stream project (GreenStream, 2017) connecting Algeria and Tunisia with Continental Europe. These pipelines provide a major share of the natural gas consumed in Europe (Carvalho et al., 2009).	0.9	With storage facilities, the loss can be substantially reduced. In case of a pipeline failure, Sicily is supplied by marine pipelines coming from northern Africa, while the supply reduction on the Italian mainland is partly absorbed by two natural gas storage facilities in central Italy.

(*Continued*)

Table 3. (*Continued*).

Index	Scenario without storage facilities (Figure 3)		Scenario with storage facilities (Figure 4)	
	$\Delta F_{\max,i}$ [%]	Description	$\Delta F_{\max,i}$ [%]	Description
3	1.8	The Turkish pipeline between the cities Silvas and Malatya connects the south-eastern part of Turkey with the Trans-Anatolian pipeline bringing natural gas from Georgia and Iran to Ankara (TANAP, 2017). The entire natural gas consumption of south east Turkey is provided with this pipeline, which amounts to ~1.8% of the consumption of the investigated system.	1.8	This loss remains the same because no storage facilities were identified in south eastern Turkey.
4	1.8/1.8	Two critical pipelines in the region of London were identified. The high loss of the south-eastern pipeline can be explained as it is the only high capacity pipeline delivering natural gas to London and the surrounding area. For the other pipeline in the north-western part the high loss is due to its high capacity as it delivers natural gas to the administrative regions of south west England.	1.8/0.0	The south eastern high capacity pipeline shows an unchanged loss as it is a dead-end pipeline. The loss of the other pipeline could be fully compensated due to compensation from storage facilities.
5	1.8	The pipeline near Venice connects the LNG port Cavarzere Porto Levante with the Italian mainland (AdriaticLNG, 2017). This indicates that this port plays a major strategic role for the continuous natural gas supply to continental Europe.	0.2	The loss of this pipeline can be reduced due to compensation of supply from storage facilities in the center of Italy.
6	1.1	This pipeline connects the European mainland with the Danish Islands Funen and Zealand. The importance of this pipeline is due to the fact that it is the only pipeline supplying Copenhagen and southern Sweden with natural gas.	0.0	Because two storage facilities are located close to Copenhagen, the loss caused by a potential failure or shutdown of this pipeline could be reduced to 0.

In this study, it is generally assumed that pipeline failures or shutdowns have a duration of one year, which is likely to be highly conservative for most cases. This does not affect the identification of critical pipelines as it is based on topological analysis and is thus independent of the duration of the loss of supply. On the other hand, the absolute loss of supply on the yearly basis as estimated here is expected to be much lower due to the expected typically much shorter duration of the interruptions.

The dependencies of the different components are assessed to the extent that in case of a pipeline shutdown, the natural gas flow is rerouted according to available pipeline capacities. Hence, in case there is no additional pipeline capacity available to compensate, there is a shortage of natural gas supply and a reduction in the maximum flow of the network.

Given the relatively conservative assumption of long duration of unavailability of critical pipelines after disruptions, the estimated losses are significant, but relatively limited. Moreover, the losses can to a certain extent be mitigated by the storage facilities.

5 CONCLUSIONS

In this study, the European natural gas infrastructure network is analysed considering the impacts of postulated failures of critical pipelines, and the potential mitigation of capacity losses by storage facilities.

Considering that the network capacity is not only limited by actual pipeline flow capacities, but also the consumption, leads to more realistic maximum flow analysis results. This is in contrast to the often-proposed maximum flow application with infinite capacities of the identified sources and sinks.

The maximum flow loss analysis showed that the failure of a single pipeline in a scenario without natural gas storage facilities can cause service losses >1% for six pipelines, with a maximum of 4.6% for the Transit Gas pipeline. Taking storage facilities into account can significantly reduce losses for all pipelines, except for south-east Turkey where no storage facilities are identified and a dead-end pipeline supplying the London area.

The Transit-Gas pipeline, crossing the Alps from Switzerland to Italy results in the highest maximum flow loss for both scenarios (with and without storage facilities).

For long-duration pipeline failures, the storage volume is required to be sufficiently large to act as a compensating source in the system throughout the whole disruption time. It is assumed that the storage capacity is not a limiting factor in reducing a pipeline supply loss. Additionally, the flows and consumption are aggregated on an annual level. This means that this study does not consider seasonal variabilities of natural gas consumption. The natural gas consumption in Europe is expected to be higher in winter than in summer (Hauser et al., 2017). Furthermore, this study assumes deterministically that the critical pipelines will be unavailabele during the whole year, which is very conservative. In summary, this study focuses on investigation of topological properties of the network and does not attempt to analyse the likely duration of disruptions.

In practice, not only the strategic placement of additional sources like storage facilities or LNG terminals, but also a temporal increase of the pipeline capacity, e.g. through increase of pressure in a pipeline, could provide sufficient natural gas to cover the demand (Su et al., 2017). This rerouting with temporal capacity increase of pipelines in case of a single pipeline failure or shutdown is partially considered. The pipeline capacities were quite roughly allocated and rather overestimated. It can be assumed that all pipelines are running at the corresponding allocated maximum capacity. This overestimation could possibly represent the credit for a temporal capacity increase of the pipelines in the system.

Although, the implementation of the findings of this study at large requires some caution due to current limitations, the described approach and results could provide the relevant stakeholders with useful indications for further enhancements of the reliability of natural gas infrastructure networks in general and of the European natural gas network in particular.

The results, and especially the approach developed in this study, could provide potentially helpful inputs for governmental agencies, the private industry and policy–makers.

It is recommended that the model could be further improved in terms of the time resolution. This would take into account the seasonal variation of the actual natural gas consumption and the actual storage capacities and storage use (source/sink). Furthermore, a network analysis methodology considering not only edge removal, but also storage capacities and the given temporal limitations could be developed.

Considering future work, the network model presented in this study will be combined with probabilistic treatments of potential losses of critical pipelines due to technical failures and selected natural events. This will provide an anlysis of the actual risks caused by potential pipeline failures considering not only consequences but also frequencies. Moreover, future work will have a risk and resilience prespective on the system level and not a reliability perspective on the component level.

ACKNOWLEDGEMENTS

The research was conducted at the Future Resilient Systems at the Singapore-ETH Centre, which was established collaboratively between ETH Zurich and Singapore's National Research Foundation (FI 370074011) under its Campus for Research Excellence and Technological Enterprise programme.

The natural gas network data are from the Transparency platform of ENTSOG and/or its members.

ABSTRACT: Common-Cause Failures (CCF) impose severe consequences on a complex system's reliability and overall performance. A more realistic assessment, therefore, of the survivability of the system requires an adequate consideration of these failures. The survival signature approach opens up a new and efficient way to compute system reliability, given its ability to segregate the structural and probabilistic attributes of the system. Traditional survival signature-based approaches assume the failure of one component to have no effect on the survival of the others. This assumption, however, is flawed for most realistic systems, given the existence of various forms of couplings between components. This paper, therefore, presents a novel and general survival signature-based simulation approach for non-repairable complex systems. We have used Monte Carlo Simulation to enhance the easy propagation of CCF across the complex system, instead of an analytical approach, which currently is impossible. In real application world, however, due to lack of knowledge or data about the behaviour of a certain component, its parameters can only be reported with a certain level of confidence, normally expressed as an interval. In order to deal with the imprecision, the double loop Monte Carlo simulation methodology which bases on the survival signature is used to analyse the complex system with CCF. The numerical examples are presented in the end to show the applicability of the approach.

1 INTRODUCTION

Common-Cause Failures (CCFs) are failure events that affect multiple components simultaneously. The origin of common cause events can be outside the system components they affect, or they can originate from the components themselves, causing the other components to fail. The proper consideration and modelling of CCFs is essential in complex systems reliability analysis, as they may have a significantly adverse effect on the system's overall functionality. They have been shown by many studies (Dhillon & Anude 1994) to decrease the reliability and availability of multi-component systems. They are, therefore, extremely important in reliability assessment and must be given adequate treatment, to minimise overestimation (Modarres 2006).

The CCF event can either impact the overall system operation or only affect specific components within the system (Wierman et al. 2007). Aldemir (1987) haa given an overview of parametric Common-Cause Failure models. To be specific, for component level, the CCF event is a component level failure. Rasmuson and Kelly reviewed the basic concepts of modelling CCFs in reliability and risk

studies (Rasmuson & Kelly 2008). One of the most commonly used single parameter models defined by Fleming (1975) is the β-factor model, which is the first parameter model applied to common cause failures in risk and reliability analysis. He then generalised the β-factor model to the multiple Greek letter model in 1986 (Fleming et al. 1986). The α-factor model which is proposed by Mosleh et al. (1988) develops CCFs from a set of failure ratios and the total component failure rate. Based on the α-factor model, Kelly & Atwood (2011) presented a method for developing Dirichlet prior distributions that have specified marginal means, but which are otherwise minimally informative. The binomial failure rate model (Atwood 1986) on the other hand, estimates the failure frequency of two or more components in a redundant system. This is computed as the product of the CCF shock arrival rate and the conditional failure probability of the components given the shock.

At for system level, the CCF event is a system functional level failure. A number of models have been developed recently. For instance, George-Williams & Patelli (2017) proposed an efficient load-flow simulation approach to assess the availability of reconfigurable multi-state systems with inter-dependencies. A robust Bayesian approach to the α-factor model for common cause failures has also been proposed by Troffaes et al. (2014). Coolen & Coolen-Maturi (2015b) presented a non-parametric predictive inference for system reliability following a common cause failure. However, there are mainly two problems within the above research works: (1) either recognise the components within the system as exchangeable single type; or (2) evaluate the system configuration for every reliability estimation trial, which is time consuming. Therefore, an extension of above works is needed. To be specific, it is necessary to perform reliability analysis on systems susceptible to CCFs, because these realistic complex systems always consist of components which belong to different types. Survival signature provides a good way to solve this problem.

Survival signature was first proposed by Coolen & Coolen-Maturi (2012) in 2012. It is a powerful methodology which can not only hold the merits of the former system signature (Samaniego 2007), but can be used in complex system with components belong to multiple types. In essence, it does not have the assumption that components of different types are exchangeable, which overcomes the long-standing limitation of the system signature. This is useful when a system consists of components that belong to different types, which means their failure times follow different probability distributions characters (Coolen & Coolen-Maturi 2015a). Therefore, survival signature is a promising method for application to complex systems. Based on the former work, Aslett et al. (2015) analysed system reliability within the Bayesian framework of statistics. Feng et al. (2016) dealt with the imprecision within the system by analytical and numerical ways respectively, what is more, new component importance measures were presented in this paper. An imprecise Bayesian non-parametric approach by using sets of priors to system reliability with multiple types of components was developed by Walter et al. (2017). Patelli et al. (2017) proposed efficient simulation approaches which based on survival signature for reliability analysis on large system. Reed (2017) put forward an efficient algorithm for exact computation of survival signature using binary decision diagrams.

This paper is organised as follows. Section 2 gives a brief conceptions about the survival signature and α-factor parameter. The survival signature-based simulation reliability approach is proposed in Section 3, in addition, this Section introduces imprecision within the components failure times. The applicability and performance of the proposed approaches is presented in Section 4. Finally Section 5 closes the paper with conclusions.

2 SURVIVAL SIGNATURE AND α-FACTOR PARAMETER

2.1 *Survival signature*

Suppose there is a complex system with m components which belong to $K \geq 2$ component types, with m_k components of type $k \in \{1,2,...,K\}$ and $\sum_{k=1}^{K} m_k = m$. Assume that the random failure times of components of the same type are exchangeable, while full independence is assumed for components belong to different types (*iid*), the survival signature which can be denoted by $\Phi(l_1,l_2,...,l_K)$, with $l_k = 0,1,...,m_k$ for $k = 1,2,...,K$. It defines the probability that the system functions given that l_k of its m_k components of type k work, for each $k \in \{1,2,...,K\}$. There are $\binom{m_k}{l_k}$ state vectors $\underline{x}^k$ with $\sum_{i=1}^{m_k} x_i^k = l_k$ (k = 1, 2, …, K), where $\underline{x}^k = (x_1^k, x_2^k, ..., x_{m_k}^k)$. Let $S_{l_1,l_2,...,l_K}$ denote the set of all state vectors for the whole system, and it can be known that all the state vectors $\underline{x}^k \in S_{l_k}^k$ are equally likely to occur. Therefore, the survival signature can be expressed as:

$$\Phi(l_1,...,l_K) = \left[\prod_{k=1}^{K} \binom{m_k}{l_k}^{-1}\right] \times \sum_{\underline{x} \in S_{l_1,...,l_K}} \phi(\underline{x}) \tag{1}$$

where $\phi = \phi(\underline{x}) : \{0,1\}^m \rightarrow \{0,1\}$ is the system structure function, i.e., the system status based on all

possible state vectors $\underline{x}$. ϕ is 1 if the system functions for state vector $\underline{x}$ and 0 if not.

Let $C_k(t) \in \{0,1,...,m_k\}$ denote the number of k components working at time t. Assume that the components of type k have a known cumulative distribution function (*CDF*) $F_k(t)$ and the components failure times of different type are assumed independent, then:

$$P(\bigcap_{k=1}^{K}\{C_k(t)=l_k\}) = \prod_{k=1}^{K} P\left(C_k(t)=l_k\right) = \prod_{k=1}^{K}\binom{m_k}{l_k}\left[F_k(t)\right]^{m_k-l_k}\left[1-F_k(t)\right]^{l_k} \quad (2)$$

Hence, the survival function of the system with K types of components becomes:

$$P(T_s > t) = \sum_{l_1=0}^{m_1}\cdots\sum_{l_K=0}^{m_K}\Phi(l_1,...,l_K)\,P\left(\bigcap_{k=1}^{K}\{C_k(t)=l_k\}\right) \quad (3)$$

Equation 3 shows that the structure of the system is separated from the its components failure times, which is the typical advantage of the survival signature. The survival signature is a summary of structure functions and only needs to be calculated once for the same system. As a result, it is an efficient method to perform system reliability analysis on complex systems with multiple component types.

2.2 α-*factor model*

The α-factor model is particularly useful in the practical engineering world as the alpha factor parameters can be got through experts' judgement of the system or past data on the system.

The parameter, α_r, of the model, is the fraction of the total component failure events causing the simultaneous failure of an additional $r-1$ components.

Let us assume there is a system with three exchangeable components, α_1 means the failure of one component cannot influence the status of the other components. α_3 denotes the failure of one component can lead to the other two components fail simultaneously, which means CCFs occur. For $\alpha_2 = p$, it expresses that there is a probability p of one additional component failing, following the failure of a component in this system. It can be drawn that $\sum_{r=1}^{3}\alpha_r = 1$.

Similarly, for the complex system with multiple component types, the alpha parameters α_r^k denotes that if one component of type k fails due to an common cause event, the probability that the other $r-1$ components fail simultaneously. If there are m_k components in this group, it can conclude that $\sum_{r=1}^{m_k}\alpha_r^k = 1$.

Based on the definition of α-factor parameter, the probability of a common cause basic event involving failure of k components in a system of m components can be calculated by Equation 4.

$$Q_k = \frac{k}{\binom{m-1}{k-1}}\frac{\alpha_k}{\alpha_t}Q_t \quad (4)$$

where, $k = 1,2,...,m$ and $\alpha_t = \sum_{k=1}^{m} k\alpha_k$. Q_t is the total probability of failure accounting both for common cause failures and independent failures. The alpha parameter estimator can be expressed as:

$$\alpha_k = \frac{n_k}{\sum_{i=1}^{m} n_i} \quad (5)$$

where, n_k is the number of events with k failed components.

The α parameter estimator represents the probability that exactly k of the m components fail, given that at least one failure has occurred. It can be seen from Equation 5 that the sum of all the α_k will be 1. The advantage of the α-factor model is its distinction between the total failure rate of a component Q_t, for which we generally have a lot of information, and common cause failures modelled by α_k, for which we generally have very little information (Troffaes et al. 2014).

3 EFFICIENT METHOD FOR ANALYSING SYSTEM RELIABILITY WITH COMMON CAUSE FAILURES

3.1 *The proposed approach*

In order to perform reliability assessment on any kind of systems without introducing simplifications or unjustified assumptions, this Section proposes a simulation method to analyse system reliability after common cause failures.

Suppose there is a complex system with m components which belong to X_c different component groups, and there are m_k components of type $k \in \{1,2,...,K\}$ and $\sum_{k=1}^{K} m_k = m$. The common cause group matrix can be expressed as M_{CCG}, the α factor parameters of each component group, $\alpha_{m_k}^k$, are stored in the matrix, recall $\sum_{k=1}^{K}\alpha_{m_k}^k = 1$.

The number of failing component of each type is depended on the number of component still functioning, therefore, it is necessary to use the α-factor model to provide probabilities for any combinations of number of components that would fail

when a common cause failure event occurs. Here has an assumption that if one component of type k fails, it can only influence the components within the same component group X_c under the CCF model. This is reasonable as the components of the same type tend to be influenced by the same common cause failure event, this is also the reason why they are grouped in the same type. Then looking at how many of the components of each type still function, and assume exchangeability within them with regard to the CCF failure model.

The reliability of the system after common cause failures can be estimated adopting the following simulation procedure:

Step 1. Initialise the counter V to store the output, define the mission time as t_m and number of samples as N;

Step 2. Define the component groups as X_c, and the common cause group matrix M_{CCG}, the α factor parameters $\alpha^k_{m_k}$ are stored in the matrix;

Step 3. Sample the failure time of each component as $t_i \le t_{i+1}$, where $i = 1, 2, \ldots, m$, and set $t_{old} = 0$, at this time the survival signature (production level) is equal to 1;

Step 4. Set the current time $t_{current} = min(t_i)$;

Step 5. At time t_i, finding out which component fails and which common cause group it belongs to. The components affected by a failure event due to CCF can be expresses as V_{comp};

Step 6. Upgrade the number of working components of each component group after the CCF, and then get the survival signature (production level) Φ_{t_i} after the corresponding failure time t_i;

Step 7. Set the failure time of the components (the failure component and its common cause failure components) as infinite;

Step 8. Repeat Steps 4 through 7 until $t_m > t_{old}$;

Step 9. Store the production level of the system over the time by $V(j) = V(j) + \Phi_{t_i}$;

Step 10. Repeat Steps 3 through 9 for N times.

Therefore, the survival function of the complex system after common cause failures is obtained by averaging the vector collecting the production level of the system over the number of samples: $P(T_s > t \mid CCF) = V_t / N$.

The algorithm of the proposed simulation method can be seen follows:

Algorithm 1 The Proposed Approach's Algorithm

Require: N, t_m, X_c, M_{CCG}, N_t: number of discretisation step
Set $V(1:N_t) = 0$ ▷ Initialise counters
Set Φ =Survival Signature ▷ Load survival signature
for $n = i : N$ **do** ▷ Loop over number of samples
  Sample t_i ▷ Sample failure time of every component in each type
  Set $[t_{current}, X_c] = min(t_i)$ ▷ Minimum failure time and component index
  while $[t_{current} \le t_m$ **do**
    $Vch = ceil([t_{old}, t_{current}]/timestep) + 1$ ▷ Define channels
    $V(Vch(1) : Vch(2) - 1) = V(Vch(1) : Vch(2) - 1) + \Phi(t_{old})$ ▷ Update counters
    if M_{CCG} is not empty **then** ▷ CCF within system
      $CCF_{CumProb} = cumsum(\alpha^k_{m_k})$ ▷ Cumsum CCF probability of the failed component group
      $r = find(CCF_{CumProb} \ge rand, 1)$ ▷ Find the number of components in the CCG to fail
      if $r > 1$ **then**
        Propagate CCF
      end if
    else ▷ No CCF within the system
      $V_c = X_c$ ▷ V_c contains affected components
    end if
    $\Phi_{t_{old}} = \Phi_{t_{current}}$ ▷ Upgrade survival signature
    $t_{old} = t_{current}$ ▷ Upgrade new old time
    $[t_{current}, X_c] = min(t_i)$ ▷ Minimum failure time and component index after CCF
  end while
  if $t_m > t_{old}$ **then**
    $V(Vch(1) : Vch(2)) = V(Vch(1) : Vch(2)) + \Phi(t_{old})$ ▷ Update counters
  end if
end for

3.2 *Imprecision in consideration*

In the engineering applications, if there exist imprecision within the components failure time distributions, or empirical distribution of components failure times are used, no analytical methods can be used without resorting to some degree of simplification or approximation (Beer et al. 2013) (Aven 2017). Instead, the proposed simulation methods can be applied to any systems irrespectively to the probability distribution for the component failure time used.

To be specific, the system reliability performance after common cause failures can be simulated using survival signature-based Monte Carlo method. This double loop simulation method (Du & Chen 2004) not only has the advantage of survival signature to handle complex system reliability problems, but can recur to Monte Carlo simulation to deal with the uncertainties within the system.

Double loop sampling involves two layers of sampling: the outer loop is called the parameter

loop since it concerns sampling different values for the set of distribution parameters for all of the uncertain quantities; while the inner loop goes by the name of probability loop because it involves sampling from precise probability distribution functions. As a matter of fact, double loop sampling implicates sampling from an analytical distribution whose parameters have been generated by sampling.

To solve the parameter epistemic imprecision within components, it is just need to add an optimization loop around the survival signature-based simulation method cited in Section 3.1 to estimate the bounds. In other words, it can be done by adding a simple Monte Carlo loop and sampling the values of components parameters from uniform distributions.

4 NUMERICAL EXAMPLE

Shown in Figure 1 is an arbitrary 13-component complex system, which components are arranged into five groups. The number within each box denotes which group the component belongs to while the number outside defines the index of the component in the system. The system is assumed to be non-repairable and components of the same group have the same failure time distribution, as defined in Table 2. In the table, an exponential distribution is defined by its mean (in hours) while a Weibull distribution is defined by a set which first element is its scale parameter (in hours).

The system is first analysed without CCF using the proposed simulation model with the data presented in Table 2 and compared to its analytical solution.

It is then re-analysed considering common cause failures with all common cause groups are active. For this system, the common cause group failure matrix M_{CCG}, with and without CCF, can be expressed in Equations 6 and 7 respectively. The results obtained are shown in Figure 2.

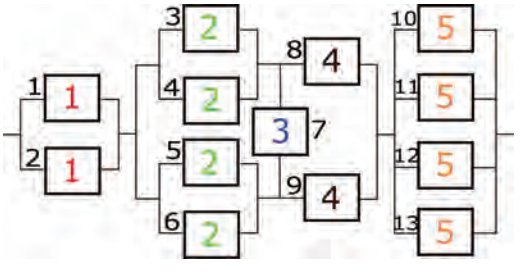

Figure 1. Complex system with thirteen components which belong to four types. The number inside the component box represents the type, while the number outside the box expresses the component index.

Table 1. Component failure data with precise distribution parameters.

Component type	Distribution type	Distribution parameters	CCF parameters
1	Weibull	(1.8,2.2)	{0.95, 0.05}
2	Exponential	1.2	{0.8, 0.1, 0.05, 0.05}
3	Weibull	(2.3,1.6)	{1}
4	Weibull	(3.2,2.6)	{0.9, 0.1}
5	Exponential	2.1	{0.75, 0.1, 0.1, 0.05}

Table 2. Component failure data with imprecise distribution parameters.

Component type	Distribution type	Distribution parameters	CCF parameters
1	Weibull	([1.68,1.86], [2.08,2.32])	{0.95, 0.05}
2	Exponential	[1.07,1.33]	{0.8, 0.1, 0.05, 0.05}
3	Weibull	([2.12,2.51], [1.38,1.72])	{1}
4	Weibull	([2.99,3.41], [2.51,2.79])	{0.9, 0.1}
5	Exponential	[2.01,2.28]	{0.75, 0.1, 0.1, 0.05}

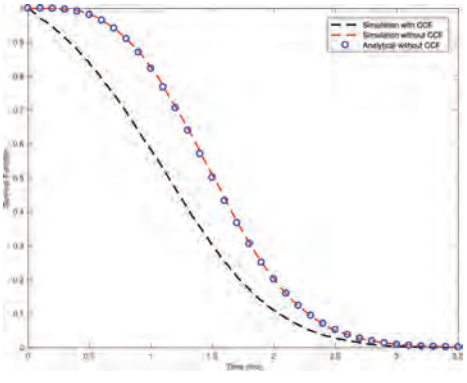

Figure 2. Survival function of the system in Figure 1 with CCF and without CCF through simulation method, along with the system reliability without CCF got by analytical solution.

$$M_{CCG} = \begin{pmatrix} 0.95 & 0.05 & 0 & 0 \\ 0.8 & 0.1 & 0.05 & 0.05 \\ 1 & 0 & 0 & 0 \\ 0.9 & 0.1 & 0 & 0 \\ 0.75 & 0.1 & 0.1 & 0.05 \end{pmatrix} \quad (6)$$

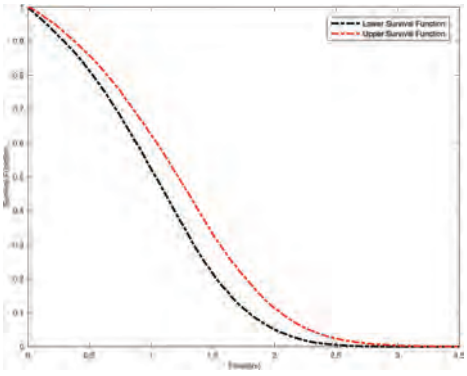

Figure 3. Lower and upper survival function bounds of the system in Figure 1 with CCF.

$$M_{CCG} = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 1 & 0 & 0 & 0 \\ 1 & 0 & 0 & 0 \\ 1 & 0 & 0 & 0 \\ 1 & 0 & 0 & 0 \end{pmatrix} \tag{7}$$

The accuracy and generality of the proposed simulation approach are validated by the plots in Figure 2, given the agreement between the simulation and analytical results. As shown, the reliability of the system reduces drastically when the effects of CCF are factored into the analysis. It exemplifies the need to consider this realistic aspect of a system's operation in its reliability evaluation.

To deduce the effects of imprecision in the failure distribution parameters of components on the system survival function, the system is analysed using the data presented in Table 2. Instead of a single curve, the survival function, in this case, could be any of an infinite number of curves lying within the bounds shown in Figure 3.

5 CONCLUSIONS

Common-Cause Failures (CCF) have an adverse effect on the reliability and performance of multi-component systems. They are normally a consequence of functional couplings between a group of components due to a variety of possible reasons. Thus, there is an inevitability about the susceptibility of realistic multi-component engineering systems to these failures. The need, therefore, to incorporate CCF considerations into system analysis is overwhelming, as the alternative may lead to overestimating the reliability of the system.

This paper puts forwards an efficient simulation method which bases on the survival signature to perform reliability analysis on complex systems with common cause failures. In fact, this approach extends the applicability of the survival signature approach to systems susceptible to common cause failures. More importantly, it holds the merits of both survival signature methodology and Monte Carlo simulation. Therefore, this approach is general and allows to know the survival function of the system after common cause failures at each time. What is more, the probabilistic uncertainty and imprecision in components parameters are taken into consideration by resorting this general simulation method. The effectiveness and feasibility of the proposed approach hasbeen demonstrated by the numerical example.

LLVM-based stochastic error propagation analysis of manually developed software components

A. Morozov & K. Janschek
Institute of Automation, Faculty of Electrical and Computer Engineering, Technische Universität Dresden, Germany

Y. Zhou
Altran Deutschland S.A.S. & Co. KG, Powertrain Automotive, Munich, Germany

ABSTRACT: Modern industrial trends such a Cyber-Physical Systems and System of Systems lead to the continuously increasing complexity and heterogeneity of components and interfaces, as well as more and more advanced software parts. Classical reliability evaluation methods, recommended in nowadays standards, such as Fault Tree Analysis (FTA) and Failure Mode and Effect Analysis (FMEA), fail to describe system behavioral aspects in a sufficiently deep manner. Therefore, additional, sophisticated and highly specialized methods for the analysis of the effects of unavoidable faults are required. Recently introduced Dual-graph Error Propagation Model (DEPM) is a stochastic framework that captures system properties relevant to error propagation processes such as control and data flow structures and reliability characteristics of single components. The DEPM helps to estimate the impact of a fault of a particular component on the overall system reliability, e.g. to compute the mean number of erroneous values in a critical system output during given operation time. A DEPM can be automatically generated from various semi-formal system representations such as UML/SysML, AADL, or Simulink/Stateflow. However, despite the common trend towards model-based system development the functional software parts usually incorporate manually programmed code. The error propagation properties of this manual code also need to be analyzed and considered during the reliability evaluation of the complete system. This paper presents a new method, based on the Low-Level Virtual Machine (LLVM) compiler framework, that allows the automatic transformation of C-code or another LLVM supported front-end into a DEPM. The source code is compiled into the LLVM Intermediate Representation and instrumented in order to analyze control and data flow structures of LLVM instructions and control flow transition probabilities. The obtained information is transformed into the formal DEPM XML for further analysis. The paper describes the transformation method and its application to a low-level flight control software of a UAV system.

1 INTRODUCTION

1.1 *Motivation*

Model-Based System Engineering (MBSE) plays an important role in the development of modern safetycritical systems. Advanced MBSE toolchains support the system development starting from high-level design up to deployment and testing. MATLAB Simulink (MathWorks 2017a) and Stateflow (Math-Works 2017b) dominate in the field of control software development. Nowadays trends such a Cyber-Physical Systems and System of Systems lead to the continuously increasing complexity and heterogeneity of components and interfaces, as well as more and more advanced software parts. The increasing complexity brings new challenges for system analysis. Classical reliability and safety evaluation methods, recommended in nowadays industrial standards, such as Fault Tree Analysis (FTA) and Failure Mode and Effect Analysis (FMEA), fail to describe system behavioral aspects in a sufficiently deep manner. Therefore, additional, sophisticated and highly specialized methods for the analysis of the effects of unavoidable faults are required. Recently introduced Dual-graph Error Propagation Model (DEPM) (Morozov & Janschek 2014) is a stochastic framework that captures system properties relevant to error propagation processes. The DEPM helps to estimate the impact of a fault of a particular component on the overall system reliability, e.g. to compute the mean number of erroneous values in critical system outputs.

A DEPM can be automatically generated from various semi-formal system representations such as Simulink/Stateflow (Morozov et al. 2016), UML/SysML (Ding et al. 2016), and AADL (Morozov

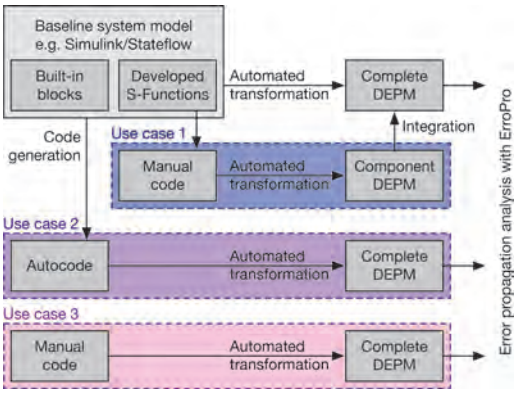

Figure 1. Three possible use cases of the proposed transformation method.

et al. 2018). Despite the common MBSE trend, the functional software parts usually incorporate manually programmed code. The error propagation properties of this code should be analyzed with a DEPM and considered during the reliability evaluation of the complete system. This paper presents a new method, based on the Low-Level Virtual Machine (LLVM) compiler framework, that allows the automatic transformation of C-code or another LLVM supported front-end into a DEPM. Figure 1 demonstrates three possible use cases:

- Use case 1: a Simulink model contains manually developed S-Function blocks, we generate individual DEPMs separately for these blocks using the proposed method and integrate them into a top-level DEPM generated from the Simulink model using the method presented in (Morozov, Janschek, Krüger, & Schiele 2016).
- Use case 2: we apply the proposed method to the automatically generated C-code of the entire Simulink model.
- Use case 3: we generated DEPMs for manually developed code in case of none-MBSE approach. An example of this use case is shown in Section 3.

The rest of the paper is organized as follows. The two following subsections give the overview of the background DEPM and LLVM technologies. Section 2 provides technical details of the proposed transformation method. Section 3 demonstrates the method with a case study, showing the transformation of lowlevel flight control software of a UAV into a DEPM.

1.2 *Dual-graph error propagation model*

The DEPM is a mathematical model that captures control and data flow aspects of a system, described using the following set-based mathematical notation:

$$DEPM := \langle E, D, A_{CF}, A_{DF}, C \rangle \tag{1}$$

E is a non-empty set of executable system elements;
D is a set of data storages;
A_{CF} is a set of directed control flow arcs, extended with control flow decision probabilities;
A_{DF} is a set of directed data flow arcs;
C is a set of conditions of the elements.

Fig. 2a shows a simple DEPM example. An *Element*, e.g. *A*, *B*, or *C*, represents an executable part of a system. Each element may receive input data and provide output data. A *Data*, e.g. *d1*, *d2*, or *d3*, represents a variable that can be read or written by an *Element*. For instance, *Element C* reads *d2* and *d3*, and writes *output*. A *ControlFlow* arc (black lines in Fig. 2a), weighted with an attribute probability, represents a control flow transition between *Elements*. For instance, after the execution of *A*, *B* will be executed with probability 0.7 and *C* with probability 0.3. A *DataFlow* arc (purple lines in Fig. 2a) describes data transfer between the elements. A *DataFlow* connects an *Element* with a *Data* or vice versa. The *DataFlow* arcs are considered to be the paths of the data error propagation.

The fault activation and the error propagation can be specified using probabilistic *Conditions* in the elements. During the execution of an element, faults can be activated and occurred errors propagate to its outputs. The elements, which can activate faults, are highlighted in red. For instance, in the element *A*, highlighted in red in Fig. 2a, faults can be activated with probability 0.1, defined in

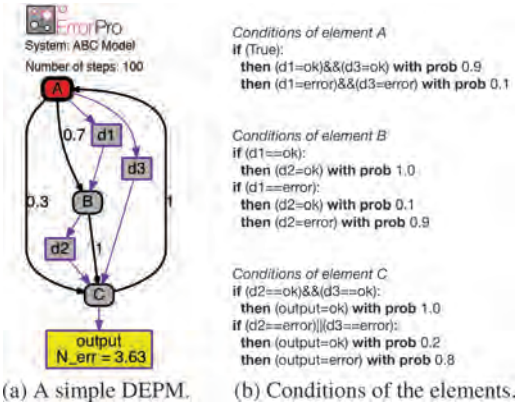

Figure 2. An example of a DEPM with specified conditions of the elements.

the conditions of *A* (see conditions *A* in Fig. 2b), and occurred errors propagate to its output data *d1* and *d3*.

The error propagation or error correction probabilities for each element are defined also using probabilistic *Conditions* (see Fig. 2b). The errors can propagate from the data inputs to the outputs. For instance, the conditions of the element *B* specify that the element *B* does not activate faults, but the errors can propagate from *d1* to *d2* with the probability 0.9.

ErrorProTM (Morozov et al. 2015) is our software tool for stochastic error propagation analysis that allows users to create and compute DEPMs. Discretetime Markov chain models that describe system execution and error propagation processes are automatically generated and computed using an interface with the PRISM model checker (Kwiatkowska, Norman, & Parker 2011). In the DEPM, the *mean number of errors* of all data, marked with yellow color, can be computed. The reliability metric, *mean number of errors*, is the average number of cumulative occurred errors in the data during the system execution. For instance, the *mean number of errors* in the data storage *output* during 100 steps (execution of one element is one step) is equal to 3.63, as shown in Fig. 2a. A DEPM model can be stored in an XML file. A fragment example of an XML file is shown in Listing 1.

1.3 *LLVM compiler infrastructure*

The LLVM Project (Lattner & Adve 2004) is a collection of modular and reusable compiler and toolchain technologies. The LLVM libraries provide a source and target-independent optimizer, along with code generation support for many popular CPUs. These libraries are built around an assembly-like low-level code representation

```
<?xml version="1.0" encoding="utf−8"?>
<model n_steps="100" name="ABC Model" version="3.0">
 <element initial ="true" name="A"/>
  ...
 <data name="d1"/>
  ...
 <control_flow from="A" prob="0.7" to="B"/>
  ...
 <data_flow from="A" to="d1"/>
  ...
 <conditions element_name="A">
  <if statement="True">
   <then prob="0.9" update="d1 = ok; d3 = ok;"/>
   <then prob="0.1" update="d1 = error ; d3 = error ;"/>
  </if>
 </conditions>
  ...
</model>
```

Listing 1. An example of a DEPM XML file.

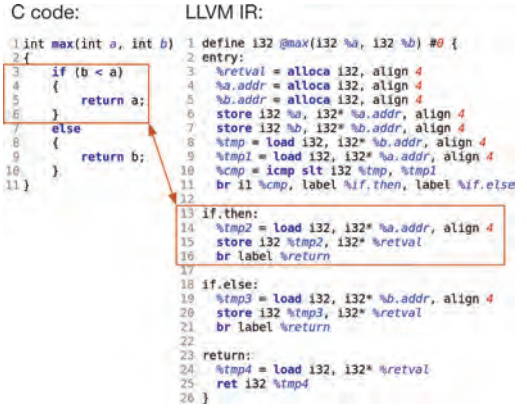

Figure 3. C-code example and its LLVM IR.

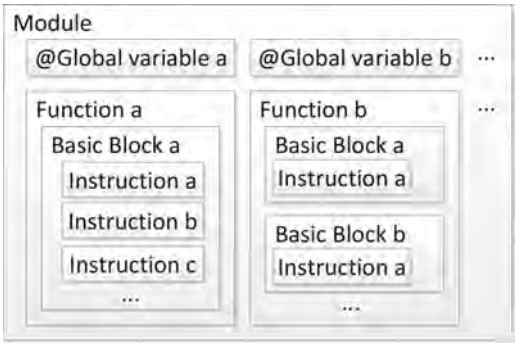

Figure 4. The hierarchical structure of LLVM IR.

known as the LLVM Intermediate Representation (LLVM IR). The LLVM IR is basically a representation in-between a high-level language and a low-level machine code. Figure 3 shows a small piece of C-code (left) and the corresponding LLVM IR code (right). The LLVM IR uses Static Single Assignment (SSA) format: Each defined variable cannot be re-defined. There are only explicit strongly typed variables in the IR code.

The LLVM IR code is structured into modules that contain functions as it is shown in Figure 4. The functions are decomposed into basic blocks. A basic block contains a sequence of single instructions. The conditional jumps between basic blocks form the control flow structure.

Figure 5 shows a typical LLVM-based workflow. An input source code, e.g. a C-code or any other of more than 20 LLVM supported languages, can be compiled with *clang* into the LLVM IR. Using the LLVM API, an optimizer can be built that produces an optimized version of the compiled LLVM

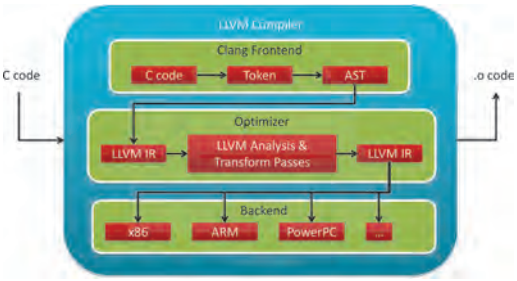

Figure 5. Common LLVM-based workflow.

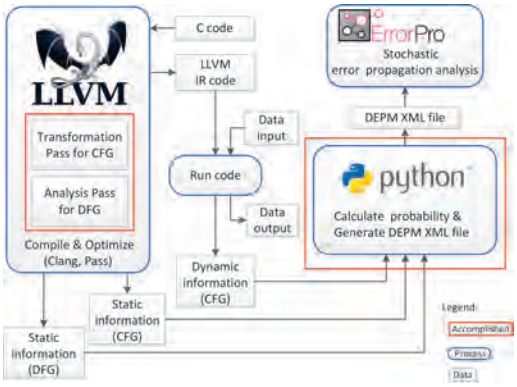

Figure 6. Top-level architecture of the C-to-DEPM transformation method.

IR, which, in turn, can be further compiled with *llc* for x86, ARM, PowerPC or other platforms. The optimizer can be built with so-called analysis or transformation passes. An analysis pass does not change the input IR, but provides analytical information, for instance, counts the number of instructions or builds a call graph. In contrast, a transformation pass changes and optimizes the original LLVM IR.

2 TRANSFORMATION METHOD

Figure 6 shows the architecture of the proposed transformation method. Rounded rectangles with blue borders represent activities and gray rectangles represent data. The red frames highlight our contribution: We have developed two LLVM passes and the python script that processes the outputs of the passes and generates DEPM XML file for further analysis with ErrorPro™. All the steps are automated and can be run with a single shell script that calls LLVM tools (compilers, linkers etc), as well as our passes, and the DEPM generation python script.

2.1 *Transformation pass for control flow analysis*

The first, transformation, pass helps to identify elements of the future DEPM, control flow structure, and control flow transition probabilities. The overview of the transformation pass is shown in Figure 7. The pass takes the LLVM IR of the original C-Code generated with *clang* as input and performs two tasks. (1) The first task is to generate the list of DEPM elements that represent single LLVM IR instructions. Using the LLVM API, the pass iterates over all LLVM IR instructions and stores the information into the *elements.txt* file. The pass gives a unique name for each instruction taking it account its location according to the LLVM IR hierarchy. The structure of *elements.txt* is shown in the right-hand side of Figure 7. (2) The

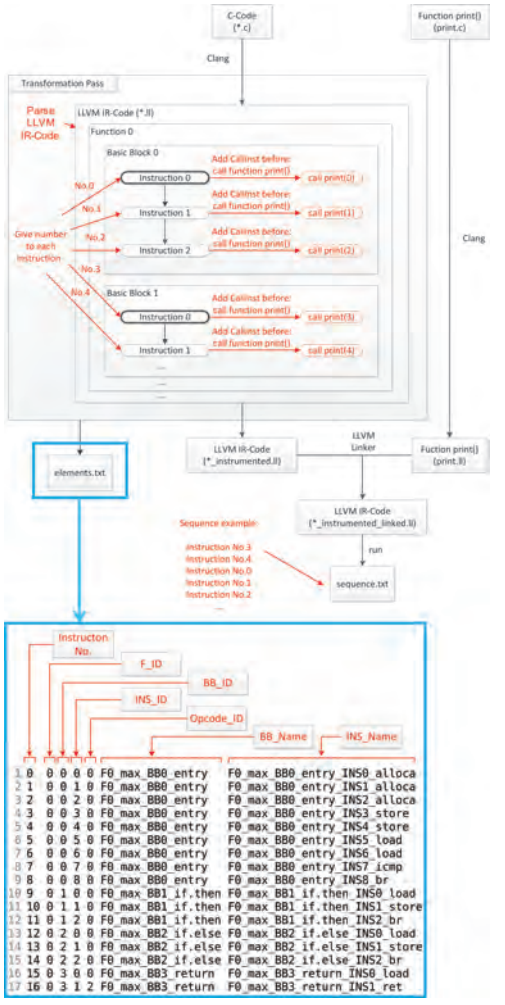

Figure 7. Structure of the transformation pass.

second task is the generation of the instructions execution sequence in order to define the structure of the DEPM control flow as well as control flow transition probabilities. In order to achieve this, we link an external C-code of a "print" function with the original LLVM IR using *llvm-link* tool and append calls to this function after each instruction of the original LLVM IR. After this instrumentation, we compile and run the program. The instructions execution sequence is stored in *sequence.txt*.

2.2 *Analysis pass for data flow analysis*

The second, analysis, pass makes no changes in the original LLVM IR but analyzes the code in order to identify variables and their relations with the LLVM instructions. The overview of the analysis pass is given in Figure 8. This pass iterates over the instructions and identifies related input and output variables (operands) and generates unique names for the future DEPM data storages. The pass also classifies the variables as local or global, and stores this information (data records) into the *datas.txt* file. An example of the data records is shown on the right-hand side of Figure 8. The general challenge here is to define rules for different types of LLVM instructions.

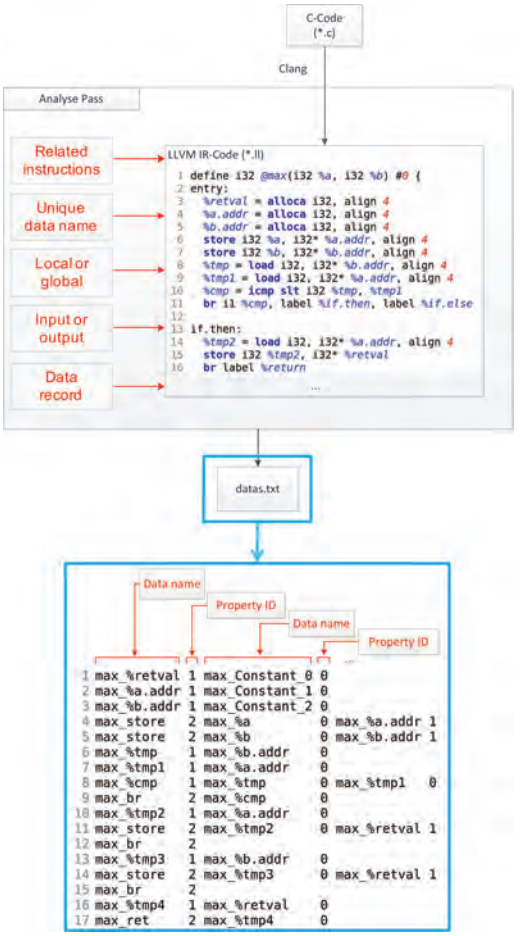

Figure 8. Structure of the analysis pass.

2.3 *DEPM generation*

The last step is the generation of a DEPM model in XML format. The python script parses the *elements. txt*, *sequence.txt*, and *data.txt* files. The information from *elements.txt* is transformed into a set of <element> tags of the DEPM XML file. The *sequnce.txt* file is processed in order to count the number of control flow transitions between the elements and transform this information into control flow arcs and transition probabilities for <cf_arc> tags. The *data.txt* file helps to create a set of data storages using the <data> tags and connect them with the elements using <data_flow> tags. The generation of DEPM conditions is left out of the scope of this method and will be considered later.

2.4 *Hierarchy*

The DEPM supports hierarchical models. A DEPM element can be compound and contain

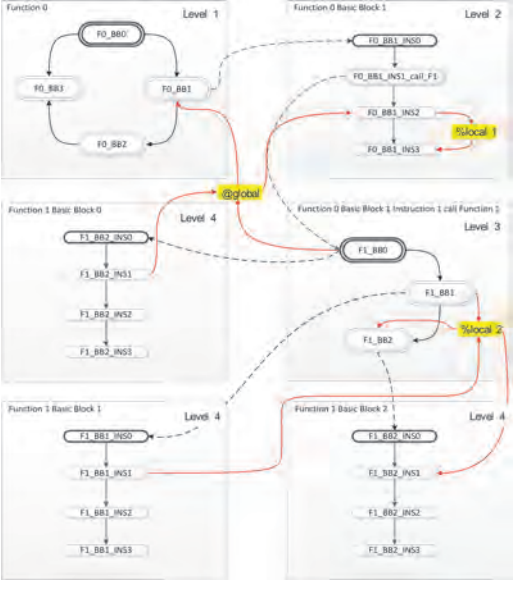

Figure 9. Composition of DEPM elements and data storages in different hierarchical levels.

another DEPM inside. This helps to map the LLVM hierarchy to the DEPM like it is shown in Figure 9. The *main* function of an LLVM module is modeled with the toplevel DEPM, see Level 1 in Figure 9. The elements of this DEPM represent basic blocks of the *main* function. Each of these blocks contains a sequence of instructions that is modeled with the elements of Level 2 DEPMs. Some of these instructions might call other functions. Basic blocks of these functions and their instructions are modeled using the Level 3 and Level 4 DEPMs respectively. The local variables are modeled with the corresponding DEPM data storages and the global variables with the data storages of the toplevel DEPM.

2.5 *Limitations*

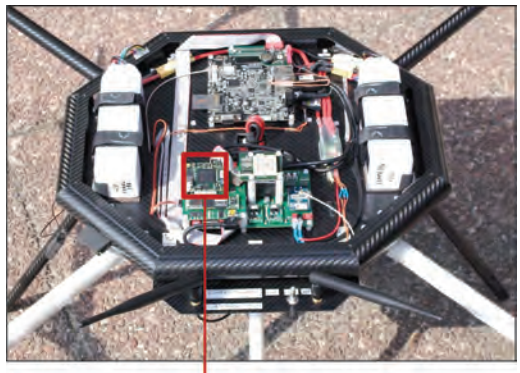
The current software implementation of the transformation method is a proof-of-concept and has a number of technical restrictions:

- A function can be called only in one place.
- A function can not call itself—no recursion.
- Pointers and arrays are not supported.
- All the functions have to be defined in a single module.

The elimination of these restrictions requires some effort, but even now the method can be applied for the safety-critical control software analysis that is usually developed or auto-coded according to standards like MISRA-C (MISRA Ltd 2004) that considerably limits the capabilities of C/C++.

3 CASE STUDY

A part of embedded flight control software of an octocopter UAV has been selected as a case study for the introduced transformation method, see Figure 10. This case study was also discussed in (Morozov & Janschek 2016). The flight vehicle contains a number of onboard computers with guidance, navigation, and control software. A part of the control software, responsible for attitude and rate control, was selected as one of the most critical part of the entire UAV. The *main* function of the selected flight control software is shown in Figure 10. The software is written in C and contains approximately 800 lines of code. It is decomposed into six functions. The functions "read_input", "rate_control", and "ecg" are invoked in each iteration of the main loop, the functions "err_quat" and "attd_ctrl" are executed in each second iteration, and the function "eul_to_quat" in each forth iteration. The software reads sensor data and external inputs ("read_input"), processes them ("eul_to_quat" and "err_quat"), performs attitude and rate control ("attd_ctrl" and "rate_ctrl"), and generates engine commands ("ecg"). The output variable "mtr cmd" is a critical system output.



```
int main(int argc, char *argv[])
{
    input_file = fopen("data/input.txt","r");
    output_file = fopen("data/output.txt","w");
    static uint32_t step = 0;
    while(step<100)
    {
        read_input();
        if(step % 2 == 0)
        {
            if(step % 4 == 0)
                eul_to_quat();
            err_quat();
            attd_ctrl();
        }
        rate_ctrl();
        ecg();
        step++;

        for(uint8_t i = 0; i < 8; i++)
        {
            fprintf(output_file, "%i;",mtr_cmd[i]);
        }
       fprintf(output_file,"\n");
    }
    fclose(output_file);
    fclose(input_file);
    return 0;
}
```

Figure 10. An octocopter UAV system. Top: an embedded computer with the low-level flight control software highlighted with the red frame. Bottom: Ccode of the main functions of the low-level flight control software.

This software was successfully transformed into a set of hierarchical DEPM models using the introduced method. The top-level DEPM is shown in Figure 11. The DEPM control flow branching correctly represents the *if-structure* of the discussed *main* function. Table 1 gives the numerical evaluation of the case study size.

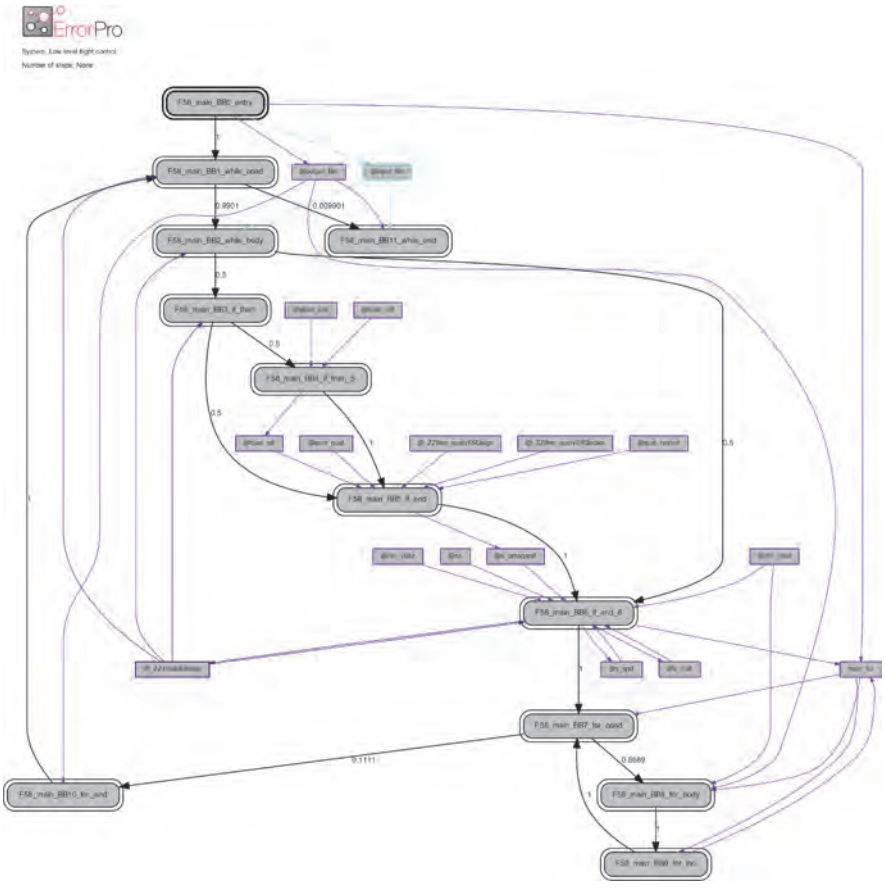


Figure 11. The top-level DEPM model, automatically generated using the introduced transformation method.

Table 1. Numerical evaluation of the case study size.

Number of LLVM instructions	2070
Number of LLVM basic blocks	906
Number of entries in control sequence	507136
Total number of DEPMs	250
Total number of DEPM elements	2976
Total number of DEPM data storages	2104
Total number of DEPM control flow arcs	1882
Total number of DEPM data flow arcs	5099

4 CONCLUSION

A new LLVM-based method for automatic transformation of manually developed code to the stochastic Dual-graph Error Propagation Model (DEPM) has been presented in this paper. The DEPM helps to estimate the impact of a fault of a particular system component or input on the overall system reliability, e.g. to compute the mean number of erroneous values in a critical system output during given operation time.

The DEPM was originally developed in order to support MBSE development approaches. However, the functional software parts usually incorporate manually programmed code and the presented method enables the analysis of the error propagation properties of the manual code for enhanced reliability evaluation of the complete system.

The introduced method maps control and data flow structures based on the LLVM IR. The further development requires the mapping of reliability properties for single DEPM elements using the discussed DEPM conditions. The current software implementation of the transformation method is a proof-of-concept with a number of serious technical limitations that shall be eliminated. The performance of the method will be also optimized.

ABSTRACT: The analysis and verification of the timing behavior is an important aspect in the model-based development of mechatronic systems. Components of a mechatronic system typically communicate and share data over a network which originates real-time requirements. The network introduced imperfections like package loss and delay have a stochastic nature and thus may lead to the violation of a real-time requirement which is considered as a timing error and has an impact on the system performance and reliability. The model-based timing analysis is a valuable task for the evaluation and prediction of the system reliability. Recently we introduced a method for the model-based analysis of timing errors. It comprises a mapping of a semi-formal baseline system model into a probabilistic model, namely a discrete-time Markov chain model. In this paper, we discuss the analysis of the Markov chain model with respect to the timing requirements with probabilistic model checking techniques. We use the probabilistic model checking tool PRISM and the probabilistic computation tree logic for the property specification. Model checking requires the appropriate transformation of the informal timing requirements to the temporal logic expressions. The verification results show whether a specific timing property is satisfied by the model or not and reveal design flaws in the early design phase. A model of a mobile medical patient table serves as a demonstrative case study.

1 INTRODUCTION

Model-based system development allows the analysis and verification of the system behavior and its conformity to the requirements early in the design phase. A challenging task is the verification of reliability properties. Our research group is focused on the model-based dependability analysis of mechatronic systems and recently introduced a method for the analysis of data errors and their propagation with the goal to identify weak design parts with respect to reliability (Morozov and Janschek 2014). A significant effort was spent in the automatic transformation of baseline system models, specified e. g. with UML and the Architecture Analysis & Design Language (AADL, see (Feiler and Gluch 2012)), into an appropriate formal model for the error propagation analysis (Ding et al. 2016) and (Morozov et al. 2018). Components of a mechatronic system typically communicate over a network. In a networked distributed system with concurrent processes that exchange data periodically, real-time requirements arise between the processes which provide data (sender) and the processes which receive the data (receiver). The violation of the real-time requirements may lead to degradation of the system behavior and has an impact on system reliability. Thus, reliability analysis in early design phases, in particular, the analysis of the timing, is a valuable but challenging task.

Recently we introduced a method for stochastic timing analysis (Mutzke et al. 2016) and extended it in (Mutzke et al. 2018). A semi-formal baseline system behavioral model which is annotated with stochastic timing properties is mapped into an intermediate representation, a formal timed Petri net model. The analysis of the Petri net model considering the stochastic timing properties results in a probabilistic Markov chain model.

In this paper, we discuss the analysis of the Markov chain model with respect to the timing requirements with probabilistic model checking techniques (the highlighted lower part in Figure 1). Verification techniques like simulation and test typically do not cover all possible system execution scenarios. In comparison to this, model checking allows verifying the correctness of the model whether a particular property is satisfied or not. We use the probabilistic model checking tool PRISM (Kwiatkowska et al. 2011) and the proba-

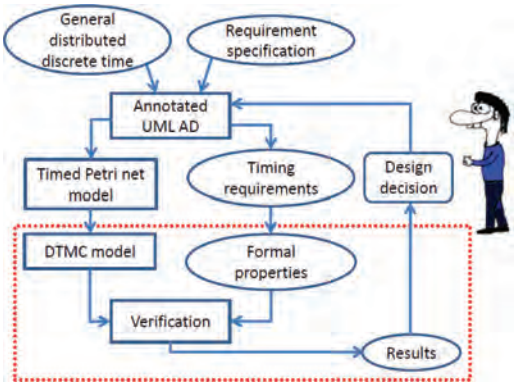

Figure 1. The top-level workflow of the methodology.

bilistic computation tree logic for the property specification. This requires the appropriate transformation of the informal timing requirements to the temporal logic expression and its mapping to the property language of the PRISM tool. The verification results provide valuable information in the early design phase whether a property is satisfied or not and support design decisions which help to achieve an acceptable level of reliability. A model of a mobile medical patient table is used as a demonstrative case study.

This article is organized as follows: Section 2 gives an overview of the related work and empathizes the contribution of this paper. In Section 3, a representative case study model of a mobile medical patient table is introduced. The analysis of the Markov chain model with probabilistic model checking techniques is discussed in Section 4. Finally, Section 5 presents the results and gives an outlook on future research topics.

2 RELATED WORK AND CONTRIBUTION

In (Mutzke et al. 2016) we introduced a method for the model-based, stochastic timing analysis based on a Discrete-Time Markov Chain (DTMC) model. The DTMC model is generated from an annotated baseline system model. In (Mutzke et al. 2016) the method is extended so that the assumptions regarding the distribution of the execution times can be relaxed. However, the scope was on proposing the methodology whereas in this paper the analysis of the DTMC model is discussed in detail.

Several authors proposed valuable methods targeting the mapping of semi-formal UML/SysML diagrams into formal models for the analysis and verification of timing properties. In Ali et al. (2015) a formal verification of SysML internal block diagrams with discrete time constraints is proposed. It is based on the mapping of the model and the requirements into a probabilistic timed automaton and probabilistic computational tree logic expression, respectively. The verification is done with the PRISM model checking tool. However, the annotated discrete time constraints are non-probabilistic. The specified properties derived by the user requirements thus are also non-probabilistic. In Baouya et al. (2015) a probabilistic and timed verification framework of SysML state machine diagrams, annotated with time and probability properties, is introduced. However, the timing properties, which are assigned to the states, are specified as an interval with minimum and maximum values and the probabilistic properties are attached to the decision nodes and represent the control flow probabilities. In Jarraya et al. (2007) an approach for the automatic verification and performance analysis of time-constrained SysML Activity Diagrams is presented. The SysML Activity Diagram is mapped directly to the corresponding DTMC models and verified with the PRISM model checking tool.

3 CONTRIBUTION

In this paper, we discuss the analysis of the Markov chain model. Probabilistic model checking is used to verify the correctness of the model with respect to the timing requirements. A model of a mobile medical patient table serves as a representative case study. We present a set of properties derived by the timing requirements, which are verified using probabilistic model checking. The properties are formalized using the probabilistic computation tree logic. We use the probabilistic model checking tool PRISM to verify whether the Markov chain model, expressed with the PRISM modeling language, satisfies the defined properties, expressed with the PRISM property language. The verification results help revealing design flaws regarding the timing behavior and estimating the system reliability to achieve an acceptable level of reliability.

4 CASE STUDY

A concept study of a mobile medical patient table (MPT, Figure 2), introduced in Mutzke et al. (2018), is used as a demonstrative example. A typical use case scenario for a mobile MPT is the patient transport between the preparation room and the examination room. In the examination room, the MPT needs to be precisely positioned relative to specific modalities, e. g. a magnetic resonance imaging device (MRI). The MPT is

Figure 2. A design concept of a mobile medical patient table (Siemens Healthcare GmbH).

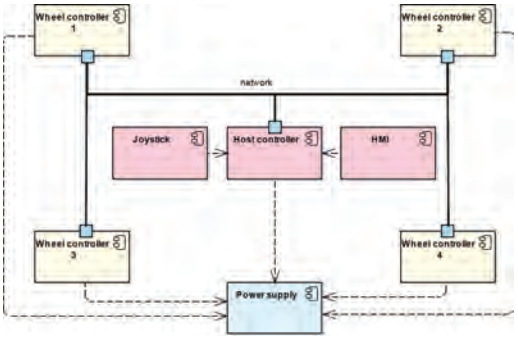

Figure 3. The UML components diagram of the MPT.

equipped with four electrical driven omnidirectional wheels. This allows autonomous movements in arbitrary directions, including lateral movements and rotations around an arbitrary vertical axis, without a steering mechanism. The movement may be commanded by an operator or a modality, e. g. position correction based on the evaluation of MRI images.

The mechatronic system MPT comprises four motion controllers for each individual omnidirectional wheel and the main controller which provides the interfaces and computes the movement trajectory based on the target position. The main controller communicates via a network with the motion controllers. Figure 3 shows the UML component diagram that describes the interfaces of the discussed MPT components. The dashed lines represent the dependency from the components to the power supply on board of the MPT.

Network induced imperfections may lead to a degradation of the system performance and reliability, e. g. a delayed position update may lead to discontinuity of position, movement, velocity or acceleration, resulting in leaving the planned movement path and fail to reach the target position.

4.1 *Baseline system model*

An abstract behavioral model, the UML Activity Diagram in Figure 4, serves as a baseline model of the MPT for the timing analysis (Mutzke et al. 2018). It represents a behavioral model for the automated positioning task. It comprises the control flow as well as the data flow of the system. The atomic executable elements, the *actions* are annotated with stochastic timing properties listed in Table 1. This abstract model is subject to refinement in follow-up design iterations, however, this level is sufficient for the timing analysis.

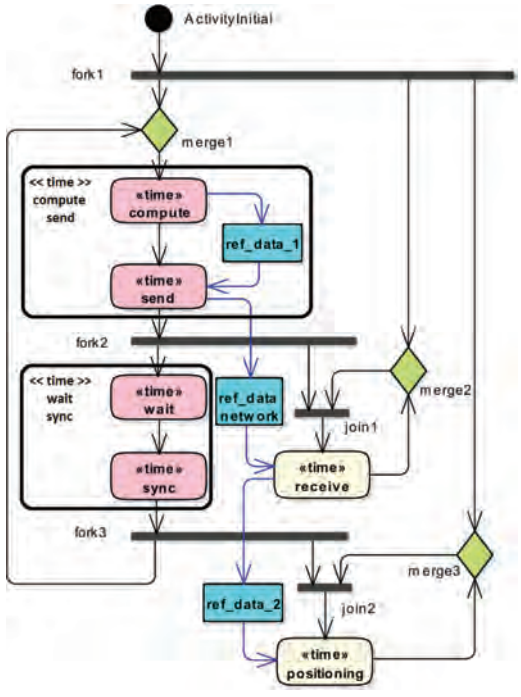

Figure 4. The UML activity diagram of the MPT.

Table 1. Annotated timing properties of the activity diagram in Figure 4.

Action	Time	Probability
compute	(6, 7, 8)	(0.05, 0.9, 0.05)
send	(3, 4, 5)	(0.9, 0.09, 0.01)
wait	(39)	(1.0)
sync	(1, 2, 3)	(0.99, 0.009, 0.001)
receive	(10, 20, 30, 40)	(0.9, 0.05, 0.03, 0.02)
positioning	(5, 10, 15)	(0.99, 0.009, 0.001)
(compute, send)	(9, 10, 11, 12, 13)	(0.045, 0.8145, 0.1265, 0.0135, 0.0005)
(wait, sync)	(40, 41, 42)	(0.99, 0.009, 0.001)

The actions on the left hand side of the activity diagram, namely *compute*, *send*, *wait* and *sync* represent the main controller process P_M (red). The actions *receive* and *positioning* represent one of the wheel controller processes P_W (yellow). For the sake of simplicity, the model contains only one of the four wheel controller processes. The Activity starts at the *ActivityInitial* node. The black horizontal bars represent *fork* and *join* nodes indicating the begin and the end of parallel execution paths. The black edges represent the control flow and the blue edges the data flow respectively. The action *compute* plans the movement trajectory, time-equidistant steps of the movement path, for every wheel and provides the data *ref_data*_1 which are used by the action *send*. The data *ref_data_network* are an output of the action *send* and input of the action *receive* of the wheel controller process. The *fork*2 node ensures that the action *receive* starts after the action *send* is finished and both, *wait* and *receive* start at the same time. The *join*1 node ensures that action *receive* need to be finished processing the data *ref_data_network*[*k*] before processing the data *ref_data_network*[*k* + 1]. The action *sync* initiates the activation of the transmitted data *ref_data*_2 from action *receive* to action *positioning*. The behavioral model implies the timing requirements (i) that action *receive* has to be finished before the action *sync* is finished which can be expressed by the statement $t_{wait} + t_{sync} > t_{receive}$ and (ii) that the action *positioning* has to be finished before the action *send* is finished which can be expressed by the statement $t_{compute} + t_{send} > t_{positioning}$. The baseline model is annotated with the discrete timing properties listed in Table 1. The values and its distributions are chosen arbitrarily and are subject to refine while the design is enhanced. However there are three types of distributions: deterministic for the action *wait*, monotonically decreasing for the actions *send,sync,receive* and a variance around a characteristic mean for the action *compute*. Figure 5 shows a timing chart for the MPT representing about three cycles of the nominal, error-free system run. The horizontal bars visualize the action execution times and their order of execution in each process P_M and P_W, respectively.

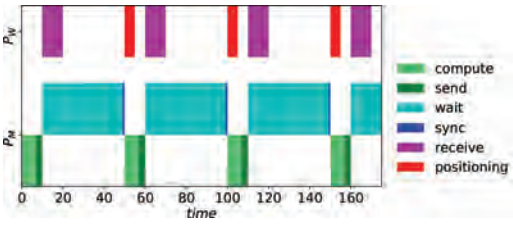

Figure 5. The nominal, error-free timing chart of the MPT.

4.2 *Stochastic timing analysis*

According to Mutzke et al. (2018), in this section, the approach for the stochastic timing analysis, applied to the case study baseline system model, is briefly demonstrated.

The analysis comprises the steps:

- Reducing the baseline system model and computing probabilistic timing properties;
- Mapping of the UML AD to a timed Petri net model;
- Generation of the DTMC model.

4.2.1 *Baseline system model reduction*

The baseline system model elements which are sequentially executed, namely *compute*, *send* and *wait*, *sync* are subject to model reduction. For the reduced single elements (*compute*, *send*) and (*wait*, *snyc*), which substitutes the elements in the baseline model, we have to compute the sum of the execution times. The execution times are assumed to be independent random variables with a discrete distribution. The sum is also a random variable and its distribution can be determined by the convolution of the distributions of each random variable. For two discrete distributions m_A, m_B it follows

$$(m_A * m_B)(j) = \sum_k m_A(k) \cdot m_B(j-k), \quad k, j \in \mathbb{Z}$$

where *j*,*k* iterates over the values of m_A and m_B, respectively. The asterisk symbol (∗) represents the convolution operator (Bronstein et al. 2005). The last two rows in Table 1 show the computed results for the reduced elements (*compute*, *send*) and (*wait*, *sync*) of the case study baseline system model.

4.2.2 *Computing timing properties*

The timing requirements now can be reformulated: (i) $t_{waitsync} > t_{receive}$ and (ii) $t_{computesend} > t_{positioning}$. The violation of a timing requirement is considered as the occurrence of a timing error. Thus, the probability of the occurrence of a timing error with respect to the timing requirements can be expressed as: (i) $Prob\left(t_{receive} \geq t_{waitsync}\right)$ and (ii) $Prob\left(t_{positioning} \geq t_{computesend}\right)$.

The probability of the occurrence of the timing error is obtained by computing the joint probabilities which satisfy the condition $t_{receive} \geq t_{waitsync}$. For (i) with $t_{waitsync} = t_A$ and $t_{receive} = t_B$ this can be computed with

$$Prob\left(t_A \leq t_B\right) = \sum_{u_2 = t_{Bmin}}^{t_{Bmax}} \sum_{u_1 = u2}^{t_{Amax}} p\left(u_1, u_2\right)$$

Where $p(u_1,u_2) = Prob\left(t_{Au_1}\right) \cdot Prob\left(t_{Bu_2}\right)$ is the joint probability of a single realization of t_A and t_B. The subscripts *min* and *max* indicate the border of the individual interval respectively.

Finally, we obtain the following results for the probability of the occurrence of a timing error for the case study model:

i. $Prob\left(t_{receive} \geq t_{waitsync}\right) = 0.0198$,
ii. $Prob(t_{positioning} \geq t_{computesend}) = 0.008735$, respectively

The results show that (i) approximately two out of one hundred data *ref_data_network* won't be received in time by the wheel controller process and (ii) approximately in nine out of one thousand execution cycles the *positionin* task exceeds the *compute* and *send* tasks.

4.2.3 *Mapping into a formal Petri net model*

A semi-formal UML Activity Diagram can be mapped into a formal Petri net model by applying the rules defined in Störrle and Hausmann (2004) and adapted in Mutzke et al. (2016). The Petri net represents the control flow of the baseline system model. Figure 6(a) shows the corresponding Petri net model of the baseline system model, the UML Activity Diagram in Figure 4, where the immediate transitions are represented by thin black bars while the timed transitions are represented by a black rectangle. The *ActivityInitial* of the Activity Diagram is mapped to the place p_1 in the Petri net model and is initially marked with a token.

Table 2 shows the assignment of the UML Activity Diagram nodes to the nodes of the Petri net model.

The timing requirements following the notation of the Petri net can be expressed with (i) the transition *t*6 fires before the transition *t*5 and (ii) the transition *t*9 fires before the transition *t*2. A precondition is that the pre-places of the transitions *t*6, *t*5 and *t*9, *t*2, namely *p*7, *p*8 and *p*2, *p*11, are marked simultaneously. The Petri net reveals that this is ensured by design.

4.2.4 *Generation of a discrete-time Markov chain model*

A reachability analysis of the generated Petri net model reveals all markings reachable from the initial marking $\boldsymbol{m}_0$. The result is a directed graph *RG* with the state space *S*. Considering the timing requirements (i) and (ii), we can identify the states $S_{nom} \subset S$ and $S_{err} \subset S$ which represents the nominal operational states and the erroneous states, respectively.

Simultaneously activated timed transitions in the Petri net model are represented by nondeterministic state transitions in the *RG* characterized by places with two or more outgoing edges. To this edges we can assign the state transition probabilities, computed

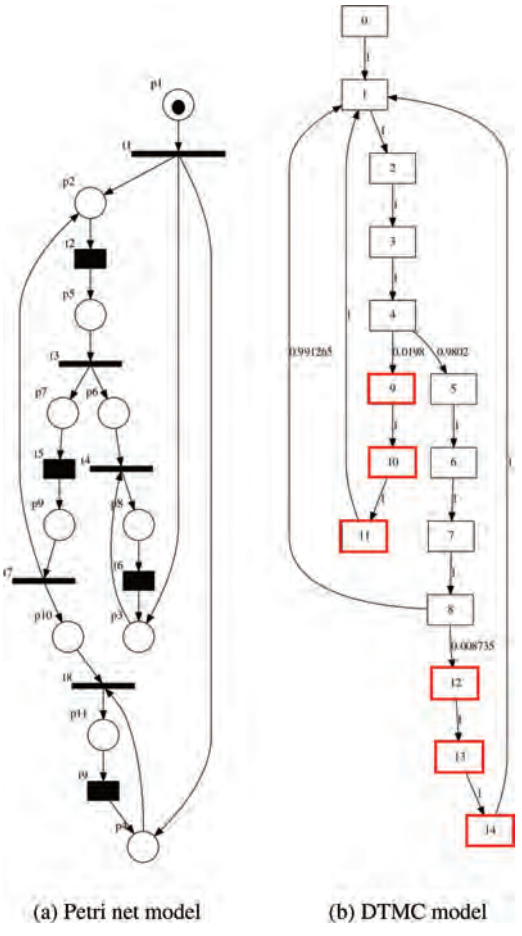

Figure 6. Graphical representations of the Petri net model and its corresponding DTMC model.

Table 2. The assignment of the activity diagram nodes in Figure 4 to the Petri net nodes in Figure 6(a).

PN nodes	AD nodes
p1	ActivityInitial
t(1, 3, 7)	fork(1, 2, 3)
p(2, 3, 4)	merge(1, 2, 3)
p(5, 6, ..., 11, 12)	auxiliary
t(4, 8)	join(1, 2)
t2	action *compute*, *send*
t5	action *wait*, *sync*
t6	action *receive*
t9	action *positioning*

in Section 3.2.2. The reachability graph attached by state transition probabilities represents a discrete time Markov chain model (DTMC). Figure 6(b) shows the obtained DTMC model with states in nominal oper-

ation S_{nom} and the erroneous states S_{err}, highlighted in red, generated out of the Petri net model that is shown in Figure 6(a). Table 3 contains the assignment of the DTMC states to the Petri net places. The occurrence of a timing error following the notation of the DTMC can be identified with (i) the state s_9 is visited and (ii) the state s_{12} is visited, respectively. The DTMC model comprises 65 states and 145 edges, however in Figure 6(b) only the states in nominal operation path with a cyclic behavior and two path fragments, each consisting of three erroneous states, are shown, which are highlighted inred.

5 ANALYSIS OF THE MARKOV CHAIN MODEL

The generated Markov chain model is the foundation for the analysis of specific properties related to the timing behavior. Formally, according to (Baier & Katoen 2008), a DTMC is a tuple

$$\mathcal{M} = \left(S, P, \iota_{init}, AP, L \right)$$

$S = \left(s_1, s_2, ..., s_n \right)$	is a finite set of states;
$\boldsymbol{P} : S \times S \to \left[0,1 \right]$	is the transition probability function such that for all states s: $\sum_{s' \in S} P(s,s') = 1$;
$\iota_{init} : S \to \left[0,1 \right]$	is the initial distribution such that $\sum_{s \in S} \iota_{init}(s) = 1$;
$AP = \left(nom, err \right)$	is a set of atomic propositions
$L : S \to 2^{AP}$	a labeling function.

The states of the DTMC model are labeled with the atomic propositions *nom* and *err*, respectively (Table 3). The analysis of the DTMC model is done with the probabilistic model checking tool PRISM. Listing 1 shows the DTMC specified in the PRISM modeling language.

Lines 31 to 41 in Listing 1 defining rewards, namely visiting the states s_9, s_{12} and the disjunction $s_9 \vee s_{12}$, that indicate the occurrence of timing error. This allows to compute the expected number of errors during specific number of execution steps.

To specify the properties, we use the probabilistic computation tree logic (PCTL). This is a temporal logic based on the computation tree logic (CTL). A PCTL formula formulates conditions on states of a Markov chain. The notation used in this paper is according to (Baier and Katoen 2008). Compared to CTL which uses universal and existential path quantifiers ∀ and ∃, the PCTL uses the probabilistic operator $\mathbb{P}_J(\varphi)$, where φ is a path formula, and J is an interval of [0, 1]. The syntax for a PCTL state formula is given by:

```
1  dtmc
2
3  label "nom" = s=0 | s=1 | s=2 | s=3 | s=4 | s=5 | s=6 | s=7 | s=8;
4  label "err" = s=9 | s=10 | s=11 | s=12 | s=13 | s=14;
5
6  module mpt
7
8  s :[0..14]  init  0;  // states
9
10 [] s=0 -> 1:(s'=1);
11 [] s=1 -> 1:(s'=2);
12 [] s=2 -> 1:(s'=3);
13 [] s=3 -> 1:(s'=4);
14 [] s=4 -> 0.9802:(s'=5) + 0.0198:(s'=9);
15 [] s=5 -> 1:(s'=6);
16 [] s=6 -> 1:(s'=7);
17 [] s=7 -> 1:(s'=8);
18 [] s=8 -> 0.991265:(s'=1) + 0.008735:(s'=12);
19
20 [] s=9 -> 1:(s'=10);
21 [] s=10 -> 1:(s'=11);
22 [] s=11 -> 1:(s'=1);
23
24 [] s=12 -> 1:(s'=13);
25 [] s=13 -> 1:(s'=14);
26 [] s=14 -> 1:(s'=1);
27
28 endmodule
29
30
31 rewards "num_error_9_12"
32 [] s = 9 | s = 12 : 1;
33 endrewards
34
35 rewards "num_error_9"
36 [] s = 9 : 1;
37 endrewards
38
39 rewards "num_error_12"
40 [] s = 12 : 1;
41 endrewards
```

Listing 1. The DTMC model expressed in the PRISM modeling language.

Table 3. Assignment of the PN places to the DTMC states.

DTMC states	PN places	DTMC label
0	(1)	"nom"
1	(2, 3, 4)	"nom"
2	(3, 4, 5)	"nom"
3	(3, 4, 6, 7)	"nom"
4	(4, 7, 8)	"nom"
5	(3, 4, 7)	"nom"
6	(3, 4, 9)	"nom"
7	(2, 3, 4, 10)	"nom"
8	(2, 3, 11)	"nom"
9	(4, 8, 9)	"err"
10	(2, 4, 8, 10)	"err"
11	(2, 8, 11)	"err"
12	(3, 5, 11)	"err"
13	(3, 6, 7, 11)	"err"
14	(7, 8, 11)	"err"

$$\Phi ::= true \left| a \right| \Phi_1 \wedge \Phi_2 \left| \neg \Phi \right| \mathbb{P}_J \left(\varphi \right)$$

Where $a \in AP$ is a atomic proposition. The syntax for a PCTL path formula is given by:

$$\varphi ::= \bigcirc \Phi \,|\, \Phi_1 \cup \Phi_2 \,|\, \Phi_1 \cup^{\leq n} \Phi_2$$

where $\bigcirc$ is the next operator. Formula $\bigcirc\Phi$ holds for a path if Φ holds for the next state in the path. $\Phi_1 \cup \Phi_2$ holds for a path if there is a state in the path where Φ_2 holds and Φ_1 holds in all states visited before. $\Phi_1 \cup^{\leq n} \Phi_2$ is the step-bounded variant meaning that Φ_2 will hold within at most n steps.

The PCTL is used to specify the following properties relevant for the analysis of the timing:

```
const int k;

// (a1) probability of a timing error (i) in k steps
P=? [ F<=k (s=9) ]

// (a2) probability of a timing error (ii) in k steps
P=? [ F<=k (s=12) ]

// (a3) probability of a timing error (i) or (ii) in k steps
P=? [ F<=k (s=9|s=12) ]

// (b1) cumulative reward: the expected number of errors (i)
// within k steps
R{"num_error_9"}=? [ C<=k ]

// (b2) cumulative reward: the expected number of errors (i)
// within k steps
R{"num_error_12"}=? [ C<=k ]

// (b3) cumulative reward: the expected number of errors
// (i) or (ii) within k steps
R{"num_error_9_12"}=? [ C<=k ]

// (c) infinitely often "nom"
P>=1 [ G F "nom" ]

// (d) always an error state implies within at most three
// steps a nominal state is reached
P>=1 [ G "err" => (X X X "nom") ]
```

Listing 2. The properties specified in the PRISM property language.

a. What is the probability of the occurrence of a timing error (i), (ii) and the disjunction (i) $\vee$ (ii) within k execution steps?
b. Cumulative reward: What is the expected number of errors within k execution steps?
c. The system will always recover from a timing error and reach a nominal operation state.
d. Whenever an error state occurs, in at most three steps a nominal operational state is reached.

To verify the properties, they have to be formalized. In Listing 2 the properties are specified in the PRISM property language.

6 RESULTS AND CONCLUSIONS

Table 4 lists the formal expressions of the defined properties in PCTL as well as the PRISM property language.

Figures 7 and 8 show the verification results for the properties (a) and (b), respectively. The graphs represent the the timing error (i), (ii) and the disjunction (i)$_\vee$ (ii) highlighted green, red and blue, respectively.

For k = 1000 steps almost sure one of the timing errors occur, but the (ii) is less probable. Hence design enhancements should be focused to decrease the probability of (i). The verification result of property (c) means that a nominal operational state is visited infinitely often. Hence the system will not remain in an erroneous state. The verification result of property (d) states that the system always recovers from an erroneous state within at most three steps.

Table 4. Formal property specification and results.

Property	PCTL	PRISM	Result
(a1)	$\mathbb{P}_{=?}(\Diamond_{<=k}\ (s=9))$	$P=?\,[F <= k (s=9)]$	see Figure 7
(a2)	$\mathbb{P}_{=?}(\Diamond_{<=k} (s=12))$	$P=?\,[F <= k (s=12)]$	see Figure 7
(a3)	$\mathbb{P}_{=?}(\Diamond_{<=k} (s=9 \vee s=12))$	$P=?\,[F <= k (s=9 \mid s=12)]$	see Figure 7
(b1)	–	$R\{"num\_error\_9"\}=?\,[C <= k]$	see Figure 8
(b2)	–	$R\{"num\_error\_12"\}=?\,[C <= k]$	see Figure 8
(b3)	–	$R\{"num\_error\_9\_12"\}=?\,[C <= k]$	see Figure 8
(d)	$\mathbb{P}_{=1}(\Box\Diamond\ "nom")$	$P>=1[G\ F\ "nom"]$	true
(e)	$\mathbb{P}_{=1}(\Box\ "err" \rightarrow (\bigcirc\bigcirc\bigcirc\ "nom"))$	$P>=1\,[G\ "err" => (XXX\ "nom")]$	true

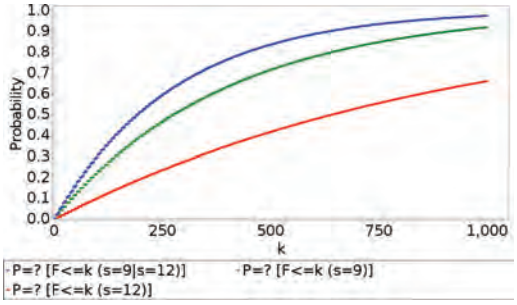

Figure 7. The probability of a timing error within k steps.

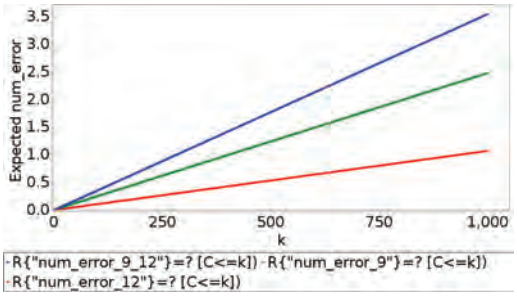

Figure 8. The expected number of timing errors within k steps.

In this paper, we discussed the analysis of the Markov chain model with respect to the timing requirements with probabilistic model checking techniques. This requires the appropriate transformation of the informal timing requirements to the temporal logic expression and its mapping to the property language of the PRISM tool. The results are valuable for the assessment of the system reliability and help to achieve an acceptable level of reliability.

A challenging task is to formalize the appropriate timing requirements from an informal requirement specification or to derive the implicit timing requirements from the baseline system model, where the latter is done manually in this paper. Thus a future research topic is the automatic recognition of the timing requirements and their mapping to a temporal logic expression.
